SUICIDE BY BLOWS AGAINST THE HEAD.

A Medico-Legal Study.[1]

BY ALLEN STAPLES, A.B., M.D.,

OF DUBUQUE, IOWA.

Although suicide, accomplished by blows against the head of such severity as to wound the contents of the cranium, is of very rare occurrence, it has been observed in a certain number of cases. Such self-murder requires more than ordinary energy, or insensibility to pain, for its execution, and these conditions chiefly obtain among the insane. There are recorded in medical literature a few instances in which the object was attained by blows on the head with a hammer or hatchet, or by driving within the skull a chisel or similar instrument. Certain of these cases, too, consist of persons who have tried to end their existence by other methods, less revolting, and have failed. Death from the self-inflicted wounds, or secondarily from the inflammation consequent upon them, as a rule, has been the final result. In the following paper I purpose to give as complete a series as I can, of cases illustrative of the remarks above, and to narrate more *in extenso* the history of a patient that came under my own observation.

The first case to be related is that of Dr. L. Langer.[1] A poacher, 37 years old, attempted suicide by beating his head with a sharp angle of an ax. There were found on the forehead, between the frontal eminences and extending into the hair, three wounds filled with crushed and splintered bone. The middle one was about two inches long, and showed at its bottom a half-inch fissure in the bone. There was also a Y-shaped wound above and behind the right ear, extending to the bone, a similar one just above, and a large swelling just below the occipital protuberance. The man recovered in two months.

Fourmet[2] relates a noteworthy case: A joiner had driven an iron chisel 3½ inches long and 3 lines broad up to its head by means of repeated blows from a hammer, into his cranium about the middle line. The patient became comatose, but, on the removal of the chisel in about seven hours, recovered within two weeks.

A remarkable case was published by Angenstein.[3] J. M., convicted of repeated arson and sentenced to imprisonment for life, was reported to have simulated epilepsy and insanity, and to have made suicidal attempts by inflicting superficial wounds on his neck and arms. In October, 1859, he drove two nails, 1½ inches long, into his frontal bone: these were with difficulty extracted by the forceps. In April, 1860, a similar attempt was made in the left parietal bone. He quickly recovered from the effects of each attempt. In September, 1860, he introduced under the skull a piece of wire. Signs of brain irritation followed this last wound, and a week later death ensued. The autopsy showed the dura firmly united to the skull at the place of the last injury, and the perforations through which the nails had been driven closed by membrane. There was purulent meningitis that had been caused by four needles that were found sticking into the meninges and brain. These needles had been introduced through the openings made by the nails.

A case presenting much analogy to the above is narrated by Dr. V. Biart.[4] It was that of a convict in the Kansas State Penitentiary, who attracted much attention among his fellow-convicts by boring a hole in his skull with an awl, and introducing therein pieces of wire. The physician-in-charge removed several pieces that had pierced both cerebral hemispheres. The wound of entrance was situated in the right parietal bone, near its posterior inferior angle. The patient stated at the time that he had passed other substances into his brain. Later he committed suicide by taking morphia; and at the autopsy his brain was found congested, and a wire three inches long and three-sixteenths of an inch thick was found running from the wound of entrance to the fissure of Sylvius. A flat nail one and three-fifths inches long was also found lying near the wire.

Carpenter[5] relates a similar case of an insane patient who sought in the following ways to take his life: First, he bored through his skull just above the right ear, and passed a heavy wire four and three-quarters inches into the brain. Second, he thrust an awl into the vertex. Third, through the first opening he pushed another wire to the opposite side of the skull, causing a left-sided hemiplegia that lasted fourteen days. Finally, after some months, he poisoned himself with morphia. At the autopsy a piece of wire two inches long and a threaded needle were found lying near each other in the middle lobe of the

right hemisphere, and in the frontal lobe were discovered a piece of wire two and one-half inches long, and a long headless nail.

Schauenstein[6] relates the case of a laborer who gave himself seventeen blows on the forehead and vertex with a hatchet, some of which penetrated the skull. Death from meningitis followed.

J. Fritsch[7] reports the case of a drunkard who cut down his child with a hatchet, wounded his wife dangerously and also struck himself several blows in the neighborhood of the right frontal eminence, in consequence of which he fell senseless. The wound healed perfectly.

Albert[8] gives the case of a joiner 32 years old, who struck himself in the right temporal region with a hammer. A large wound resulted. Patient became unconscious, tongue was deflected to the right. The next day there was return of consciousness, and in two months cicatrization of the wound.

Fabrice[9] reports the following case: A man who suffered much from headache dealt himself severe blows on the head with an ax, split his lower lip, wounded his throat, cut off a testicle, and on his recovery could not tell what impelled him to the act.

Zaggl[10] reports the case of a patient *in puerperio*, who attempted to suicide with a meat ax. There was contusion of the scalp on the vertex, with a stellate fracture and a bruised wound on the right parietal eminence.

E. von Hofmann.[11] A woman first stabbed herself in the liver, and as death did not ensue seized a hatchet and struck herself so many blows on the forehead and vertex, that she fell back senseless. When she was brought into the hospital, consciousness had returned; linear cuts with contusions of the scalp were found. Much suppuration followed, and the patient died of pyæmia. The autopsy revealed that the outer table of the vertex had been penetrated by the cutting edge of the hatchet.

Krugelstein[12] reports that a skeleton of a person who had run away from fear of punishment, was found in a wood. On the vertex was a wound evidently made by a hatchet that was lying near by.

Casper Liman:[13] A laborer long afflicted with melancholia, struck himself such heavy blows on the head with a flax-beater, that he died of their effects in a few hours.

Otto[14] reports the case of a jealous butcher, who first struck his head violently against a wall, then beat his head with an ax so long and heavily that he sank back senseless. Death from hæmorrhage resulted. The autopsy showed a hole in the frontal bone one inch long and two inches broad, with several depressions about it.

Maschka:[15] A woman 63 years old stabbed herself in the abdomen with a knife, then beat herself heavily on the head with an ax, and finally attempted to open the veins in the elbow. She died in six days from meningitis. The post-mortem examination showed a large fracture on the right side of the frontal bone.

Riambault[16] reports the following case: A man 53 years old, among whose relations were sixteen insane, and who suffered from severe headaches, was found hung in a barn. He had first cut his scalp with a pocket knife, then dealt himself heavy blows on the head with a hatchet, and finally hung himself. There were found, at the autopsy, a large fracture at the juncture of the parietal and frontal bones, and nine parallel incised wounds of the scalp.

Kupfer[17] reports the case of a man, 40 years of age, who was found drowned in the Spree. There was a history of overwork and anxiety, and a slight temporary mental aberration. There were found above and behind the right ear thirteen parallel wounds of the integument, some of which reached the bone. Over the left ear were many wounds with a large loss of substance, seventeen incisions being counted posteriorly, fourteen anteriorly. The bone was much splintered and fissured.

Krugelstein[18] records the following: On the head of a woman found hung were thirty parallel wounds, one half inch long. These were situated on the forehead and vertex and had penetrated the outer table. There were in addition some small parallel incisions in the cardiac region that, as they were suppurating, must have been three or four days old.

Von Haumeder[19] gives the case of a hostler, ill of typhoid fever, who was found hung. At the centre of the vertex was a sharp-walled hole two inches long and half an inch broad, at the bottom of which the bone was laid bare. Both hands were stained with blood. A short distance from the body lay a heavy hatchet, on which were traces of blood, and yet further off was found, near a pool of blood, a large hammer. An examination showed that there were at least sixteen blows directed against the head, seven of which penetrated the skull. There was typhus abdominalis in the ulcerative stage. The expert opinion on the case was that it was one of suicide; this opinion was founded on the facts that the wounds were of comparative insignificance from such heavy instruments, that they were parallel in their course, that they were all near each other, that there was no evidence of resistance, and that typhoid fever was present.

Howe[20] reports the case of a man who, according to the statement of his wife, first dealt her blows on her head with a pistol, then fired two shots upon her. He next attempted to blow his brains out, but as the pistol missed fire, he struck himself very violently on the head. Death from shock followed. The autopsy showed the right malar region suffused and penetrated by an incised wound one inch in length, two incised wounds in the right temporal region, nine on the vertex close together, a lacerated wound over the right ear, and one on the vertex, and a triangular cut

on the arm. The patient had previously showed signs of mental aberration.

R. Frank's[21] case: This remarkable case, together with the result of the judicial investigation into it, I will relate more fully, as the history is of much interest from a medico-legal point of view:

In the Vienna Allgemeines Krankenhaus, Surgical Section, a woman 64 years old presented herself on the forenoon of September 28, 1884. Her statement was, that her wounds were self-inflicted and made by a hatchet. In consequence of her injuries she died on October 4. Except some mental hebetude, she did not show any cerebral symptoms. But because of her mental dulness, her ante-mortem assertion that her injuries were produced by her own hand was not deemed trustworthy, and a judicial investigation was ordered. It was elicited that the woman lived in easy circumstances, but was somewhat peculiar and secretive in habit. Her family energetically scouted the idea of suicide, and the wounds were explained by a fall from a chair or table while she was dusting pictures.

An examination revealed the following injuries: Hair in the anterior parietal and frontal regions abraded; a wound with ragged edges, four inches long, extending from between the eyebrows upwards and backwards, and forking above, was continued to the right an inch farther. This large wound had a stellate appearance, and at its widest portion was two inches across. On the left side of it were two smaller wounds, and on its right side were two others, incised and parallel, that penetrated the skull. Their walls were inflamed and purulent. Numerous smaller wounds were found on the right forearm, elbow, knee, and on the left knee. The frontal bone showed a fissure two inches long, half an inch wide. In addition, there were seven punctures that had more or less completely penetrated the skull. Besides the above named lesions, on the inner surface of the calvarium were found blood clots with fragments of bone. The anterior portion of the right upper frontal convolution showed degeneration, and was dotted over with small hæmorrhages. The rest of the brain was anæmic and soft, the ventricles contained a turbid fluid; there were clots in the sinuses and purulent meningitis.

The expert opinion of Prof. Hofmann in the above case was as follows:

1. J. N. died of purulent meningitis.

2. This was caused by violence through the above named injuries, especially by that reaching from the base of the nose directly backwards, forking posteriorly, and producing the fissure on the frontal bone.

3. This fissure, as well as the neighboring elongated and sharply defined wounds of the scalp, coursing generally from before backwards, was caused by vigorous blows with a sharp and heavy instrument, probably with a hatchet, and the number of blows must have been nine or ten. The straight fissure of the frontal bone, and the incisions at the posterior end, from the fact that between the cleft walls, large pieces of bone are wanting, and the walls of integument bounding the wounds can be recognized, must have been caused by two or more blows.

4. Since these numerous wounds were compacted together upon a comparatively small surface, and easily accessible to the hand of the patient, and were in the same direction from before backwards and almost parallel, and since some of them scarcely break the skin, therefore the suspicion is very strong that these injuries were produced, not by a foreign hand, but by that of the patient herself, for the purpose of suicide. This suspicion is confirmed by the circumstance that on the inner surface of both forearms, on the flexor surface of the left wrist and under both knees are, huddled together, numerous parallel superficial wounds that doubtless arose from an attempt to open the veins, and were produced by the hand of the patient.

A suicide caused by blows directed against the head is a rare event, yet one sometimes observed; and experience teaches that this extraordinary mode of self-murder is chosen chiefly by the insane; it is therefore to be justifiably suspected that this patient, while she was insane, accomplished the deed.

The last history of a case that I shall relate, is one that came under my own observation:

On December 16, 1885, Dr. G. M. Staples was called to see J. A. M., a short, thick-set German, about 45 years of age, of florid appearance, and stone-cutter by trade. He saw M. about 10 A.M., and found him sitting up in a saloon that adjoined his shop. The patient was semi-conscious, and had the appearance of a man somewhat intoxicated. On inquiry, it was found that he had left the saloon about 9 A.M., after drinking several glasses of beer. The proprietor stated that he had appeared considerably depressed in spirits, but returned to his shop to work as customary. Twenty minutes thereafter two gentlemen attempted to enter his shop to consult him about work, but found the door, which was partially glass, locked. Looking through the door, they discovered M. walking towards them with a long chisel protruding from his forehead; he stooped down and attempted to unlock the door, but after trying some minutes and appearing unable to turn the key, those from the outside forced the lock and entered. M. then said to them, "Drive the chisels further into my head," and then, shortly after, "For God's sake pull them out." The patient was immediately taken to the saloon above spoken of, a distance of perhaps forty feet, and walked thence with but little aid.

Dr. G. M. Staples was summoned at once, and found on his arrival the following condition:

The head of a small stone chisel was found protruding about three lines from the scalp on the right side of the head, at a point about one and five-eighth inches above the meatus auditorius, and one inch in front of a line dropped from the vertex to the meatus.

The point of the chisel had emerged on the left side, about one and one-quarter inches, at a point one inch above, and half an inch in front of, a vertical line bisecting the meatus. The length of the chisel was eight and one quarter inches, the diameter of its head, three-eights of an inch, and it tapered to a flattened point. A similar chisel had been driven

[21] Wiener, Med. Wochenschrift, Nos. 15, 16, 17, "Selbstmord durch Hiebe gegen den Kopf," von R. Frank.

perpendicularly into the centre of the forehead, five-eighths of an inch above the plane of the upper margin of the superciliary ridges, and had penetrated one and one-quarter inches.

The pupils were dilated, the left irregularly; the pulse was slow and full. Forcible traction with strong forceps was necessary to extract the first mentioned chisel, and an assistant pressing against the protruding point with a block of wood. The second chisel was bent to an angle of 20 degrees, five-eighths of an inch from its point, and was firmly imbedded on the frontal bone, requiring for its extraction, the greatest efforts with the forceps. Moderate hæmorrhage from the orifices made by the first chisel, followed. It is of interest to note, that a superficial puncture was discovered one-eighth of an inch above, and to the left of the point of entrance of the second chisel.

Absorbent cotton was placed on the orifices, the head was bandaged, and the patient sent to his home half a mile distant. After the chisels were removed the patient became more comatose, and at noon he could be but slightly aroused. The pulse continued slow and respiration was somewhat laborious and stertorous; there were signs of restlessness and rhythmical flexion and extension of the lower extremities. At 1 P.M. his restlessness became much more marked. He continually endeavored to arise in bed, and get upon the floor, requiring two powerful men to hold him down. His eyes were constantly closed, and the urine had been voided in bed. Morphia, ¼ grain, was given hypodermically.

At 4 P.M. Drs. G. M. Staples and Bready visited the patient together; he was then resting more quietly. The lower extremities exhibited rhythmical movements as before. Respiration continued labored and there were ecchymosis and swelling about the eyes. Pulse was 80 and pupils contracted. Deglutition was slowly and very imperfectly performed.

A rubber drainage tube was inserted, one and one-half inches into the right temporal orifice, and half an ounce of dark blood evacuated. The temporal wounds had been previously probed and bone, supposed to be the posterior clinoid processes, had been touched. After the tube had been inserted and the wound drained, the patient was visibly easier. The tube was padded with absorbent cotton and retained in the wound. The clothing and bed were saturated with the urine that had been involuntarily evacuated.

At 10 P.M. the patient was seen by Dr. Bready and the writer; he was found very restless, continually throwing himself about the bed. The pulse was 90 to 100. He indicated by motions a desire to urinate and passed water freely. Deglutition was quite impossible. He was given, hypodermically, morphia, $\frac{1}{3}$ grain, and atropia, $\frac{1}{120}$ grain.

The patient was seen by Drs. G. M. Staples and Bready at 8 A.M. on the following day; he had passed a comparatively quiet night, sleeping heavily. His respiration was 36, pulse 120, and fever, temperature 101. He could not swallow at all, fluids being retained in the mouth, and flowing out at the corners. Grumous blood, with some debris of cerebral tissue, kept slowly oozing from the drainage tube. Urine had been passed involuntarily during the night. Patient seemed to be sinking, and a solution of spts. ammon. aromat. was made to trickle down his throat.

At 3 P.M., he was again visited by Drs. Staples, Bready and Minges. He had died at 2:30 P.M. The dressings were removed, and a Nélaton probe with porcelain tip, was passed through the temporal wounds, from side to side, showing that the chisel had traversed brain tissue its entire length, after it had perforated the skull.

Although with our utmost persuasion, no autopsy was permitted, yet we were able to obtain very carefully made measurements. From these it was estimated that the first mentioned chisel must have penetrated the skull at the upper anterior angle of the squamous portion of the right temporal bone and lower margin of the right parietal traversing the base of his skull, in the region of the Sella Turcica, and emerging at nearly the centre of the squamous portion of the left temporal. The second chisel passed through the frontal bone, and must have entered the frontal lobe of the brain, at least half an inch. The mallet with which the chisels had been driven, was of wood, and weighed two and three-eighth pounds. It was covered with blood and presented about fifteen indentations, that, from their peculiar situation and correspondence to the heads of the chisels, were supposed to indicate the number of blows needed to accomplish the deed described. Inquiry into the patient's family history, failed to reveal any hereditary tendency to insanity; it was discovered, however, that he had been greatly concerned about some business matters, that he was a hard drinker, and that he occasionally showed depression of spirits.

In the absence of an autopsy, any statement as to the particular cerebral structures wounded, is at the best, mere conjecture; but after careful study and measurement, on the subject, I have arrived at certain conclusions, and I give them to the reader for what they are worth. It is my belief that the first chisel penetrated the right tempero-sphenoidal globe, or entered the fissure of Sylvius, passed just below the Island of Reil, traversed the lenticular nucleus, internal capsule, and right optic thalamus. On the left side it must have passed a little lower through the substance of the tempero-sphenoidal lobe. That the region about the Island of Reil was not injured, I hold to be probable, by the fact that no aphasia existed.

The internal capsule being a part of the pyramidal tract, the course of nervous influence through it, from the cortical centres of motion, would be more or less modified and this, it may be, was the cause of the rhythmical motions exhibited by our patient. If, as was thought, the posterior clinoid processes were fractured, there probably resulted pressure on the pons; and if the patient had lived any time, the issue would perhaps have been similar to that of a case related by Belhomme.

In this case an exostosis from these processes pressed upon the pons; the patient was subject to attacks of vertigo, and impairment of the motion of the legs, followed by forced movements from left to right. Towards the close of the case, convulsions and rotary motions from left to right ensued.

From the lesions in the lenticulo-striate region, we would expect that the senses of vision and olfaction would be impaired, though this, in our case could not be ascertained. A wound in this locality according to Ferrier, would induce dilatation of the pupils, a phenomenon which we noted in the case of M. A wound in the tip of the frontal convolution would not be followed by any marked effect.

Such wounds as those in our case belong to the punctured or perforating variety of wounds of the head; of this class there are but six reported in the large surgical volumes of the "Medical and Surgical History of the War of the Rebellion," and in no one of these was there absolutely complete perforation. Five of these patients were wounded by a bayonet, one by a sword, one survived, permanently disabled, five died with extravasation of blood in one case, cerebral hernia in one, encephalitis in one, and abcess of the brain in two cases.

As to the treatment of our case there is little room for discussion. All surgeons will agree that the immediate removal of the foreign bodies was indicated. The best authorities, too, are in favor of establishing and maintaining the most complete drainage possible. Dr. Harlow who treated the famous tamping iron case, says that it was due in great measure to the free outlets in the skull above and below, that the man Gage owed his life.

In wounds of the head where the skull is perforated the mortality is always very high, no authority giving it as less than 80, and some giving it 100 per cent. "If death follows in twenty-four or thirty-six hours, it will be from shock and the extravasation of blood and serum, when the fatal result is longer delayed, encephalitis or abscess will ultimately prove fatal. When the projectile remains within the cranium, the danger is greater than when it passes through or perforates, as in the former case there is one foreign body more in the cranium. The statistics of our late war show a difference of 5 per cent in favor of perforating over penetrating fractures, the mortality in the former being 80 per cent. and the latter 85.5 per cent."[22]

A study of the above cases shows that death often does not result from the immediate effect of the injuries, more often the patient either gets well of them, dies from the resulting inflammation, or tries some other method of suicide. Another lesson to be drawn from these cases is, that even heavy blows against the head do not necessarily produce concussion of the brain.

In a given case, the diagnosis between murder and suicide may be of great importance, and attention to the following points, will be of use:

1. The situation of the wounds must be one readily accessible to the hand. The majority of these injuries, as the cases given above attest, are situated on the frontal and parietal bones, more rarely on the temples, very rarely indeed upon the occipital bone.

2. Usually more than one wound, frequently many, are found. It is easily comprehensible that the first blows are made somewhat cautiously, and being comparatively unimportant, do not render the suicide incapable of completing the act.

3. The injuries are, as a rule, huddled together in a comparatively small space, and take a parallel course. This is easily explained by the quick motion that has been taken by the hand. This disposition of the wounds almost characteristic, is one of the most constant and weighty signs to which our attention can be directed.

4. Heavy strong instruments are regularly used. If they are blunt, fewer wounds are to be looked for, as unconsciousness would be the more quickly induced.

5. In many of these cases, other injuries made with suicidal intent, or traces of them, can be found in other portions of the body.

6. Signs of resistance or non-resistance, should in every doubtful case be looked for. Regularity of the wounds, and a grouping together of them, are not compatible with resistance.

8. The history of the patient, as concerns the mental state is always of importance. Most of these suicides had shown aberrations of intellect, perhaps of a transitory character, and hereditary taint came often into play. Delirium and cephalalgia were also the causes in one case each.

It goes without saying, however, that to avoid an error of diagnosis, all the circumstances in a given case must be carefully considered.

SURGICAL METHODS FOR THE RELIEF OF PRURITIC RHINITIS (HAY FEVER).

BY THOMAS F. RUMBOLD, M.D.,
OF ST. LOUIS, MO.

My method of ascertaining who will require operative procedure, is to treat by the spray producers *every case* for a few days, giving from ten to fifteen treatments. From the effect of these applications, I judge whether or not the case will require severer measures. It is seen that I operate on as few patients as possible, because I fear the effects that will follow the formation of scar tissue in the nasal cavities. I do not wait until the pruritic season has passed away, but operate as soon as I find that the spray producers will not prove effective.

Relief by Surgical Measures.—This consists in the removal of the diseased, hyperæsthetic mucous membrane that covers the turbinated processes and portions of the septum nasi. This is best done by means of Jarvis's wire snare, or some modification of this valuable instrument.

I prefer this instrument to the galvano-cautery, because it can be employed to remove even an extensive hyperplasia of the turbinated processes without leaving a large cicatrix, certainly not the one-tenth of the size of the portion removed.

To be enabled to apply this instrument with comparative ease to the patient, a nasal speculum will be required. With it the passage can be dilated to some extent.

I have had a nasal speculum made that has handles eight inches long. It is illustrated in Figure 1.

Such a length enables the patient to hold the instrument in position in the nasal passage, thus allowing the physician to use his hand for other purposes. If the patient does not hold the instrument in the best position for complete inspection—and they seldom do at first—the physician must properly adjust it. Thus held, it will be far more comfortable for the patient than if the physician were to hold it, and the parts will be fully as well seen.

If this is the case why cause great discomfort, if not excessive pain by employing a self-retaining nasal speculum?

To apply the wire snare, the nostril should be dilated to its utmost, and the loop passed in with its transverse diameter held vertically. It will not be possible to prevent the wire from touching both the septum and the turbinated process, which may excite sneezing. If it does the loop will have to be withdrawn, and a new attempt made.

Placing the wire loop around the growth is difficult to accomplish, and frequently requires great patience and dexterity. The loop is slowly passed into the nostril, and made to surround the growth. If this is large enough to protrude a quarter of an inch, it may

FIG. 1.—NASAL SPECULUM, eight inches long, with reversible blades. This length is given it to enable the patient to dilate his own nasal passage.

FIG. 2.—Modified Jarvis Wire Snare.

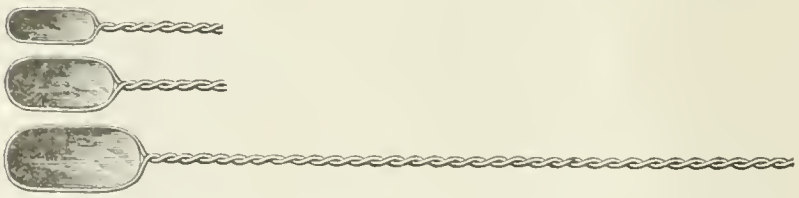

FIG. 3.—ANTERIOR NASAL MIRRORS.—The mirrors are represented full size. The handles are five inches long. The desired angle may be given to each mirror by bending the wire handle near the glass.

FIG. 4.—PHARYNGEAL MIRROR.—By pressure on the lever on the handle the mirror may be made to take any desired angle, thus reflecting the posterior, superior and anterior surfaces of the pharyngo-nasal cavity, while rotation on its axis reflects the lateral surfaces.

FIG. 5.—SOFT PALATE RETRACTOR.—A, lever to separate arms. B, the soft rubber band that closes the arms and holds the uvula out of the operator's way. C, the lever that raises the wedge. After the instrument is introduced behind the velum and the arms spread by the lever A, then the wedge retains them in position

One of the blades of this speculum is flatter than the other, the flatter one should be applied to the nasal septum, and when the other passage is to be inspected the blades are to be turned over or reversed, as shown by the dotted lines in the illustration.

I employ this speculum in all operations in the anterior nasal passages and during all applications of the spray producers to the anterior naris.

be easily surrounded by the wire. As soon as it is ascertained, by slight traction, that the wire is engaged, the milled nut is slowly turned, time being given for the wire to sink into the hyperplastic and partially œdematous tissue, as it always does; and in about half a minute the nut should be again turned partly around. As soon as it is ascertained that the loop has a good hold on the growth, the patient

should be directed to take hold of the instrument with the left hand. He should then turn the nut so slowly that he experiences but little pain.

An important direction, is to keep the end of the instrument, from which the loop extrudes, held close to the outer wall of the nostril. If this is not done, the loop will slip off over the anterior extremity of the hyperplastic growth. It should be borne in mind. that the loop seldom slips off over the posterior extremity of the growth.

It generally takes about half to three-quarters of an hour to remove even a small enlargement, while for one of so great dimensions as to fill the nasal passage, from one to three hours are required. The only sure guide is not to cause too much pain.

When the instrument has cut itself out, if the patient does not blow his nose—which he should not do—there will be no loss of blood, or at least but very little. This insures a small scar, one about the size of a large pin's head.

Not unfrequently the hyperplasia is a rounded body only, such as the wire loop will not take hold. In this case I have taken the needle of a hypodermic syringe and transfixed the growth and then placed the loop over it. This gives the wire a hold on the tumor. Since then I have had long needles made, taking my pattern from some I saw in the hands of Dr. Jarvis, in June, 1882.

This led to the idea of having the needles so attached to the ecraseur, that they could be used after the loop of wire was placed around the growth. Figure 2, illustrates the instrument I have had made for this purpose.

In some instances I find that this snare, as modified by me, has a little advantage over the original Jarvis snare, but in very many cases I use the Jarvis snare, with his needles in the place of this instrument. The modification consists in the following:

1. The excising nut is placed at the outer extremity of the instrument, so as not to intercept the surgeon's view of the parts to be operated upon.

2. A ring is employed for holding the instrument. I prefer the patient to hold the instrument while the excision is being performed, as he can do so far more comfortably to himself than can be done by any one else, I also direct him to turn the excising nut. As the exision should be performed slowly—to prevent hæmorrhage and the foundation of an extensive cicatrical surface—his sensations are the best guide as to the speed of the cutting process. As the pain lessens he is directed to turn the nut; and the placing of the nut on the outer extremity of the instrument, I have found to be a little more convenient also for the patient.

3. The wire holder is a rod, not a tube. There is not the least advantage in this, but this is required if the excising nut is placed on the outer extremity of the instrument. This rod is long enough to extend beyond the inner extremity or operating end of the instrument, and the portion thus protruding has a small opening in which to fasten the excising wire. After the wire is firmly attached, the extremity of the rod is then drawn into the barrel of the instrument, leaving the loop of wire extending one inch, more or less from the instrument, and ready to be applied to the hypertrophied tissue to be removed.

4. Two needles are permanently fixed on a perforated slide, which moves easily on the instrument and is seen next to the ring. To make the needles take the right direction, their points pass through a guide that is also slipped on the instrument, but at its outer extremity. This guide fits so tightly on the instrument that it does not leave its place while the needles are being pushed through it by the finger of the operator applied to a perforated slide, which, as has been said, moves easily on the barrel of the instrument. This mechanism insures the needles taking the desired direction.

5. The instrument is bent on itself, at the location of the perforated slide. This is done to make a sufficient angle to prevent the nut from interfering with the operator's view of the parts inspected. The illustration given above does not indicate this angle very clearly, as the instrument is made to lie on its side to show the ring.

The Galvano-Cautery.—Every one has a favorite manner of applying the galvano-cautery. Some allow the platinum to become almost white-hot before passing it into the nasal cavity. I did this on several occasions, to my patient's detriment, the radiating heat being so great as to cause acute inflammation of the whole cavity and great swelling of the face. The electrical energy should be sufficient to make platinum white-hot in one second of time while held in the air. Of course if the current was allowed to continue, the wire would be burnt through in about three or four seconds, but when the electrode is laid on the tissue, this keeps the wire from becoming sufficiently hot to be destroyed.

I prefer to place the electrode on the spot to be cauterized and then make the connection with my foot, never using my finger or thumb for making the connection, as this would necessitate holding the instrument so firmly in my hand that I could not be certain of the degree of pressure I was making on the part being burned.

Immediately on the withdrawal of the electrode, I spray the cavity with spray producers Nos. 2 and 5, employing the vaseline comp. given on page 497, October 30. This will have a soothing effect, but if the patient still complains of the distress from the burning, I apply the oleate of cocaine. This is an excellent preparation, and produces a much more lasting effect than the solution. The strength that I now employ is 5 per cent.

The next day the patient should receive the regular treatment with the spray producers.

As soon as the patient can endure a second application of the cautery, it should be applied. Generally one or two applications a week can be borne without great discomfort.

Caustic Applicators.—The applicator that I have most frequently used, has been a silver probe. When I desire to use chromic acid—which is very seldom—I heat the point of the probe and then touch it to a crystal of chromic acid; the crystal instantly melts and coats the probe point, and the instrument is then ready for use. Cocaine, a 5 per cent. solution, should

be applied to the parts frequently for half an hour before the acid is applied. Care must be taken not to hold the acid too long on the part to be destroyed; but just to touch the parts is quite sufficient. The spray of vaseline, with No. 2 spray producer, should be applied immediately after the touch is made.

Crushing.—I have grasped the sensitive portions of the membrane with a slender, but strong pair of forceps, maintaining the hold on the membrane for two or three minutes, first spraying the parts with a 2 per cent. solution of cocaine. The results are quite satisfactory.

Locating the Diseased Membrane.—In locating the hyperæsthetic spot or spots, I employ, if possible, a small reflector (Fig. 3.) if it can be passed into the anterior nares without producing much, if any, irritation, using, at the same time, a nasal speculum. I then insert a probe, bent slightly at the point, and ascertain according to the method employed by Dr. Roe, of Rochester, N. Y., the location of the most sensitive spot known by the patient experiencing a *burning sensation.*

Nitric Acid.—I have used nitric acid but once. The disturbance occasioned by its application was so great that I think I will not use it again.

Posterior Nares.—If the posterior portions of the turbinated processes or the septum nasi are to be inspected or operated upon, I hand the patient the tongue depressor and direct him to hold his tongue down with it, using his left hand. If the space between the porterior wall of the pharynx and the soft palate is sufficiently large, I place the pharyngeal reflector (Fig. 4.) back in the fauces to get a reflection of the posterior extremities of the inferior and middle turbinated processes and the septum nasi, using my left hand, leaving the right hand for the manipulation of the diagnostic probe, the electrode, the Jarvis snare, or the chromic acid probe.

If the volume hangs too close to the posterior wall of the pharynx, I hook the pendent portion with the spreading soft palate retractor (Fig. 5). Before drawing the palate forward, I spread the limbs of the instrument a little, and then draw it slightly outward. I then lift the right hand of the patient to the handle of the instrument and direct him to draw it as far forward as he can without causing unpleasant sensations. The patient can hold the instrument very much better than an assistant, as he knows how to control it so that it will not cause him to retch or occasion pain.

The reflection from the pharyngeal mirror will assist the operator in locating the sensitive spots, and in adjusting the Jarvis snare.

In making all caustic applications to these parts I employ the same methods.

A CASE OF PURULENT INFLAMMATION OF THE MIDDLE EAR WITH BRAIN COMPLICATIONS.[1]

BY BOERNE BETTMAN, M.D.,
OF CHICAGO, ILL.

Acute purulent inflammation of the middle ear is certainly a very common occurrence, and in the majority of cases runs its course in a few weeks without any complications. In some instances, however, the inflammation invades adjacent parts, and may give rise to very annoying, and even serious and grave results. Cases are on record where the inflammation has spread to the brain, giving rise to severe meningitis and death.

I will report one of these complicated cases, with, fortunately, a happy termination.

On April 1, 1885, I was kindly asked by Dr. Doering to examine the ears of a young lady, æt. 18, suffering with an acute purulent otitis media. The patient had contracted a severe cold five days previously. Two days later she complained of pains in the ears and loss of hearing. Counter-irritation, in the form of blisters to the mastoid region, and instillation into the ear of mild astringents, had been ordered by the attending physician. The young lady also employed a warm water spray very energetically, hours at a time, as she told me afterwards, to ease the pain. When I first examined her, the discharge from one ear had lasted three days, from the other ear but a day or two. Her condition was as follows:

Aur. sin.—Discharge of sero-purulent matter. M. T. very much injected, large perforation on its lower posterior quadrant.

Aur. dex.—Profuse discharge of creamy pus mixed with blood. M. T. almost totally destroyed. Mucous membrane macerated and very succulent—the slightest touch with a probe producing hæmorrhage. Watch was not heard when placed against auricle, mastoid and glabella Loud conversation was understood only when spoken directly into the ear. The otorrhœa was so profuse that the cotton batting over the ear had to be changed every half hour. I recommended frequent cleansing of the ears with lukewarm water and peroxide of hydrogen, also the instillation three times daily of the following solution:

℞. Zinc sulph..... 0.20.
Acid carbol..... 0.40.
Aq. dest..... 30.00.
M.

The discharge from the left ear ceased in one week, with perfect restoration of hearing. Two small furuncles which appeared later on at the mouth of the external auditory meatus yielded to warm applications. Several granulations in the right tympanum were destroyed with nitrate of silver.

April 12. Patient complained of pain in the right mastoid region. I sent her to bed and ordered cold applications to the part. She soon obtained relief.

April 14. Severe frontal headaches caused much distress. The discharge from the right ear was less. Temperature not much increased. Prescribed soda salicyl. grs. 10 every three hours.

April 18. A slight internal strabismus of the right eye was noticed. Temperature but slightly elevated.

April 21. Dr. Doering examined the case with me. We found little change in her condition. Otorrhœa less, but still profuse. Temperature 100. No tenderness in mastoid region; frontal headaches. The doctor concurred with me in the opinion that the inflammatory process had invaded the brain, in

[1] Read before the Chicago Society of Ophthalmology and Otology.

all probability through a dehiscence in the tegmen tympani. Pressure on the abducens nerve by exudative material would account for the strabismus. Ice bags, which had been applied to the head since two days, were continued, also the cleansing of the ear with the oxygenated water. Salicylate of soda was discontinued. Being troubled with dysmenorrhœa, bromide of potash and tincture of gelsemium were recommended by the family physician.

April 22. Headache was intense. She was supported in a half reclining position by pillows; she could not lie down, owing to the severe pain in the head. Vomited frequently after taking food.

April 23. Discharge from ear much less. Slight pain in the mastoid again quickly subsided on the application of ice bags.[1]

April 24. No pain in mastoid region. Frontal and occipital pains less violent. Vomited once or twice during the day.

April 26. Motion of ext. rectus much better; lachrymation ceased. Conjunctival injection of right eye entirely gone; it had existed but a few days. Right ear perfectly dry.

April 28. Appetite better; pain in head less; slept better.

April 29. Very little headache all day, slight during the night, and pain confined now to the left side of head.

May 1. Slight headache on left side. Slept well, discarded supporting pillows. Left eye epiphora. Temperature and pulse normal.

May 14. Out of bed. Diplopia produced only when the eye is turned far to the right side.

June 1. Eyes normal. Hearing on the left side normal; right ear, hearing $\frac{20}{30}$. The points of interest attached to this case may be classified as follows:

1. Constant poulticing in this form of disease is reprehensible practice, and fraught with destructive changes. The patient, contrary to the physician's instructions, applied a spray of warm water, hours at a time. The natural result was a maceration and breaking down of the tissues, accompanied by intense engorgement of the vesssls and infiltration of the surrounding parts. Granulations and consequent suppuration completed the picture of a most intense acute inflammation. All forms of continuous poulticing must be carefully avoided unless it is desired to favor suppuration.

2. The invasion of the cranial cavity is not at all a frequent accompaniment of otitis media purulenta acuta, neither is its termination usually as favorable as in the recorded case. We know that the osseous partition between tympanum and cranial cavity is extremely thin, and in some instances natural fissures exist in the tympanic roof, covered only by the mucous membrane. This naturally favors the progress of the disease by direct continuity of tissue and involvement of the meninges. In chronic forms of the inflammation these complications arise only after the bony barrier has been broken down by the protracted process of caries and necrosis.

3. The relief obtained by the application of ice bags to the mastoid was immediate, and substituted the ordinary method of applying fomentations. Last spring I had six or eight cases of acute inflammation of the middle ear accompanied by slight puffiness and extreme tenderness of the mastoid region. I regarded this as a slight periostitis, or rather congestion of the bone covering, associated, perhaps, with a hyperæmia of the mastoid cells. These cases yielded very readily to the cold applications. In one instance the puffiness was extensive enough to push the auricle forwards, usually indicative of a severe inflammatory process in the mastoid. The pain was intense, temperature high. The condition certainly justified a Wilde's incision, but before resorting to operative interference I resolved to try Leiter's tubes. They were kept *in situ* forty-eight hours, with the most satisfactory result. The complication rapidly disappeared.

I invariably order cold compresses or Leiter's tubes to the mastoid, as soon as the slightest tenderness is experienced. This procedure restricts, localizes the inflammatory process to the tympanum. Warm applications in the early stage encourage increased blood supply and infiltration of the tissues. The inflammation is thereby induced to invade adjacent parts.

[1] Dr. H. A. Johnson kindly saw the case with me on two occasions during the absence of Dr. Doering.

A CASE OF PSEUDO-MEMBRANOUS LARYNGITIS TREATED BY ELECTROLYSIS.[1]

BY F. E. WAXHAM, M.D.,

PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO.

Almost every organ of the human body, when in a diseased condition, has been subjected to the influence of electricity. The urethra, the prostate, the ovaries, the uterus, the brain, the liver, and the spleen, have all been treated by this silent, strange and powerful agent. Until recently, however, the larynx has not been invaded. If it be true that strictures of the urethra can be cured by the galvanic current; if it be true that enlarged prostates can be reduced, and fibroids of the uterus successfully treated, it has occurred to me that stenosis of the larynx from membranous exudation might be reduced in the same manner. If false membrane can be destroyed or detached in this manner, it will be a great advance in the treatment of one of the most distressing, frightful and dangerous diseases of early life. The thought that this is a field worthy of investigation is the apology I make for this brief report.

On October 26 I was called to see Esther J., a little girl of eight years. The little patient had been sick nearly a week with membranous croup, and had been attended by Dr. E. C. Helm. The patient was also seen by Dr. Sanders. The child was in a most desperate condition, and all hope of recovery had been abandoned. The pulse was rapid and feeble, the face of a deadly pallor, the lips livid and the respiration laborious in the extreme. The child was in the last stages of asphyxia, already semi-comatose, and was roused with difficulty.

[1] Read before the Chicago Medical Society, December 6, 1886.

An intubation tube was threaded with platinum wire and used as a negative electrode. At 5 P.M. the tube was introduced into the larynx without difficulty, and the respiration at once became easy. The child was soon resuscitated, and after coughing out considerable softened membrane and ropy mucus, once more became conscious of its surroundings. The platinum wire was now insulated by passing it through a very small rubber tubing. The platinum wire projecting from the tubing was now attached to a twelve-cell McIntosh galvanic battery. The positive electrode consisted of the ordinary sponge, which was moistened with warm water. The sponge was placed over the larynx, and a current from ten cells employed. This current caused some pain and considerable redness of the skin under the sponge. The current was reduced to eight cells, which was borne more comfortably and was passed five minutes, during which time considerable mucus and softened membrane were expelled. The tube was now accidentally withdrawn and the respiration appeared very easy without it. The little patient, who had taken no nourishment for several hours, and but very little for two days, now drank eagerly two glasses of milk, and passed into a quiet sleep. At 7.30 P.M. I was again called and found the respiration becoming labored. The tube was reintroduced and electrolysis again performed in the same manner. A current from eight cells was first employed, and then from ten, the sitting lasting ten minutes and the current causing some discomfort. One could not doubt the effect of the current upon the false membrane, for it was rapidly detached and expelled in small patches, together with considerable ropy mucus. The tube was removed and the respiration was again comfortable. The child seemed bright and interested in those about her.

Nine P.M.—Sleeping soundly. Pulse 140, temperature 103°, respiration 32. The respiration, although noisy, was not labored. The voice, which had been suppressed and whispering before the operation, now became louder, and the cough, which had been smothered and husky, became stronger and clearer. The respiration as well as the voice and cough indicated swelling of the mucous membrane about the vocal cords, rather than the presence of membrane. At 10.30 P.M. gave tr. opium gtt. vi *per os*, antipyrin gr. xii *per rectum*, and cold applications applied to the neck.

At 11.15 P.M. temperature 102, pulse 120°, respiration 32. The little patient took nourishment well and was left feeling quite comfortable.

At 2 A.M. I was again called and found the respiration labored and the dyspnœa well marked. Not feeling justified in experimenting further with the patient, electrolysis was not again employed. The intubation tube was introduced and left *in situ*, giving the child immediate relief. No membrane was expelled when the tube was introduced. There were now evidences of pneumonia, the respiration being rapid, although perfectly easy, the temperature high, and increased fremitus over both lungs.

Eleven A.M., pulse 150, temperature 105½°, respiration 40, taking nourishment fairly well, but restless and very thirsty. Directions were given to sponge the child frequently with cold water, and antipyrin was given in 15 gr. doses, *per rectum*.

Three P.M., pulse 150, temperature 105½°, respiration 40. Growing weaker and taking but little nourishment. Five P.M., pulse 150, temperature 103°, respiration 60. The respiration, although rapid, is perfectly easy. The patient restless and refuses all nourishment. Nine P.M., pulse very rapid and feeble, temperature 104½°, respiration 64.

The little patient died at 2 A.M.

It was expected that the galvanic current would have little or no effect upon the false membrane, but we confidently hoped that it would relieve the congestion and swelling of the tissue. Contrary to expectation it certainly seemed, to one watching this case closely, that it had a most decided effect in loosening and detaching the membrane, but that the secondary effect was to increase the swelling and congestion.

In this connection the result of a few experiments may not be uninteresting. Wishing to observe the effect of the galvanic current upon the healthy larynx, two rabbits were subjected to electrolysis, with the assistance of Dr. Bütner. The first rabbit, a half-grown one, was given chloroform and the tube introduced into the larynx with considerable difficulty, on account of the small size of the mouth. The attachments were made and a current from eleven cells was passed for five minutes and the tube removed. Some dyspnœa followed the operation, but it was attributed to the rough usage to which the larynx was subjected, rather than to the effect of the current. The dyspnœa gradually subsided and the rabbit recovered.

The second rabbit was given a current from eight cells, in the same manner, and seemed to suffer no inconvenience.

No deductions can be drawn from the report of a single case, but we may express the hope that this subject may be still further investigated. It is possible that too strong a current was employed, or possibly the current was not of sufficient strength. It may be necessary to employ a current that will verge on cauterization, and employed with an anæsthetic. These queries, however, can only be answered after further investigation.

3449 Indiana Avenue.

TRANSPLANTATION OF TEETH.[1]

BY WM. N. MORRISON, D.D.S.

OF ST. LOUIS, MO.

I will give the history of one very interesting case. In the *Missouri Dental Journal*, of July 15, 1882, is a paper by me upon this subject, and among other cases reported is a prospective case which presented itself last fall: A young lady of slight build, about 22 years of age, teeth not of extra quality, arch perfect, and articulation correct, except the left-erratum; read right- instead of left-side of the mouth;

[1] Read in the Section on Dental and Oral Surgery at the Thirty Seventh Annual Meeting of the American Medical Association.

superior canine, which was missing. The left-central was very loose. On careful examination I found it to be caused by the absorption of the root below the cervical line, by the crown of the canine, which lay horizontally in the process with its point to the median line, entirely across the root of the central, the latter being as thoroughly absorbed as though it was a deciduous tooth.

I had decided to extract both and transplant the canine to the socket of the central, after enlarging and deepening it to correspond to the root of the canine; after the canine had become fixed, if the crown could not be made to look as well as a central, I intended to cut it off and substitute a porcelain crown with a metallic pivot; but this heroic operation was indefinitely postponed by reason of the young lady being called home from our city.

This case is all the more wonderful from the fact that six dentists had already identified themselves with it; two of a neighboring city told her it had been broken off by blow or fall. Although previous to that decision one had constructed and adjusted regulating plates which were worn for months; exostosis being assigned as reason for enlargement; but a tooth never until I demonstrated it. Such was the case up to the time I first saw it, and gave my diagnosis and plan of operation. Other members of the patient's family had their favorite dentists, and she was taken to one and my plan duly explained and criticised; it was pronounced an impossible, impracticable and dangerous thing, but my diagnosis was pronounced correct so far as the canine was concerned, and its extraction was urged; to make this decision more forcible another was called in consultation, and they administered ether, and gouged away the process, exhausting themselves and the patient after breaking off a piece of the crown.

Further operations were postponed till some days later, when Dr. —, who was called to use his persuasive powers and hold her hands, renewed hostilities, but with no better success. About three weeks later she was taken by the above or by their order to Dr. —, who administered gas and extracted the canine, which was laid away to dry, and the patient assured that the central would grow firm again and be as useful as ever. When the root was entirely absorbed and the crown only suspended by slight attachment to the gum, the patient returned to her home, carrying with her the extracted canine trophy. All this occurred in the fall of 1881, and I had no knowledge of it until the discussion of my paper in the St. Louis Dental Society.

Now two years later, or three years after I first saw the case, the patient came to see if I would not transplant her right lower canine in the place of the upper central. The canine was condemned to extraction by another dentist, as its occlusion against the superior lateral was forcing the lateral out of place and making it assume an unsightly angle to the others. The central was hanging loosely to the gum and had been for three years, the other teeth supporting it latterally, and the lip and tongue antero posteriorly; the patient was in constant dread of swallowing it, particularly at night. Contrary to the opinion of my brother dentists in the society, and statistical evidence collected from best dentists all over the country, (see discussion of the paper, *Missouri Dental Journal*, page 247, July 15, 1882), the operation was performed; the loose tooth was removed and with a drill, (using cocaine). The process was opened up exactly in the track of the root which should have been there; at any rate I expected to find a piece of the root, but not a particle was there; with drill and fissure buri enlarged and deepened the socket quite to the floor of the nose, and antero-posterially from plate to plate; and remember the anterior plate was cicatrical bone and not any to spare at that, owing to former extractions of canine, above described; the teeth and general shape of the socket being now known. The right lower canine was extracted, and root vessels removed, and canal filled with gold wire, and a prominent contour filling built upon its distal face or long angle, with platinum gold, which made the median edge of the new right central which it was to be. The root was long, and instead of being round as its predecessor, was oval or flattened on the sides, it was a fortunate thing that there was a thin scale of plate left upon the labial side when the socket was enough enlarged to receive the root.

A black rubber splint capping the crowns was worn about four weeks, shielding that tooth from injury; no unusual results followed; it was speedily taken into fellowship without an unfavorable symptom. The right lower first bicuspid was much within the arch, and by forcing it out with a jack-screw it performed excellent service as a canine. By this operation, although not as good as the one first contemplated, this beautiful young lady is spared the uncomfortable and humiliating necessity of wearing an artificial appliance, and has her own home-grown natural teeth distributed where they will do the most good.

MEDICAL PROGRESS.

Iodoform Gauze in Gynecology.—In *Volkmann's Sammlung*, No. 288, Fritsch, of Breslau, gives the manifold uses to which he puts iodoform gauze in gynecological practice. A 10 to 50 per cent. article is made, and the former may be easily made stronger in iodoform by incorporating the gauze with more iodoform, either in powder or in solution with ether, or in form of a glycerole. Iodoform gauze should be the only substance used in making tampons. In aseptic cases these tampons may remain *in situ* for ten days without showing any signs of putrefaction. In making these tampons a strip of gauze five cm. broad and two m. long is cut off, folded upon itself fan-shape, and inserted by means of the hand or dressing forceps, the end being allowed to hang out of the vulva. Simply drawing on this end will unravel the tampon and remove it without pain or inconvenience. At the head of palliative cancer treatment he shows the great advantages of making use of iodoform gauze tampons. Formerly, in bleed-

ing and ulcerating cancer, irrigation was used for the double purpose of disinfecting and removing the offensive secretion. If the hæmorrhage was considerable a tampon soaked in liquor ferri was introduced. In twenty-four to forty-eight hours this tampon had become offensive, and if its removal was delayed to the third or fourth day it was a mass of putridity. It had become hard, was removed with great pain and difficulty, its removal was followed by a mass of offensive coagula and discharge, and it left the vagina irritable and contracted.

In *ædème* and cauterization the iron tampon was applied to the oozing surface, to stop the hæmorrhage. If the tampon was well applied it accomplished this object, but if it was simply packed up into the vagina, the hæmorrhage continued, the tampon had to be reapplied, or the patient died from loss of blood, as he has had an opportunity to observe in two cases. This procedure is certainly not one of ideal perfection, and from a theoretical standpoint grave objections can be brought against it. Instead of introducing fluids into parts already bathed in profuse discharge, a method by which the secretions are absorbed, disinfected and restrained would seem more rational, especially if it combines the advantages of less frequent dressings. He makes use of the following dry method of treating cancer: A small Sims' speculum is introduced, the vault is stuffed with gauze, the gauze is then stuffed round about the portio so that it lies imbedded in iodoform gauze. It is not necessary to use great quantities of gauze in this dressing, for it may be stuffed up very loosely. If, however, the cancer is ulcerating, the gauze must be firmly packed into the cavity. If one piece of gauze is not sufficient, several may be used, the ends being made to hang out of the vulva. In most cases an astringent adjuvant becomes necessary. Tannin and iodoform are intimately mixed, and the gauze filled with the powder and then packed into the cavity. A tampon of this kind stops hæmorrhage, checks secretions, it disinfects, absorbs, and has an anodyne effect. It can be kept *in situ* four or five days, and may be removed easily and without pain. The advantages of this method are very apparent after an operation. After the cancer has been scraped with the spoon and cauterized with the thermo-cautery, the cavity is tamponed with iodoform tannin gauze, or it is first filled with the powder and the tampon applied over the powder. This dressing is left unchanged for five to six days, and is then renewed. If the hæmorrhage is obstinate, glycerine may be added to the powder, iodoform, tannin, aa 10, glycerine 200, and the tampon soaked in it. As soon as the tampon is no longer stained with blood, the dry treatment is resumed. In this way cancer may be kept free from smell and discharge until the death of the patient, the tampon, even in large and profusely secreting cavities, being changed only twice a week.

Iodoform gauze may also be inserted into the cavity of the uterus. In puerperal metritis, with offensive discharge, the womb is syringed out, and then stuffed with gauze. If pieces of placenta have been retained, or in case of ulcerating polypus, these are removed and the gauze is applied. In endometritis he also introduces the gauze, filled with the iodoform-tannin powder, or soaked in its glycerole. The gauze is very readily introduced into the uterus, even in the multiparous womb a strip 20 cm. in length can be easily inserted. In incision of the cervix the gauze is packed into the cervix and between the cut surfaces.

Tamponing or filling large wounds in abdomen or large abscess cavities with the iodoform gauze has replaced wound drainage in his hands. In vulvar and vaginal cancer where, from loss of tissues, the deeper parts cannot be approximated, the cavity is stuffed with gauze. In the two cases operated on the cavity closed rapidly, there was no fever, and recovery was complete. He cites one case of perityphlitis abscess, refers to several cases of ecchinococcus cysts, gives three cases of laparotomy for ovarian tumors, and two cases of extra-uterine pregnancy, in all of which the abscess cavities, or the extensive wound surfaces, were dusted with iodoform and then packed with iodoform gauze, folded in fan-shape, the ends being carried out at the lower angle of the external wound. After seven or eight days these strips were drawn out, and if necessary replaced by one or two fresh strips. No fever followed these operations, recovery was rapid, and the patients could be discharged cured in a very short time. He claims that all discharges from the abscess walls or the wounded surfaces are absorbed, disinfected and carried out into the external dressings by capillary drainage; that if any wound secretions remain behind these are aseptic and innocuous; also that a large part of his splendid results is due to filling up the cavities with the dry iodoform gauze, and that the removal of this dressing is easy, and can be accomplished through an opening in the abdominal wall.

THE USE OF SEDATIVES IN INSANITY.—In the *Practitioner*, September, 1886, p. 181, DR. SAVAGE contributes a most valuable paper on the use of sedatives in insanity. The old practice of restraint by means of chain, cord, or whip was most barbarous, and the practice of producing quiet by means of narcotics is most strongly condemned. The principle of controlling patients by means of drugs will continue to be used by general practitioners until the public overcome their prejudice against asylum treatment. In nearly every case the history is the same. Sleeplessness and depression are tried to be overcome by opiates, or it is attempted to subdue violence and restlessness by narcotics. Something must be done if the patient be treated at home, and it is on this account that the author enters upon the subject of drugs in insanity, giving his experiences when they may do good and when they are harmful. At the Bethlehem Hospital such drugs as the bromides, morphine, chloral, and opium are seldom if ever used. In studying the treatment of mental disorders by means of sedatives, it must be remembered that two very opposite conditions give rise to mental disturbances: In one the brain is the chief cause of the disorder, in many cases the evil being organic decay of this organ; in other cases the mental disorder is functional, and may be due to bodily disease react-

ing on the mental processes, or to perversion of the senses and allied disorders of intellectual processes. In cases of brain decay you must be careful not to begin with large doses; in functional disorders you must sometimes not be afraid to give large doses, for in functional disorders of the mind profound impressions produced by therapeutical or accidental circumstances may effect wonders. In these cases the old term "alterative" has some meaning. In some functional cases, a whitlow, or a toothache, a severe attack of diarrhœa, or sickness, may cause relief, and in the same way a blister or a seton, an emetic, or a powerful sedative may effect a similar result. The author does not believe in treating the symptoms of insanity as if they each had a definite meaning. Sleeplessness may as often be removed by a stimulant as by a narcotic. Bromide of potassium is supposed to be the strongest remedy we have for nervous excitement, and in some cases of restless excitement it is very useful, if given in doses of 20 grains three or four times a day; it is most useful in young cases belonging to nervous families, especially those who complain of vague uneasy feelings in the head. In cases of sexual perversion of one kind or another, bromide is very useful. In young men and women, with a tendency to commit suicide or be violent, a dose of from 20 to 40 grains at bedtime has good effect. Any tendency to epilepsy is often treated by bromides, but here frequently the number of fits are reduced at the expense of harm to the mind. Bromide is generally given in combination with chloral, and the author's experience is that they do no good. In the sleeplessness of the early stage of puerperal insanity it is well to try them, and they may tide over a dangerous time; but if rest be obtained at the expense of appetite for food, more harm than good is done. Dr. Savage lays down the law: if sufficient food be taken, bromide or bromide and chloral may be pushed in cases of mental excitement. Objection is taken to chloral because it soon disturbs digestion; but in cases of acute delirious mania, if given with abundance of food and stimulants, it will save many from death.—*London Medical Record*, Nov. 15, 1886.

Natural History of Tuberculosis and the Bacillus Theory.—Dr. R. B. Davy, of Cincinnati, has lately read two papers before the medical societies of that city, in which he thinks he has shown the infectious theory of tuberculosis to be supported in every respect by the natural history of the disease. He does not lay particular stress on the "bacillus tuberculosis," and speaks of the poison more as the "tubercular virus," but insists that, like all other organisms, it is a creature of heat and moisture. From the fact that its appearance and extension are only noticed to occur in confined spaces, and its disappearance most favored in unconfined spaces, he concludes that the danger of infection depends more upon quantity than quality of poison. After extensively discussing the natural history and climatic treatment of the disease, he comes to the following conclusions: 1. That tubercular phthisis occurs most frequently and most fatally in warm or hot regions characterized by a non-porous soil and the ordinary accompaniment of excessive humidity of atmosphere. 2. That it depends upon a specific organism, which can be made to produce the disease by inoculation. 3. That the key to the introduction and development of this organism in the system is ordinarily some form of irritation. 4. That the disease is plainly curable in all its forms except the acute, and even this may not always be fatal. 5. That to the predisposed it is communicable by infection through the medium of a polluted atmosphere. 6. That the infection depends upon quantity rather than quality of virus. 7. That on the open sea, where every condition favoring the development of tuberculosis is present except the tubercular spores, the disease speedily disappears. 8. That the nearest approach to perfect immunity from tuberculosis is to be found on high mountains where, on account of extreme rarefaction and accompanying dryness of the air, the tubercular organism cannot exist.

Diagnosis and Treatment of Tobacco Amblyopia.—Dr. Geo. H. Powers, of California, says: It has been my practice for several years to use inhalations of amyl nitrite in all amblyopia cases, and I have found it of great value, especially (if not exclusively) in the cases of tobacco amblyopia. I believe that it is of great assistance in differential diagnosis, for thus far it has proved that, in progressive atrophy from other causes, no benefit is derived from the exhibition of the amyl, while in tobacco amblyopia vision is immediately and markedly improved.

For instance, a patient presents himself with a history of rapidly failing vision, without pain or inflammation, and examination discovers a dirty grayish hue of the disk, with diminution of circulation, and $S.=\frac{20}{CC}$. Inhalation of a few drops of amyl, pushed only to the point of lively hyperæmia of the face and headache, will cause a decided increase in the circulation in disk and retina, and within five minutes $S.=\frac{20}{XL}$. This evidence that vision is not permanently lost is of great value in fortifying the patient for the abstinence which is necessary to his cure. The sudden improvement is, for the most part, temporary, as, after an hour or so, S. recedes to perhaps $\frac{20}{C}$, but it is not wholly lost, and daily inhalations, combined with tonics and abstinence from tobacco and alcohol, have in my hands proved much more rapidly curative than the strychnine and electrical methods. As the only action of the amyl seems to be to increase the blood supply, it would seem that tobacco amblyopia is due simply to a loss of function from anæmia, which may result in atrophy if long continued.—*Medical News*, Dec. 4, 1886.

Treatment of Chronic Constipation in Children.—Dr. W. B. Cheadle, at the close of a clinical lecture on this subject, points out the disastrous results of mistaken treatment, and shows the necessity of a more rational procedure. "Look at the evil effect of strong purgations—how they enervate

and wear out the tone of the bowel. No occasional purge of rhubarb or scammony is efficient to cure. Look, again, at the evil effect of frequent enemata. Enemata are only to be used on an emergency. They, equally with strong purges, impair tone and do direct harm by actual dilatation. In confirmed cases of constipated habit, treatment must be not intermittent, but continuous; the daily administration of appropriate remedies steadily, for a considerable period, is absolutely essential. Intermittent treatment is abortive, ineffectual, and aggravates the evil. What, then, is the proper treatment for these cases? First, be sure that there is no malformation, no intussusception, no sore about the anus, rendering defecation painful. Then use saline laxatives. Their mode of action is by increasing the flow of secretion rather than by stimulating peristalsis. Thus tone returns when distension is relieved by the easy evacuation of fluid stools. Further aids to this are strychnia, nux vomica, iron and belladonna. They act by increasing muscular tone and nutrition, not by stimulating peristalsis directly. In the case of little children up to two years old simple carbonate of magnesia in milk is sufficient (5 to 10 or 20 gr.); this is better than the piece of soap in the rectum, or the repeated castor oil or manna so constantly advised. In older children the sulphates of magnesia and soda, with the tonics named above, and daily massage with castor oil or cod-liver oil, are most useful. In older children still, a pill of aloes or euonymin, with sulphate of iron and nux vomica, may be given as an alternative to the salts and strychnia, but no frequent rhubarb, or scammony, or podophyllin or jalap (these are for the relief of temporary difficulty only); in mild cases, perhaps, or if the liver is not acting, a dose of calomel, grey powder, and soda, or senna. Regimen is an important element in the treatment if the child should have chronic constipation; abundant water, pure, not hard; "salutaris water" is excellent. In little children add a good infant's food to milk; fruits, fruit jellies, treacle, cooked green vegetables of the softer and more delicate kinds. Some variety in food is useful; a good mixture is better than a monotonous diet. It is, I think, extremely doubtful if coarse food is useful in the long run. It causes atony and weariness of muscle eventually by over-stimulation. And you must insist on regular evacuations. Take care that the stools are not dry and hard, or the child will resist action and increase constipation. Other useful adjuncts are—abundance of fresh air, which aids in improving nutrition; and exercise, which aids the passage of the contents of the intestine down the tube, and improves general health and muscular tone."—*Lancet*, Dec. 11, 1886.

SANTAL OIL IN BLENNORRHAGIA.—DR. LITZEL, of Munich, furnishes (*Allg. Med. Central Zeitung.*, Nos. 76 and 78, 1886) a somewhat detailed account of his experience of the use of santal oil and essence of copaiba, in the treatment of this troublesome affection. He at first gave this medicine with extract of coffee, but as at least half the patients showed extreme aversion to the drug, gelatine capsules were substituted, two or three capsules, each containing five minims of oleum santali, being taken three times a day. Of ninety-seven patients thus treated, four had gastro-intestinal disturbance; two of these had violent diarrhœa, and the other two severe dyspepsia. Eructations and burning sensations in the stomach were often noticed in the rest, but the drug was persisted with. It should not be given on an empty stomach. One bad symptom, which occurred in five cases out of the whole ninety-seven, consisted in severe congestive pains over the kidneys. Louis Jullien, in his recent work on *Venereal Diseases* (Paris, 1886), speaks of this symptom, also of urticaria, as being not infrequent. Sandal-wood oil is much better tolerated than balsam of copaiba, and if pain in the liver should arise, it suffices to discontinue the drug, and order a warm bath. The use of about thirty minims daily is generally enough to give the urine a distinct odor of the oil. The capsules used were Grimault's (Paris), and Paulcke's (Lepsig). Both these makers sell the pure oil in their capsules. The general indifference and distrust towards sandal-wood oil is apparently due to the fact that owing to its high price, it is extensively adulterated with copaiba balsam and castor oil, so that the commercial oil often contains only a small percentage of the genuine oil. Dr. Hager gives the following test of its purity: "Genuine E. I. sandal-wood oil (.0980 specific gravity) requires, to produce turbidity, from four to five volumes of dilute alcohol of specific gravity .0889, added to a clear mixture of one volume of the oil, and two volumes of absolute alcohol (.0799 specific gravity)." Dragendorf's test is simpler; namely, a solution of one part of bromine in twenty of chloroform. When from ten to fifteen drops of this test are mixed with one of the oil, the color becomes a brownish violet, and later on dark-blue. The pure oil is clear, light-yellow in color, and very pungent on the tongue; it has a slight odor of copaiba balsm. The results of treatment were these: 1. Given in an early stage, the secretion diminished rapidly, and the pain on micturition ceased. This result happened in thirty seven out of forty-two cases. 2. If, after ten or twelve days, the oil be discontinued, the old symptoms reappear. 3. The best results were obtained when the oil was commenced in the third or fourth week of the gonorrhœa, together with the use of weak astringent injections. 4. Cystitis. 4. Cystitis and gonorrhœal prostatitis were always greatly benefited by the oil. 5. Cases of gleet did best under local treatment.—*British Medical Journal*, Dec. 4, 1886.

SECONDARY INFECTION THROUGH TYPHOID ULCERS.—SENGER reports a case of a woman who died of typhoid fever, in which he found the following lesions: Vast ulcerations of the lower part of the ileum, colon and rectum; enlargement of the spleen and mesenteric ganglia; recent verrucous endocarditis limited to the mitral valve; tumefaction of the liver and kidneys; and pronounced pulmonary œdema. No bacilli could be found in the ulcerations, but the intestinal mucosa, the mesenteric ganglia, and the tissues near the endocarditis were infiltrated with streptococci.—*Gaz. Méd. de Paris*, No. 49, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

Per Annum, in Advance.....$5.00
Single Copies.....10 cents.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

SATURDAY, JANUARY 1, 1887.

A COMPLETE ORGANIZATION OF THE MEDICAL PROFESSION, AND HOW TO ATTAIN IT.

"We want 80,000 doctors enrolled under one Constitution and By-laws believing that their common interests are faithfully looked after by the great central body. Perhaps such a hope is Utopian. But we are sanguine enough to believe that it can be wrought out, and must be if the American profession shall attain the power to which it is entitled."—*American Lancet*, p. 422, for November, 1886.

The above paragraph from an editorial in our valuable contemporary simply expresses the desire to have the entire number of members of the regular profession of medicine in the United States actually enrolled under one general organization, and a degree of confidence that it can be practically accomplished. The idea of such an enrollment or nominal membership of the whole profession under one Constitution and By-laws, to be governed by a comparatively small select Council or Senate, is not new, but was the fundamental idea or principle on which the British Medical Association was founded more than half a century since; the same that shaped the organization of the Massachusetts State Medical Society with its Branch or District Societies; and the same was actively discussed by the Committee appointed in 1846, to report a "Plan of Organization for the American Medical Association." We are satisfied that our *confrère* of the *American Lancet* and all others who will thoroughly study the history and practical results of Medical Society Organizations among all English-speaking people, will become convinced that such a complete enrollment under one organization can never be effected or perpetuated either in Great Britain or the United States of America, except by an Act of Parliament for the one, and an equally imperative law of Congress for the other, enforced by adequate penalties. The probability of the procurememt of such a National law susceptible of practical enforcement, in either country, is too remote to justify its further consideration at present. The development of such a complete organization or literal enrollment under one Constitution, by the voluntary act of the entire membership of the profession, if even attained, would require at least one or two centuries if we may judge by the progress made in the past.

Great Britain, from the comparatively limited extent of her territory and the density of her population, presented conditions much more favorable for the success of such a plan, than our own country. Notwithstanding, the British Medical Association organized with a limited and stable Council for the management of its business affairs, and rules favorable for the formation of Branches in all parts of the country, the members of which thereby become members of Association, has been in existence fifty-four years, and has enrolled as members to this date only about one-half of the members of the profession in England and Wales, Scotland and Ireland, who are legally authorized to practice medicine, surgery and midwifery. With our vast territory divided into between thirty and forty States with no uniform laws regulating either medical education or practice, and not even a general registration of the members of the profession in many of the States, the prospect of bringing them all into actual membership of one organization capable of wielding an united influence, is certainly very remote. While it may be justly deemed impracticable to bring the whole profession of our country into actual voluntary membership of one organization under one constitution, it certainly is not impracticable to so far complete the organization of the profession into municipal, country, district, State and National Associations, on the representative basis, as to give it all the unity and power, with far greater facility of expression, that has ever yet been attained by other methods. A complete organization of the profession on this basis would require the voluntary formation of the regularly educated members of the profession in each county of each State; each State Society should be composed essentially of delegates elected anually by the County Societies in accordance with a uniform ratio of representation; and the National Association should consist of delegates appointed by the State Societies, also in accordance with a uniform ratio of their membership, thus

combining the whole profession in one National representative body, based directly on the State Medical Societies, and indirectly through them, on the municipal and county societies of all the States, in strict accordance with the political institutions of our country, and in harmony with the prevailing habits of thought of our people.

The organization of the American Medical Association commenced in 1846 and completed in 1847, was based essentially on this principle of representation, though imperfectly applied on account of the limited number of county and State Societies then in existence and the diverse organization of such as did exist. But the adoption of the fundamental principle by which the responsible *voting membership* of the National Association was made to consist of direct delegates from local and State societies gave so much impetus to the work of organization of these, that for several years past regular organizations have existed, and have been sending delegates to the National Association in every State, in many of the counties, and all the larger cities of our country. A full investigation will show that during the forty years since the organization of the American Medical Association it has increased its direct constituency in the local, County, District, and State Medical Societies to an aggregate number three times greater than are enrolled as members of the Branches of the British Medical Association resulting from the fifty-four years' existence and work of that great and influential medical body. During the past history of the American Medical Association such improvements have been made from time to time, in the practical application of the principles of its organization, as experience has shown to be necessary, leaving, at present, but few further changes of importance desirable. But the most important work that needs attention, is that of organizing the profession in every county or district where no society yet exists, and the making of those already in existence more full and efficient. To the details of this part of the work and its importance we will give attention in another number of THE JOURNAL.

FERMENTATION, PUTREFACTION, AND SUPPURATION.

Notwithstanding the deluge of matter that has been published of late years in regard to bacteriology, DR. HERMANN KNAPP, in introducing a recent lecture on "Fermentation, Putrefaction and Suppuration" before the New York Academy of Medicine, expressed his conviction that the importance of the subject was not sufficiently appreciated in this country. He quoted a recent opinion of Professor Brieger, of Berlin, to the effect that the great majority of all diseases now seem to be of bacterial origin, and in support of the correctness of this proposition referred to the weekly mortality lists of the various American cities. Thus, during the week ending August 28, 1886, the number of deaths from infectious diseases in New York was set down at 33 per cent. of the total mortality; those from consumption at 16 per cent.; and those from croup and diphtheria at about 5 per cent. Here were nearly 55 per cent. of all deaths attributable to diseases of undoubtedly bacterial origin. In addition, 20 per cent. of the deaths were from diarrhœal diseases, and at least 90 per cent., if not all of them, may be regarded as cases of germ disease. This brings the percentage up to 75 per cent. But such affections as pneumonia, peritonitis, syphilis, gonorrhœa and skin diseases, are not included in the estimate; and if only 10 per cent. of these were classed as of this character, it would increase the present percentage to 85. This is exclusive of surgical diseases in which undue suppuration is caused by microbes; and estimating the mortality from these at 5 per cent., we have a grand total of 90 per cent. of all deaths to be attributed to disease of bacterial origin. It seems, then, that Professor Brieger is right.

Bacteriology has shown its principal fruit in the department of surgery, and there can be no sort of doubt that antisepsis has advanced this branch of medical science to its present high position. Antisepsis, however, is in reality nothing but the practical application of the three words, *fermentation*, *putrefaction*, *suppuration*. Fermentation may be described as the decomposition of carbohydrates through the agency of the yeast-plant; and we may compare the action of the latter to that of the bacteria which are believed to cause putrefaction and suppuration. There are two grades of putrefaction (which is brought about by different kinds of microbes, fifteen or twenty varieties of which have now been discovered); the first grade is met with when there is but little oxygen present; the products being water, carbonic acid and ammonia, and the process of decomposition is attended with little or no offensive odor. The second grade, or putrefaction proper, as generally understood, is seen when there is a larger quantity of oxygen present. Dr. Knapp then discusses the question, whether suppuration and putrefaction are one and the same thing. Surgeons, he said, use the two terms indifferently, and after speaking of the experiments of Recklinghausen and others with the cornea of the frog, he refers to the common assertion

of surgeons that if all germs be excluded, suppuration could not take place. Personally he has investigated three special points in this connection, viz.: 1. Does mere traumatism produce suppuration? 2. Do foreign bodies alone produce suppuration? 3. Do chemical agents of themselves produce suppuration?

In regard to the first inquiry, both in Berlin and at home he has made a number of experiments on the eyes of rabbits. If a wound be made by a perfectly clean instrument, he has found that it will heal by first intention, with no suppuration whatever; but if the wound be made with a contaminated instrument, suppuration invariably results. One of the axioms in antiseptic surgery is that simple fractures never suppurate. It is true that there are rare exceptions to this; but when suppuration does occur, it is always in cases in which some other process of suppuration is present in the body. Whenever the individual is healthy, therefore, no suppuration will take place. In support of this statement may be mentioned the experiments of Becker, who, having made fractures in animals, injected pyogenic fungi into the ear; with the result of at once producing suppuration, although the exciting injury was only a simple fracture. Where no such injections were made the process of repair was never attended with suppuration. Other similar experiments show how ulcerative endocarditis and other suppurative processes can be produced by the introduction into the system of pyogenic organisms.

In regard to the second inquiry, Are foreign bodies by themselves capable of producing suppuration? Dr. Knapp concludes that if they are introduced antiseptically, they will not produce suppuration, and that they may remain indefinitely without giving rise to it. In support of this, he showed a rabbit into one of whose corneæ he had introduced, by means of sterilized instruments, a piece of rusty hair-pin, after having first brought the latter to a glow, in order to destroy any organic matter that might be adherent to it. No suppuration whatever had occurred, although the foreign body had been in the eye for a very considerable time. Into the cornea of the other eye of the same rabbit he had introduced a piece of the same rusty hair-pin which had been dipped in fluid containing pyogenic fungi; and within twenty-four hours a violent phlegmon was set up, which soon completely destroyed the eye. Still, the truth of the proposition that foreign bodies alone will not cause suppuration is not generally admitted, and Pasteur, in 1878, stated that even if foreign bodies be introduced antiseptically, they are capable of producing suppuration. Whether he still adheres to the same view or not, we do not know.

Do chemical agents by themselves produce suppuration? is almost invariably answered in the affirmative. Especially in the case of croton oil is it claimed that suppuration is caused without the intervention of germs. If this exception can stand, however, the whole theory of suppuration, according to the views here taken, must fall to the ground. It is a very difficult question to satisfactorily test in a practical manner; but the solution of the problem has been undertaken by four observers under very strict precautions. The results of these experiments go to show that chemical agents do not of themselves produce suppuration. In repeating some of them Dr. Knapp had much difficulty as regards croton oil, on account of the extreme irritation caused by it. Oil of turpentine, however, is much more manageable. He followed the method of J. Straus in these experiments. On account of the practical impossibility of otherwise completely disinfecting the fur of the animal, he sterilized the skin of a rabbit by means of the actual cautery. Then, having made the injection of the chemical agent under the skin by means of sterilized apparatus, the opening made by the needle was sealed up again by the actual cautery. Some of the experiments were made with a pipette, the opening in the skin through which its point was inserted having been made with a heated knife. With the experiments made with oil of turpentine and croton oil (although there were but five in which the latter was used), suppuration resulted in only 10 per cent of the cases. As a rule, there was coagulation of fibrin, with some necrosis, but no suppuration. In the cases in which suppuration did occur, it was found that there were always germs present, on account of some imperfection in the technique of the experiment. Roice, of Utrecht, has made the same experiments in connection with the anterior chamber of the eye; and this method of procedure has the great advantage of allowing the whole process set up by the chemical agent to be under observation. Dr. Knapp has repeated Roice's experiments, and he also in one instance introduced the chemical agent into the abdominal cavity. No appreciable effect was produced upon the animal, and when, two weeks afterward, it was killed, no pathological changes whatever could be observed at the autopsy.

In Dr. Knapp's experiments upon the eye, inflammation was caused, but no suppuration, even with croton oil; which he finds can be used more satisfactorily when mixed with olive oil, in the proportion of

one to two. In some of the animals operated on the injection was made through the sclerotic. When the same chemical agent (either croton oil or turpentine) was introduced into the other eye in connection with pyogenic fungi, the most violent suppurative inflammation was always produced. He has also made a large number of cultures from the two classes of eyes. From the eyes containing pus, an increased quantity of microbes, with pus, resulted. But microbes (although no pus) were also obtained from the eyes from which pyogenic fungi were excluded; and this is a point that calls for an explanation. The microbes were found not only in the eyes, but also in the kidneys and the blood, though not in the brain. It is evident, therefore, that the system had become infected through the suppurating eye; and the microbes found in the other eye no doubt originated from this source. He therefore made the two classes of experiments in two different series of animals, instead of operating on both the eyes of the same rabbit. When the cultures were now made, no microbes were found to have come from the non-suppurating eyes. These experiments seem to be satisfactory and conclusive. In the eyes into which pyogenic germs were introduced in connection with the chemical agent, suppuration occurred and microbes were found in large numbers; but in the eyes from which such germs were excluded there were neither suppuration nor microbes. The results observed in the latter were merely coagulated fibrin and fibrino-leucocytic exudation. He thinks, therefore, that so far as this whole series of experiments go, we are justified in formulating the proposition that *suppuration is always produced by microbes;* and hence there can be no suppuration without the intervention of these morbific agents.

What, then, is suppuration? First, as in the case of fermentation, the microbe ought to enter into its definition. Fermentation, as has been seen, is the splitting up of a hydro-carbon into simpler forms through the agency of the yeast-plant. Putrefaction, again, is the similar decomposition of a nitrogenous substance through the agency of microbes. Finally, suppuration is likewise the splitting up of a nitrogenous substance, by the same kind of agents. The difference between the two is that in putrefaction, the process is always concerned with dead matter, while suppuration always takes place in living matter.

CENTENNIAL CELEBRATION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.—Full preparations have been made for an interesting and elegant celebration of the Centennial Anniversary of this well-known Society, January 3d and 4th, in Philadelphia.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Monday, December 6, 1886.

THE PRESIDENT, EDMUND J. DOERING, M.D., IN THE CHAIR.

DR. JOHN A. ROBISON read a paper on the

ANTIPYRETIC ACTIONS OF ANTIPYRIN AND THALLIN,

in which he had collected and condensed the results of the experiments of a large number of clinicians. The largest number of observers agree that antipyrin is a safe, efficient and unobjectionable antipyretic. Contrary to belief in general it does not have a depressing or debilitating effect on the heart, whereas thallin has. Antipyrin causes no change in the blood, whereas thallin has a deleterious effect on the blood and veins. In conclusion, the author believed antipyrin should always be given to produce a pyrexia in cases where the temperature is excessively high. He does not believe the drug has any influence to lessen or prolong the duration of the continued fevers. He also stated that it not only lowers the temperature, but relieves the pain that accompanies acute articular rheumatism with endocarditis, especially if given with alkalies.

DR. J. J. M. ANGEAR said: I have not given this subject any special study, but the subject of temperature I have, and it may not be amiss to speak of some difficulties which we have to contend against. If radiation is increased or diminished and metabolism remains normal, we have increased or decreased temperature; or if metabolism of the body be increased or diminished and radiation remains normal, then we have increased or decreased temperature. We have no means of arriving at any definite conclusion whether our patient, with increased temperature, is suffering with increased metabolism or decreased radiation, or both. We know from observation and from various experiments that the internal part of the body is very frequently hotter than normal during the cold stage of fever, and cooler than normal during the febrile stage. May not the sum total of caloric in the body be diminished when the thermometer tells us that it is increased, and *vice versa?* If we answer yes, then we are found trying to diminish the temperature, when we should be husbanding what we have. Does not this show that there is a certain amount of pathological knowledge in regard to body temperature which we have not yet arrived at? And our therapeutical knowledge is necessarily as defective in this regard.

Do antipyretics facilitate radiation or check metabolism, or both, or do we know anything about it except its action upon the thermometer? If we could arrive at some definite, pathological conclusion as regards the pyrexial state of the patient, then we could, perhaps, arrive at some scientific knowledge of the action and use of all antipyretics. Had we an instrument by which to measure the amount of radiation and metabolism, it would be of far greater value to us than the thermometer.

Dr. C. C. Paoli said: The paper was well prepared and interesting, but the question arises, do we know anything about the essential nature of fevers? I answer, no. But we know the effect, if we do not know the nature, and in fevers we generally use remedies to lessen the temperature. I have used antipyrin in only eight cases, two of typhoid fever, two of scarlatina, two of lung trouble. In regard to the fever, I admit that the remedy had an antipyretic effect. In two cases the patients vomited as an effect of taking this remedy. I commenced with ten grains, and it diminished the temperature but did not stop the course of the fever, which lasts usually from five to six weeks. One effect I have found from the use of antipyrin, is the lessening of nervous irritability. In a case of tuberculosis, after using antipyrin I began with quinine and found it more of a tonic. In the cases of scarlatina in which I used antipyrin I did not observe any favorable effect; it lessened the temperature, of course, but the same effect was produced by quinine.

Dr. H. Gradle said: Although my line of practice does not often enable me to watch the effects of antipyretic drugs in disease, I can speak of the effect of antipyrin in one disease, viz., the dentition fever of infants; which, although not usually serious, is in a great many instances annoying, and in which, when the fever is high, there is a possible danger of convulsions. I have never heard of any drug that will reduce the fever under these circumstances as promptly and with as little disturbance as antipyrin. With a temperature of 103° a child can be rendered quiet in the course of an hour by one dose of four grains, and perhaps a second dose of two grains, and be pacified for the entire night. I wish to ask the author if he has had any experience in the continued use of thallin in typhoid fever, with the effect of aborting the disease? According to some rather startling statements made several months ago by Ehrlich, it was claimed that it reduced the fever permanently in the course of eight to twelve days.

Dr. G. W. Webster favored the use of antipyrin. He had used it in cases of typhoid pneumonia. One point is the favorable action of antipyrin on the headaches of typhoid fever. One of the most distressing symptoms when the temperature is very high is the severe, continued headache and the delirium which always accompanies it. He had not found any other remedy that would have as good an effect in these cases as antipyrin, which always relieved the headache promptly.

Dr. H. T. Patrick said: I am quite partial to antipyrin and have used it in a number of cases. It will often effectually reduce the temperature when baths and sponging will not. In a case of pneumonia in a child of eight years I gave antipyrin from the beginning to the end, with good results, except for one day when I tried sponging instead. The child was sponged off six times in six hours, five to ten minutes each time, without any reduction in temperature. Sometimes cold baths have no effect in reducing the temperature because of a very thick panniculus of adipose tissue. Here antipyrin is indicated. The continuous administration of antipyrin in tuberculosis I have found in a few cases very gratifying. In one case ten to fifteen grains were given every afternoon for a term of ten weeks, with great relief to the patient. His temperature was 103°, and there was prostration and irritability of mind. The antipyrin was a relief to the patient, and to his family on account of the improvement in his disposition.

Dr. J. Frank had had a personal experience with antipyrin, having taken it two years before while suffering with typhoid fever. The temperature ran as high as 106°, and quinine had no effect in reducing it. He took antipyrin in 15 and 30 grain doses, first by mouth and then by rectum, with the effect of rapidly reducing the temperature. He has used it in practice in the treatment of erysipelas and typhoid fever, but does not depend upon it entirely, giving it when the temperature rises very high. In erysipelas he has always found that antipyrin will reduce the temperature.

Dr. C. W. Leigh said: I have seen antipyrin used in a limited number of cases, three or four, of typhoid fever, and none of the patients were older than twenty-one. In these cases there was a visible decrease in temperature and the delirium was lessened very much.

Dr. J. A. Robison said that he had not pretended to give anything except the results of the observations of a large number of physicians who had used this drug and recorded their experiences. Also the results of quite a number of experiments of therapeutists, as for instance Umbach's experiments in regard to the decrease of tissue waste. I did not try to detail all these different experiments, but attempted to epitomize the well known actions that have been observed of the drugs. Two of these actions, the increase of heat radiation by the dilatation of small blood vessels, and the decrease of oxidation, are the main factors in producing the fall of temperature. Dr. Angear says if we can arrive at some conclusion in regard to the manner in which the drug acts, we can use it. I think we have arrived at a conclusion; these experiments have been carefully conducted and we have seen that antipyrin actually reduces high temperature without any danger to the patient, and it is only in cases where the high temperature itself is a danger to the patient that its use in large doses is to be recommended. In regard to its use in aborting typhoid fever, I have not tried it except in four cases; one was a boy under seventeen and another one fourteen. The temperature was about 103°. I gave large doses and in three days all signs of fever had disappeared. A few days afterwards another member of the same family was taken sick, and the antipyrin was used as before, but that patient went through all the stages of typhoid fever. In another family there were five cases of typhoid fever. Two of the family had had the fever, one of them dying; then three others took sick. Antipyrin was given in large doses in all these cases, but it failed to abort the fever in any of them.

Dr. Henry Gradle read a paper entitled

DISEASES OF THE VAULT OF THE PHARYNX.

He emphasized the fact that this region is too

much neglected by general practitioners in spite of the importance and curability of some of the diseases occurring there. According to his experience the best examination can be made by means of a large mirror and a palate hook, and this is facilitated by using cocaine when necessary. He gave the history and symptoms of enlargement of the pharyngeal tonsil, which trouble is often called adenoid vegetations, but as usually seem in this country there are no coxcomb-shaped vegetations, it amounts rather to a uniform enlargement of the tonsil at the roof of the pharynx. The condition is of especial importance on account of the liability of ear disease to which it gives rise. Often reflex symptoms are observed like asthma, cough, bronchitis and headache. The tonsil should in every case be removed when enlarged. This can be done by means of the galvano cautery, but it generally requires many sittings and the process is tedious. The quickest way is by means of scoops or sharp curettes according to the plan of Trautman. The hæmorrhage is never alarming and the pain not very great. The result of the operation is always very gratifying to the patient. The pharyngeal tonsil may require treatment even when there is not much enlargement. Sometimes irritation is produced by the presence of white plugs consisting of bacterial masses in the crypts of this gland, which condition can be removed by the galvano cautery. In other instances the glandular tissue forms reddened, tender spots at the junction of the lateral walls and the roof of the pharynx above the Eustachian orifices. This condition may keep up inflammatory ear trouble until removed by the galvano cautery. The speaker further contrasted the relative curability of hypertrophic chronic catarrh of the nasal pharynx with the almost hopeless condition of that form of catarrh, in which no lesions are found on careful inspection. In the hypertrophic form of disease he has found nitrate of silver most serviceable. The form of catarrh in which no lesions of any account are found, has been attributed by Tornwaldt to catarrh localized in a small recess of the mucous membrane in, or just back of the pharyngeal tonsil, known as the bursa pharyngea. The speaker has not been able to verify the existence of this bursa, and considers the pit which is sometimes seen with the rhinoscopic mirror in this region, as a part of the pharyngeal tonsil. He has followed Tornwaldt's directions to cauterize this spot in obstinate cases of catarrh with some little success, but without believing that there is any catarrh limited to this recess. He has seen a few cysts in this locality, but considers them as being formed in the substance of the pharyngeal tonsil and not due to the closure of the alleged bursa pharyngea.

DR. W. E. CASSELBERRY said: I agree with the author on the importance of the pathological states which occur in the naso-pharynx, and I would particularly emphasize the importance of the subject in connection with ear diseases. It is usually neglected because the practitioner does not use the rhinoscope. This can readily be used since the introduction of cocaine; formerly, the pharynx being so irritable, it was a different matter, and considerable practice was necessary in order to acquire the use of the mirror, but now a 2 per cent solution of cocaine sprayed around the pharynx will so reduce the sensibility that the introduction of the rhinoscopic mirror is comparatively easy. I was somewhat surprised at the size of the mirror recommended; usually a small one about one-half inch in diameter is used. This, of course, will not show the entire nasal-pharynx at one time, but it can be easily rotated from side to side. With a large mirror a hook is always necessary, which usually complicates the case and is more apt to gag the patient than the use of a small mirror without the hook. I am accustomed, in considering the diseases of the nasal pharynx, to divide the inflammatory affections into three classes. First, the simple chronic naso-pharyngitis; second, the hypertrophic naso-pharyngitis, and third, the atrophic naso-pharyngitis. In the first there is a simple inflammation of the mucous membrane and of the connective tissue beneath the membrane, the connective tissue being sometimes involved to such an extent as to form, here and there, thickened areas of infiltration. I think that many of the cases in which the author sees no perceptible lesion in the naso-pharynx can be graded in this class. The hypertrophic form of disease may be sub divided into two classes, one in which the follicular structures are uniformly hypertrophied, the group of follicles constituting the tonsil of Luschka being enlarged and appearing in the rhinoscopic mirror of about the size and configuration of an ordinary tonsil of the throat. And the other sub-class in which the enlargements are pendant, pear-shaped bodies resembling stalactites and hence called the stalactitic form. This is the form which was originally described under the name of adenoid vegetations, and the one which is met with most commonly in Germany, whilst the uniform enlargement is more common in this country. The atrophic naso-pharyngitis, as is the case in the pharynx itself, may be regarded as a later stage of the hypertrophic naso-pharyngitis, although in rare instances it may commence in the atrophic form. During the hypertrophic stage the proliferated connective tissue cells gradually encroach upon the glandular structures, and, so to speak, squeeze them to death, whilst the connective tissue cells themselves, as in cirrhosis of other organs, of the liver, for instance, later contract and atrophy. The mucous membrane is now pallid and thin, and is encrusted over with a dry secretion. This is the form of disease which so often gives rise to fetor of the breath, especially when it involves the naso-pharynx, although the disease is not restricted to that locality. In reference to the treatment there is little to add to what has already been said. I have not employed the curette much as my patients will not tolerate the blood and pain. The pain now is not as great as before the introduction of cocaine, but the blood horrifies the younger patients, and the parents. I have found an equally efficient, although a more lengthy treatment, in the galvano-cautery. It is bloodless and painless. In cases of stalactitic growths the best method is the galvano-cautery snare. For the uniformly enlarged variety I employ a Hemming naso-pharyngeal elec-

trode. Nitrate of silver as a means in the treatment of catarrhal conditions, although it has been greatly abused, is unquestionably effective if properly used. In cases of simple chronic inflammation of the mucous membrane, where there is thickening of the subcutaneous tissue, a strong solution applied by means of the cotton swab, 40 grains to the ounce, used by the physician every day, then every two days and finally twice weekly, will lead to the absorption of the infiltrated material. Strong solutions of nitrate of silver (40 gr. to ℥i) cause absorption of infiltration whilst weak solutions (10 gr. to ℥i) stimulate the further production of infiltrated material and the activity of the glands. Consequently weak solutions will only aggravate the hypertrophic form of disease. For the same reason a week solution will benefit the atrophic form. In reference to the pharyngeal bursa, I am of the opinion that too great importance has been ascribed to it.

Dr. F. O. Stockton said: My experience in the treatment of chronic nasal pharyngitis by the use of nitrate of silver has been anything but pleasing, and I have never seen a beneficial result from it. It is recommended by many in the form of powder, 1 grain of nitrate of silver powdered with some drug and distributed over the membrane, but my experience has been negative. Solutions I have found to be of no benefit whatever. It discolors everything, is a dirty, useless drug, and greatly overestimated. The use of the curette in removing adenoid vegetations is quite a recent thing. The method that the author speaks of I have not tried to any great extent, and I prefer the gouge forceps; I generally use the galvano-cautery, as it is now possible to use it without difficulty with the aid of cocaine, and there being no blood lost is a very important consideration in the treatment of young subjects, because, even if they have no pain, if they see a drop of blood they think they are being killed and begin to scream.

Dr. M. R. Brown said: In regard to the mirror, the size recommended by the author I think rather large, and apt to produce gagging by coming in contact with the pharyngeal walls, but if cocaine is used this may be avoided, and should a mirror about half the diameter of the one shown be employed in posterior rhinoscopy, nine out of ten instead of three out of four cases can be examined at the first visit.

Referring to the pharyngeal tonsil producing bronchitis and cough, the irritating mucus finding its way into the larynx has a great deal to do with producing laryngitis, which will give rise to cough; and the case of bronchitis mentioned by Dr. Gradle was evidently of a reflex nature. After having treated the pharynx with nitrate of silver for any length of time there results a thickening of its mucous membrane; there is absolutely nothing to be gained from the use of this remedy in the conditions mentioned; at least, such has been my experience after having employed it in various strength solutions in the different diseases of the pharynx. I occasionally make use of the cold wire snare, but prefer the galvano-cautery. The gouge or curette I also employ with satisfactory results; but, owing to the pain it causes the patient, have devised a punch forceps, the use of which is attended with less pain than, and is as satisfactory as the gouge.

Of the hypertrophied tonsil receding between the ages of 25 and 30 years, I have seen a number of cases in which the patients with this growth were beyond this age; to-day examined a man 35 years of age, and a short time since removed a similar growth from a male who was over 50 years old.

Speaking of the microscopic appearance of the naso-pharyngeal growths, Mackenzie says that in adenoid vegetations "the glandular element is, as a rule, more marked in growths taken from the vault of the pharynx, whilst in vegetations taken from the lateral walls the stroma of Kis is found in greater abundance."

Dr. H. Gradle said: As to the size of the mirror, of course where the patient will not permit you to use a large one you will have to use a small one, but where you can use the large mirror, there is an advantage in gaining a full view of everything. In speaking of being able to examine three out of four I referred to patients as they come. As a rule, I do not use cocaine in the first examination, because it is so disagreeable. I do not use the hook where the distance between the posterior wall and the pharynx is considerable. As regards nitrate of silver, there are many conditions in which it is entirely useless. One is the practice of cauterization with the solid stick. I have never done this. But there are certain conditions where nitrate of silver is useful and acts promptly, viz.: chronic hypertrophic catarrh. And it is sure to give relief in the more acute forms of catarrh where the pharyngeal tonsil is not enlarged enough to cause damage, but swells from temporary congestion. The patient can use a preparation of 4 per cent. and apply it himself with a brush, but it is preferable to have the physician use it. The spray, according to my experience, is more effective and not so disagreeable as a dry powder, but it requires considerable care on the part of the physician to avoid staining the clothing.

Dr. F. E. Waxham reported a case of

PSEUDO-MEMBRANOUS LARYNGITIS, TREATED BY ELECTROLYSIS.

(See page 9.)

Dr. W. E. Casselberry said: The report is an extremely interesting one, and I suggest that the experiments be carried further, to ascertain if the galvanic current has any effect in softening the false membrane outside of the body.

Dr. Franklin H. Martin said: I have used electrolysis for about three years in the treatment of strictures of the urethra, stenosis of the uterine canal, chronic inflammatory exudations surrounding the uterus, and in fibroid tumors. In listening to this interesting report the question occurred to me whether the effect of loosening the croupous membrane could be attributed to the electrolytic effect of the current of electricity, or merely to the mechanical effect of the electrode. Electrolysis describes the terms upon which it acts; in the case reported we get no evidence of this action. I should be in

clined to attribute any beneficial effect that might have occurred to a counter-irritant effect of the positive sponge electrode that was situated externally. In regard to the power of electricity to dissolve substances similar to the exudate found here, I should judge from my experience that it possesses that power. I have been told that a current of electricity passed through a culture of bacteria had the effect of destroying the life of the germ. May this not explain an action that might be worth considering in similar troubles to the one under consideration?

DR. J. FRANK suggested that that if the author had used a weaker current he would have had a better result. In stricture of the urethra five cells of the McIntosh battery, with the fluid reduced one-half with water, are used. Twelve cells could hardly be borne on the skin. It would dissolve the membrane and produce inflammation.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, November 19, 1886.

THE PRESIDENT, CHARLES WARRINGTON EARLE, M.D., IN THE CHAIR.

DR. W. W. JAGGARD read a paper entitled

A CASE OF CHRONIC INVERSION OF THE UTERUS, OF TWENTY-ONE MONTHS' STANDING, REDUCED BY COLPEURYSIS.

History.—E. S., 36 years old, German; married at the age of 22 years; seven children, no miscarriages. Her first six confinements were normal. She was in the habit, common among German peasant women, of rising upon the third day and making up her own bed. In each of her labors she was attended by a midwife. Her seventh confinement occurred in October, 1884. According to the statement of the patient and the attendant midwife, the delivery of the child was normal. The placenta was removed, as in the six former labors, by traction on the cord. During the labor and the *puerperium*, no unusual loss of blood was observed, and the patient does not remember any extraordinary sensations of pain or faintness. The midwife consulted a physician on the second day of the lying-in period, with reference to the sudden development of high bodily temperature. On the same day, a well known obstetrician saw the case. He made the diagnosis of puerperal fever, instituted the usual plan of treatment, but declined further connection with the case, as he feared the infection of his regular puerperal patients, of whom he had a large number. No examination of the uterus, either by abdominal palpation or vaginal exploration, was made. On the third day an equally competent practitioner inspected the patient, confirmed the diagnosis of puerperal fever, and gave directions with reference to treatment. The contour of the uterus was not investigated either through the abdominal parietes or by the vagina. He continued to visit the patient for eight days, when he pronounced her convalescent. At the expiration of three weeks the woman rose from her bed for the first time, when she observed a fleshy tumor protruding from the vulva. Seven weeks after delivery she resumed her work as a washerwoman. She suckled her child fourteen months. During this period, painful coitus and the sensation of the presence of a foreign body within the vagina were the only symptoms which attracted her attention to her condition. She noticed no fluor, no hæmorrhage, and felt no pain except during coitus. The sexual act was not attended by any perceptible loss of blood. On account of the two symptoms mentioned she sought medical advice. The fleshy mass, situated entirely within the vagina, was supported by a large sponge.

The child was weaned in December, 1885. About March 17, 1886, she experienced severe metrostaxis, entirely without pain, and lasting six days. She supposed menstruation had been reëstablished and gave the subject no further thought. About April 15 another severe hæmorrhage occurred, painless and lasting one week. On May 28 she came under the writer's observation, and was admitted into the wards of Mercy Hospital. She sought relief, as she very distinctly expressed it, on account of painful coitus, the sensation of the presence of a foreign body within the vagina, and the excessive loss of blood during her last two menstrual periods. The woman was of medium size and height, with well developed muscles and clavicles like a man's. She presented evidence of marked anæmia.

Diagnosis.—Bimanual palpation revealed a pyriform tumor, the size of a hen's egg, protruding through the *os uteri*. The base of the tumor rested upon the pelvic floor, and upon coughing or straining appeared at the genital fissure. A shallow sulcus between the pedicle of the tumor and the walls of the cervical canal, extending around the left semicircumference of the canal, could be felt by the finger and traced with the sound. On the right side, no sulcus could be detected, and the membrane covering the tumor was reflected directly upon the external os. The long axis of the tumor was deflected to the left of the median line. The *corpus uteri* was absent from the normal position. The tumor, insensitive to pressure, was covered by a soft, villous membrane, and possessed the consistence of an œdematous myoma. The enveloping membrane was of a bluish-red color, presenting some spots of superficial ulceration, and bled upon the slightest touch. Tubal ostia were nowhere visible. Traction of the tumor downwards caused the sulcus on the left side to disappear entirely. An important diagnostic sign of inversion of the uterus, to which Carl Braun, Robert Barnes and Schroeder in particular have called attention. Reamy, of Cincinnati, has recently described a sign which might have furnished corroborative evidence at this stage of the diagnosis in the case under consideration. Reamy says that when the tumor, grasped by the fingers within the vagina, can be easily rotated on its vertical axis, it is probably a polyp, since such rotation could not occur to any marked extent in an inverted uterus, stiffened as it is by its muscular walls and the thick, strong, fibrous guy ropes furnished by the broad ligaments.

To make the differential diagnosis between inversion of the uterus and a pedunculated fibroid, positive, the patient was etherized. A sound in the bladder and a finger in the rectum were easily approximated above the tumor. The funnel-shaped cavity at the seat of inversion was easily recognized by the finger in the rectum, and by the hand on the abdomen in bimanual palpation.

No appearances were present that would indicate the invasion of the uterine walls by any new formation.

Treatment.—The patient was etherized, the contents of the rectum and bladder were evacuated, and the genitalia disinfected. The right hand was passed into the vagina, "and with the fingers and thumb encircling the portion of the body close to the seat of the inversion, the fundus was allowed to rest in the palm of the hand. This portion of the body was firmly grasped and pushed upward, and the fingers were then immediately separated to their utmost; at the same time the other hand was employed over the abdomen in the attempt to roll out the parts forming the ring, by sliding the abdominal parietes over its edge." At the expiration of forty-five minutes, the writer's hand was almost powerless, and Dr. E. C. Dudley kindly relieved him. Dr. Dudley gave up the attempt at reduction after thirty minutes' trial, fearing perforation of the fundus. Apparently not the slightest progress in the inversion of the organ had been made. Some hæmorrhage occurred as the result of manipulation, although the fundus had been enveloped with absorbent cotton and gauze. The manœuvre was repeated on the following day, under the same conditions, through the same period of time, with no more favorable result.

Emmet's method was then abandoned for the following reasons: The separation of the fingers to their utmost had no effect whatever in the dilatation of the *os externum*. As pointed out by Fenger, and as brief reflection will convince the most casual observer, mere extension of the fingers can have but little effect in the dilatation of the cervix, owing to the relatively feeble character of the extensor muscles of the forearm. The necessary manipulation of the congested *mucosa*, even when protected by cotton or gauze, caused a loss of blood of moment in an already anæmic woman. The uterine musculature had evidently undergone fatty degeneration, and there was serious danger of perforation. Finally, there was reason to entertain fear as to the patient's power to endure the shock from taxis, and the effect of prolonged anæsthesia.

Compression of the body of the uterus opposite to each tubal ostium, between the thumb and forefinger, so as to produce indentation of one side or the other—the Kiwisch-Noeggerath method—was equally ineffectual.

On Sunday, May 30, at the suggestion of Dr. W. H. Byford and Dr. Christian Fenger, the writer began an attempt to effect reinversion by colpeurysis. After the evacuation of the contents of the bladder and rectum, and disinfection of the genital canal. the colpeurynter was introduced while empty, so that it lay on the posterior wall of the vagina, and the *fundus uteri* was adjusted so that the long axis of the uterus and the axis of the pelvic inlet were coincident. The bag was then injected with water until it was fully distended. The patient was placed in bed in the dorsal decubitus. The instrument was removed at the expiration of twenty-four hours, and the genital canal disinfected. A bacillus containing 30 grains of iodoform was placed in the vaginal culde-sac, and the colpeurynter, after being cleansed, was reintroduced. Colpeurysis was continued in the manner indicated without interruption until June 9. Very gradually the sulcus between the pedicle of the tumor and the neck of the uterus deepened, until on the eleventh day the organ was so far reinverted that the fundus was on the same plane with the *os externum*. During this period gentle efforts at taxis were made daily, but without any apparent effect. No perceptible progress was made during the succeeding eight days. June 17, a serous fluid tinged with blood began to escape from the vagina, and it was thought the patient was about to menstruate. The colpeurynter was accordingly withdrawn.

During the nights of June 18 and 21 the patient suffered severe uterine hæmorrhages which threatened to prove immediately fatal. Hot vinegar was used as a vaginal douche, but did not prove so efficient a styptic as a hot saturated solution of alum. Menstruation ceased on June 23. On account of the hæmorrhages, it was deemed inexpedient to expose the patient to the fatigue consequent upon any attempt to observe the *mucosa* during menstruation. During the subsequent nine days the writer was indisposed, so that the treatment by colpeurysis was resumed on July 2. On examination, before replacing the bag, the inversion was found to be as complete and as irreducible as the day on which the treatment began. The uterus was gradually inverted, as before, until on July 8 the fundus was on the same plane with the *os externum*. From the 8th until the 10th of July no apparent progress was made in reduction. On the evening of July 16 the writer was very much pleased to find the uterus completely reinverted, and the vaginal portion of the cervix occupying its normal position. The sound passed into the uterus to the extent of 3½ inches. The *corpus uteri* was felt on bimanual palpation, in a position of slight retroversion, below the promontory of the sacrum. The patient was not aware of any change in her condition. She said, however, that she had felt a sudden, sharp pain in the hypogastric region some four hours previous to the examination. Owing to the patient's enfeebled condition—due in the main part to anæmia—she was not permitted to leave her bed until July 18.

The colpeurynter was in the vagina altogether thirty-three days. On three occasions during this period the bodily temperature rose to 102° F., but invariably fell to the normal after irrigation of the vagina and disinfection of the rubber bag. The presence of the colpeurynter in the vagina did not interfere at all with the functions of urination and defecation. The writer desired to express in words his appreciation of the constant attention devoted to the somewhat tedious plan of treatment, by Dr. Louis E. Lawson, late Resident Physician, Mercy Hospital.

Dr. Alex. J. Stone, of St. Paul, kindly repaired the bilateral laceration of the cervix, on July 20. The operation was unusually difficult on account of the extent of the tear, and the shortness of the vaginal portion. Dr. Stone's method of operative procedure differs materially from Emmet's, but its description is obviously out of place in the present report. The sutures were removed on August 4, perfect union having been secured.

The patient, after leaving the hospital, gained rapidly in strength. Menstruation occurred September 26; the process was painless, lasted four days, and the quantity of blood lost was normal. At the time of writing she had resumed her former occupation.

Remarks.—The case is of particular interest with reference to 1, anatomy; 2, symptoms, and 3, treatment.

1. Anatomy.—The uterus was in a state intermediate between the second and third degree of inversion. In the second degree of inversion—the incomplete inversion of Puzos, Levret, Leroux, Donnce, the third degree, or perversion of Crosse—the anatomical limit of inversion has been indicated by Baudelocque as the vaginal insertion around the *cervix uteri*. Under these conditions, according to Veit and Freund, the cervical canal is intact, the uterus is only inverted as far as the internal os, and the uterine globe remains within the vagina. In the third degree, the complete inversion of Puzos, Levret, Leroux, the utero vaginal inversion of Donnce, the *corpus uteri* and *cervix uteri* are completely inverted, and the anatomical limit as indicated by Levret, is the vaginal insertion at the vulvar orifice. Under these conditions, the inverted uterus is also prolapsed and protrudes beyond the place of the genital fissure.

In the case under consideration, the cervical canal was completely inverted on the right side, the cervico-uterine sulcus (Donnce) had disappeared, the cervico-vaginal sulcus was shallow. On the left side, the cervico uterine and cervico-vaginal sulci were perfectly distinct. In consequence of the complete inversion of the right half of the cervix, the long axis of the uterine globe was sensibly deflected to the left of the median line. The vaginal portion of the cervix was short, and lacerated on either side to the vaginal junction. The inverted uterus was perfectly mobile, and no trace of inflammatory infiltra could be detected about the pelvic peritoneum or in the connective tissue. The position of the ovaries, tubes and round ligaments could not be mapped out with any degree or certainty.

2. Symptoms.—The writer thought it was fair to assume that the inversion of the uterus, in the case under discussion, occurred at the time of delivery. The weight of probable evidence is in favor of this assumption. The inversion must have occurred before the third week following labor, because at that time the presence of an intra vaginal tumor was discovered by the patient. This interval of three weeks was spent quietly in bed in the dorsal decubitus. The condition for inversion would be at no time during this period so favorable as during or at the completion of the third stage of labor. During this period no cause adequate to the result was in operation. On the other hand, during or at the completion of the third stage of labor, all the causes and conditions known to be necessary to the production of inversion were present, *i. e.*, the enlarged and relaxed corpus. dilated cervix, traction on the cord, possibly, also fundal insertion of the placenta (Hennig), and paralysis of the placental site (Rokitansky). If this assumption be granted, the case demonstrates that inversion of the uterus may "take place without sufficient symptoms to attract attention or to indicate that anything has gone wrong." Dr. J. C. Reeve has already called attention to this subject, and has sustained the proposition just quoted, by the citation of well anthenticated cases, in his classical essay, "Moot points in Regard to Inversion of the Uterus."

The patient, a woman of at least average intelligence, and the midwife, a "qualified" practitioner, *i. e.*, examined and registered by the State Board of Health of Illinois, observed no symptoms sufficient to attract attention or to indicate that anything unusual had happened at the time of delivery. A well-known and skilful obstetrician saw the case forty-eight hours after the probable time of the occurrence of the accident, and the absence of symptoms was so marked that the condition escaped his critical observation. Seventy-two hours after the probable time of occurrence of the accident the patient was seen by another thoroughly competent medical man, who also failed to recognize the complication upon his first, or upon any subsequent visit.

Dr. Reeve's proposition has an important bearing upon the differential diagnosis between inversion of the uterus and sessile polypus, and indicate that no reliable evidence can be obtained from the history of the case.

3. Treatment.—Carl Braun, in 1851, introduced a simple, convenient and safe method of the vaginal tamponade (colpeurysis) by means of a caoutchouc bag (colpeurynter). The reduction of chronic inversion of the uterus by colpeurysis was inaugurated by a communication from Tyler Smith to the Royal Medical and Surgical Society of London, April 13, 1858. In this communication Tyler Smith reports the reduction of a chronic inverted uterus by taxis in connection with continuous elastic pressure by means of Gariel's air-pessary. Barrior, of Lyons, in 1852 employed an air-pessary to retain the uterus in position, but with no avowed intention of using continuous elastic pressure to effect reduction, as intimated by Donnce. M. P. Teale, Jr., of Leeds, and West effected reductions of the inverted uterus in 1859 by Tyler Smith's method. It was reserved for Sockenthal, as remarked by Thomas, to demonstrate in the same year that reduction could be effected by the colpeurynter unaided by taxis.

As a matter of practical import, the colpeurynter used in the case described was a quadrilateral, caoutchouc bag, 10 cm. long, 3 cm. wide when collapsed, and possessing a maximum circumference of 21 cm. when distended. It is known in the shops as "No. 5 pear-shaped watery-pessary." The selection of a properly shaped and properly sized instrument demands some care. Dr. Byford's treatise is the only

American textbook on gynæcology which gives an adequate exposition of colpeurysis as one of the methods of reduction of chronic inversion of the uterus. This fact may be interpreted as indicating the method is not extensively practiced in the United States, and a survey of American medical literature upon this subject will serve to confirm such an opinion. In the very large majority of cases more heroic measures have been adopted. On the other hand, colpeurysis has largely replaced all other modes of treatment in Germany. Fritsch says, "Gradually almost all gynæcologists have gone over to Braun's colpeurynter." "The treatment with the colpeurynter is the sovereign method of treatment in cases of inversion of the uterus. Inversions yield to it which have resisted all other methods. The resistance which the cervix opposes may be so great that Muzeaux (four) forceps inserted into the portico tear out, and still the uterus remains unmoved. If colpeurysis is now resorted to, earlier or later a successful result is bound to follow without danger. It is therefore urgently advised to give up every attempt at forcible reposition of the uterus." He adds the significant sentence, "Colpeurysis cannot be held as without effect, even if the end is not immediately attained, it may be continued with interruptions fourteen days, yes, even three weeks." The best method of treatment of chronic inversions," says Rheinstaedtor, "is the introduction of a colpeurynter, which is gradually distended with water." Schroeder has repeatedly effected the reduction of the chronic inverted uterus after the failure of all efforts at manual reposition.

(*To be concluded.*)

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Treatment of Gout—Renal Lithiasis—Pathogeny of Renal Congestion—Bright's Disease without Œdema and Albuminuria.

In a very interesting paper by Dr. Lecorché, on the *Treatment of Gout*, the author divides the therapeutics of this affection into two distinct parts: 1. The treatment of the gouty subject in the intervals of the attacks, which he considers the only important and truly fruitful part of the treatment. 2. The treatment of the attack. After having thoroughly studied the subject, both theoretically and clinically, and after having carefully studied the influence of the so-called anti-gouty substances commonly in use, from the various mineral waters to the preparations of colchicum and of the salts of lithia, Dr. Lecorché formulates his conclusions as follows: If there be any specific in medicine, colchicum and the salicylate of soda may be considered such for gout and its manifestations; the former reduces the proportion of lithic acid in the blood, while the latter favors its elimination.

One of the causes of the non-success of these drugs in certain cases, is the extreme reserve with which they are too frequently administered; they then do more harm than good. The author concedes to Professor Germain Sèe the credit of having been the first to employ the salicylate of soda against gout, and had brought out the advantages of this substance in the multiple indications of this affection, in which it is utilized for the analgetic power of the medicine, its decongestive or resolving property, and for its power of eliminating lithic acid in certain cases. In fine, the faculty of using, in part, the glycocol, which constitutes one of the most important albuminoid substances. The conclusion of Dr. Lecorché is that the physician should intervene in all cases of gout: 1. By the aid of diet to prevent the gouty diathesis. 2. By the aid of diet and of alkalies to combat the diathesis and to prevent the attack of gout. 3. By the aid of specifics, colchicum and the salicylate of soda, in the generality of cases, to combat the attack of articular or visceral gout.

In connection with the treatment of gout, it may be interesting to learn what Professor Jaccoud says on the subject. He, too, lays great stress on treatment in the intervals between attacks, or, if individuals of a gouty diathesis, temperance in all things, and regularity in the hours of repasts and those devoted to sleep being his fundamental precepts. The diet should be mixed, but more vegetable than animal. Highly nitrogenous substances, such as game, crustaceæ and sea-fish, should be avoided. Pure water should be the general drink, or if this be not well tolerated, a little white or red wine may be added thereto, or a little weak beer may be allowed. The gouty subject should go to bed early and rise early, and take daily moderate exercise. This treatment should be followed during the whole life, and as a complement to the above, Dr. Jaccoud prescribes that in spring and autumn a course of butter-milk should be gone through. Should these hygienic measures not be sufficient to modify the economy and to rid the patient of the divers gouty manifestations, therapeutic agents must be resorted to. These consist of the daily use of alkaline waters, the benzoate of lithia, in doses of from 0 centigrammes to 1 gramme per day. The bowels should be kept freely moved by small doses of some saline aperient, the best for the purpose being Carlsbad salts, which has the advantage over the other purgatives of having the faculty of increasing the urinary secretion, whereas with most others it becomes scanty and loaded with sediment. A season or two at some of the following watering places would act as powerful adjuvants to the routine treatment: Ems, Royat, Kissengen, Homburg, will be found best suited for the articular disorders which remain after gouty attacks.

For manifestations of renal lithiasis the patient should be sent to Coutrexéville, Evian, Martigny (Vosges), and Vittel. Finally, the waters of Ragatz are best adapted for gouty patients in whom the malady has been of long standing, and who are weak and in a cachectic condition. The treatment during the attack consists in enveloping the joints with cotton wool, narcotic liniments, low diet, or rather

one which must be modified according as the patient is febrile or apyretic. The best article of diet at such time would be milk. The bowels must be kept free, not, however, by strong purgatives. Thus it may be seen that Professor Jaccoud is in favor of the "expectant" mode of treatment during an attack of gout, and it is only when the pains are exceptionally severe, or when the fit is of abnormal duration, that he could prescribe the salicylate of soda (3 grammes per day), or the wine of colchicum in doses of from 5 to 6 grammes in the twenty-four hours.

At a recent meeting of the Medical Society of Hospitals, Dr. Albert Robin read a paper on the *Pathogeny of Congestion of the Kidney*. From two cases which came under his own observation, he was induced to conclude that cold excites the reflex action of these organs, which then refuse to let pass the waste tissues of the organism. These, not being eliminated, poison the patient in different degrees, according to the duration of the suppression of the functions of the kidneys.

At the same meeting Dr. Dieulafoy made some observations on cases that came under his notice, exhibiting all the symptoms of Bright's disease minus œdema and albuminuria. The autopsy confirmed the diagnosis that was made during life.

In one case, that of a man 63 years of age, and who had not been alcoholic or syphilitic, the autopsy revealed a typical form of arterio-sclerotic nephritis. The heart was small and sclerotic, with notable atrophy of the muscular tissue. With reference to these cases Dr. Dieulafoy dwelt on the fact that there is no strict correlation between albuminuria and Bright's disease. There are some symptoms, however, which will enable us to recognize the renal lesion. These consist chiefly in the troubles of the urinary secretion, and above all pollakiuria, or necessity of frequent micturition during the night, cephalalgia, oppression, occular disturbances, auditory troubles (deafness, rumbling), the sensation of "doight morts," or numbness in the fingers, which latter the author considers pathognomonic. He referred also to Professor Bouchard's test, according to which, the secretion of urine being a process of depuration, it may be conceived that if the kidneys work badly, the urine which they excrete, not containing all the ordinary products of elimination, will be less poisonous than normal urine, which fact has been verified by experiments on animals. For instance, while in the normal state, 15 to 20 grammes of urine suffice to kill a rabbit, it would take 250 to 300 grammes of Brightic urine to produce the same effect. It is precisely this last circumstance which is found in Bright's disease, and which, in certain exceptional cases can, even in the absence of albuminuria, establish the diagnosis of nephritis. In the cases which came under Dr. Dieulafoy's notice the different varieties of albumen were very carefully sought for, even those which are not revealed by the ordinary tests. A. B.

DOMESTIC CORRESPONDENCE

THE MEDICAL SERVICE OF THE U. S. PENSION BUREAU.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—I have been much interested in a communication which appeared in THE JOURNAL for November 20, entitled "The Medical Service of the U. S. Pension Bureau," and written by Dr. P. S. Conner, of Cincinnati. Briefly stated, the article referred to is simply an arraignment of the Pension Examining Boards, as at present constituted, virtually charging the members thereof with professional incompetency, and proposing as a specific for the evils complained of, that the entire business of the examining of pensioners, and applicants for pensions, be transferred to the Medical Corps of the Army. After detailing at length the duties of the examiners, Dr. Conner says: "Even the most hurried glance at what is required of an examining surgeon, will suffice to show that he ought to be well educated, experienced in the detection of pathological conditions, of good judgment, honest, and independent, having regard solely to what is right and just to the applicant on the one hand, and the Government on the other."

Thus, basing his plea for the charge above referred to, upon the assumed fact that the Boards, as at present constituted, are destitute of the qualifications which he mentions—in other words, that they are composed of physicians who are *not* well educated, *not* experienced in the detection of pathological conditions, *not* of good judgment, honest, and independent, etc. Now, upon all these points, I take direct issue with Dr. Conner, and express the belief that he cannot make good any of the propositions which he advances. From a personal knowledge of the make-up of several Boards of Pension Examiners, the writer believes that they are composed of a class of physicians who, as a rule, will not in the least suffer by comparison with a like number of the medical officers of the Army, in all that relates to education, experience, and in the possession of the various qualifications necessary for thorough and impartial examinations. The Pension Examining Boards are, in the main, composed of the best medical talent in the various cities and towns wherein the Boards are located. A very considerable number of their members are men who have had a large experience as Army surgeons during the late war, and who have made high reputations in long and successful professional careers. The Boards, as a rule, are thoroughly equipped with all the various aids to diagnosis which the inventive genius of the profession is continually giving to the world.

The competitive examination, which Dr. Conner states is a requisite to membership in the Medical Corps of the Army, has by no means succeeded in placing that Corps upon so high a plane as our author would have us believe, for it is a well known fact that these examinations are not, never have been, and in the nature of things never can be, wholly freed from personal and political influences. It is

not the purpose of the writer to belittle or to misrepresent the Medical Corps of the Army. That body is doubtless composed, in the main, of men of a good degree of professional ability; men competent to discharge, intelligently and well, the duties devolving upon them; but I desire simply to show that the comparison which Dr. Conner institutes is not warranted by facts. It is, however, true, that just as the "West Pointer" was, during the late war, disposed to arrogate unto himself all military knowledge, so was the regular army surgeon disposed to put on airs over the volunteer surgeon; but that this assumed superiority was groundless, the writer, as well as many others, had ample opportunity for observing. In field, or in post hospital, no better work was done than by the volunteer surgeon.

But I have not yet mentioned all the beneficent results which Dr. Conner is confident would ensue, both to the Government and to the pensioner, should his plan be adopted. He says that, as a result of the adoption of his scheme, "deserving applicants would get *what they deserve*, and the ratings would be far more uniform than at present." To this I reply, that deserving applicants, as a rule, now get what they deserve, and in regard to the uniformity of ratings, what reason have we to doubt that as great a diversity of opinion would exist among the Army surgeons as now exists. Dr. Conner says further: "There would be no more complaints or charges that pensions were recommended or advised against because of the applicant's connection with this or that political party." To this we reply, that not many complaints of this nature have been made, and these, no doubt, for the most part groundless. Yet surely, the surgeons of the Army are members of some political party, and there is no earthly reason why they would not be just as susceptible to political influences as are the present examiners.

Dr. Conner also informs us that, under his plan, "the end results of excisions and of amputations might be determined, as *they now cannot be!*" The italics, and exclamation point, are mine. Also, he says further: "The Government would be benefited, meritorious soldiers and sailors *in some degree rewarded* for privations, sickness, wounds," etc., but this is enough. He also states, and truly, that the establishment of such a board as he advocates was, at one time, strongly advocated by the authorities of the Pension Bureau. He might have stated further, that the measure failed, because the debate thereon in Congress completely demonstrated the utter impracticability of the measure, and also during that discussion, the present system of pension examinations was warmly endorsed for its thoroughness and efficiency, by leading members of both houses of Congress, and of both political parties.

The plan proposed by Dr. Conner would give us one pension examiner where there are now about thirty, an average of about one Board to a State. Under this management, it is hardly necessary to state that thousands of pensioners could not afford the time and money necessary to reach the Board, while under the present arrangement, few need to be absent from home over night in order to reach some Board of Examiners; while should the Government, as Dr. Conner suggests, undertake to pay their traveling expenses, the present cost to the Government would be greatly increased, while there is not the remotest ground for believing that any compensating good could result, in the way of increased thoroughness or efficiency of the examinations. I am, very truly,

L. Brown, M.D.

BOOK REVIEWS.

The Physician's Visiting List (Lindsay and Blakiston's) for 1887. Philadelphia: P. Blakiston, Son & Co. Chicago: W. T. Keener.

This "Visiting List" is now in its thirty-sixth year of publication, and is so well known to the profession that but little need be said of it. It is published in several sizes, for 25, 50, 75 and 100 patients weekly, at prices ranging from $1.00 to $3.00, the latter price being for large lists in two volumes (January to June, and July to December). A perpetual edition is also published, and an interleaved edition at a moderately increased price. It contains calendars for 1887 and 1888, Marshall Hall's "ready method in asphyxia," a table of poisons and antidotes, tables of the metric system, a dose table rewritten to accord with the sixth revision of the U. S. Pharmacopœia, a table of disinfectants, directions for the examination of urine, a table of standard reference books, table of incompatibles, a new table for computing the period of utero gestation, a list of new remedies for 1886–7, Sylvester's method for artificial respiration, and a diagram of the chest, besides the blank leaves for visiting list, monthly memoranda, addresses of patients, nurses and others, of accounts rendered, memoranda of wants, obstetric and vaccination engagements, record of births and deaths, and cash account.

MISCELLANEOUS.

Prof. Kolomnin's Suicide After a Fatal Operation.—Professor Kolomnin, of St. Petersburg, recently committed suicide after the death of a patient from cocaine. The patient, says the *British Medical Journal*, who was operated on was a young woman who had been sent from the medical out-patient department into the surgical wards. Professor Kolomnin found a large ulcer of the rectum, which he believed to be of a tuberculous nature; he decided to scrape and cauterize it. Proposing to employ cocaine as an anæsthetic, he made a number of inquiries as to the maximum dose, and looked up the literature of the subject, which comprised about thirty cases, in which from 6 to 90 grains (the Russian grain = 1.0417 grain English), had been employed. Most of these cases were operations for crushing urinary calculi, and though the bladder, if healthy, is

known to be quite unable to absorb such a quantity of the drug, in some cases vesical disease was present, and in these absorption must have occurred. Again, Professor Dieulafoy had employed 48 grains of cocaine in a rectal operation with success. Having regard to all these reported facts, Professor Kolomnin thought himself justified in disregarding the opinion of his colleague, the Professor of Pharmacology, who said he considered two grains a maximum dose. He, however, decided to give rather less than half the quantity used by the French professor, and to administer it in four rectal injections. After the third of these, it was found that anæsthesia had not been produced, so Professor Kolomnin introduced a speculum, touched the surface of the ulcer with a dry sponge, and gave another injection, which produced anæsthesia, though not of a very complete character. The ulcer was scraped, and an oiled plug left in contact with it. The pulse was then somewhat rapid. Forty-five minutes afterwards the pulse became greatly enfeebled, and the respiration labored, the face and hands assuming a livid appearance. Everything was tried without avail—faradization, artificial respiration, subcutaneous ether injections, ammonia, stimulating and nutrient enemata, and even tracheotomy, with inhalation of oxygen—death being evidently due to the toxic action of cocaine. In some quarters Professor Kolomnin was much censured, but he himself considered that, with the authority of numerous reported cases, he was not to blame for using the quantity of cocaine that he did. He, however, fancied that he had made an error in diagnosing the ulcer as of a tuberculous nature, and worried himself about having undertaken the operation. As to his own personal condition, he had lived for some years a most secluded life, devoting himself entirely to his scientific work, and making no intimate friends. He had latterly complained of palpitation and sleeplessness, and had become very irritable and, in some instances, forgetful, so that there is no doubt in his eminent colleague's mind that when he committed suicide he was not really aware of the gravity of what he was doing. The day before he had gone to Professor Botkin to ask him to give an address at a medical society for him, as he felt too unhinged to do it. This request was complied with, his own death serving, alas! as the subject.

Accouchement During Hypnotic Sleep.—In the *Wiener Med. Wochenschrift* a case is mentioned of a woman whom Dr. C. Braun succeeded in rendering unconscious during labor by throwing her into a condition of hypnotic sleep; the uterine contractions were particularly painful. They were equally violent during the period of unconsciousness, but the intervals were somewhat longer; dilatation of the passages took place in the most satisfactory manner, and delivery was speedily accomplished. The placenta was expelled into the vagina, and was easily withdrawn with the hand. On awakening, the patient did not complain of pain, and afterwards slept naturally for several hours. One of the most interesting features of the case was that the uterine contractions induced contraction of the abdominal muscles without awakening the patient. Hæmorrhage was very slight.—*British Medical Journal*, Dec. 11, 1886.

The Pasteur Institute.—M. Pasteur states that the amount subscribed to the proposed Institute now amounts to almost 1,800,000 francs, and that contributions still continue to come in. English brewers, who have been shown that they are indebted to Pasteur for his experiments on ferments, have contributed largely.

Eulylyptol is the name given by Dr. Schmeltz to a mixture containing six parts of salicylic acid to one part of carbolic acid and eucalyptol, and which he considers a better antiseptic than iodoform, corrosive sublimate or carbolic acid. A small quantity added to urine will preserve it for months.

Cholera in Europe.—Several deaths from cholera have recently occurred in Bulgaria. The disease originated, it is said, with a Hungarian peasant bringing clothes with him of a man who had died of cholera. Cholera has reappeared at Gorizia.

A Health Exhibition in Warsaw will be held in May and June, 1887. The exhibits will be chiefly Polish, but foreign goods will not be excluded.

The U. S. Life-Saving Service has saved, from its establishment in 1881 to July 1, 1886, 28,317 persons.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 18, 1886, TO DECEMBER 24, 1886.

Major W. H. Forwood, Surgeon, granted leave of absence for one month. S. O. 129, Dept. Dak., Dec. 16, 1886.

Capt. J. V. Lauderdale, Asst. Surgeon, ordered from Ft. Concho to Ft. Clark, Texas. S. O. 174, Dept. Texas, Dec. 16, 1886.

First Lieut. Edward Everts, Asst. Surgeon, ordered from Ft. Grant to Ft. Apache.

First Lieut. Chas. F. Mason, Asst. Surgeon, ordered from Ft. Huachuca to Ft. McDowell.

First Lieut. W. B. Banister, Asst. Surgeon, ordered from Ft. Wingate to Ft. Lowell.

First Lieut. W. D. Dietz, Asst. Surgeon, ordered from Ft. Stanton to Ft. Bayard. S. O. 136, Dept. Ariz., Dec. 16, 1886.

First Lieut. A. S. Polhemus, Asst. Surgeon, ordered for duty as Post Surgeon at Ft. Gaston, Cal., relieving First Lieut. H. I. Raymond, Asst. Surgeon, ordered for duty at Angel Island, Cal. S. O. 123, Dept. Cal., Dec. 13, 1886.

First Lieut. C. L. G. Anderson, Asst. Surgeon, temporarily to duty at Whipple Bks., Arizona. S. O. 132, Dept. Ariz., Dec. 7, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED DECEMBER 18, 1886.

Banks, C. E., P. A. Surgeon, granted leave of absence for twelve days. Dec. 16, 1886.

Carrington, P. M., Asst. Surgeon, granted leave of absence for fifteen days. Dec. 6, 1886.

Williams, L. L., Asst. Surgeon, upon expiration of leave, to proceed to Boston, Mass., for duty. Dec. 17, 1886.

THE PROBLEM OF THE INEBRIATE.[1]

BY W. W. GODDING, M.D.,

SUPERINTENDENT OF THE GOVERNMENT HOSPITAL FOR THE INSANE, WASHINGTON, D. C.

Speaking after the manner of the street, we may say that there is no harder conundrum proposed to modern civilization than this same inebriate. Utterly useless to himself, he becomes a nuisance to everybody else. This difficulty meets us at the outset of the discussion, what is meant by the inebriate? We are accustomed to consider drunkenness and inebriety as synonomous terms, and yet not every man who gets drunk is what we call an inebriate. The best man in the world, at least in his age—it is true that age was sunk rather low—was Noah, and he was barely out of the ark when he got drunk; yet, in view of his previous as well as subsequent history, we should hesitate to call him an inebriate.

To better illustrate the meaning of the term inebriate, I present to you in this paper the brief memoir of a typical inebriate, no fancy sketch, but one of real flesh and blood. For obvious reasons I withhold his name, but for convenience of designation will call him "the Col."—a common title about Washington—which will answer our purpose as well as any. This is not a temperance lecture in disguise, introducing the Col. as an object-lesson, after the manner of the Athenian teacher who exhibited a drunken man to his pupils. He is presented simply as a pathological specimen, and I do this with no feeling that in doing so any confidence is violated or that I am exposing anything which the Col. would have preferred should be kept covered now that he is gone, for this man, while living, had no affectation of virtue; delicacy of feeling was a weakness of which he was never suspected; public opinion he despised; the wages of sin were satisfactory to him so only he had the sin; he was content to pose as an "awful example;" and I think he would have consented that his viscera should be photographed to illustrate Sewall's lectures on the coats of the stomach, merely stipulating that their membranes should be occasionally moistened with whiskey. What study the anatomist might make of his bones when he had done with them, what lesson the moralist would draw from his finished life, were matters of profound indifference to him, as I do not think he expected to pass this way again.

My first acquaintance with the Col. was in May, 1878, when he was brought to St. Elizabeth on the certificate of two physicians to his insanity. In May, 1886, almost exactly eight years later, I parted with him for the last time, to hear within three weeks of his death. Just turned of forty when I first knew him, and, looking only on that magnificent physique with which Nature had endowed him, he would pass for a young man. Scrutinizing more closely you saw that the arcus senilis had come, the vital energies burned down, the wit was at its dregs, and in every sense was it true that the virtue had gone out of him. There was left only an insane thirst for whiskey, and, what his uncle in a conversation with me once styled "his fatal facility in writing." The latter, although deterlorated with all the rest, still afforded him, as a newspaper hack writer, a precarious income from his articles. These were society articles of the lightest sort, but with now and then a scintillation of the old wit which still "set the tables in a roar." All else was gone; property, if he ever had it, positions of trust which he had held and lost by his vices, and "troops of friends" that he had alienated; for this Bohemian prince of dead-beats was as supremely selfish a man as I have ever known. The affection of two wives had been wasted on him; the devotion of the last, which was something inexplicable, availed no more to turn him to virtuous courses than signing the temperance pledge did to wean him from his cups; and the influence of both had less restraining power over him than the lightest whiff from his cigar. As the typical reformed inebriate he was the making and the undoing of I know not how many temperance organizations. Of the various antidotes for drink he was the universal solvent: the thirst within him was his one strong point, the only thing that waxed not old.

What was the disease? Looking for intellectual insanity, you did not find it; yet there were observed phenomena psychic in character worthy of note. When first received, and so long as the alcohol was circulating in his tissues, there was more or less incoherence and confusion of ideas, but apparently no more than would follow a debauch in any one. Then came a period of rest, when everything was first class and he apparently at peace with all the world; was even tolerant of the vagaries of the insane patients about him; life was a pleasant jest, and his comfortable shelter in an insane hospital the greatest

[1] Read before the Medical Society of the District of Columbia, December 11, 1886.

joke of all. Then came a time when life was real and of a very bitter earnest. Sore-headed was no name for it; he found fault with everything; complained of his food; abused his wife; maligned his nurses; made even the unfortunate insane who came within his reach, miserable by one diabolical device or another; then claimed that his own life was being made wretched by being immured with grinning, idiotic lunatics, and attendants of a still lower order of intelligence. Still held in durance, he would, after months of enforced abstinence, his periodic cravings for rum remaining unsatisfied, become moody, dull, almost imbecile, as if a kind of mental dry-rot had come over him. Now let the opportunity be given him to rouse his brain and liver by a fortnight's debauch and its accompanying abstinence from food; the old life would come back; the wit sparkled again, and, with Bulwer's Margrave, he felt the elixir tingling in his veins, for

> "Like to the Pontic monarch of old days,
> He fed on poisons, and they had no power,
> But were a kind of nutriment."

From a moral standpoint the mental obliquity, not to say aberration, was simply appalling. This was by no means exceptional in the Col.; it is the keynote to all these cases of inebriety, but I take him as the illustration, and remarking the keenness of his wit and the correctness of his observation, associated as it was with the most utter disregard of his own best interests, and his complete helplessness in the presence of stimulants, I wondered how long, even with the support of the certificate of insanity from two eminent physicians, I could hold him against a writ of habeas corpus, brought before the tribunal which, in the Guiteau case, had pronounced a knowledge of right and wrong to be the true criterion of responsibility, and that regarded moral insanity as only a synonym for depravity. So, doubtingly, I often let him go.

"Not as other men are,"—but leaving to you, as medical men, to say what ailed him, let me rapidly outline his eight years' record at St. Elizabeth, premising that this was only about one-third of a career as completely bounded by whiskey as the world of the ancients was by the ocean. In that period of eight years the books of the hospital show that he was sent to the institution no less than ten times as insane; the insanity was certified to by two physicians; and once he remained for a considerable time on a voluntary commitment. The time thus passed with us amounted to two years and four months, or something less than one-third of the whole period. There were also voluntary visits, of short duration, where no record was kept. It is safe to say that during the eight years he was for an equal length of time "sobering up" in one of the city hospitals, the work-house, the alms-house, or the sheltering arms of some other eleemosynary institution. It was during a stay in one of these havens of rest, already becoming restless for a drink, that he writes he had "now run the gauntlet of all the institutions (naming them) except a lying-in establishment, of which he yet hoped to find one sufficiently respectable for him to enter, unless, as he feared, he should be found physically disqualified for the situation."

Seeing how large a portion of these eight years was passed in institutions of one kind and another, one wonders when he was sober, just as his frequent appearance at the bar of the police court led Judge Snell to exclaim, "Col., are you always drunk?" To which, with the gravity of a pundit, the Col. replied, "Does your Honor take me for a millionaire?"

There was a noticeable periodicity about the Col.'s infirmity. Remaining at the hospital, as a general rule, only so long as he could be induced to remain voluntarily, it is instructive in our pathological study of the case to note how frequently, after a residence and abstinence of but little more than a month, "important business" made it imperatively necessary that he should return to the city and "his wallowing in the mire." Of his eleven recorded sojourns with us I find six of duration as follows: two of one month and seven days each; one of one month eight days; one of one month twelve days; one of one month eleven days; and one of one month four days. The two longest detentions, seven months and twelve days, and four months and five days, respectively, were both after strenuous voluntary efforts for his own commitment, and were associated with a long preliminary training in police court and work-house. There were times when he was anxious to get into the hospital—and accomplished it against decided opposition—as at others he was as anxious to get out. He always went forth confident in his strength; he came back like the prodigal in his weakness, but with this difference, that the hospital authorities soon got over ordering *veal* on his arrival.

Running over my letters and memoranda of that period, I find "the old, old story," with endless repetitions, from which I make a few extracts as samples: (Before going out.) "My affairs have got to a point now where I *must* lay hold of them and straighten them out. . . . As far as whiskey is concerned (I find I must refer to the subject, nauseating as it is), you need have no fear," etc. (After going out.) "He appreciated your kindness as much as I do, and if he hadn't 'fallen by the wayside' we would have come over to pay you a visit; but before he got time to exhibit his sobriety he got drunk." (Some time later.) "Dear Doctor: The poor soul—I think I may reasonably say—*which* accompanies this note, left Providence Hospital on last Saturday week and took his old room, donned his new forty-five dollar suit, and got drunk. At two o'clock they had to send for the police. He broke the front door, assaulted the cook and the chamber-maid, and produced general hilarity. He has been thoroughly dead drunk ever since (not eating anything as far as I can learn); sleeping up an alley in preference to a bed; and has been three times arrested. . . You will see his condition. He has been in the station for thirty hours, and is rational. For the Lord's sake keep him over there for the rest of his life."

So I might go on for an hour illustrating the varying phases of his infirmity from correspondence and note books, but with my limited time a single episode—that of the Montana trip—must suffice:

In January, 1883, an army officer, moved by I know not what good impulse, secured a fairly remunerative position for the Col. in the Quartermaster's Department of the U. S. Army, station to be in Montana. It is needless to say that our hero was overjoyed. Thenceforward there were to be no more spicy letters from "our occasional correspondent," dating nominally from Saratoga, from Newport, or from the Thousand Isles, but really written within the purlieus of a lunatic hospital. And there were "to be no more cakes and ale." Here was an opportunity to redeem himself or perish in the attempt. I thought it would be the latter, for in the dead of winter and the destination Montana, I felt morally certain that he would freeze to death on the road. He left the hospital on Thursday to make the necessary preliminary arrangements to start on Saturday night for his destination. I need hardly say that one of these preliminaries was to get so drunk on Friday that he was brought to the station house in the evening perfectly unconscious. He got out later, was found asleep on the floor of the telegraph office, and again gathered in. A devoted friend writes: "He hurried off on Saturday night but illy equipped for his five days' journey, promising to write from Chicago. I haven't heard a word, and I believe he is drunk, or dead, or *both*," and adds, "I never expect to see him again, but if *I* do *you* will." We felt that at least St. Elizabeth was done with him. Like Mark Twain watching the Arab on his foot race up and down the pyramids, I said now he *will* slip, now he *must* break his neck, certainly in that all day ride in a coach in Montana, with a temperature of 40° below zero, he can't fail to freeze to death. But he didn't; other passengers were lifted out stiff and frosted, but alcohol will not congeal. In a letter from a hospital of the Sisters in Montana he says of his journey: "At Deer Lodge I strengthened the garrison with a quart bottle in my overcoat pocket. The result was I arrived at Helena dead broke down from fatigue, cold, want of food and sleep, and the awful and to me hitherto unknown poisons in Rocky Mountain whiskey." But though he did not freeze, he was at once in hot water with the military authorities. It was on Gen. Terry's request to be relieved of the Col.'s presence in his department that Gen. Sherman wrote this famous endorsement, which appeared in the daily press at that time: "This man was appointed for the purpose of developing the latent good which is supposed to be in him. Let him be subjected to a severe course of discipline; send him to jail; put a ball and chain on him; shoot him if necessary, but don't discharge him." Nevertheless, he was discharged, and like Mark Twain's Arab, he brought up at the starting point. As the officer helped him out of the ambulance at the portals of St. Elizabeth, I said: "Well, Col., I didn't expect to see you here again." Pretty drunk, but with all the old time assurance, he replied: "All roads lead to Rome, doctor."

His last residence at St. Elizabeth was one of his longest. After much buffeting he had procured for himself the necessary order of the District Commissioners admitting him to the hospital. He came, to use his own expression, "to have us grow a moral nature in him as a man would grow a moustache." There was sore need of it, for "the keepers of the house" had begun "to tremble, and the strong man to bow himself." So he rested for the winter. I committed the entire management of his case to my able assistant, Dr. Stack, promising that he should have all the credit if he cured him. I gave him *carte blanche*—he might put the batteries on him; soak his brain in hellebore; purge him with hyssop; cleanse his heart—do anything and everything, so only he resuscitated his moral nature. It is needless to say that the doctor did his level best, and in the spring told me he thought the time had come to test the Col.'s strength by sending him to town unattended. He went, and came back *sober*. A second trip, and wonderful to relate, he returned as *perpendicular* as he went. I said to myself, Has the growth indeed taken place? Is it possible that there was any moral nature left to grow? And has the change really come that I did not look for before the resurrection? And even then, while I wondered, there came into his brain a scheme for getting aid from his uncle and going on a ranch in the far West to commence life anew, and he began to talk of removing to the city to make his arrangements. Then I knew what was coming. I urged him to remain where he was and leave to others to make his arrangements. But he had reached the time when he wanted no advice; so we parted, he going on his own wild way to the end.

He was born with godlike faculties, but he drank of the cup of Circe till it transformed him to a beast. I know not what vice of organization, what inherited taint or what sinful indulgence first wrought this woe. Whatever it was, he was so hopelessly enmeshed in its folds that from the first time that I saw him his moral responsibility was, to say the least, an open question. If it was sin, has he not suffered for it? If it was disease, shall not the sufferer rest? I like to think of him at his best in a life that had but little best to recommend it. He was better than he wished to seem. I have seen him take slyly from his pocket and give to the dog who accompanied him on his morning walk portions saved from his own breakfast, and then apologize for what might seem a human weakness. Let us, in our human weakness, each cast a shard above him for sweet charity. Taken from out the freezing alleys and gutters where he had so often lain in this world, I hope that burning thirst has not followed him whither he has gone, and I cannot think of him as lying cold o' nights.

I have not given you here an exceptional case; Washington is full of them. I doubt not they are within the experience of every one of my audience. Treating it only as a pathological specimen in this necessarily fragmentary and hurried sketch, I have left unrevealed the tragedy in the home, but it is there none the less. And that is the most moving, realistic side of all these cases. Every month—nay, almost every week, they come to me to know what they shall do that their friends may be saved? Alas! that I have no answer I can give. Mothers bring to me their breaking hearts in confidence that I shall not profane here; wives with a devotion which tells

me the age of martyrdom has not passed; sisters with streaming eyes implore me to save their brother —my brother and your brother too. It is time that as medical men we had some answer to make to this question, What shall be done with them? As scientists curious of the bacillus we forget the worm of the still. As *savants* we show a pardonable enthusiasm over the shards of a jug on which we may with laborious pains decipher the symbol of Annubis or Osiris, but manifest an inexcusable indifference to that human "treasure" which we have in these frailer than "earthen vessels" on whose shattered fragments we might still trace the lines of the image once stamped there. It is time that the scientist and the scholar spoke; that he turned from the contemplation of cliff dwellings and bone caves, and drew out from dens of infamy and caverns of despair where he has been hiding this troglodyte of our time. When the medical men of the community move in earnest in this, we shall have public sentiment, and out of that sentiment will come law, and an answer to the prayer, "Lord, that I might be healed."

NOTE. Let me venture a word in a foot note touching the solution of this problem, lest I be accused of leaving my moral lesson without a moral.

The inebriate can be controlled legally in one way or another; there is no doubt about this. For a person who cannot take care of himself the law provides a guardian; or when a man from any cause so far loses self control as to become dangerous to others, society has the right to restrain him. Such dangerous person, either *in posse* or *in esse*, is the inebriate; and at all times he is unable to take care of himself.

Having shut him up, the next thing is to keep him. Hitherto the detention has been too short to afford a chance for reformation. Sentences for thirty days rather aggravate the craving for drink. For any lasting benefit a year's confinement is necessary with some, a lifetime with others. The commitment in confirmed cases should be for a term of years, with a power lodged in the court committing, and perhaps also in the board of managers of the reformatory, to grant furlough or ticket-of-leave, its continuance to depend on good behavior.

Such house of detention should be self-supporting or as nearly so as is possible to make it with a system of compulsory labor. Since idleness is a great incentive to drink, all able bodied inmates should be set to work at some productive industry. Whatever the institution falls short each year of being self sustaining should be made up from the District treasury out of funds received from licenses for the sale of intoxicating drinks.

The entire management of the establishment should be under the immediate control of an executive officer who should be a medical man skilled in his profession, with qualities of heart and brain fitted to his work, and an autocrat in his position. He will need the wisdom of Solomon, the patience of Job, an abiding hope and a double portion of that "charity which never faileth." Anything short of this will land him within five years in a lunatic asylum, and his institution in the slough where some so-called inebriate homes are already stranded.

In a majority of these cases a cure is hardly to be expected, for the malady is of many years', often of some generations', standing. But will it be a light matter to have made these inebriates decent, orderly, and self-supporting in industrial schools while they live, and to have taken their children out of the blight and shadow of a drunkard's home, and given them back their birthright? And for that "saving remainder," fallen but not lost, going forth restored, whose lives from ruined prospects and dead hopes shall rise again—with what line will you measure, in what balances weigh the value of such refuge to them?

CANNED FOODS AS A CAUSE OF ACUTE POISONING.

BY JNO. NORTH, A.M., M.D., F.S.Sc. LOND.

PROFESSOR OF CHEMISTRY, TOXICOLOGY AND LARYNGOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, KEOKUK, IOWA.

When we take into consideration the enormous amount of canned foods put up and consumed each year, and the comparatively few cases of poisoning, both real and imaginary, that have been attributed to the use of canned foods, we ask the question, Is the use of canned foods injurious? 500,000,000 cans of food are annually consumed as follows:

Of salmon	an average	per	annum	of	.....	50,000,000	cans.
"tomatoes	"	"	"	"	.....	52,000,000	"
"corn	"	"	"	"	.....	30,000,000	"
"peaches	"	"	"	"	.....	15,000.000	"
"meats, oysters, fruits, vegetables, etc.					.....	253,000.000	"

In vegetables alone there are about 400 farms that have small canning factories, putting up the products of the adjoining land fresh from the fields. Adding these to the number of regular canning factories, we have about 800 in all. These figures do not include the canning of fruits, vegetables, etc., by families for their own consumption, which would increase the amount to a considerable extent.

Before coming to any conclusions regarding the injurious effects of canned foods, it will be necessary to consider the various materials out of which the cans are constructed as well as the composition of the contents of the cans. We will not consider the foods canned in glass, but will devote our attention to the foods put up in tin cans. Tin-plate is the form in which tin is used in canning food. It consists of thin sheets of iron covered with tin. There are several methods by which tin-plate is made, the usual one being about as follows: The very best refined sheet iron is first cleared of all oxide by immersing in dilute sulphuric acid, then rubbed dry with sand to remove all traces of the acid. It is then plunged successively into a bath of melted tallow and a bath of tin covered with tallow. On contact with the iron the tin forms a true alloy, which is covered with pure tin. The cheaper grades of tin-plate are dipped once or twice, while the best goods are dipped three times. One pound of tin will make twenty-eight plates of tin-plate 14 × 22 inches, and of the best grade. Commercial block tin, such as is used in the manufacture of tin plate, usually contains various other metals, but in such small quantities that, with the exception of lead, they are never found in the contents of the can, so we will not consider them.

A large quantity of tin-plate is made from an alloy of tin and lead, the proportion of lead varying from 1 to 50 per cent. or more. A grade containing about 10 per cent. of lead is as poor as is generally used in making cans. The greater the proportion of lead, the cheaper the tin plate. This alloy of lead and tin is more easily acted upon by the vegetable and fatty acids than pure tin. The principal examiner of chemicals in the U. S. Patent Office says that all commercial tin is alloyed with lead. Chemists who have examined cans for alloy of lead and tin find lead in almost every case. Dr. Onderdunk finds only two samples free from lead in a great number examined.

Dr. Darsh reports that out of a large number of cans tested, he found lead alloyed with tin in almost every case. Dr. Dagget has examined twenty cases of different brands and found lead alloy in every can. I have examined a great many different brands of canned foods, also the very best brands of charcoal tin used by our tinners, and found lead alloyed with the tin in every case; not one was free from lead. The most convenient test for lead alloy is to place a few drops of a weak solution of nitric acid (1 to 10) on the tin plate and allow it to remain a few minutes to react on the metal. If lead be present the nitrate of lead will be formed, and by placing a small crystal of potassium iodide in the centre of the acid, the characteristic yellow iodide of lead will appear. The chemical changes may be expressed by the following equations:

(a) $Pb + 2HNO_3 = Pb(NO_3)_2 + H_2$.

(b) $Pb(NO_3)_2 + 2KI = PbI_2 + 2KNO_3$.

If the tin is pure there will be no change of color on the addition of potassium iodide.

The ordinary solder used in the manufacture of tin cans is an alloy of tin and lead. Three grades of solder are in use: common solder, consisting of equal parts of tin and lead, fine solder, composed of two parts of tin to one of lead, and "coarse" solder, containing one part tin and two of lead. The old hand-made can was soldered from the outside, and rosin used as a flux. It was soon found that the work could be done faster by soldering on the bottom and top from the inside, still using common solder and rosin. Still later it was discovered that the same work could be done faster and cheaper by using a liquid flux, consisting of chloride of zinc and water. The caps are usually soldered on by means of the chloride of zinc flux. Some of this frequently finds its way under the cap and into the contents of the can. The Legislature of Maryland has passed a law prohibiting the use of this flux in canning foods. There has been a great deal of groundless prejudice against the use of machine-made cans. An attempt has even been made to boycott all cans made by machinery. I have tested samples of the tin plate, solder and flux used by one of the largest manufacturers of machine-made cans, and find the materials to be practically unobjectionable.

It would be impossible to give the analysis and composition of all the foods preserved by the canning process. Most, if not all of them, contain organic acids of either the vegetable or fatty acid series. The acids found are either natural in the fruits, vegetables or meats, or are the result of chemical change. In replying to the question, "Is the use of canned foods injurious?" we must take into consideration not only the tin-plate, solder, and flux used, but also the nature and composition of the food in its natural condition, and after partial decomposition has taken place. When we take elementary substances alone we find them harmless, as a rule. It is when new combinations take place, or old compounds are decomposed and poisonous ones are formed as the result of recomposition, that we look for harm. In the substances mentioned we have tin, lead and zinc present as baselous or positive radicals, and chlorine, vegetable and fatty acids as acidulous or negative radicals. From these we can have tin chloride or tin salts of the organic acids, lead chloride, or lead salts of the organic acids, or we may have zinc chloride or zinc salts formed by the union of zinc with the organic acids. Rosin used as flux does not combine with any of the metals; it is only when a liquid flux containing chlorine or a chloride is used, that we may have all of the above combinations. If chlorine or a chloride is used as a flux which of the metals, tin, lead or zinc, will it combine with? There is a law of chemical affinity known as "Bartholet's Law," as follows: "Whenever, on mixing two substances in solution, a compound can be formed by a rearrangment of their atoms, which is insoluble in the menstruum employed, such a compound will be formed and will appear as a precipitate." The liquid or juice in canned foods consists of water and in most cases of an acid. Chloride of zinc is soluble in water and acidulated water. Stannic chloride is soluble in water and acidulated water, stannous chloride in acidulated water. Lead chloride is almost insoluble in water and acidulated water. According to the law of Bartholet, the chlorine would enter into combination with the lead, and if in considerable quantity would be precipitated. Our works on toxicology do not mention lead chloride as a poison. The chlorides, oxides, hydrates and organic salts of tin, lead and zinc have never been found in sufficient quantities to give rise to the symptoms sometimes produced by eating canned foods. They have never been found in as large quantities as some of our textbooks give as the medicinal doses of these same salts. And again, we find that the symptoms of canned food poisoning differ materially from the toxic effects of the metallic salts.

The following symptoms have been recorded as occurring in acute poisoning from canned foods:

Brain—Headache, throbbing of temples, vertigo, delirium, stupor, coma.

Face—Livid.

Eyes—Red, suffused, lids swollen, pupils dilated.

Tongue—Fiery red, heavily coated.

Throat—Dry, burning sensation, extreme thirst.

Stomach—Want of appetite, repeated eructations, nausea, retching, violent vomiting, both bilious and alimentary.

Bowels—Tender, painful, griping, diarrhœa, violent colic, gastro-enteritis, very offensive stools, bloody stools, dark tawny liquid from bowels, stricture of rectum and colon, tenesmus, prolapse of rectum.

Respiration—Alternate strangulation and paralysis of lungs.

Temperature—Normal, 101° to 105° F.

Pulse—Weak and slow, thin, thready, 100 to 150.

Integument—No heat of skin, skin hot and dry, profuse sweating, fiery red eruption all over body, intolerable itching, rough skin, greenish or yellowish patches.

Kidneys—Urine scanty, loaded with urates, no sugar nor albumen.

Muscles—Convulsive tremors, all movements painful, cramps of thighs and legs, epileptiform convulsions, partial paralysis of extremities.

General Symptoms—Cross, irritable, great languor, extreme weakness, typhoid condition, cold extremities, etc.

We find most of these symptoms in cases of poisoning by the narcotic alkaloids of hyoscyamus, conium, stramomum, etc. The symptoms of acute poisoning by canned foods are not such as we find in corrosive metallic poisoning, but are such as would arise from the action of some substance having especial effect on the nervous system.

If poisoning does occur from eating canned foods, and does not arise from the tin-plate, solder, fluxes, or organic acids or their combinations, where does the poison come from, and what is its nature?

Putrefaction is the spontaneous (so-called) decomposition taking place in nitrogenous substances. As the result of this process we have artificial alkaloids, and extractive matter formed. Alkaloids are alkaline or basic substances found in organic matter. The *natural* alkaloids already exist in organic substances; the artificial alkaloids do not pre-exist in organic substances, but are the results of chemical changes, generally that of decomposition. When artificial alkaloids are formed by the putrefaction of dead animal matter they are called "ptomaines," or "cadaveric" alkaloids. When they are formed by the decomposition of animal matter under the influence of life force, they are called "leucomaines," or "animal alkaloids." There has also been discovered in both living and dead animal matter non-crystallizable nitrogenous matter, called extractive matter. All of these three classes of animal nitrogenous substances are highly poisonous even in very small quantities. The extractive matters possess great toxic properties. The leucomaines are not found in canned foods. There is little doubt that the artificial alkaloids are the cause of poisoning in canned foods. The ptomaines have been found in canned meats. They are produced by putrefactive changes that take place in the meat before being canned, or may be developed in the can if it be imperfectly canned; or they may be formed after *opening* the can and exposing the contents to the atmosphere.

Lengthened putrefaction destroys the ptomaines. Brieger, in his great work on "Ptomaines," gives the results of his investigations:

1st. The ptomaines of gastric fibrin.

2d. The ptomaines from the putrefaction of albuminoids.

3d. The ptomaines from the putrefaction of mammalian flesh.

4th. The ptomaines from the putrefaction of fish.

5th. The ptomaines from the putrefaction of cheese.

6th. The ptomaines from the putrefaction of gelatine.

7th. The ptomaines from the putrefaction of yeast.

He also gives a full description of his chemical results and physiological experiments. The following are the names and chemical composition of the ptomaines examined by him:

A. Peptonized Fibrin.—A toxic substance was obtained from this called *peptotoxine*. Its chemical formula was not discovered.

B. Albumoids.—The same substance was discovered during the putrefaction of albumonids.

C. Putrid Mammalian Flesh gave two ptomaines. Neuridine ($C_5H_{14}O_2$), and neurine ($C_5H_{13}NO$), both of which are crystallizable and form salts.

D. Putrid Fish, from which five ptomaines were obtained:

1. Neuridine.
2. Ethylene diamine. $C_2H_4(NH_2)_2H_2O$
3. Muscarine. $C_5H_{15}NO_3$
4. Gadinine. $C_7H_{17}NO_2$
5. Triethy-amine. $N(CH_3)_3$

E. Putrid Cheese.—This yields the following bases:

1. Neuridine.
2. Trimethylamine.

F. Putrid Gelatine gives three ptomaines:

1. Neuridine.
2. Dimethylamine. $(CH_3)_2HN$.
3. Isophenylethylamine. $C_8H_{11}N$ (but not well established.)

G. Putrid Yeast yielded dimethylamine.

But few of the alkaloids and extractive matters formed by the decomposition of vegetable matter have been examined, but they are known to exist and to be very poisonous.

The symptoms of poisoning arising from eating canned foods are identical with those produced by putrefactive alkaloids and extractive matters. When sudden illness takes place after eating canned food it is usually attributed to metallic poisoning.

In a paper read before the Medico-Legal Society of New York, April 9, 1884, and published in the *Medico-Legal Journal* of June, 1884, Dr. J. G. Johnson reports six cases of poisoning from eating canned tomatoes. He attempts to prove that in these and all other cases of poisoning from canned goods, the poisoning comes from the metals, losing sight altogether of the possibility of poisoning by putrefactive alkaloids or extractive matter. He says: "Even if the tomatoes had begun to spoil she (the housewife) had cooked them, and cooking would have cured them. Putrefaction and decay, instead of being death, is really giving birth to myriads of little living plants. Now heat kills all of these ferments, and if the food had commenced to decay heating would have removed that danger." He does not even mention the possibility of artificial alkaloids or extractive matter. With many others, he seems to be under the impression that the toxic symptoms must necessarily be caused by a metal or a microbe. Now, heating to the boiling point, 212° F., will destroy all organic germs, but not all the alkaloids. It is no wonder that Dr. Stevenson, of London, in speaking of Dr. Johnson's paper, says: "Dr. Johnson arrives at very positive conclusions on altogether insufficient data, and he has failed to grasp the chemistry of the subject on which he writes."

When a number of persons are taken sick after eating foods that have not been canned, the food is analyzed for the purpose of ascertaining what poison has been introduced into the food by some malicious person. Failing to find metals or natural alkaloids, the case is reported as one of mysterious poisoning Cases of this class are reported nearly every day by the public press. Poisoning of wedding and other parties from eating ice cream, made in old freezers

with portions of putrid milk adhering to the creases and corners of said freezers, are known to all of us.

On May 5, 1884, Professor Attfield, of England, read a paper before the Pharmaceutical Society, detailing a large number of analyses of sixteen varieties of foods, in which he arrives at the following conclusions: "The public has not the very faintest cause for alarm respecting the occurrence of tin, lead, or other metal in canned goods."

Dr. Thos. Stevenson, Government Toxicological Analyst, London, in an article on "Poisoning by Canned Foods," read before the Medico-Legal Society of New York, on November 19, 1884, says: "Acute metallic poisoning by canned provisions is not known to have certainly occurred in this country. I have been Government Toxicological Analyst for thirteen years, and have never met with acute metallic poisoning by canned foods."

In conclusion, if care is used in canning foods, and they are not allowed to decompose before or after canning, they will not give rise to acute poisoning.

HÆMATEMESIS.[1]

BY SAMUEL S. ADAMS, M.D.,
OF WASHINGTON, D. C.

In offering for your consideration a case of hæmatemesis, I have nothing unique to present, nor is there anything new in its pathology or morbid anatomy. The interest in the case is mostly centred in the rapidity with which the bleeding stopped after the administration of the hæmostatic, and the speedy reaction from impending collapse.

Miss O'K., aged about 26, a brunette, of Irish parentage, with an excellent physique and high color, was taken ill October 31, 1886, but did not have any medical advice until I was summoned to see her just after a profuse bloody vomit on the evening of November 1. Her family history does not point directly to a hæmorrhagic diathesis, although some years ago, in the case of a sister, I had great difficulty in controlling a profuse and alarming hæmorrhage from the gums, following the extraction of a tooth, which had continued forty-eight hours. Her mother died of consumption; her father is said to have died of Bright's disease; and a brother of apoplexy following yellow fever.

From her infancy she had always been considered delicate, but cannot recall any sickness until 1881, when she was taken ill just as in the present attack. She had apparently been well and was engaged in household duties when she was suddenly nauseated, and soon after vomited a large quantity of blood; she vomited blood a second time that day. During this illness she was confined to her bed for one week, but did not regain her strength and vigor for several months. From her recovery to the present she had enjoyed excellent health, with occasional slight attacks of indigestion. She began to menstruate quite early; the periods and flows have always been normal, and she has never had any uterine disease. She has no history of vicarious menstruation; she has had teeth extracted without excessive bleeding, and she has never had nose-bleed.

Only words of commendation can be spoken of her ambition and industry, which have led her into irregular habits of living and to an almost absolute disregard of the rules for the preservation of health. It has been her custom to sit up until 1 or 2 o'clock at night engaged either in reading or fancy work. She would go to her office after taking a cup of coffee, and never more than one biscuit. She has been compelled to sit all day on the ground floor of the worst ventilated of the Government buildings writing letters. In the half-hour allowed her at noon she would hurry home, eat a very small luncheon, and frequently run back to her desk. She would dine at 6 P.M., when she usually ate a hearty but not an excessive meal. Her bright color, powers of endurance, cheerful disposition and apparent good health have excited the admiration and envy of her female friends. Whenever they would admonish her for disregarding the hygiene of life, she would reply that she was always well. On one occasion when she was boasting of her good health in spite of her irregular mode of living, the writer warned her that nature would not always be so obedient to her wishes, but would ere long assert her rights. Little did he think then that the prediction would be fulfilled so soon.

For a few days she had had "sour stomach," belching, suffocative feelings, pain in the back of the head and in the cardiac region which almost made her faint, and was very sleepy most of the time—all of which she attributed to "dyspepsia and biliousness." On October 30, after taking her usual breakfast, she went to a studio where she painted for seven hours. She returned late in the afternoon feeling very tired, but ate a good dinner and then repaired to her room, but did not retire till after midnight.

October 31. She did not get up until 10 A.M., when she felt very uncomfortable from a feeling of oppression in the epigastrium which she thought was indigestion. At breakfast she only drank a cup of coffee. She remained in the parlor till 1 P.M.; then went upstairs and took a warm bath and dressed for dinner. She now felt very weak, but thought it was from hunger, as she had not had a bit of solid food for twenty-two hours. While seated at the dinner table waiting for her soup she was seized with a feeling of suffocation, nausea and dizziness. She left the room and went into the parlor to her sisters. They, supposing that she was about to faint, procured some hot water, which she drank. In about ten minutes she became very much nauseated. She went up to the third story of the house, where she vomited seemingly a pint of blood. This frightened her, but she was quieted by her sisters, who expressed the opinion that the blood was from the nose, as it came from that passage as well as from the mouth in the effort of vomiting. She then went to her room and rested till 6 o'clock, when she felt somewhat better; she would have kept to her bed but for the solicitations of one of her sisters, who was anxious to see her in a new dress; so she put it on and went to tea, but could not eat. She remained in the parlor until

[1] Read before the Medical Society of the District of Columbia, November 10, 1886.

8, when she went to the fourth floor; soon after she was taken sick again with oppression, nausea, and cold clammy sweats, but did not vomit. She then went up another flight of stairs to her room, went to bed, and slept well all night.

November 1. She tried to get up at 10, and again at 12 o'clock, but could not dress on account of an indescribable feeling of weakness and faintness. Later in the day she tried to dress several times, but failed. At noon she was served with toast and tea, but partook sparingly of them. The nausea having returned every time she raised her head from the pillow, she was convinced by her sisters that she was "bilious," so she took a wineglassful of Hunjadi water, which operated very freely about 5 o'clock. Just after the stool, while combing her hair, she again vomited blood. She then walked down a flight of stairs to send a message to me, and back again. She "thought she would die" before she could get into bed again.

I found the patient ashy pale and sweating profusely; her voice was scarcely audible; her pulse about 140, small and compressible; respirations sighing, and she complained of a suffocated feeling. In the "slop-jar" I found at least a pint of dark blood which had not coagulated. She said that from the appearance of the stool it also contained blood. There was no acute pain, but she felt exhausted. She had no cough, and insisted that the blood was vomited. I auscultated the chest thoroughly, but found the normal vesicular murmur. My attention was called to a dull, gnawing pain just under the ensiform cartilage which was not increased by pressure. I was now satisfied that the blood came from the stomach, but the nature of the lesion was in doubt. There seemed to be no hæmorrhage from any other viscus, and as the intervals between the vomitings were so long, I felt certain that I had a simple ulcer of the stomach to treat.

The patient reacted so promptly that stimulants were not indicated. I ordered a mixture containing gallic acid, fld. ext. ergot, aromat. sulphur acid, syrup and aqua to be taken every two hours. Rest in the recumbent posture was strictly enjoined; cracked ice *ad libitum* allowed, and milk and lime water in small quantities, frequently repeated, were ordered.

9 P.M. I found the patient recovering from an attack of hæmatemesis. Her condition was described to me by her attendants about as I have detailed above. She had vomited more than a half pint of blood, which was less disorganized than that previously seen, This attack was induced by getting up to stool. This evacuation also looked as if it contained blood.

November 2, 3 A.M. I was called to see her because she had vomited blood again. She had slept very quietly since about 10 o'clock, but by getting up to use the *commode* she had brought on another attack. The quantity this time was fully a pint; the blood was more disorganized than the preceding, but did not coagulate. Her general condition was about as that described in the previous attacks. By the time I reached the house the syncope had passed away.

Early the previous night, when speaking to Dr. Busey about the case, he had advised the administration of the tinct. ferri chloridi if the medicine she was then taking did not control the hæmorrhage. In recommending this drug he remarked: "If it is given immediately after the vomiting I have never seen the hæmorrhage recur." In accordance with his suggestion the drug was procured in about an hour after the vomiting, and a half teaspoonful, in water, was then administered. She was instructed to remain in bed in the recumbent posture and, if necessary, to use the bed-pan. The cracked ice was continued; 20 drops of the iron to be given every two hours, and in case the hæmatemesis recurred, a half teaspoonful immediately thereafter.

8 A.M. The patient slept quietly until 6 o'clock, when she again vomited about a pint and a half of partly coagulated blood. Just as soon as the nausea had passed away a half drachm of the iron was administered. From that time there has been no evidence of hæmorrhage.

10 A.M. Dr. Busey saw the patient with me, and emphasized the importance of absolute rest and quiet, recumbency, milk and lime-water, cracked ice and small doses of iron, or in case of hæmatemesis the larger dose—the directions that had already been given. The iron was continued for several days in 20-drop doses every three or four hours, and then stopped. The patient gained strength and color very quickly; was permitted to sit up on the 8th, and was given soft bread and the juice of tender broiled steak.

The etiological factors in this case correspond with those laid down by Dr. W. H. Welch.[1] The irregular mode of living; the insufficiency of food; the exposure to bad hygienic surroundings; and the overtaxing both of body and mind, undoubtedly favored the ulcerative process. The present attack of hæmatemesis, it seems reasonable to suppose, had its exciting cause in the great mental and physical strain to which she had been subjected during the twenty-four hours preceding the first vomiting.

From the previous history; the chronic dyspepsia; the localized pain after eating; the age and sex; the bloody stools; the oppression and nausea; and finally the vomiting of blood—which recurred at varying intervals—surely make the diagnosis simple.

The prognosis was favorable during the illness because the patient rallied so quickly after each hæmatemesis, without the use of stimulants or external heat. If, however, the prognosis had been based on the loss of blood instead of on her powers of recuperation, it would have been very unfavorable. Still another element in the favorable prognosis was the prompt action of the iron in checking the hæmorrhage.

In the treatment of the case there is much to be gained. The mixture that was given at first apparently had no effect in controlling the hæmorrhage, but its failure may have been due to the patient getting out of bed to use the *commode*. When the iron was begun early in the morning an hour had passed since the patient vomited, and undoubtedly some blood had effused into the stomach, thus pre-

[1] System of Medicine, Pepper, vol. ii, p. 480.

venting its speedy action. After she had vomited the last time, at 6 A.M. November 2, Dr. Busey's advice "to give the iron immediately after the vomiting" was carried out, and his prediction that the hæmorrhage would be arrested was fulfilled. This method of treatment seems to have originated with Dr. Busey, as the books I have examined make no reference to it.

It is important to state that, although the patient took about a quart of milk daily, her bowels were not moved from the night of the 1st until that of the 7th. Enemata of warm water were given for several days, but they were either voided immediately without fæcal matter or else absorbed by the intestinal mucous membrane. The iron is very apt to form scybala and thereby prove a troublesome complication. So long as the tongue is clean and the patient is not inconvenienced by the constipation it is better not to force an action for several days. When the necessity of opening the bowels becomes imperative, great care should be taken to avoid nauseating and drastic cathartics, in order to prevent violent peristaltic action of the alimentary tract. Saline cathartics are the indicated agents in such cases. This patient took on the 7th magnesium sulphate dissolved in aromatic sulphuric acid, syrup and water, which had the effect of clearing the tract by three profuse, watery stools, without exhausting or injuring her.

In conclusion, it is but just to say that the success of the treatment was materially aided by the obedience of the patient and the good judgment and excellent care of her lady friends, who were untiring in their attentions.[2]

1525 I St., Washington, D. C.

EXPLORATORY INCISION AS A DERNIER RESSORT FOR DIAGNOSTIC PURPOSES.[1]

BY R. STANSBURY SUTTON, M.D.,

OF PITTSBURGH, PA.

Many cases will present themselves in which a diagnosis is not possible. It will not be possible to determine anything beyond a certainty that the disease is within the abdominal or pelvic cavity. A tumor may be present; no certainty of its relations may be ascertainable through the closed abdominal wall. What is to be done? Will we satisfy our consciences that our duty is done and turn away, or temporize with drugs? It is to be hoped not. *In every man or woman dying or in danger of dying from an obscure intra abdominal trouble an exploratory incision should be made and the diagnosis should, if possible, through it, by touch, or touch and vision, be perfected.* Is such a procedure to be lightly undertaken? By no means. But with the following precautions it is safe:

1. Have the patient clean from head to foot, and the surface of the abdomen especially clean, made so by soap and water and a brush. Surround the parts with clean towels fresh from the hot iron.

2. Have your hands and forearms scrupulously cleansed with soap and water and turpentine.

3. Have your instruments clean and immersed in hot water.

4. Thoroughly etherize your patient.

5. Make an incision two inches long; before opening the peritoneum secure every bleeding vessel. Pass in two fingers and make search.

6. If you have failed to gain the desired information, withdraw your fingers, pass in a sponge, locate it directly under, below and above the wound, and enlarge the latter with a clean cut over the sponge, to a length sufficient to let in your hand. Secure all bleeding vessels, withdraw the sponge, and pass in the hand and complete the search. Through such a wound much may also be seen. *Never make a longer cut than is necessary, and make a clean cut.*

7. Before closing the abdomen cleanse the cavity thoroughly, but be gentle in your use of the sponges; if you deem it necessary, pour in a pitcher of clean warm water and wash the cavity out. Gently sponge it dry. In closing the wound, pass the sutures over a flat sponge laid beneath the wound.

8. Reject the use of carbolic acid or bichloride of mercury in your operations; they are useless *and a source of danger.* They may be useful in cleansing your hands prior to operating, *but they are to be kept out of the peritoneal sac.* Keith, Tait, Bantock, and others abroad have proved the worthlessness of carbolic acid, and I have for some time been satisfied from experience that they are right.

9. Never permit any one but the operator to pass a hand into the cavity, unless his hand has been prepared by a careful cleansing with soap and water and brush, and with turpentine or a 1.200 solution of bichloride of mercury. Even a 1 in 20 per cent. solution of carbolic acid is not reliable for this purpose.

10. In tying the sutures, dry the lips of the wound as you go along with a bit of iodoform gauze.

With the above precautions I have opened the abdomen many times, and I have yet to see a single wound so treated fail to unite by first intention.

[2] November 24. The patient is steadily improving, and has resumed her official duties.

[1] Remarks made before the Pittsburgh Gynecological Society, December 2, 1886.

HOSPITAL REPORTS.

MERCY HOSPITAL CLINIC.

Service of DRS. EDMUND ANDREWS AND E. WYLLYS ANDREWS.

A BULLET AND FRAGMENTS OF A KNIFE IMBEDDED TWENTY-TWO YEARS IN THE PERINEUM.

Case 12,710 Andrews' Surgical Record.—This patient was a pontonier under Gen. Sherman in the Atlanta campaign in the spring of 1864. At the battle of Resaca he was on duty as steersman to one of the pontoons used in ferrying troops across a river. A shot from the enemy's side struck him in the right groin, passing through the pocket of his pantaloons, shattering a bone-handle pocket knife, and entering the body about where the femoral vein emerges from beneath Poupart's ligament. Thence it traversed inward, backward, and slightly down-

ward, crossing the perineum, cutting the urethra behind the scrotum, and lodging alongside the tuberosity of the ischium. The man being plucky, continued for a time to steer his pontoon, but the blood flowed so freely that he became faint, and was put ashore, where he lay behind a stump until a lull in the firing permitted his removal to the field depot. He was also wounded in the forearm.

The surgeon in charge of his case failed to discover the bullet, owing to its peculiar location, and dressed the wound as usual. Urinary infiltration and abscess of the perineum followed, which gradually healed, as also did the original wounds in the groin and arm. From that time on there was a constant flow of pus with the urine. Eight years later he passed from the urethra some pieces of the bone handle of his pocket knife, without any material benefit.

Twenty-two and a half years after the battle he appeared at the clinic, much weakened and exhausted, still discharging pus freely from the urethra, and suffering from a stricture of the wounded urinary passage. Examination with sounds showed that instruments turned off from the urethra to the left and ran into a cavity alongside the ischium, where a gritty sensation was felt. There was also a hardness and a tenderness to the touch in the same region.

On making an external perineal section behind the scrotum four pieces of the bone handle of his pocket knife were found, partly covered with a strong crust deposited from the urine. A small orifice ran downward from the main abscess cavity to a pocket nearer the surface, where a hard object could be felt. A separate incision opened this pocket and disclosed the bullet. On extraction, it was found to be an old-fashioned spherical bullet, somewhat battered by its tussle with the pocket knife, and crusted in spots with urinary calculus. The abscess was disinfected and tubed, and the stricture of the urethra opened out to full size. The wounds are now healed and the patient is rapidly returning to full health.

MEDICAL PROGRESS.

BIOLOGO-CHEMICAL PROPERTIES OF MICROBES.—At a recent meeting of the Russian Chemical Society in St. Petersburg, PROFESSOR A. V. POEHL (*Vratch*, No. 8, 1886, p. 157) made a very interesting communication on his experimental study of the vital process of various microbes. The formation of ptomaines in nature, he says, is mostly caused by the vital action of micro-organisms. While studying the microbes of human fæces, the author found that in morbid cases there appear in the intestines several kinds of microbes, possessing the property of decomposing proteid bodies. To use Hoppe-Seyler's words, the decomposing action of bacteria on proteids resembles that of caustic alkalies (while ferments act on proteids like weak acids). Under the splitting action both of bacteria and caustic alkalies, there simultaneously appear the products of oxydation and those of reduction, which fact is explained by decomposition of water (H_2O) into an oxydizing hydroxyl (HO) and a reducing hydrogen (H).

Ptomaines belong to the products of disoxydation. Dr. Poehl succeeded in demonstrating the reducing action of certain micro-organisms on the surrounding nutritive medium during their growth. He recommends taking a neutral nutritive jelly, to which is added 0.05 per cent. of perchloride of iron and 0.05 per cent. of red blood salt (ferric potassium cyanate). Micro organisms endowed with a reducing power give rise to a blue coloration of the jelly (in consequence of formation of Berlin blue), which commences in the lowest part of the track left by an inoculating needle, but subsequently spreads around in the jelly (since ptomaines, on their being absorbed by the jelly, also deoxydize the latter).

Dr. Poehl examined in that way cholera bacilli brought by Professor Raptchevsky from Spain, typhoid-bacilli, Finkler's and Prior's bacilli, certain microbes of pus and fæces, as well as microbes of water from the Neva. A quite distinct reduction was obtained from the cholera-bacillus, typhoid bacillus, some of the microbes of pus, fæces, and the Neva water, and from "Bienstock's Bacterium," No. 4. But Finkler's and Prior's microbe of cholera nostras gave no reduction, since it does not produce ptomaines (though it freely peptonizes syntonine). Hence the author proposes to use that biologo-chemical behavior as a means of distinguishing between Koch's microbe of Asiatic cholera and Finkler-Prior's bacillus of European. As a rule, micro-organisms liquefying (under ordinary conditions) nutritive jelly do not possess either a reducing power or a power of forming any ptomaines. When present in the intestines, the cholera-bacillus also produces a reducing action on the surrounding medium and leads to the formation of ptomaines (the presence of which in cholera cases has been actually proved by Klebs, Pouchet, Nicati and Rietsch, etc.). The author feels sure that cholera could be usefully treated by the administration of oxydizing remedies, such as chlorinated water, peroxide of hydrogen, salts of permanganic acid, etc.; they are indicated the more strongly, since most of ptomaines are destroyed by the action of oxydizing agents. [Referring to the therapeutic dictum of Professor Poehl, Professor Manassein expresses his doubt that chlorinated water and peroxide of hydrogen, taken internally, could reach the intestines undecomposed.—*Rep.*]—*London Medical Record*, Dec. 15, 1886.

GENKIN ON THE USE OF HYPNOTICS.—DR. M. S. GENKIN, of Kaluga, lays down (*Proceedings of the Kaluga Medical Society*, Nov. 30, 1885, p. 42) the following rules for the use of various hypnotics in treatment of sleeplessness:

1. *Sleeplessness from physical excitement of the brain, or so-called "physical hyperæsthesia from moral causes."*—As a rule, the removal of causal influences and the administration of bromide of potassium prove successful. When the bromide remains inactive, morphine must be given to an anæmic

patient, and ether, chloral, or paraldehyde to a strong one. In the latter, morphia is contra-indicated, since it would only increase "psychical hyperæsthesia" in him, and may even give rise to acute delirium.

2. *Sleeplessness from pain sensations in peripheral nerves.*—Remove the cause; when the latter is unremovable, the best means is a hypodermic injection of morphia.

3. *Sleeplessness from the rise of temperature and cerebral hyperæmia in febrile cases.*—The best treatment consists in giving paraldehyde, in the dose of from 20 to 40 grains. The latter quantity of the drug induces quiet sleep of from four to six hours' duration. Dr. Genkin, generally, thinks highly of paraldehyde, which, according to his extensive trial, is as effective as chloral, and does not produce any unfavorable influence on the heart. In the first period of febrile diseases—that is, before high temperature has produced fatty degeneration of the cardiac muscle and blood vessels, chloral also may be used.

4. *Sleeplessness from cerebral congestion, depending upon an irregular cardiac action in cases of fatty degeneration, or organic defects of the heart, arterio-sclerosis, etc.*—Paraldehyde should be given. Chloral is strongly contra-indicated even in small doses. Preparations of opium and morphine are also out of place.

5. *Sleeplessness from intense anæmia of the brain.*—Subcutaneous injection of morphine, or aqueous extract of opium, a glassful of wine or beer or aquavitæ *(vodka)* internally, and warm applications to the head, are the best means in the form of insomnia in question. Chloral and paraldehyde remain here entirely inactive.

5. *Sleeplessness from alcoholism.*—In absence of arterio-sclerosis, etc., the best remedy is chloral. Otherwise paraldehyde should be administered. Dr. Genkin emphatically advises the utmost caution and discretion in the administration of hypnotics, since sometimes even relatively small doses of an unduly used drug of the kind may produce disastrous effects. For the sake of illustration, he adduces two instances of the use of chloral in patients with arterio-sclerosis. In one of them, two 15-grain doses were given, one at bed-time, another at noon on the next day. In the evening, after the second dose, the patient suddenly died from paralysis of the heart. Another patient self-administered three 10-grain doses of the drug, at three hours' intervals, and made only a narrow escape. According to the author, chloral and bromide of potassium are used in Russia in truly enormous quantities. Indeed, "bromide of potassium has become almost a food-article in every Russian home."—*London Medical Record*, Dec. 15, 1886.

Fracture of the Thigh—Absorption of the Callus from Erysipelas.—Dr. Ferret reports the case of a youth, aged 17 years, of good constitution, and without taint of disease, who came under observation in February, 1884, for simple fracture of the thigh at its middle. It was treated by continuous extension, and recovery ensued without shortening. In April, after consolidation was complete, the patient contracted erysipelas on a portion of the leg where the skin was abraded by the diachylon used. It rapidly invaded the whole limb, and was very severe. On the sixth day after the outbreak of the erysipelas it was noticed that the limb was bent almost at a right angle at the seat of the old fracture, but there was no pain. The limb was placed in good position, and extension again applied. Within ten days the erysipelas had disappeared; but the patient suffered deep pain at the site of the fracture. Four days after this the region was inflamed, swollen and fluctuating, and a considerable amount of pus was removed by aspiration. Pus reappeared, and four days after the aspiration the abscess was laid open. It was found that the extremity of the lower fragment was adherent to the internal face of the upper fragment. It was replaced, after about 4 cm. of bone were removed, and the suppurating cavity was then packed with iodoform gauzes. The extension apparatus was kept on, the iodoform gauze renewed every three or four days as long as necessary, and by the end of May bony union was again complete.

Cases of this kind are very rare, and may be classified as those in which the callus is only softened, and those in which it is completely absorbed. Of the first class Clarke reported a case in the *Medical Times* and *Gazette*, in 1867, and Poinsot reported a case to the Société de Chirurgie in 1878. Of the second class Norris ("Contributions to Practical Surgery") says that he has seen rapid absorption of a large callus under the influence of erysipelas. Schilling (*Med. Zeitung*, Sep., 1840) reports a case of absorption of callus during typhoid fever. Mantell reports in the *Lancet*, Oct. 9, 1841) a case in which a callus was absorbed at least three months after bony union from the patient contracting an epidemic fever.—*Progrès Médical*, Nov. 13, 1886.

A Modification of Weigert's Method of Staining Tissues of the Central Nervous System.—Dr. W. M. Gray, Microscopist, Army Medical Museum, Washington, D. C., says:

The specimens, hardened in Müller's or Erlicki's fluid, are transferred directly (without coming in contact with water) to alcohol 70 per cent. The pieces to be embedded are now gradually dehydrated, advancing from 70 per cent. to 95 per cent. alcohol, and finally to absolute. After soaking in absolute alcohol for several days, they are transferred to a mixture of equal parts of ether and absolute alcohol, and allowed to soak for one or two days; they are then transferred to a solution of celloidin, and are embedded in celloidin on cork. The pieces, fastened to a cork with celloidin, are immersed in a solution of neutral acetate of copper (a saturated filtered solution of this salt, diluted with an equal volume of water), and allowed to remain in an incubator at 30° or 40° C. for one or two days.

The specimens become pea green after the copper treatment, the celloidin mantle more of a blue-green; they may now be preserved in 80 per cent. alcohol indefinitely.

After having made the sections, which must still

be kept clear of water. they are immersed in the hæmatoxylin solution, the formula for which is as follows: hæmatoxylon (Merck's, in crystals), one part; absolute alcohol, ten parts; water, ninety parts; boil twenty minutes, cool and filter, and to each one hundred parts add one part of a cold saturated solution of lithium carbonate.

The time required for staining varies with different specimens; in general, the rule prevails that the longer one colors, the surer the result; for cord sections, two or three hours are usually sufficient; in brain sections, twenty four hours are required in order to color the very fine fibres of the cortex.

After staining, the sections, now black in color, are differentiated by immersion in the following solution: borax, two parts; ferricyanide of potassium (red prussiate), two and one-half parts; water, one hundred parts. It will be found that the time required for perfect differentiation varies in different specimens; in cord sections, it usually takes one-half hour to several hours before the desired contrast between white and gray matter is obtained, and in brain sections it is longer. No fear of spoiling the sections need be felt. I have frequently allowed sections to remain in this solution for twelve hours without ill result.

From this solution the sections are transferred to water and well washed; then to 80 per cent. or 90 per cent. alcohol; they are then spread on slides and dehydrated thoroughly with absolute alcohol, and then clarified. I prefer xylol or creasote for clarifying, and xylol or benzole balsam for mounting.

If the steps in this method are carefully followed, success is certain; and it is without exception the method for tracing nerve fibres or demonstrating nerve lesions.—*Medical News*, Nov. 6, 1886.

LYCOPUS VIRGINICUS IN THE TREATMENT OF VENOMOUS BITES AND STINGS.—DR. J. R. BRIGGS, of Ft. Worth, Texas (*Trans. of the Texas State Med. Assoc.*, 1886), calls attention to the efficiency of *Lycopus virginicus*, commonly called bugle-weed (the charmweed of the Indians), in the treatment of the effects of the bites and stings of venomous reptiles and insects. "Any one," he says, "who has attended the fairs and other gatherings held throughout Georgia, Tennessee, and Kentucky during the egress of the Indians from that country doubtless remembers that on such occasions there were many Indians who would, with impunity, allow the poisonous rattlesnake to bite them. It was observed that, in order to counteract the effects of this poisonous reptile, they masticated large quantities of the bugle-weed and swallowed the juice. That the bugle-weed was the identical weed used at the time, I have absolute proof." He then gives a brief account of the case of a man who was suffering severely from the effects of the sting of a large centipede. Ordinary stimulants, such as whisky and ammonia, having produced no perceptible results, Dr. Briggs gave a decoction of bugle-weed (made with an ounce of the plant to a pint of water, a small quantity of alcohol being added to preserve it) in tablespoonful doses every hour, and applied it on linen cloths to the trail of the insect on the patient's abdomen, extending from the crest of the ilium to the umbilicus, an inch wide, of an erysipelatous redness at first, afterward black, roughened, and elevated. The man became comfortable in four hours, and was able to attend to his business at the end of three days.—*N. Y. Medical Journal*, Dec. 4, 1886.

EGGS IN THE DIETARY IN BRIGHT'S DISEASE.—In order to solve the problem of alimentation in the subjects of Bright's disease, LÖWENMEYER placed a number of patients upon a regimen which was as regular as possible, and added to the diet-list from six to nine eggs a day. In four of the patients, of whom three suffered from amyloid kidney and one from nephritis consecutive to cardiac disease, the addition of eggs to the dietary was followed by no increase in the excretion of albumen in the urine. In three others there was a notable increase; but the experimenter excluded two of them, one because the patient was not carefully watched, and the other because menstruation occurred just after the beginning of the experiment. In the third case, one of interstitial nephritis, the author remarks that the increase in albumen might be accounted for by the fact that the patient took the eggs raw, while the others ate them cooked. He concludes, as a result of these experiments, that an alimentation even very rich in albumenoid matters causes no increase in the amount of albumen in the urine.—*Lyon Médical*, No. 36, 1886.—*Medical Record*, Dec. 11, 1886.

RHUBARB IN THE TREATMENT OF THREAD-WORMS. DR. SIDNEY MARTIN, (*Practitioner*, October, 1886), thinks that in many cases, although the irritation about the anus may have been relieved by injections, the persistent irregularity of the bowels and disturbance of sleep are owing to the fact that worms still remain in a higher part of the intestine. In such cases he has found that small doses of rhubarb are efficient in bringing the worms away and in regulating the bowels, so that in most instances injections may be dispensed with. He has found the following formula most useful, varied slightly according to the age of the child:

Tincture of rhubarb	3 mmims;
Magnesium carbonate	3 grains;
Tincture of ginger	1 minim;
Water	to 1 drachm.

This amount is to be taken two or three times a day, according to the effect on the bowels. Whether the rhubarb acts as a vermicide or simply by "moving the worms on," he is unable to say.—*N. Y. Med. Jour.*, Oct. 30, 1886.

COCAINE IN MERCURIAL STOMATITIS.—BOCKHART has found that painting the gums with a 5 to 10 per cent. solution of cocaine a few minutes before eating will enable the patient to eat without trouble or pain. —*Revue des Sciences Méd.*, July, 1886.

CHRYSAROBIN IN INFANTILE ECZEMA.—STAQUART reports that in doses of 5 millig. to 2 centig. in young children, and 4 centig in children 7 years old, chrysarobin causes rapid dessication of the inflammatory redness.—*Revue des Sc. Médicales*, T. 38, No. 1.

THE SURGERY OF THE PANCREAS.

The most important surgical paper of last year, in this country at least, was read by Dr. Nicholas Senn, of Milwaukee, before the American Surgical Association at its last annual meeting, and has now been issued as a reprint from the *Transactions* of the Association. Those who are familiar with former papers of Dr. Senn, with the records of his careful experiments, and with his lucid style, need not be told more as to the importance of the paper. But whether our readers be or be not familiar with his writings, they will at once recognize that a carefully written paper of 129 octavo pages on the surgery of the pancreas must contain much valuable material, and positive additions to our knowledge of this very obscure subject. The surgery of the pancreas has no history except as to the treatment of a few cases of cysts of the gland, but the results in these cases have been so encouraging that there is much hope for the future of the surgery of the organ.

The experiments of Dr. Senn as to complete section of the pancreas tend to show that this lesion, unless complicated by other and more serious lesions, is not dangerous to life if the chief source of danger, hæmorrhage, be properly treated. "The coaptation of the divided ends would be desirable, but is not essential, as the continuity of the duct is not restored after this injury." No disturbance of digestion was noted in either of the two experimental cases, since a sufficient amount of pancreatic juice was secreted from that portion of the organ in communication with the intestine. In case of this injury the most important indication is to arrest bleeding, and to suture the two cut ends of organ so as to keep them in place, and thus maintain normal blood-supply. In an experiment with regard to the effect of laceration of the pancreas death resulted from the accidental re-opening of the abdominal wound. "Hæmorrhage was arrested spontaneously, and the process of repair, so far as the wound in the pancreas was concerned, appeared to be satisfactory. The divided ends were displaced considerably immediately after the laceration, but were subsequently brought into close contact by the cicatricial contraction." Believing that putrefaction cannot occur without specific germs, Dr. Senn crushed the pancreas of a cat to the extent of two inches in order to test the matter. The animal lived until it was killed, on the eighty-sixth day. It was found that the crushed portion was removed by absorption, which seems to be very rapid in this locality, and which may be explained by assuming that the peritoneum takes an active part in the process. No infection took place, nor could any evidence of putrefaction be found. "Subsequent degeneration, atrophy and sclerosis, take place in that portion of the gland which is no longer connected with the intestine by a permeable duct."

It was found that complete extirpation of the pancreas is invariably fatal, though Schiff has asserted the contrary; and it is important to know that in the two specimens from experiments which showed evidence of gangrene, this was seen on the convex surface of the bowel, but did not in either case involve the entire diameter of the intestine. Surgically speaking, partial extirpation of the pancreas is less serious than complete removal, though physiologically the consequences may be the same if the portion removed embrace the common duct or the two principal ducts from the two portions of the gland. In all of Dr. Senn's experiments the common duct was removed with the excised portion, and thus left the animal, physiologically, without a pancreas. In two cases the animals lived long enough to show the influence of the pancreatic juice upon digestion and assimilation. In each of these animals "the general health and nutrition remained unimpaired for four weeks, when emaciation, with fatty stools, followed, which resulted in death from marasmus in, after seventy days, and reduced the second to a skeleton in 126 days." As from the beginning no pancreatic juice passed into the intestine it is difficult to account for the good condition of the animals for the first four weeks. Had the marasmus been due to the resection of the mesentery of the duodenum, by diminution of intestinal absorption, it should have begun earlier. We may assume that the pancreatic tissue left continued to secrete until it was incapacitated by

degenerative changes; and with this assumption we must believe that the pancreas could absorb its secretion, and that this, entering the circulation, must have had some influence upon digestion. It is also important to know that in one case almost the whole duodenum was suddenly deprived of its blood-supply, and yet gangrene did not occur, as collateral circulation was set up by the development of two vessels in a band of cicatricial tissue along the concave surface of the bowel.

Seventeen experiments were made to prove the feasibility of ligation of either portion of the pancreas near the common duct as a surgical measure, and the regularity with which the pancreatic tissue is removed by degeneration and absorption of the detached portion of the gland. The ligatures used were of rubber. In every case in which complete physiological detachment was produced by the ligatures, resection, crushing, or any other means, atrophy followed. In no case was anything like a cyst produced. The facts of this atrophy and the non-formation of cysts shows that "in operations upon the pancreas it is not essential or necessary to remove peripheral portions of the gland, for fear that if any of the parenchymatous structure should remain a retention cyst would follow. In partial resection for injury or disease it would be advisable to ligate the peripheral portion, and permit it to remain, as it would lessen the danger by the infliction of less traumatism, and we can confidently expect that it will be removed in a short time by absorption." So also the important pathological question of retention cysts is settled by the experiments; such cysts cannot be due to obstruction of the duct. Again, we are taught the importance of removing those portions of the organ which are not supplied with blood-vessels rather than to trust to absorption, as dead pancreatic tissue is very putrescible.

Experiments were made for the purpose of studying detached portions of the pancreas, and the method of operating in these cases is worthy of the attention of physiologists, though it need not be detailed here. The experiments showed conclusively that when a portion of the pancreas is separated secretion continues until complete degeneration and absorption have caused the disappearance of the parenchyma. "That the atrophy in the part of the organ which has been detached from its connections with the intestine is not due to a traumatic interstitial pancreatitis is proved by the normal appearance and structure of the remaining portion of the gland which has retained its anatomical and physiological relations to the intestine:" which again supports the author's view that physiological detachment of any portion of the pancreas is invariably followed by degeneration and complete atrophy, consequently also by complete cessation of functional activity. Eleven experiments were made for the purpose of determining the action of the pancreatic juice on the peritoneum. In only two of the cases was death caused by purulent peritonitis, and the results justify the conclusion that normal pancreatic juice does not cause peritonitis when brought into contact with the peritoneum; and the further conclusion that such juice is absorbed. The duodenum in these cases was denuded of its mesentery, and thus of its vascular supply, for from one to three inches, but no gangrene occurred. One experiment showed that even if no pancreatic juice be produced, digestion may remain good; and the ligation experiments show that the introduction of normal pancreatic juice into the circulation is not harmful, and may be tolerated for two or three weeks without bad consequences.

It has already been seen that crushing and laceration of the pancreas are not of themselves necessarily fatal; and if, during an exploration for abdominal injuries, this organ be found extensively crushed, "it would be good surgery to remove the crushed portion after preliminary ligation of the organ on each side of the comminuted portion. Ligation of the pancreas can be safely none with a single catgut or silk ligature, as the friable texture of the organ will permit of burying the ligature deeply." Crushed pancreatic tissue and pancreatic juice must be removed to prevent traumatic infection. In a case of prolapse of the pancreas, if the prolapse be recent and there are no signs of inflammatory or other changes, it should be thoroughly disinfected and replaced with great gentleness; and if reduction be difficult the wound should be enlarged. Should the organ be in an inflammatory or gangrenous condition "the parts should be thoroughly disinfected and the organ pulled further into the wound until healthy tissue is reached, when a ligature is applied and the diseased portion removed with the knife or scissors. After thorough disinfection the stump is dropped into the abdominal cavity and the external wound closed. Thorough primary removal of infected tissue is the only safety against subsequent extension of the infection to the peritoneal cavity, and the only guarantee for primary union of the abdominal wound." Gangrene, one of the terminations of acute inflammation of the pancreas, may also be included among the diseases of the pancreas which may be treated by surgical measures; inasmuch as spontaneous recovery has followed

the elimination of the necrosed organ, it seems not unlikely that timely removal of the necrosed pancreas would add to the chances of recovery. It should not be forgotten that the pancreas may be a part of the intussusception in a case of invagination, and in abdominal section for the relief of this condition the pancreas should not be overlooked. In searching for the cause of this condition, or that of peritonitis, when it is found that the primary disease is located in or around the pancreas radical measures should be adopted when practicable. "Whenever the sac can be stitched to the external incision this should be done, and the sac opened, disinfected, and drained. Search should be made for the necrosed pancreas, and when found detached it should be removed. As in most of these cases the retroperitoneal tissue is extensively infiltrated, a counter-opening should be made in the lumbar region above the kidney, and thorough drainage established. If an anterior abdominal fistula cannot be established, the course to be pursued should be the same as in treating a pancreatic abscess under similar conditions."

In a subsequent issue we will notice that portion of this valuable paper which deals with other pathological conditions of the pancreas.

SOUR GRAPES.

The editor of the *Boston Medical and Surgical Journal*, in the number for December 30, 1886, devotes six pages to an enumeration of the more important events of a medical character during the year, in which is included one rather facetious paragraph concerning the International Medical Congress to be held in 1887. With characteristic unfairness he says: "For this reason, as well as in accordance with the territorial policy of the management, the *cities* of the *Atlantic coast* will have but a small representation in the *honors* of the Congress." Had our learned confrère taken the trouble to examine the list of general and executive American officers of the Congress, including the Vice-Presidents, and also the Presidents of the Sections, he would have found them to number thirty-three, twenty-one of whom are residents of the Atlantic States, and *seventeen* of the twenty-one are residents of the five Atlantic cities. Boston, New York, Philadelphia, Baltimore, and Washington; while only twelve of the thirty-three chief American officers are distributed to the great cities and universities of the vast country west of the Atlantic States. It is certainly amusing to see with what gravity our Boston annotator of medical events repeats the statement, originating with some mischievous wag, "that Dr. Pancoast, of Philadelphia, had personally invited the Queen of England to be present." Credulity and self-complacency are often coincident traits of the same mind.

International Medical Congress—Vacancies Filled.—J. J. Chisolm, M.D., of Baltimore, Md., has been appointed President of the Section of Ophthalmology of the Ninth International Medical Congress, in the place of Dr. E. Williams, who was compelled to resign on account of ill-health. Judson B. Andrews, M.D., Superintendent of the Hospital for the Insane, Buffalo, N. Y., has been appointed to the office of President of the Section of Psychological Medicine and Nervous Diseases, made vacant by the recent death of Dr. John P. Gray. These are excellent appointments, both parties being widely known and eminently well qualified for the respective positions assigned to them. No vacancies now remain in the list of chief officers of the Preliminary Organization of the Congress or of its Sections; and our information from all departments is of the most encouraging character.

Professor J. S. Jewell, Editor of the Neurological Review.—We much regret to learn that this eminent and most indefatigable worker continues to suffer so much from ill health, that he is constrained to give notice of an indefinite suspension of the publication of the *Review*. With a mental activity and erudition seldom equaled, he is compelled to yield to physical infirmities that would have long since overwhelmed any man of less tireless energy and steadfastness of purpose. We hope more rest, and perhaps a milder climate, may yet restore his physical health and endurance.

As Others See Us.—What is wanted in America, says the *Lancet*, is the establishment of some general principles of action rather than the intermittent and varying action of a number of separate States; and we entirely sympathize with the request which has gone forth from more than one State, that the general health defences of the country should be subject to some central organization.

Alumni Association of the Woman's Hospital in the State of New York.—The third meeting of this Association will be held at the New York Academy of Medicine, January 19, 1887. Important communications are announced from six or eight members.

SOCIETY PROCEEDINGS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, November 19, 1886.

THE PRESIDENT, CHARLES WARRINGTON EARLE, M.D., IN THE CHAIR.

(*Concluded from page 25.*)

DR. W. W. JAGGARD read a paper entitled

A CASE OF CHRONIC INVERSION OF THE UTERUS, OF TWENTY-ONE MONTHS' STANDING, REDUCED BY COLPEURYSIS.

DR. PHILIP ADOLPHUS: The author of this excellent paper has adopted in the reposition of the uterus of his patient, as efficient a mode of procedure as any hitherto in use. It is also the safest mode of replacing the organ. In the treatment of chronic inversions, success has followed all methods of replacement, whether effected gradually or rapidly. But forcible taxis ought to be the last resource, when gentler and as sufficient means are exhausted. It may lead to laceration of the vagina, peritonitis and death. Gradual pressure, sustained or interrupted, solid or elastic, to which taxis has been added, has been equally successful, and has been practiced since 1858. It is absolutely safe. In some cases air pessaries or other elastic contrivances have been left in the vagina constantly, or have been replaced at intervals, for a period of three to eighteen days, and *uteri* have been returned by this method, which were inverted from one to fifteen years. The essential to success in the return of an inverted uterus is patient, gently continued manipulation of *some portion of the uterus*, by the fingers in the vagina with the application of the other hand externally to overcome the constriction of the cervix, and to prevent the forcible elongation of the vagina. A small hand, which observes the course of the pelvic axis, and avoids the promontory of the sacrum, and goes on one side of it, is also an element of success. Old adhesions opposing reduction of the inverted uterus are rarely present. An inflammation of the serous tissue in some portion of the pelvis may, however, be present as a complication, for this is an extremely common affection in all kinds of pelvic disease. Doubtless, in cases in which peritonitis followed manipulations, a chronic or subacute inflammation of the serous tissues was the predisposing cause. However, the most interesting portion of this subject to me is that of diagnosis, *in all tumors lying in the vagina*, which do not pathologically implicate that organ and the vulva.

A correct diagnosis in inversion of the uterus is absolutely essential to treatment, and the safety of the patient. The question of differential diagnosis between inversion of the uterus, and polypi and fibroids, is almost daily presented to the gynæcologist for solution. Not much reliance can be placed on the history in *chronic* inversion, for the diseases present similar symptoms. The size of an inverted uterus of some standing is scarcely larger, and is often smaller than in the natural state. It is desirable to look on the case under examination as one of inversion as long as any doubt exists. The bowels and the bladder should be emptied and the patient examined under ether. It is certainly *not* a case of inversion, when by bimanual *palpation*, with fingers in vagina, fingers or hand into the rectum, or sound in the the bladder, the *unimpaired roundness* of the uterus presents itself for palpation, either in the normal or retroverted position. In the just mentioned condition, if the sound enters the uterus two and one-half inches or more, the uterus merely contains a fibroid or polypus which emerges from the cervix. The diagnosis may be rendered more difficult if no opening in the *cervix uteri* can be found, the cavity having been agglutinated by previous inflammation, to the polypus. Here downward traction of the vaginal tumor to the vulva, by a vulsellum as recommended by Susdorff, and I copy his words, will at once confirm the presence of a polypus. "For the relations of the parts to each other as they existed in the vagina will be greatly changed when exposed to view. The lips of the cervix which surrounded the pedicle will have disappeared, having also become inverted, and along with it, probably, the vagina at its junction with the neck." The insinuation of the sound into the uterus will at once confirm the information procured by bimanual palpation. If the same manner of examination disclose the body of the uterus indented or cupped, we have a partial inversion, either with or without a fibroid, a condition which is not as unfrequent as is generally supposed. The presence of a tumor in the vagina, the absence of the *fundus uteri* in the abdomen, and the presence in its place of a well defined ring or cup-shaped cavity, unmistakingly announces an inversion of the uterus; traction confirms the diagnosis. An incision, not a puncture, along the sides of the tumor, after the patient emerges from the ether, will at once show whether we have to deal with the fundus of the organ or a polypus. In the one case it will induce pain, in the other it will prove painless. In the former it will relieve the congestion and possibly lead at once to its reposition, or prepare for its successful replacement in the future.

DR. H. P. MERRIMAN: I would like to ask whether, after the uterus had been partially restored so that the fundus was on a level with the lips, and the colpeurynter seemed to do no good for eight days following, taxis would not probably have promptly, almost immediately, accomplished the remaining portion of the work?

DR. H. T. BYFORD: Every method has danger, and there is one danger in this method which should be mentioned; that is the danger of sepsis or resorption of decomposing secretions. That there was danger even in this admirably managed case was evidenced by the rise in temperature, followed by the disappearance or decline in temperature on cleansing the bag and vagina. I have seen the immediate decline of fever by washing out the uterus when enlarged and filled with decomposing matter. I object to the introduction of the hand into the rectum to diagnose a case of inversion, as suggested by Dr.

Adolphus. I consider it a dangerous practice because it does a violence to the part which sometimes has done an irreparable injury, and is unnecessary.

Dr. W. H. Byford: With reference to the subject of inversion and more particularly the diagnosis, there are two points which I think are very important in addition to those mentioned by Dr. Jaggard. In cases of polypus attached to the neck of the uterus and filling up a good part of the vagina, the uterus is always enlarged and may be palpated above the pubes. Another point in the diagnosis is the difference in the sensation imparted to the examining finger. A polypus feels as if covered by a shining smooth membrane, unless it is decomposed, while the surface of the uterus gives the sensation of pushing the finger into plush or velvet. I give these two points of diagnosis as the results of my own observation and as being usually present.

With reference to the mode of reducing inversion, I will give some of my own experiences during the last thirty years. In the year of 1859–60, I had a patient sent to me from Lafayette, Ind., with a chronic inversion of the uterus, which I attempted to reduce. I had just read a long treatise on the subject by Dr. White, of Buffalo, and Drs. Thomas and Emmet were then beginning to talk and write about these things, and I went at it with considerable enthusiasm. I got up the cup that Dr. Jaggard mentioned, and I also got a large rectal bougie, an instrument which Dr. White had praised very highly in his first operations, and I made the first attempt lasting about an hour an three-quarters, and when I got through I was worse off than the patient, although she was pretty badly used up. I waited two or three weeks and made another attempt, but after a protracted effort I found my finger passing through the *fundus uteri*. I had been as cautious about the force as I could be, making the effort as gradually as possible but I perforated the fundus. I fully expected that the damage done would be fatal to the patient, but it did not produce any bad effects whatever and she entirely recovered in two weeks and went home. Two years later she came to see me again, but did not wish to have another effort made to have the uterus reduced. Two years later the uterus was found in its normal position. I saw the patient and her physician, and I am certain that nothing had been done to reduce it. I tried two other cases, and made the same efforts but without success. I then concluded that it was hardly worth while to make trials of that nature again, and in the next case I tried the colpeurysis treatment. For some days I was nonplussed, from want of experience, as to the mode of placing the instrument in the vagina. I used the quadrilateral colpeurynter, and after I placed it in the vagina, I found the next day that I had gotten it under the uterus lengthwise, that the fundus was directed toward the vulva, and the neck directly backwards. I was merely compressing the body of the uterus against the *symphysis pubis*. I reflected considerably before I could get the right idea as to the manner of placing the instrument in the vagina. Finally I pushed back the fundus until the axis of the uterus corresponded to the axis of the superior strait, and then introduced the colpeurynter as has been described by Dr. Jaggard, and applied the force. The next day when I came back I found there had been some impression produced, and I went on with the use of it, taking it out every day and replacing it in this manner, until in seven and a half days the inversion was reduced. The patient was a poor woman and it was necessary for her to take care of her child. She did so, attended to it in every way and also cooked three meals a day for her husband. She was on her feet nearly the whole day time, and yet the instrument acted as well as if she had been lying in bed.

Three out of the five cases I have operated on have been as painless as this. I should judge that a young primipara would probably suffer more from the use of the colpeurynter than one who had had children. I have now reduced five cases of inversion by the colpeurynter and have not failed in any case since I commenced using the instrument. The first case of inversion I had, I amputated the uterus. In considering the matter since, I doubt if any other treatment could have been adopted which would have been effectual. The uterus and vagina were inverted, the vaginal canal was entirely outside of the body and the uterus hung down from it, both making a tumor nine inches long. The uterus was very much enlarged in consequence of its being dependent for so long a time. I was in consultation with two German physicians of this city, and they suggested as the patient was living a miserable life and would die before long, we should cut it off. After half an hour's use of the écraseur, it was removed. We amputated a little below the centre of the cervix. There was no bleeding, nothing to give rise to uneasiness. We pushed the vagina back again, put the parts in place and the patient recovered in the course of a month. Having spoken of one spontaneous cure, I will tell you of a patient that I attended in Mercy Hospital in 1864–5, whose uterus was much in the same way as the one that I first operated on, coming out entirely beyond the vulva and dragging down the vagina very low, so that there was simply a circular sulcus between the labia and the vaginal wall. I tried to restore it by manipulation and failed; I proposed to amputate it but the patient would not consent. Meantime one of the internes had fallen in love with her and they went off to Missouri and got married. About six years afterwards, the doctor came back and told me that he had a son and his name was Byford. Upon inquiry I found that the child had been borne by this woman. One case of inversion occurred in my own practice. I attended the patient during confinement, and as far as I know she had no difficulties whatever for seven or eight days. By that time I was on my road to California, and I think Dr. Roler looked after her for some little time after I was gone. In two months I returned home and was informed that she had inversion of the uterus, which I did not believe. I went to see her and found that she was suffering from complete inversion. That was one of the cases I cured by colpeurysis. When the inversion occurred I do not not know. I am certain that I made two or three

examinations as I always did at that time, always one the second day after confinement. I did not notice anything of the kind, and yet it might have been commenced and finished afterwards. I saw a case with Dr. Henry Byford, which had been attended by a midwife, in which the inversion occurred so that the fundus could be touched through the mouth of the uterus, and it remained in that way two or three weeks. The patient was bleeding, but I believed the contraction of the mouth of the uterus was sufficient to prevent it coming through, I advised ergot, and in a few days the uterus was in its proper position.

DR EDWARD WARREN SAWYER: One point is the persistence that one can observe in applying the colpeurysis, without a fatal result following. The interesting case that Dr. Byford has spoken of last, also shows the possibility of the obstetrician, seeing nothing in the first few days of the puerperal state to suggest that anything has gone wrong. Cases are recorded in which the inversion has taken place without the obstetrician knowing it. In the fatal case that occurred in my practice the symptoms were so profound that it was impossible to overlook it, and I think the diagnosis of recent puerperal inversion of the uterus is much easier than of chronic inversion.

In the case which occurred in my practice, the rim of the crater marking the upper border of the uterus, which I palpated through the abdomen, was fully as large as a common bowl, and its edges were very sharply defined. In addition to that the fundus could be distinctly felt through the os uteri. One feature of the paper, which is by no means the least to be commended, is the very admirable and graphic way in which the case was presented.

DR. H. P. NEWMAN: My experience has been limited, but I remember a single case, in which I assisted a surgeon of this city in attempting the reduction of a chronic inversion of the uterus. It was in a hospital, where they had every facility for the operation and it could be proceeded with leisurely. Some two hours were taken up with the various devices for reducing the inverted fundus, all of which were of no avail. There was a complete inversion of the uterus but not of the vagina, and I think previous to the attempt at reduction a fibroid was removed from the fundus of the uterus. No further myomatous condition was discovered at the time, but the difficulty was exceedingly great in this case and nothing whatever was accomplished. I have no knowledge of the subsequent condition of the patient, whether she suffered materially from this, or whether she was afterwards successfully operated on, or the uterus amputated.

THE PRESIDENT asked Dr. Jaggard what means he used to disinfect the colpeurynter.

DR. JAGGARD replied that he washed it thoroughly with soap and warm water, afterwards disinfecting it with a 5 per cent. solution of carbolic acid. The vagina was irrigated with a 2 per cent. solution of carbolic acid, and a bacillus of iodoform introduced.

DR. ADOLPHUS, in reply to Dr. Henry T. Byford said: In complicated cases of tumor in the abdomen or pelvis I would not do without the introduction of the hand into the rectum. I am not alluding to Simon's method, putting the hand in as far as the elbow, but I am talking of the hand. And when the patient is under ether, it can be done easily. It depends upon the size of the hand, perhaps, but with a hand well greased and introduced slowly it does a great deal of good, and gives an immense deal of information which we cannot get in any other way. I examine every case, without conception, *per rectum*, with the finger.

THE PRESIDENT asked Dr. W. H. Byford if he regarded it good practice after all ordinary means had been exhausted and the uterus was still inverted, to amputate?

DR. W. H. BYFORD: When all other measures have failed to effect the object and the patient is suffering so much as to make relief imperative, yes.

THE PRESIDENT: I saw Prof. Chiara, in Florence, operate upon a case of that sort. He placed a silver wire around the uterus and left it in position and the parts gradually sloughed away.

DR. W. H. BYFORD thought that mode of operating upon the uterus bad, that it would have been better to have used the wire ecraseur to stop circulation, and cut it off. But a sloughing mass in contact with the parts would be likely to produce pyæmia.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, November 10, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D., IN THE CHAIR.

H. M. CUTTS, M.D., Secretary.

DR. D. S. LAMB presented the history of a case and specimens of

SYPHILITIC DISEASE OF BONE.

Annie W., age 41, mulatto, died August 25, 1882. Necroscopy by Dr. D. S. Lamb. Body much emaciated; thick scabs along tibial crests, one foot long and one or more inches wide; bed-sore on each trochanter major and on sacrum. Umbilicus dilated into small pouch, containing an adherent portion of greater omentum. Heart normal, except some fatty degeneration of anterior segment of mitral valve. Small patch of fatty degeneration on ascending aorta. Old pleuritic adhesions at base of right lung and between lobes; œdema and hypostasis of lower lobe and some tubercles. Firm old adhesions of left lung and between lobes; lung anæmic contained tubercles; tubercular cavity and evidences of bronchitis in upper lobe. Bronchial glands pigmented. Thin blood clot in lower part of œsophagus. Omentum adherent to left side of abdomen and to bottom of hernial sac. Stomach displaced downwards; contained large quantity of blood, clots, etc.; clotted blood in small and large intestines, which, with the stomach, were normal. Liver anæmic; firm adhesions to diaphragm and hepatic flexure of colon; weight, 120 ozs.; left lobe disproportionately en-

larged; edges rounded; iodine test showed amyloid degeneration. Gall-bladder contained some green bile. Spleen 26.5 ozs., amyloid. Kidneys large; left weighed 8 ozs., amyloid. Uterus showed patches of inflammatory exudation on peritoneum. Right ovary converted into cyst size of walnut in which were colloid masses size of small shot; left ovary enlarged, contained several cysts and colloid deposits. Bones as far as examined showed results of inflammation, probably syphilitic. Sternum; surface irregular; depressions; periostosis and osteoporosis. Costal cartilages porous. Clavicle much atrophied throughout; surface irregular at sternal end. Knee joints contained fluid and showed erosions of cartilage and existence of the bones. Lower ends of femora, patellæ, tibiæ and fibulæ showed surfaces irregular, depressions marked; new growths of bone; general osteoporosis. Bones of feet, especially of tarsi, somewhat eroded; fine periosteotic growths; some osteoporosis, especially of calcanea.

Microscopical examination by Dr. J. C. McDonnell showed that liver and spleen were amyloid; kidney, amyloid and cirrhotic; and the colloid degeneration of ovary involved the stroma.

Dr. Samuel S. Adams read the history of a case of

HÆMATEMESIS.

(See page 35).

Dr. A. F. A. King said that Dr. Adams stated that he had to do with a simple gastric ulcer. This might be doubted, as there were apparently no symptoms of its presence now, and, further, some of the usual symptoms were absent before the hemorrhage. There had been no pain after eating for one thing. He did not mean to dispute Dr. Busey's claim to priority in the use of iron in hæmatemesis, but several years ago he had reported a case of this affection in which everything had been used without avail. Finally, twenty drops of the liquor ferri subsulphatis in water were given. There was immediate vomiting of clotted blood, but no more hemorrhage. The hemorrhage in this case was from alcoholic gastritis. There was good recovery, but the patient died from the same cause some years later.

Dr. G. L. Magruder said that fifteen years ago he had a patient suffering from a violent malarial fever. One morning he began vomiting bile, and about noon vomited a large quantity of blood. He had used a mixture of acetate of lead, acetic acid and morphia and there had been no return of the hemorrhage. The patient was much prostrated for several days afterwards. Last winter he had had a second case and the same remedy stopped the hemorrhage in two days. The acetate of lead is a sedative and a mineral astringent, which class he thinks better than the vegetable astringents. This was so in Dr. Adams' case. Gallic acid and ergot, he thought, were nauseating and hence not useful in the premises. Tannic acid would work better, where drugs could be applied directly to bleeding vessels. Gallic acid acts after absorption, but is less of a styptic than tannic acid when applied directly.

Dr. I. Bermann thought that gallic acid was a very valuable styptic when applied directly. He recollects a case of an old gentleman who had had twelve teeth drawn. Hemorrhage being persistent for six hours, a doctor was sent for and Monsel's solution was applied on cotton, but without success. About 2 A.M. he was called in and succeeded in stopping hemorrhage with ice. He went home, but was called again in a few hours. This time he took along with him a powder of two parts of tannic acid to one part gallic acid, a mixture highly recommended by Morrell McKenzie. The exhibition of the powder stopped the hemorrhage and there was no return. This was in favor of vegetable astringents.

Dr. Magruder said that, nevertheless, tannic acid precipitated albumin much more readily than gallic acid. Besides, two parts of the powder used by Dr. Bermann were tannic acid.

Dr. S. C. Busey said that he did not claim the priority of the use of tinct. ferri chloride in hæmatemesis, but he had never seen it recommended in such large doses as he gives it. His first case was a lady with cirrhotic liver. She had been having hemorrhages from the stomach and he had given her all sorts of things. He arrived one day just as she went into collapse from a severe hemorrhage. He stepped to the mantel and poured out a teaspoonful of the tincture of the chloride of iron from a bottle-full which was there. The patient had just vomited. He gave the iron in a half glass of water and there was no recurrence of the hemorrhage. About a year later he did the same thing with a like success. His method of giving the iron was on an empty stomach—*i. e.*, just after vomiting, and in about one-half glass of water, in order that it may be well diffused over the stomach. Dose, one drachm. He has had several other cases with equally good results. The authorities do not approve of the use of iron. In his cases he had obtained the best possible results and should continue to employ the agent. There is doubt in almost all cases as to whether we are dealing with a gastric ulcer or not. There is no pathognomonic symptom of this affection. It is one of the most difficult of diseases to diagnosticate. That it frequently occurs without being suspected is proved by the number of cicatrices, less often ulcers, we find in the stomach at autopsies upon persons who present no history of ulcer. There may be for years only the symptoms of ordinary gastritis, and until hemorrhage occurs ulcer may never have been thought of. Hemorrhage was the most sure sign of the disease. The age and sex were important factors in diagnosis also. It occurs most frequently in the female between the ages of twenty and thirty. Males between thirty and forty are most likely to have it in that sex. It is often associated with nervous disturbance and may present the symptoms of gastralgia. He thought Dr. Adams' case was one of gastric ulcer, as there was no cirrhotic liver, obstruction to portal circulation, miliary aneurisms or traumatism to account for the hemorrhage. The patient, moreover, was of the the right age and sex, and had lived a life liable to

produce ulcer. Pain after eating, he thought, was absent in a majority of cases. Hemorrhage or perforation were the usual causes of death.

DR. C. W. FRANZONI said that three years ago he was called to see a gentleman who had lived much in tropical climates. He had been having copious hemorrhages from the stomach, reported as enough to fill a good-sized basin. While he was present the patient vomited nearly a quart. He exhibited a drachm of gallic acid in one dose and there was no return of hemorrhage. The next day the patient's whole body was covered with an urticarious eruption which he supposed was due to the gallic acid.

DR. BERMANN remarked that he had seen some cases of atrophy of the optic nerve, an affection which frequently follows hæmatemesis. The only treatment for it is large doses of strychnia.

DR. KING said he was not yet convinced that Dr. Adams' case was one of gastric ulcer. Possibly, he thought, the greater frequency of gastric ulcer in woman than in man might be accounted for by the supposition that corsets obstructed the portal circulation. He does not claim priority in the use of iron for himself, for in the case he reported the drug was suggested by Dr. J. T. Young, who was present.

DR. BUSEY said that gastric ulcer occurs largely in women during their active menstrual life and the hemorrhage is often called "menstrual hæmatemisis." It is common in neurotic and chlorotic women, but whether as cause or effect he cannot say. He thought that the neuroses as causative elements were over-estimated. Perforation by ulcer was more common in women than in men, as for some reason the ulcer is oftener situated on the anterior wall of the stomach.

DR. ADAMS said that though he himself was convinced that the hemorrhage was from an ulcer, it did not absolutely prove its presence. He had seen the patient frequently for the past two years and is certain that if she had been sick during that time she would have consulted him. There was no malaria, and aneurium was unthought of. The history reported was just as he found it, and from these symptoms he had drawn his conclusions. There was no biliousness, and the attacks of indigestion might have been serious or of slight account. The hæmostatics used were those recommended by Dr. Welch in "Pepper's System of Medicine." The patient was said to lace tightly, but for this he could not vouch. The amount of blood vomited was as he himself saw it, and not as reported by her friends.

Meeting of December 1, 1886.

THE VICE-PESIDENT, J. B. HAMILTON, M.D., IN THE CHAIR.

DR. W. W. GODDING, Superintendent of the Government Hospital for the Insane, read a paper entitled

THE PROBLEM OF THE INEBRIATE.

(See page 29.)

DR. TONER said that the medical profession would welcome the incorporation of an institution for the care of these persons. The question of the laws and regulations for its government, however, was one that could not be decided hastily. He moved "that a committee of three be appointed to consider the question of the best management of the inebriate, and to suggest legislation to that end."

DR. GODDING remarked that he was in hopes that his paper would draw out discussion on the question of the propriety of sending inebriates to St. Elizabeth's. At the last session of Congress a bill had passed the Senate which permitted the sending of inebriates to St. Elizabeth's. The bill had not yet passed the House. He did not think that inebriates should be confined with the insane. They needed special treatment for their disease, for in his opinion inebriety is a disease. Nor do the insane people like the contact with the inebriate. He hoped that the Medical Society would take some steps looking towards the establishment of a special hospital for the inebriate.

DR. J. E. MORGAN said that he had seen some reports of such special institutions, and they showed failures.

DR. GODDING said that the only State establishment that he knew of was at Binghampton, N. Y. This had been a failure, partly through bad management. The Washingtonian Home in Boston had done good work, and there was also one in New York city. The system had not yet been sufficiently tried. In Canada and England such special hospitals are in existence, and their necessity is fully appreciated.

DR. J. M. TONER said that failures of these institutions were undoubtedly due to the manner of commitment and to the indefiniteness of the time for which the person is incarcerated. The craving for drink may never be cured, but, in his opinion, the public are none the less responsible for patients' care.

DR. R. REYBURN said that in advocating an institution of this kind we should consider how far the community should be saddled with the care and expense of persons who are personally responsible for their deplorable condition. He did not believe that reformation could be accomplished so well in a public asylum as by private communications, and he thought that every citizen was morally obliged to attempt the cure of an inebriate with whom he comes in contact. Institutions for the purpose under discussion had nearly always proved a failure.

DR. S. C. BUSEY said that Dr. Reyburn's arguments were equally effective against hospitals for the insane or any other special disease. If inebriety was a disease—which he himself was not quite prepared to believe—why not have a hospital especially for inebriates? The community could be taxed with equal justice for this as for any other hospital. In fact the municipal authorities, who derive an immense income from the too frequent drinking places, should be compelled to help support the inebriates they produce. Moreover, well-to-do people do not go to free hospitals or asylums. They or their friends can usually pay for their keeping. Drunkenness is the cause of nine-tenths of the crime and poverty of the country. It fills our prisons, insane asylums and

poor-houses, and the community is directly responsible for the care or cure of its victims. Because previous attempts have failed was no reason why we should not try again. He fully agreed with Dr. Godding, that the inebriate and the insane should not be confined together. He knew of no man to-day who could be called an expert on inebriety, and it will take years of experience, and that not in private practice, to make one. A hospital for inebriates would be the development of another specialty, which, like all specialties, would add something to our general medical knowledge.

Dr. J. T. Howard said that there had been for some years a law incorporating the Washington Inebriate Asylum. An appropriation had been several times asked for from Congress, and interested gentlemen are still at work with this end in view. They are waiting for the passage of the bill mentioned by Dr. Godding. In reply to Dr. Busey, he would state that there are already doctors who make this disease a special study, as for instance Dr. Croth ers, of Walnut Hill Lodge. He even publishes a journal devoted to the subject.

Dr. N. S. Lincoln said that he was heartily in favor of establishing an inebriate asylum, which he thought most important to the whole community. There is scarcely a family in town which is not cursed with, at least, one relative given to excess, and with whom it is utterly useless to reason. Such persons should be confined for a year, or a life-time, and the institution could be easily made self-sustaining. The patients should be compelled to work at their trade or profession, and should remain as long as they are incapable of self-restraint. He fully agrees with Drs. Godding and Busey, that an insane asylum is not the place for drunkards. Nor are the general hospitals suitable, for in these, as a rule, the patient is given a small amount of stimulant daily and he comes out no nearer cured than when he went in. He does not believe liquor necessary in such cases, and he has never known delirium tremens to follow complete and sudden stoppage of stimulant. He has seen cases of relapse, after treatment, from all the best institutions and hospitals, and he only knows of two cases where there had been a permanent cure.

Dr. Reyburn hoped that Dr. Lincoln would not make the argument that relapses were so frequent and cures so few, before a Congressional committee. He thought such institutions an attempt to do at public expense what should be done by individual efforts. He thought that Dr. Busey's argument that the municipal authorities, who get an income from drinking places, should support the drunkard, was beginning at the wrong end. It seemed to him better to limit the evil of drinking, and not first make drunkards and then take care of them.

Dr. A. F. A. King requested Dr. Godding to give the Society some of the reasons why it was not advisable to confine the inebriate and insane together. He said that many people did not care to see their friends in an insane asylum. Certainly there was no suitable place in this city to send a drunkard.

Dr. Godding replied that if the pending bill passed Congress it would legalize the sending of the drunk to the insane asylum. In a week or so these people would be sane in the eyes of the court, and on obtaining a habeas corpus the patient could set himself free. These persons were not committed as insane, but as inebriates, and their association, when sober, with the morally insane, was not a good thing for them. Most of them can never be permanently reformed, and certainly there is no chance of this in the thirty to ninety days for which they may be committed. If committed as an insane person, the question arises as to how far such an individual could be compelled to work. In his opinion, if inebriates are to be benefited they should be made to work under the supervision of a medical officer.

He thought that an inebriate asylum could easily be made self-sustaining.

Dr. J. T. Howard said that the rules of the Washington Inebriate Asylum contemplated maintaining the inebriate one year and at work. He hoped that when a committee was appointed they would support this institution.

On motion of Dr. J. M. Toner, it was

Resolved, That a committee of three be appointed to consider the question of the best management of the inebriate, and to suggest legislation to that end.

The Chair appointed Drs. W. W. Godding, N. S. Lincoln and J. M. Toner a committee under the resolution.

Meeting of December 22.

REPORT OF COMMITTEE ON DR. GODDING'S PAPER.

The committee appointed to consider the question of inebriates and what treatment and legislation can better their condition, have had the subject under consideration and beg leave to make the following report:

It is clear that there should be some change in the present manner of dealing with persons afflicted with this infirmity, some treatment more radical and efficient than has been hitherto attempted here, and that to this end there should be legislation recognizing their defective will power, and providing for their care as incapables. We do not claim or imagine that this abnormal condition exists in every person who drinks or even occasionally gets drunk, but we believe it is present, disturbing the emotions and judgment and dominating the will of the confirmed inebriate, and it is his case that we are here considering. Of this victim of a confirmed appetite for intoxicants we affirm that he is a non-producing, wasteful, disturbing factor of the body-politic, his influence is everyway bad, the life he leads worthless to himself and his conduct an open scandal to the neighborhood. We therefore conclude respecting him, that he is a public nuisance to be abated, a survival of the worst, an anachronism in the civilization of the nineteenth century.

In regard to the disposition to be made of him there are three questions to be considered: First, What does society demand? Second, What does the inebriate need? Third, What legislation will meet these requirements?

What society demands in the first instance is pro-

tection; protection against violence at the hands of a maudlin frenzy whose records are in each morning's paper, that day by day is writing tragedy all over the land; protection against that deterioration of moral fibre, a deterioration born of the saloon and the brothel, which with its deadly dry-rot is sapping the old time virtues of the commonwealth; protection against that race deterioration—those inherited neuroses, chorea, epilepsy, idiocy and insanity—of off-spring begotten in a debauch, where by a strange nemesis the innocent are made to suffer for the guilty under a visitation of the "sins of the fathers on the children unto the third and fourth generation."

Society further asks, that those whom nature or affection has allied to the inebriate shall be protected from the misery and wretchedness, the poverty and degradation which come to the drunkard's home. To the old time question "shall I not do what I will with mine own?" society emphatically answers, "No." The social compact, with or without public office, is in the nature of "a public trust" and you may not violate it, besotting your manhood and squandering your property to the beggary of your family and not expect society to interfere. For those hapless children of inebriate sires, weighted with a "heritage of woe" in the only life that is theirs to live—and yet poor as it is, the right to live in the world is still their birthright—will not society see to it that they have all the chance there is, nor permit a drunken father to trample it out? Shall we not take heed that he "offend not one of these little ones?"

Secondly. What the inebriate needs is correction and reformation. Correction first, because until the idle habits of his life are corrected there can be no reformation. With compulsory detention, and labor also compulsory, he will then be favorably situated for reformation to begin. If this is ever to take place in the victim of this morbid craving for intoxicants it will be through a period of enforced abstinence, an abstinence which must be total and life long. So, too, if the reformation is to be lasting, out of the compulsory labor of his sentence must spring habits of industry that he will take back into the world and into his life. Very important in the direction of reformation is hygienic treatment. With tonics, heathful exercise and simple nutriment, the system is to be gradually brought back to something like a normal condition. To be permanently reformed he must be built up from the bottom. The secretory organs will require a long course of alterative treatment—a very much altered man he must become before society will have any use for him, and he be of any use to society. Most especially does the inebriate need moral hygienic treatment and the strength to be gained from moral teaching. This is placed last in order, not because it is less important than the physical, but, as in the evolution of the race moral and religious sentiments are evolved latest, so in the deterioration of inebriety they are the first to suffer and the hardest to restore.

Thirdly. Of the legislation needed to bring about these results. The bill introduced and passed in the Senate at the last Session of Congress provides for the legal guardianship of the inebriate, with authority to commit to an institution for detention and treatment. The defect of the proposed law is that it fails to make labor compulsory. We believe that the power to compel the inebriate to work is essential to the success of his treatment. The idleness of his dissolute life must be rooted out before better resolutions will grow there. The commitment should be by a judge of the supreme court of the D.C. after due hearing, and should be for a term of years, or, perhaps better for an indefinite period. The power to discharge should be in the hands of any judge of the court, and a power to furlough should reside with the board of managers of the institution; this a kind of ticket-of-leave system, the continuance or extension of the furlough to depend upon the conduct of the individual. Voluntary commitments might be allowed, but with the time of detention to be stipulated as not less than one year. Any enforced abstinence short of this will seldom prove of any lasting benefit.

Associated with the necessary legislation for confinement is the provision for the house of detention and its management. This should be an Inebriate Home for actual residents of the District of Columbia, and under the control of the district commissioners. As already indicated, we think it should have the character of a correctional reformatory. The site should be selected and the buildings constructed with especial reference to custody and employment. It should be protected from intrusion and so guarded as to prevent the escape of its inmates. An island would be the best possible site for such an institution, but since we have no suitable island a large farm in the outskirts of the district with ample grounds for out-door work should be selected. The buildings themselves should be plainly built—simple brick structures, with no ostentatious architecture to swell the cost and set the fashion for lavish future expenditure, but carefully planned, conveniently arranged, with light, airy and pleasant workshops suited to varied forms of industry These buildings should be in groups to afford opportunity for classification of the inmates. Men of means and talent, but victims of an unfortunate appetite, coming voluntarily to this city of refuge to be healed of their infirmity would be neither pleased nor benefited by a daily contact with abandoned sots, who scoff at misfortune and have no wish to reform. Nor should the fallen statesman, even though without means, be required to mess with drunken negroes from the fish landings. Yet the scope and the accommodations of such an institution should be wide enough to gather in and care for all these victims of a common infirmity, and the physician in charge should be a man broad enough and keen enough to recognize and provide for these difficulties as they arise. To this institution should also come, perhaps, for a limited restraint and special provision in a district infirmary department those unfortunate victims of a recurrent appetite, properly designated as dipsomaniacs, who now and then, overtaken by the consuming thirst, breaking over all barriers of self-respect and family ties in their periodic sprees are for a time more violent and dangerous than the ordinary

maniac; and yet when the storm has passed over, casting down everything before it, they go back to their work and are again for a time useful, law-abiding citizens. A law that provides for inebriety should not overlook them. We think that the superintendent should be a medical man, a physician who has made inebriety and its treatment a special study. More than this, he should be equal to his great office, with the support of an ample and able staff; he should be an autocrat in his authority, alive to his responsibilities, with the power which goes with an active brain, an iron nerve, a cheek of brass, ribs of steel and a great heart beating beneath them; never afraid to take the consequences; a man fertile in resources, ready to attempt the impossible of other men and to accomplish it, because he has faith in himself and in his work. With such a man at its head the District Inebriate Home would be a success from the start.

How should it be supported? By voluntary contributions from philanthropic individuals, by the proceeds of sales from the shops and gardens, by receipts from voluntary pay patients, and then whatever it lacks of being self-supporting—and it will probably always lack something, for the individuals who voluntarily come to it for healing will, as a rule, be as completely stripped of means as He was who went down from Jerusalem to Jericho—should be made up "by appropriations from the U. S. and District treasuries in such proportions as Congress may determine." And while our present liquor licensing system remains, your committee would suggest that all liquor licenses be doubled, and that one half, or the whole if necessary, of the revenue derived from this source be set apart for the support of the Inebriates' Home. So at last might their "sowing of the wind" gather its own harvest, and the people see a relation established between the cause and the effect.

Your committee beg leave to present herewith a copy of the Inebriate bill now before the Judiciary committee of the House of Representatives and to say that in their judgment the inebriate should not be confined with the insane as therein proposed. Respectfully submitted,

J. M. Toner,
W. W. Godding,
N. S. Lincoln.

A BILL

To Provide for the Confinement of Inebriates in the Government Hospital for the Insane.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That whenever by petition, under oath, of either parent, brother, sister, son, daughter, or guardian, or commissioner or justice of the peace of the District of Columbia, any person actually resident in the District of Columbia shall be alleged to be an habitual drunkard, incapable of taking care of himself or herself, or his or her property, the supreme court of said District, in special term, shall have the power, in its discretion, on such preliminary examination or inquiry as it may think proper to make *ex parte* to issue an order of notice to such person to appear before said court, or in its discretion, to issue a warrant to the marshal of the United States for the District of Columbia to arrest and bring the person so charged before such court; and it shall be the duty of the said marshal to obey such warrant; and said court shall cause a jury of good and lawful men, to be summoned by the said marshal, to be impaneled forthwith, and shall charge said jury, under oath, to inquire, in the presence of such person, whether he or she is an habitual drunkard, incapable of taking care of himself or herself; and the proceedings in such case shall be like those now authorized by law in cases of persons alleged to be lunatic or insane. When such petition is filed by any person other than a commissioner or justice of the peace, the court shall cause notice of the filing thereof to be given to the attorney of the United States for the District of Columbia, whose duty it shall be to attend such hearing in the public interest; and the rules of law and proceedings applicable to the property of lunatics shall apply to cases of persons declared to be habitual drunkards under the provisions of this section, except when herein otherwise directed; and all persons who may be alleged to be habitual drunkards may dispense with the legal proceedings to establish the same, and may, with the approbation of the court, when said petition may be filed, appoint his or her own guardian, and may voluntarily enter the Government Hospital for the Insane for a limited time; and the superintendent of the said hospital may retain such person the length of time he or she may have agreed therein to remain; and if the person against whom the petition may be filed shall be found by the jury to be an habitual drunkard, incapable of taking care of himself or herself, it shall be the duty of the court to appoint a guardian of such person; and such guardian shall, with the written assent and approbation of the court have the power of confining such person in the said asylum for such length of time as the court may in writing approve; but said guardian, with the written assent and approbation of the court, may at any time release from confinement such habitual drunkard; and the period of confinement of said habitual drunkard may, by the said guardian, with the written assent and approbation of the court, be from time to time extended for such periods as may be necessary for his or her complete reformation. Said court shall have power to discharge such guardian and appoint another in his or her place, and shall have power to discharge the guardianship altogether whenever the court shall, on due inquiry and hearing be of opinion that such guardianship is no longer necessary. The expenses of maintaining such habitual drunkard in said hospital shall be governed by the same provisions now in force in regard to the support and expenses of insane persons therein: *Provided*, That no person shall be admitted to said Hospital for the Insane under the operations of this act who shall appear to the court on such hearing to have come or to have been brought into the District for the purpose of being admitted therein.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

The Better Sanitation of Houses—A Chair from Hunter's Bedstead—Hospital Sunday Fund—The Conjoint Scheme.

Early in the next session of Parliament an introduction of a new bill is promised, to be brought in by Dr. Farquharson "for the Better Sanitation of Dwelling-houses, Schools, Hotels, Hospitals and other Buildings within the United Kingdom." In scope and aim, it would, therefore, seem the bill is of an exhaustive character, so much so, indeed, that aspiring sanitarians will be well content if at first a modicum of the things sought for get parliamentary consent. In principle the bill is simple and far-reaching. Its sub-title is given as the "Sanitary Registration of Buildings Act." It provides in the first instance for the adoption of its provisions in the City of London and in the area under the jurisdiction of the Metropolitan Board of Works. All towns in England of 50,000 inhabitants and upwards are included in the localities in which it is to be applied, while "such other districts in the United Kingdom as may adopt the act" are to have the option of adopting it should its provisions become law. The local authorities charged with administering the Public Health Act would thus become the Sanitary Registration authorities for their respective areas, towns or districts. It is proposed that prior to June 1, 1888, each sanitary authority shall cause the owner, lessee, sub-lessee or occupier of every building, "occupied or intended to be occupied," to deposit with the said authority a certificate for each building in accordance with the terms of the act. This certificate, which is naturally the pivot on which this entire question of sanitation turns, forms the subject of a special clause in the proposed measure. Here difficulties begin, as is evident from the results of an adjourned discussion on the measure which took place a short time since at the Society of Medical Officers of Health. If a certificate of the sanitary safety of buildings is to be granted, and if on the possession of this document people are asked to found an assurance that a building is sanitarily trustworthy, it certainly behoves them to inquire somewhat minutely into the status of the persons who are by the act qualified to inspect and certify under its provisions. The certificate may be granted as the bill now stands by members of the Royal Institute of British Architects and members of the Institution of Civil Engineers who are in practice as architects, surveyors, or civil engineers. Furthermore, that architects or civil engineers who have been in practice five years at the passing of the act, and who register their names accordingly, may also grant certificates. Sanitary associations incorporated by license of the Board of Trade, medical officers of health and medical practitioners qualified in sanitary science are to be entitled to sign those documents. Last on the list come surveyors and engineers of local authorities, so far as their own districts are concerned, and, adds the act "such other persons as the Local Government Board may authorize." Here are clauses and persons enough and to spare. Are they all duly qualified?

At the late meetings of the Society of Medical Officers of Health, it was considered by certain speakers that among the persons named in the section of the act whose terms have just been quoted, there are included many men whose knowledge of sanitation, and of house sanitation particularly, must be somewhat slight. It is not every architect who professes a knowledge of house sanitation, hence it is easy to understand how the provisions of a well-intentioned act may lead to more harm than good. Of what value would, for instance, be the certificate of a local surveyor, who either wilfully or in gross ignorance neglected to provide for trapping off the house from the public sewer. Professor Corfield went so far as to advise his society to petition against the bill in its present form, and to insure that it should be so remodelled as to ensure persons entitled to certify the healthiness of premises, should at least possess some definite qualification or other in sanitary science. Dr. Corfield's objection was expressed by saying that as it stood the new act was one for specialists, and for them alone, the specialists being architects, civil engineers and surveyors. As such, he held the measure should be rejected. Dr. Corfield would have medical officers of health alone entitled to grant certificates, but it was considered by many present that this practice would simply make the bill as narrow in Dr. Corfield's direction as in that of the architects.

An interesting relic of that great surgeon, John Hunter, has just been presented to the Royal College of Surgeons. It consists of a chair formed out of the materials composing the bedstead on which John Hunter slept nightly for many years, and on which his remains were laid previous to removal for burial. The idea of converting the unwieldly frame of an old-fashioned four-poster into a remarkably handsome and imposing looking chair was due to the late Mr. Frank Buckland, to whom the bed had been given as a birthday present by Professor Owen. The chair, up to the present, has only once been used in public, on October, 1879, when Dr. Wadham presided at the annual dinner of St. George's Hospital. Another point of interest in connection with the presentation lies in the fact that it was owing to Mr. Buckland's personal exertions that the remains of John Hunter were removed from the vaults of St. Martin's-in-the-Fields and deposited in the more honored resting place in Westminster Abbey. Mr. Buckland spent days, amidst not very pleasant surroundings, searching for the coffin containing John Hunter's remains. Mr. Buckland used to be fond of remarking that he felt prouder of being the means of laying John Hunter's remains in Westminster Abbey than of anything he ever did in his life.

It is gratifying to find by the report presented by the managers of the Metropolitan Hospital Sunday Fund that the receipts this year were larger than

they have ever been before, amounting to £40,399 7s. 7d., as against £34,320 8s. 5d. last year, and an average of £30,121 6s. 8d. in the thirteen years preceding. The total expenses entailed in the collection and distribution of this sum amount to rather over £2,000. It is considered that the Saturday and Sunday movements might well be combined, and the expense of two offices—secretary's and clerk's—be thereby saved.

The Councils of the Royal College of Physicians and the Royal College of Surgeons are steadily working to effect the scheme to grant a medical degree to students who pass the examinations of the conjoint board. The feeling prevails that students should not receive an M.D. degree at the time of qualification, or after a qualifying examination, but that some further proof that opportunities for obtaining experience in the practical work of the profession have been utilized should be required. The conjoint boards are shortly to meet again in connection with this matter. G. O. M.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Pathology of Scarlatinal Nephritis— Removal of the Vermiform Appendix.

At the last meeting of the New York County Medical Association Dr. Frank Grauer, of the Carnegie Laboratory, who during the past summer has been making special researches on the subject in Friedländer's laboratory in Berlin, presented a valuable contribution to our knowledge of the *Pathological Anatomy of Scarlatinal Nephritis*. He followed Friedländer's classification in general; dividing the varieties of the affection met with post-mortem into three types, viz.: initial catarrhal nephritis; large, flabby, hæmorrhagic kidney; and acute glomerulonephritis; or nephritis post-scarlatinosa.

The initial catarrhal nephritis is the form met with in the first week of scarlatina; generally accompanying the rash, lasting for a few days to a week, and then gradually disappearing. It rarely tends to death, and is liable to be entirely overlooked. It is only recognized by a chemical and microscopical examination of the urine, in which are to be found a slight amount of albumen, mucous and hyaline casts, and, more rarely, red and white blood corpuscles, renal epithelium, and granular casts. The kidneys in this variety he described as slightly enlarged and hyperæmic. The capsule strips off very readily, and on a cut surface there is some thickening of the cortical substance, with more or less loss of striæ. The glomeruli appear as red clots. A microscopical examination, he said, showed swelling and granular degeneration, with desquamation, of the epithelium, especially that lining the convoluted tubules. Hyaline and granular casts were often found in the straight tubes, and, when the process had been more severe, the beginning of a round cell infiltration in the interstitial tissue. It was only in those cases in which children die from the sequelæ or complications such as diphtheria and broncho-pneumonia, that an opportunity was afforded for noticing these changes.

From the description given it might be supposed that the changes are those belonging to a parenchymatous inflammation, but Friedländer has pointed out the following differences: Parenchymatous inflammation, according to Virchow, leads to fatty degeneration of a cell, with disturbance of its function; and this process does not occur in the epithelial cells lining the uriniferous tubules in the form of nephritis under consideration. Then, on the other hand, we have a cellular proliferation in initial catarrhal nephritis; which, as a rule, does not occur in parenchymatous inflammation of the kidney.

The second form of nephritis met with, that characterized by the large, flabby, hæmorrhagic kidney, is not as common as either of the others; Friedländer having found it present in only twelve out of 229 autopsies made by him in cases of scarlatinal nephritis. It generally occurs from the first to the fourth week of the disease, and runs a rapid course; in some cases the urine remaining normal until within twenty-four or forty-eight hours of death. It is generally found in those cases accompanied by extensive angina and diphtheritic inflammation, and the post-mortem appearances are as follows: The kidneys are enlarged, and the cortex is studded with ecchymoses and large hæmorrhagic infiltrations. The cortical substance is thickened and greyish red in color, there is complete loss of the striæ, and the glomeruli are, as a rule, invisible.

Microscopically, Dr. Grauer said, the tubules were found to contain the various forms of casts, and blood corpuscles, degenerated and desquamated epithelium, and an increase in the connective tissue characterized by a round cell infiltration which was situated mainly around the glomeruli and between the convoluted tubules. In addition, small abscesses were often found in the cortical substance, in which, by means of one of the aniline dyes, micrococci could not infrequently be detected. Whether the latter had any direct relation with the etiology of scarlatina or diphtheria, or whether they were merely one of the forms of micrococci found in acute abscesses, he was unable to state. This form of nephritis is characteristic of scarlatina alone, as it has been found in cases of primary diphtheria, and Friedländer regards it as a septic inflammation of the kidney.

The larger part of the paper was devoted to the third and most important form, acute glomerulonephritis, or nephritis post-scarlatinosa. This is the affection which generally occurs in the third or fourth week of scarlet fever, when the patient is convalescing. Having described its main features and the characteristics of the urine in light and in severe cases, he stated that Friedländer found this form of nephritis present in forty-two out of his 229 cases. To Klebs was due the honor of first pointing out that the glomeruli were affected. He noticed, in making fresh sections of the kidney with a double knife, that the glomeruli were anæmic, and after

washing them out with water, that they became dark and cloudy.

Having given a description of the microscopical anatomy of the glomeruli, in regard to which there still exist some differences of opinion among histologists, and of the microscopical appearances noted by Klebs, Klein, Ribbert and Langham in glomerulo-nephritis, Dr. Graner went on to give some account of his own observations based upon nine cases of the disease which he studied in Friedländer's laboratory, and a report of which he embodied in the paper. The results obtained by him are as follows:

Macroscopical Appearances.—The kidneys are enlarged and hyperæmic. There is no loss of cortical strie, and in some cases the cortex may be somewhat thickened. The glomeruli are pale, prominent, and more or less enlarged.

Microscopical Appearances.—The glomeruli are bloodless, but very rarely a red blood corpuscle may be seen in the lumen of a capillary. When examined with a low power, the glomeruli are found larger than normal, and covered with a mass of nuclei. With an immersion lens the following changes are noticed in the capillaries: In some the only change found is a thickening of the endothelial layer, which becomes more granular. In others the lumen of the vessel is filled with a rich nuclear protoplasm. Dr. Graner thinks that these nuclei are the nuclei of the proliferated endothelial cells, and not those of white blood corpuscles, as contended by Ribbert and other observers. With reference to the glomerulo-epithelium he has noticed swelling and proliferation. It is still considered by some authorities that it is the proliferation of the glomerulo-epithelium that produces a compression of the capillaries, and thereby obstructs the circulation. In all the specimens which he examined, although proliferation of the glomerulo-epithelium was present, the loops, as a rule, were larger than normal; showing that the pressure was from within, and not from without. Proliferation of the capsular epithelium, as described by Klebs, was not observed in eighty-two sections examined by him; but he has observed it in other forms of scarlatinal nephritis. Hypertrophy of the left ventricle of the heart, as first pointed out by Friedländer, is always present in glomerulo nephritis. In concluding, Dr. Graner, who exhibited under the microscope a number of specimens illustrating points brought out in the paper, expressed the opinion that the term glomerulo-nephritis ought to be restricted to those affections in which there is obliteration of the loops of the capillaries, and not applied to those in which there is only a proliferation and desquamation of the glomerulo and capsular epithelium, as this change has been noticed in all forms of chronic nephritis.

The discussion on the paper was opened by Dr. Flint, who in the course of his remarks said that one of the questions of greatest interest suggested by it was that relating to death from so called uræmic poisoning. This was a live question, and personally he had very decided convictions in regard to it, which were very considerably at variance with the views which he had formerly held. From the investigations concerning excrementitious substances which he had made during the last few years, he had come to entertain some doubt whether urea was a poison after all. His experiments had convinced him that water is formed *de novo* in the system from a combination of the elements composing it; so that under these circumstances water itself was an excrementitious product, and yet it was certainly not a toxic agent. As to the cause of death in these cases of scarlatinal nephritis, which was commonly attributed to uræmic poisoning, he believed that the parenchymatous changes which were noticed in the patient after death were due very largely to the excessive pyrexia of the scarlatina. The special direction which these parenchymatous degenerations took in different infectious fevers was governed, he thought, by the special cause of the disease; each affection having its own peculiar *contagium vivum*, with its specific mode of action in the system. In scarlatina this showed a strong predisposition toward the kidneys, and in scarlatinal nephritis the urine was diminished in quantity, of high specific gravity, and contained a large amount of albumen, because these organs became choked with excrementitious matter, and could no longer be washed out by the water derived from the Malpighian tufts.

Dr. Isaac E. Taylor, having referred to the fact that in the cases studied by Dr. Grauer death had occurred in from four to eight weeks, said he would like to inquire what the condition of the kidneys was in those cases which terminated fatally within thirty-six hours from the onset of the attack of scarlatina? He related in this connection several cases which had occurred in his own experience.

Dr. Daniel Brown thought that the virus of scarlatina found a soil peculiarly fitted to it in the skin, the intestines and the lining membrane of the glands, and that by its effect upon these structures an irritation of the nervous system was set up that was sufficient to account for the class of cases referred to by Dr. Taylor. It was very much, he said, as though the child died from shock. Scarlet fever had the effect of arresting almost all the secretions of the body, and in his treatment, therefore, he was in the habit of employing such remedies as tend to stimulate the secretions. By pursuing this course he had found that the temperature was kept down, and that the danger of unpleasant sequelæ was greatly diminished.

Dr. Gouley said that a number of years ago, during several epidemics of scarlatina at the Nursery and Child's Hospital, it had been somewhat surprising to him, as well as to the late Dr. George T. Elliott, who was one of the attending physicians, that so many of the children were affected with nephritis; and the point that interested him most was, that of the many who recovered, the larger number recovered promptly and completely. He should like to inquire, therefore, whether it was not rare for chronic nephritis to result?

The President, Dr. Leale, said that some fifteen years ago, when he was attending physician for diseases of children at one of the largest dispensaries in the city, he was struck with the large number of cases of dropsy that presented themselves; and he found that the great majority of them were in chil-

dren who had passed through an attack of scarlet fever without any medical attendance. An interesting point which he had noticed in examining the urine from day to day in cases of scarlatina was, that although for a time there might be no sign of kidney trouble, it was a fact that almost invariably albumen appeared in it on the twenty-first day; thus following upon the desquamation of the skin. When scarlatinal dropsy was moderate in amount, there was, he thought, usually very little difficulty in promptly relieving the patient. Some of the microscopical points treated of in the paper also were discussed by Dr. L. J. MacNamara.

In some concluding remarks, Dr. Grauer said that in the cases referred to by Dr. Taylor, in which death occurred within twenty-four or forty eight hours, there was complete suppression of urine, and that the condition found after death was acute glomerulo-nephritis. In reply to Dr. Gouley's question he stated that while, in the majority of cases, the children undoubtedly recovered promptly, in a certain proportion of cases the kidney trouble became chronic. He had at present under observation a child 8 years old who had an attack of scarlet fever two years ago, and who was now, as a result of it, suffering from chronic interstitial nephritis, with bloody urine.

Professor Joseph D. Bryant presented a vermiform appendix which he said he had removed from a patient last summer. The case occurred in a neighboring town, and was seen in consultation with Drs. Janeway and W. T. Bull. The cause of the illness, which occurred in a gentleman 45 years of age, previously in good health, was entirely unknown.

About fifty hours before Dr. Bryant saw him he was suddenly attacked, without appreciable cause, with a moderately severe pain in the epigastric region. He attached but little importance to it, and, attributing it to a slight diarrhœa which he had had for some ten or twelve hours previously, took a mild cathartic, which afforded him marked relief. He noticed no pain or tenderness in the right iliac region.

About fifteen hours afterward the pain became more severe than at the outset; but was still located in the epigastrium. The family physician was called, and he prescribed another cathartic, followed by an anodyne. The medicine did not move the bowels, and the pain increased; while the abdomen now became tympanitic, and nausea, with occasional vomiting, set in. The vomiting, however, was not characteristic of any special morbid process. Enemata were administered, but seemed to dislodge only a few small scybalous masses. The condition of the patient became gradually worse, and Professor Janeway was called in consultation; arriving about forty-five hours from the first attack of pain. Five hours later he was seen by Drs. Bryant and Bull, and the following facts were noted: The patient's perceptions were intact, although somewhat blunted by the previous use of opium. Persistent, though not severe, nausea existed, with occasional vomiting. The matter vomited had no distinctive characteristics. The abdominal walls were extremely distended, with tympanitic resonance well marked in all situations. Hepatic dulness normal. Tenderness on pressure very general, but best marked at the lower portions of the abdomen. No isolated point of special tenderness was discovered, and all pain was still referred to the epigastric region. The abdominal walls were too tense to render deep palpation of any service as a diagnostic measure, and digital rectal examination disclosed nothing abnormal. Temperature 102; pulse 108. Respiration increased in frequency, but painless. Bowels obstinately constipated, with an absence of all intestinal sounds and of appreciable vermicular movements. The thighs were flexed. Urine drawn off with a catheter.

As the result of this examination the consultants believed, 1, that a more or less general peritonitis existed; 2, that it was secondary to either obstruction of the intestinal tract or perforation of it; 3, that immediate measures of relief must be taken to insure a chance for recovery; 4, that medicinal measures afforded no such chance; 5, that an exploratory incision of the abdomen was warranted.

The patient willingly gave his consent, and the operation was performed in as thoroughly antiseptic manner as the contingencies of the case would admit. As soon as the peritoneum was incised a very small amount of thin, non-offensive, reddish colored fluid escaped. The small intestines were extremely distended, and their serous surfaces were deeply congested. The sigmoid flexure (which extended across to the right iliac process) presented similar appearances. In some situations evidences of recent lymph were seen. No characteristic local indications of an obstruction could be found anywhere. The intestines at and about the right iliac fossa presented the evidences of a more profoundly inflamed condition, and for this reason the caput coli was closely examined. It, too, presented appearances similar to the contiguous intestines.

The vermiform appendix was then sought for and found, but with considerable difficulty. It arose from the inner and peritoneal surface of the cœcum, was about 2½ inches in length, and covered entirely by peritoneum, and was unattached, except at its origin from the cœcum. It was standing nearly erect between the intestinal folds, and was swollen and darkly congested; presenting somewhat the outline of a distended leech. At its base three perforations were found, two of which were each about the size of a small pea, while the other was of somewhat smaller size. In one of the openings was a small mass of fæcal matter. At and around the base of the appendix a considerable amount of the reddish, non-offensive fluid mentioned was found, and it was mixed with flakes of recent lymph.

The appendix was tied at its base, below the point of perforation, with a strong silk ligature, and removed with scissors. The abdominal toilet was performed with antiseptic sponges and a warm solution of bichloride of mercury (1–10,000). A drainage-tube was introduced, and the abdominal wound closed and dressed antiseptically. The patient rallied from the immediate effects of the operation, but died twelve hours afterwards from exhaustion.

In concluding his narrative Dr. Bryant called attention to the following special points of interest in connection with the case: 1, the preceding diarrhœa;

2, the absence of distinctive pain at the seat of the lesion; 3, the location of this pain in the epigastric region; 4, the comparative quiet following the first attack; 5, the existence of normal hepatic dulness; 6, the extension of the sigmoid flexure to the right iliac fossa; 7, the unusual arrangement of the vermiform appendix; 8, the absence of the evidence of any restricting inflammatory process; 9, the uncertainty attending the diagnosis of the exciting cause of the patient's condition; 10, the unusual means adopted for the relief of the patient. P. B. P.

PAROTIDITIS AND PREGNANCY.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—The following case is to me one of interest and rarity: Mrs. S., aged 29, three months pregnant, was taken with parotiditis. On the third day the swelling abandoned the parotid glands, and miscarriage followed. She has had four previous pregnancies, of which the first, third and fourth were normal. The second pregnancy miscarried, which was attributed to fright. Are there any instances in which metastasis from the parotid glands to the uterus has occurred with results like the above?—Very truly yours, J. FRANK PAGE, M.D.

MISCELLANEOUS.

OHIO STATE SANITARY ASSOCIATION.—The fourth annual meeting of the Ohio State Sanitary Association will be held in the Board of Trade Room, City Hall, Columbus, Ohio, on Thursday and Friday, Feb. 10 and 11, 1887. Among others the following papers will be read:

"The cause of deafness and blindness with special reference to the eruptive fevers." S. L. McCurdy, M.D., Surgeon for the Penna Co., Dennison, Ohio.

"Cremation of the lower animals." E. S. Rickets, M.D., Portsmouth, O.

"Water Closets and Privy Vaults." John McCurdy, M.D., Youngstown, Ohio.

"Injurious Gases." David O'Brine, M.E., M.Sc., M.D., Assistant Professor of Chemistry, Ohio State University, Columbus, O.

"Our Fever Epidemic from Drinking Sewerage." C. E. Kurz, M.D., Bellaire, O.

"The Sanitary Condition of Sandusky before and after the Completion of Water Works and a Sewerage System." Elwood Stanley M.D., U. S. Marine Hospital Service, Ohio.

"Syphilis from a Sanitary Standpoint." C. E. Beardsley, M.D., Ottawa, O.

"School Sanitation." Hon. LeRoy D. Brown, Ph.D., Ex State School Commissioner, Hamilton, O.

"Some of the Practical Results of our Criminal Laws from a Sanitary Standpoint." R. Harvey Reed, M.D., Mansfield, O.

"Diagnostic Responsibility." H. M. Lash, M.D., Athens, O.

"Examination of Air of Apartments." Curtis C. Howard, M.C., Professor of Chemistry, Starling Medical College, Columbus, O.

"Hygiene of the Sick-Room." F. C. Larimore, M.D., Mt. Vernon, O.

"The Sanitary Condition of the City of Mexico, from Personal Investigation." E. D. Shreve, C.E., Bucyrus, O.

"Ptomaines and Poisoning by Tainted Foods." J. U. Barnhill, B.S., M.D., Lecturer on Toxicology, Columbus Medical College, Columbus, O.

"The Relation of Climatic Changes to Certain Diseases, with chart illustrations." E. M. Mark, Esq., Sec'y Ohio Meteorological Bureau, Columbus, Ohio.

"The Chronic Insane under County Care and in the Care of Families." F. H. Darby, M.D., Chairman of Sanitary Committee, Morrow, O.

Reduced rates have been secured on all lines centreing in Columbus, and will be granted to all persons desiring to attend the meeting, who, on application to the Secretary, at least one week prior to the time of the meeting, will be furnished with the proper certificates, which *must* be secured before leaving home.

REGISTRATION OF BIRTHS AND DEATHS IN ILLINOIS.—In the city of Chicago the death reports are as complete as they can be made, owing to the burial permit system, but there are about one-fourth of the returns of births lacking. This is mainly owing to neglect upon the part of the profession, as the midwives as a rule make these returns promptly. An effort will again be made at the coming session of the General Assembly to so amend the law as to relieve the certifying physician of unnecessary labor in connection with these returns, and the Illinois State Board of Health cordially invites the exercise of influence to this end. The returns last year indicate an increase of 25 per cent. over the previous year, in consequence of a circular letter sent to the delinquents in February and March. It is to be hoped that all returns will be made promptly.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 25, 1886, TO DECEMBER 31, 1886.

Major Egon A. Koerper, Surgeon, U. S. Army, granted leave of absence for two months, to take effect about January 1, 1887. S. O. 297, A. G. O., Dec. 27, 1886.

First Lieut. Jno. L. Phillips, Asst. Surgeon, granted one month's extension of his leave of absence. S. O. 297, A. G. O., Dec. 27, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING JANUARY 1, 1887.

Anderson, F., P. A. Surgeon, to U. S. S. "Thetis."

Auzal, E. W., Asst. Surgeon, detached from R. S. "Independence" and ordered to Coast Survey Str. "McArthur."

Green, E. H., P. A. Surgeon, detached from Naval Laboratory for temporary duty on R. S. "Independence."

Gatewood, J. D., P. A. Surgeon, to Naval Academy, Jan. 5, 1887.

ADDRESSES.

STATE REGULATION OF MEDICAL PRACTICE.

The Retiring President's Address, delivered at the Tenth Annual Meeting of the Detroit Medical and Library Association, Oct. 4, 1886,

BY C. J. LUNDY, A.M., M.D.

Ladies and Gentlemen, Members of the Detroit Medical and Library Association:

We are assembled this evening to celebrate our society's tenth anniversary, and, I trust, the year about to close has been one of pleasure and profit to us all. When one year ago you conferred upon me the honor of the presidency of this society, I accepted the office with doubt and misgivings. The year preceding my installment in office had been one of unusual activity and prosperity. Such prosperity has seldom been enjoyed by a local society, especially outside the large cities of the East. Numerous valuable papers had been presented; interesting discussions, upon given topics, had been held, and a large amount of pathological material had been exhibited during the year. The membership of the society had greatly increased and the regular attendance had been unusually large during the incumbency of my predecessor. No wonder, then, that I should have entertained fears lest the year during which I was to preside over your deliberations might witness a diminution in the interest and good work of the society. Still, I was in no small degree encouraged by the fact that we had an indefatigable secretary, to whom this society owes so much, and also by the fact that we have a large number of members interested in society work—members who had large resources from which to draw—and I think you will agree with me when I say they have drawn upon these resources most generously, and they have made this another prosperous year for this society. Such work as you have done during the past year could not fail to prove interesting, profitable and instructive, and it is somewhat surprising that so many busy practitioners have found it possible to devote so much time to society work.

According to the secretary's report, I find that there were read during the year twenty-three papers on numerous and interesting topics. There were held five discussions upon various subjects, mostly chosen by the advisory council. More than seventy pathological specimens and microscopic mountings were presented. A large number of patients was exhibited, either to illustrate some interesting disease, or to show the results of some important surgical operation. Indeed, the number and character of the pathological specimens alone would have done credit to a pathological society. I doubt if any local society in the country has done more profitable, interesting and instructive work during the year than has the Detroit Medical and Library Association.

In addition to the many valuable papers presented by our resident members, we have had the pleasure of listening to able papers from several gentlemen residing outside the city. Among others were one by Dr. T. K. Holmes, President of the Canadian Medical Association; one by Prof. V. C. Vaughan, of the State University; one by Dr. Henry M. Hurd, Superintendent of the Eastern Michigan Asylum; one by Dr. George Tye, President of the Ontario Medical Society; and one by Dr. E. P. Christian, President of the State Medical Society. While the inviting of eminent men outside the city to read papers before us is not exactly a new departure, yet it has been done to a much greater extent this year than heretofore. In my opinion it is a good course to pursue, and I am sure all will admit that we were both entertained and instructed by the able papers presented by the gentlemen named. We have also been delighted and encouraged by the frequent presence of gentlemen, prominent in the profession, who are not members of this society. Many of these are either officers of, or prominently connected with, sister societies, and their presence at our meetings has always been a source of great pleasure to me.

Our society has increased its membership by the election of thirty new members. Of these nineteen were elected as active members, ten as corresponding members, and one was elected as an honorary member. We have now a total membership of 136. It is possible that some may contend that a society with a large membership may prove unwieldy, but I certainly do not entertain such views. Instead of having a few members present, we have had an average attendance of thirty one. On several occasions the attendance has been between forty and fifty. When so many gentlemen interest themselves in society work, it may be relied upon that the meetings will be of interest and profit to all concerned. I have attended most of the meetings during the year, and I have no hesitation in saying that I always went away feeling I had been instructed by the papers,

discussions and reports of cases. I doubt if this unflagging interest could have been kept up throughout the year were our society a small one.

Now, while our society has done much good work during the year, and while we have had interesting discussions, interesting reports of cases, interesting pathological specimens, and interesting and valuable papers, yet I think our society might do other valuable work, and might wield its influence to remedy an evil which has grown to great proportions, and which has done great harm in our commonwealth. It is an unfortunate fact, but fact it is, nevertheless, that in Michigan the ratio of quack doctors to the population is greater than in almost any other State. It is a well-known fact that in other States Michigan is regarded as the asylum of quacks. It is a well-known fact that when a law is about to be enacted against quackery in other States, the charlatans of those States turn their eyes towards Michigan as a land flowing with milk and honey—a land in which they will find protection, and where they may pursue their nefarious business without let or hindrance. In our State any man, no matter how ignorant, no matter how illiterate, no matter how unskillful he may be, any man, I say, may undertake without let or hindrance to cure all ills to which human flesh is heir; may undertake to treat any disease or to correct any deformity of the human form divine.

In this great State of Michigan, in which we have such a grand system of public instruction, such fine educational institutions, such fine facilities for obtaining an education, whether lay or professional, it is a disgrace to see men and women, without any preparation, or training, or qualification whatever, setting themselves up as physicians, and through false pretense swindling our citizens out of enormous amounts of money. It is generally well known that the charlatans of this State rob and beguile the unwary with a merciless hand, and that the amount of money which is annually filched from our people by these swindlers is very large. But I am satisfied that few even of you, ladies and gentlemen, could form an approximate estimate of the amount of money which is taken yearly by the wily and unscrupulous charlatans of this State. In my presidential address before the medical alumni of the State University (extracts from which I have embodied in this paper) I took occasion to refer to the "Medical Practice Act" of Illinois, and upon that subject I made the following quotation from the writings of ex-Governor John M. Hamilton:

"The Medical Practice Act was primarily a police regulation. Incidentally it was educational. Primarily the purpose of the law was to rid the State of incompetent, ignorant and dangerous mountebanks and quacks, who were carrying on a fraudulent and nefarious business by all manner of deceit in a pretended practice of medicine among the people. It was to protect the lives, the health, the morals and the property of the people of the State from the shameless depredations of swindlers and adventurers who, by all manner of false representations and deceptive promises, were taking advantage of the misfortunes of the people in sickness and ailments of all kinds, to still further injure their health, endanger their lives and rob them of their money."

To me it is incomprehensible that in Michigan all attempts to regulate the practice of medicine, to suppress quackery and to protect the people from the depredations to which Gov. Hamilton has so forcibly referred, have been practically unavailing. We boast of the intelligence of our people and of our educational facilities, and it would seem that there is some foundation upon which to base these claims. But if we are to judge of the intelligence of a people by the laws which they enact for the protection of their rights, their property, their health, their morals and their happiness, we must admit that the people of this commonwealth lack the intelligence to grapple with one of the most important questions of our time. In every State there is a law against obtaining either goods or money by false representation. Indeed, it was only a few days since that a culprit was brought to justice in one of the towns of this State because he represented the circulation of a small paper to be much larger than it was in reality. However, a man may pretend he is a physician, and in this guise he may swindle and rob the people of this State with impunity, and there is no law to prevent him. If, as Gov. Hamilton has said, the people of Illinois found it necessary to enact a law "to protect the lives, the health, the morals and the property of the people of that State from the shameless depredations of swindlers and adventurers who, by all manner of false representations and deceptive promises, were taking advantage of the misfortunes of the people in sickness and ailments of all kinds, to still further injure their health, endanger their lives and rob them of their money," why should not Michigan, with her boasted intelligence, be ready and willing to afford her citizens similar protection and enact similar laws? Laws to suppress quackery have been enacted in other States, and we see that the people of Iowa, of Wisconsin, of California, of Mississippi, of Alabama, of North Carolina, of Virginia, of New York, and of other States, have cried out against quacks and charlatans, and the law-makers of these States have had the intelligence to give the citizens of their respective States that protection to which all civilized communities are entitled. Can it be possible that our boasted intelligence is only a myth, and that after all the citizens of Michigan are intellectually inferior to the people of other States? If it is the will of the people that we should, in the space of three years, pay out to swindling mountebanks and quacks as much money as would pay for all the school houses and school property in this great State of Michigan, then must we answer the question in the affirmative. But I, for one, do not believe it is the "people's will" that this condition of affairs should exist within the borders of our fair State. I believe the fault lies elsewhere. I believe that if this monster were shown to the people in a proper light they would rise up as one man and crush it. Can the fault be charged to our legislators? Can it be possible that the men who represent us in the legislature of this State are not a fair criterion by which one can judge of the intelligence of our people? Or can it be possible

that the majority of these legislators have venal motives in casting their votes when the interests of the people are at stake? And can it be possible that the chief of a corporation of quacks spoke truly when he said he had "fixed the legislature and defeated the medical bill, but that it took money to do it?"

Let the fault lie where it may, one thing is certain, and that is, the State of Michigan has thus far utterly failed to grant to her citizens that protection from swindling mountebanks and quacks which she is in duty bound to afford them. Michigan should learn wisdom from other States; and her legislators should show that degree of intelligence which was shown by the legislators of Illinois, when they passed the "Medical Practice Act" nine years ago. It is true, a pretence for a bill against quackery became a law at the last meeting of the legislature. This law is an utter failure, and for the following reasons: First, it did not contemplate the prevention of quackery within the State, because it was not intended that it should interfere with the nefarious business of the quacks already here. Second, because all manner of men have been allowed to register under the law. We find that not only druggists and others who had not been heretofore engaged in practice, but still others, who thought they might desire to practice medicine at some time in the future, have enrolled themselves, and in the eyes of our farcical law they are your equals. Third, the law is a failure because it has not been enforced, except in a single instance. To-day the people of Michigan are as fully at the mercy of the relentless charlatan as they were a quarter of a century ago.

The passage of the "Medical Practice Act" in Illinois forced about three thousand charlatans to quit their nefarious business or leave the State. After nine years' experience with this great and good law, we see that there are nine hundred fewer physicians in the State of Illinois than there were when the law was enacted nine years ago, while the population of the State has increased nearly one million within that time. To reduce the matter to a mathematical calculation, let us suppose that the average amount of money which each of these swindling quacks succeeded in filching from his dupes was $2,500 per annum. By many this will be considered too small an estimate, for many of them spent money lavishly in advertising their business. Now, multiply the $2,500—the sum which each obtained—by 3,000—the number of quacks forced to leave the State—and we get the sum of $7,500,000 which has been saved in one year. Let us again multiply this by nine—the number of years the law has been in operation—and we find that $67,500,000 have been saved the people of Illinois by the passage of this law regulating medical practice within the State.

Let us apply this mathematical calculation to our State. The population of Michigan is equal to one-half that of Illinois. Upon that basis we have 1,500 quacks in this State. Indeed, it is probable that the number is considerably greater. There are at least 1,500 men and women in Michigan who pretend to be physicians, but who have no qualifications for the profession which they pretend to practice. Upon the same basis of calculation which applied to Illinois, the people of this State have been robbed of more than $37,000,000 within ten years, or $3,750,000 annually.

Thirty-seven and a half million dollars, the amount of money of which we have been robbed in ten years, is three times greater than the entire cost of all the school houses, high schools, academies and colleges of this State, even including our State University. Thirty seven and a half millions of money is equal to four times the cost of erecting all of the penal, pauper and charitable institutions of Michigan, even including the three asylums for the insane. Thirty-seven and a half million dollars would cover the cost of erecting all the church edifices in the State. One-third the money which is annually paid to the quacks would build and equip all the hospitals in the State, and one-tenth of that amount would cover the cost of maintaining these hospitals. One fifth of the money annually filched from our people by these charlatans would maintain a large free hospital in every town in the State having a population of 5,000 or over. The money of which the citizens of Michigan are annually despoiled by these wily quacks would pay the yearly salary of all the teachers and professors in our public schools, normal school, agricultural college and our State University. One-half the money of which the people are yearly robbed, because our legislators have failed to give them protection from a horde of swindling mountebanks, would more than pay the salaries of all the clergymen in the State.

I have said that few even of you had formed a correct estimate of the appalling condition of affairs which exists in this State. To me the study of the question has been a series of surprises, and in more than one instance have I doubted my own figures. I am quite certain that few, or none of the laity have any correct idea of the extent to which a sort of licensed robbery is carried on in this fair State of Michigan.

Now comes the question of prevention. Many physicians will say, it is none of our business; if the people are willing to be swindled by these fellows, it matters not to us; if the people will not avoid these mountebanks, let the people suffer for it; if the people cannot choose between properly educated physicians and those who are mere pretenders, they should bear the consequences; if the people will not learn to avoid the charlatans who put forth glittering advertisements, and who try to dupe them by all manner of false promises, they, the people, should pay the penalty. I well remember hearing one physician say: "So and-so's advertisement sends me many patients who would not think of consulting a doctor had not the advertisement frightened them." All these things indicate a niggardly, uncharitable, unphilanthropic spirit, and they show such physicians to be unworthy their noble calling.

The business of most physicians is unaffected by the presence of the charlatan, because the victims of the latter are largely those upon whose imagination and credulity he can play. One of the princes of this class of swindlers held forth in this city not long

since, and he admitted to an acquaintance of mine that he "did not pretend to cure people," he "preferred to humbug them, as it paid best." This wily quack must have robbed the people of Detroit and vicinity of several thousand dollars in a few weeks.

In every town in this State you will find physicians coöperating with the State Board of Health to enlighten the people, and trying to protect them from influences which tend to produce sickness and death. And to the honor of these noble men and true physicians, these true friends of humanity, who compose our State Board of Health, be it said, they have done much to enlighten the people, to warn them of the dangers which surround them, and to instruct them as to the best means of guarding against many of the preventable diseases. So, also, our Board of Health has done an invaluable service to our city, not the least of which has been the instruction of our citizens regarding the importance of sanitary measures, and the best means of limiting the spread of contagious diseases.

Who will say, then, that the medical profession, as a whole, not only those of the regular school, but also the homœopathic brethren, should not unite as one body of teachers, to instruct the people of this State regarding the importance of a law which, in the words of Gov. Hamilton, "will protect the lives, the health, the morals and the property of the people of the State." I maintain it is the duty of the medical profession to point out to the people the dangers which surround them. I maintain it is the bounden duty of every true physician to use the power that in him lies, to alleviate the sufferings and right the wrongs, protect the lives, the health, the morals and the property of his fellow beings, and to warn the community in time of danger. I believe that this, the largest local society in the State, could render valuable assistance in bringing about a much needed reform in medical practice in Michigan. If the Detroit Medical and Library Association would take the first step in enlightening the public, I think other medical societies would follow their example.

We should have a law prohibiting all non-graduates of respectable colleges from practicing medicine until they had passed a satisfactory examination before a State board of examiners, similarly constituted to the State board of examiners in pharmacy. After the enactment of such a law, no man, whether a graduate in medicine or not, should be allowed to commence the practice of medicine in the State until he had passed a satisfactory examination before the State board of examiners. Such a law is in force in Virginia, Mississippi, and other States, and it works well. Such a law tends to make medical colleges more careful in regard to graduating incompetent men. For my part, I would like to see a law in Michigan which would compel all candidates for a medical degree to go before a State board of examiners, which board should be entirely independent of the medical colleges in the State.

It may be difficult, it may even be impossible, for us to enact in this State a law which will afford the people all the protection to which they are entitled, but if we can arouse public sentiment upon this question, much can be accomplished. The public press is the great moulder of public opinion, and if we can call this powerful engine to our aid, we can accomplish what we desire. As an evidence of the influence of the press we are reminded that one of the newspapers of this city actually drove out of existence the "Skuce Thomas" bogus medical college and diploma mill which began its nefarious business here a few years ago. If the public press of this city and State will come to our aid, we can have enacted in Michigan a law which will rid her of her mountebanks and quacks, a law which, in the words of Gov. Hamilton, will "protect the lives, the health, the morals and the property of the people of the State from the shameless depredations of these swindlers and adventurers."

ORIGINAL ARTICLES.

A CASE OF CHRONIC PSEUDO-MEMBRANOUS BRONCHITIS.[1]

BY H. A. JOHNSON, M.D., L.L.D.,

EMERITUS PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE IN CHICAGO MEDICAL COLLEGE.

Pseudo-membranous bronchitis is rarely met with. In making this statement I exclude the persistence of a diphtheritic bronchitis and croupous pneumonia, in both of which diseases the expulsion of false membranes may occur. It is, perhaps, not always easy to make an absolutely correct differential diagnosis of these cases. This difficulty rests upon the fact that (1) membranous inflammation of the bronchii of an acute character, such as diphtheria, may become chronic. I have seen several such cases, but in all of them the acute stage had been well marked, and the chronic condition seemed to be only delayed convalescence. (2) Croupous pneumonia may certainly become chronic, but so far as my own experience enables me to judge, the membranous exudate, if present, disappears with the acute stage.

The literature of the subject is quite voluminous in titles, as may be seen by reference to the index catalogue of the library of the Surgeon-General's office, but the number of cases is small.

Among the cases reported in our own country, one by Dr. W. C. Glasgow, of St. Louis, in a paper read before the American Medical Association for the year 1879, is especially noticeable. In this article the author embodies the experience of several of the more prominent physicians of the United States.

Dr. Richardson, of New Orleans, "in a practice of nearly a third of a century" had "never encountered a case of plastic bronchitis."

Dr. Geddings, of Aiken, South Carolina, had "never met with a case." It should be remembered that Dr. Geddings had a very large experience in lung troubles.

Dr. F. R. Porcher, of Charleston, had seen one case.

Dr. T. G. Simons of Charleston, had seen one

[1]Read before the Chicago Medical Society, December 20, 1886.

case, and had known of three others in the practice of other physicians.

Dr. Jerome Cochran, of Mobile, says it is unknown in that section of the country.

Dr. James H. Hutchinson, of Philadelphia, had seen one case.

Dr. H. I. Bowditch, of Boston, had never seen a case.

Dr. R. H. Fitz, of Boston, had seen four specimens of casts. Does not seem to have seen the patients.

Dr. T. Parvin had seen no cases.

Dr. Geo. P. Andrews of Detroit, had never seen or heard of a case in that region.

Dr. Roberts Bartholow had seen one well-marked case.

Dr. J. R. Leaming, of New York, had seen, in consultation, two cases.

Dr. Austin Flint, Sr., had seen three cases.

Dr. Gleitzman, of Ashville, North Carolina, had seen one case.

Dr. J. M. Da Costa, of Philadelphia, had specimens of casts from five cases; cannot say whether he had seen more cases.

Dr. Alfred Statle, of Philadelphia, sent report of one case.

Dr. P. E. Robinson, of St. Louis, reported one case.

Dr. Maxwell reports one case.

Dr. Samuel G. Armor, of Brooklyn, had seen "a few cases."

Dr. Frank Donaldson, of Baltimore, had seen one case.

Dr. Henry Gibbons, Sr., of San Francisco, had never seen a case during a practice of fifty years.

Dr. Charles Denison, of Colorado, had never seen or heard of a case in Colorado.

Dr. Baumgarten, of St. Louis, reports one case.

These facts collected by Dr. Glasgow in 1879, perhaps fairly represent the experience of the profession in America. I am, however, inclined to think that these meager statistics of the practice of some of the most active physicians and careful observers by no means give a correct estimate of the relative frequency of the affection. I imagine very many cases are never diagnosed, or if seen and recognized they are not recorded, and therefore lost sight of.

In the records of the literature upon this subject there are reports by L. H. Angel, *Chicago Medical Journal*, 1859, pp. 501 to 504.

J. S. Cohen, "Transactions of the Pathological Society," Philadelphia, 1876.

Austin Flint, Sr., *Medical Record*, 1874.

J. H. Hutchinson, "Transactions of the Philadelphia Pathological Society," 1874.

A. L. Payne, *Stethoscope and Va. Medical Gazette*, 1852.

J. C. Reeves, "Pathological Society," Philadelphia, 1859.

P. G. Robinson, *St. Louis Medical Journal*, 1878.

S. Rogers, "Transactions Medical Society of New York," 1866.

L. Smith, *Medical Record*, 1872.

T. H. Streets. *American Journal Medical Sciences*, 1880.

E. D. Worthington, *Canada Medical and Surgical Journal*, 1876.

These, in addition to the case reported by Dr. Glasgow, comprise all the titles I am able to find in the United States and Canada. They evidently include also some of the cases referred to in the correspondence reported by Dr. Glasgow and briefly summarized above. In some of these cases it seems to me there was simply an acute or diphtheritic inflammation running its course in a few days and terminating in death, with such symptoms as are seen in the ordinary forms of diphtheritic inflammation.

Among foreign authorities the reports are also meager. Eichhorst, in the last German edition of his work on special pathology and therapeutics, finds only 100 cases on record. The article in Ziemssen's Encylopedia gives a very clear statement of what is known as to the etiology and pathology of the affection. Among other writers Cheyne thinks old age predisposing; Valleix doubts this. Gintrac says that the larger number of cases are observed in adult life. If we exclude the cases of diphtheria extending to the bronchii, this is true.

The male sex is predisposed to the affection according to most authorities. Enfeebled health from previous disease, poverty, fatigue, exposure, are among the most common causes noted. Of course all these are so many synonyms for ignorance. The cause remains to be discovered. It may be some local colony of parasites. The relation of this disease to the ordinary forms of membranous inflammation in some of which bacteria are believed to be a pathogenic factor suggests this, and perhaps makes it probable.

The relations to antecedent disease are by no means constant; neither diphtheria, nor simple bronchitis, nor pneumonia, except in rare instances, eventuate in chronic pseudo-membranous inflammation of the bronchial tubes. Rugel says, "a special predisposition, or the influence of some special unknown agency is always essential in addition" to the hypothetical causes enumerated.

The pathology of the affection is better understood. There is an exudate which coagulates upon the surface of the mucous membrane. This is often laminated by successive deposits. In the meshes of this coagulum a few leucocytes are found. The membrane proper is not necrosed, but continues to produce epithelium and the exudate is pushed off by the multiplication of this epithelium which in turn degenerates, becoming fatty and purulent. It seems also to be certain that while the mucous membranes do not become the seat of necrosis they do become the seat of morbid processes, possibly similar to that which in the endothelium of blood-vessels determines the formation of a thrombus, and which in this case determines the formation of the plastic deposit.

The patient in the case which I beg to report is G. T. P., aged 37 years, a native of the eastern shores of the Adriatic. The family history on both sides is good. He enjoyed good health as a child and during early manhood; at 17 had a suspicious sore, but apparently escaped any other manifestations of specific disease; was for several years a sailor, but

abandoned that calling at the age of 25. Has been for some years keeping a saloon. Eight years ago he gives a history of pneumonia involving the right lung; was six weeks ill. His general health from that time was good, till in March, 1884, when he "caught cold." At that time he was in bed ten days, had cough with expectoration, but does not know what was the character of the matter expectorated; had pain in the right side, locating it in the mammary region, this was not severe, but it continued more or less at intervals to the time of consultation. The cough and expectoration also continued during the spring and summer with, however, upon the whole a slow improvement till four days before first seen, when he thinks he caught cold, cough became more troublesome and he spat up once only a little blood. He consulted me on August 23, 1884.

I found him a well built man, 5 feet 7 inches in height, dark hair and eyes, weighing when well, 147 pounds, but now evidently much reduced, 125 to 130 pounds. He stated that he had lost his weight since last winter; his appetite was poor; bowels torpid; urine normal in quantity but high in color; pulse 75, temperature 99.3, respiration 17 per minute, sleep fair, tongue coated. The cough and expectoration led him to fear phthisis, and the consultation was had with the expectation that there would be found evidence of that disease.

Upon inspection the chest was found to be noticeably flattened, but not more so on one side than on the other; over the right side and especially in the mammary region vocal fremitus exaggerated. Upon percussion there was found dulness over the whole right side, the left side normal. Auscultation revealed bronchial expiration over superior portion of right side, front and back. Left side normal. Cardiac sounds normal. The diagnosis then entered in the case book was a "pneumonia not completely resolved, with bronchitis." He was placed upon tonics, syrup hypophosphites with hydrobromic acid.

September 9. Seventeen days later, he came again, and in every respect seemed to be better. No physical examination was made, but he was ordered to continue the medicine.

September 16. After quite a severe coughing fit and the expulsion of a mass of what was found to be a cast of a large bronchus, he spat blood. The hæmorrhage persisted, and he was ordered extract ergot in capsules, and to continue the syrup hypophosphites and acid hydrobromic. The diagnosis was corrected so as to read "chronic pseudo-membranous bronchitis."

September 23. Bleeding continued two days after last visit, none since. Has had a great deal of pain in the inter-scapular region, not more on one side than the other. At times very tender to the touch at right of the eighth dorsal vertebra. This he describes as a "soreness." Has expectorated thin pieces of membrane since last consultation.

Physical examination. Find no dulness over the right side, or as the record says "no noticeable difference in the percussion noted on the two sides." This was one month after the first examination, when there was dulness over the whole of the right side. The breath sounds over the right side feeble, in every other respect normal. Pulse 68, temperature 98.6.

October 2. Had been doing well until yesterday, when he again coughed up a large cast of a bronchus. (I may remark that all of these which I saw were probably from the first and second size tubes, and were from two to four inches in length.) After this there came what he describes as pus streaked with blood, but the hæmorrhage not copious. The ergot had been stopped; he thinks he was better while taking it and asks to be permitted to return to it.

October 17. The casts continue to be coughed up; microscopically they consist of coagulated plasma with a few leucocytes. Since the last date, October 2, he had been taking balsam copaiba and oleores, cubeb, with the ergot. I was under the impression that the copaiba had increased the plasticity of the exudate. Keeping in mind the specific history in his early life I thought possibly that there might be some lingering impression still. I therefore put him on pot. iodid. 0.50 t. i. d.

October 25. Casts continue almost daily; continue pot. iodid. and add hydr. prot. iodid. 0.01 t. i. d.

November 5, his wife comes to the office, says that he has thrown off a large number of casts, and each is followed by copious hæmorrhage. Has continued to take the ergot, and is now a little better but weak; continues pot. iodid. and hydr. prot. iodid, and in addition R elix. calisayæ 450. and acid. sulphur. arom. 50.00 grams, M. and take a dessert-spoonful in water three times daily.

November 21, patient comes himself. Has been better since last date. Has had no hæmorrhage, or but little. Still a few casts, appetite has improved under the tonic. Bowels regular and sleep good.

December 26. Has been doing well till recently, but is now evidently losing in weight and strength. Hæmorrhages from chest and occasionally from nose. Appetite poor. Bowels regular. or occasionally diarrhœa. This. however, does not persist. Has lancinating pains in the abdomen, more in the epigastric region. Coughs up very few casts, and these very thin and delicate. Has taken now the hydr. prot. iodid. since the 25th of October, 0.01 three times daily, and a part of the time 0.50 pot. iodid. He has also taken, according to the amount of hæmorrhage, ergot at his own discretion. Stop both ergot and hydr. prot. iodid. and take syr. fe. iodid. 1.00 t. i. d.

January 9, 1885. Has been feeling better for the last two weeks. Appetite fair, bowels regular, no more pains in bowels since change in medicine, cough less, expectoration mucus, occasionally tinged with blood. No free bleeding and no casts. Has some pain in chest, bilateral, and not marked at any one place. Pulse 78, temperature 98, respiration normal. During the last week in January his wife came, said that he was still coughing a little and that the expectoration was streaked with blood. I directed an emulsion of oleum terebinth., each dose containing 0.50 of the oil, three times daily, and to omit the ferri iodid.

February 4, he was visited at his home. He has expectorated no casts since December 26, 1884, but

continues to cough sputum streaked with blood, and occasionally very slight epistaxis. Is still taking the turpentine; thinks the cough is looser than when taking the iron. During the past week has had a good deal of pain, intermittent in character, in the lower half of the right chest; has been in bed for last three days because of this pain.

Upon examination find the motions of the lower right side restricted; on percussion, dulness over the lower third of right lung, line of dulness seems to change with change of position; breath sounds indistinct, voice sounds exaggerated. Friction sounds distinctly heard over anterior portion of chest when patient lying on back; less so when patient is sitting up. Diagnosed, pleurisy, question of effusion doubtful; a hypodermic needle was introduced with negative results. Chest was ordered to be painted with iodine. The turpentine was continued.

Dr. Frank S. Johnson, to whom I am indebted for the larger portion of these notes, had made this visit, and on his return from the patient, in the extreme northwestern part of the city, became seriously ill. I was unable to look after the patient, and I asked my friend, Dr. S. D. Jacobson, to take charge of the case. This was, I think, on the 5th of February, 1885.

I beg to add extracts from a letter from Dr. Jacobson, giving in a general way the further treatment of the case:

"As to my ideas about the therapeutics of this case I can be short. I am not troubled with an *embarras de richesse*, but rather find my excuse in the old saw, *simplex sigillum veri*.

"The case was to me one of great interest, having never seen a similar one in twenty-five years of practice, and finding little or no mention of such cases in the books at my disposal. True, I have had one case of bronchial croup, which terminated fatally in a couple of days (a man about 48 years old). But your case had already been under your care and observation for several months before I saw him.

"During the earlier months of my attendance he was about the same as when you saw him, intensely harassing cough with dyspnœa until relieved by the expulsion of greater or smaller masses of bronchial casts, which relief was generally paid for by severe hæmorrhages, which told on the little strength he possessed before, so that he not only dwindled down to a skeleton-like appearance, but when able to sit up his legs would not support him, and his hands grew so weak that he could not for some time lift the spoon to his mouth. During the summer of 1885, he improved some, but the fall and winter reduced him below his former level.

"Having no authorities to guide me in the treatment of such a rare case, I applied the general principles to the best of my abilities. I had two indications before me, (1) *indicatio symptomatica*, and (2) *indicatio morbi*. As to the first class, I had in view the cough, dyspnœa, hæmorrhages, weakening of all the organs and functions. Those I tried to meet by the exhibition of *solventia*, *expectorantia*, *narcotica*, *styptica et roborantia*. As to the *indicatio morbi* I was more in the dark, knowing almost nothing about the pathology or etiology of this disease. But I reasoned like this: Since our pathology seems to drift more and more into bacteriology, it is but just that our therapeutics follow suit and be more in the nature of bactericides and antiseptics. In this light I wish you to judge my prescriptions containing such poisons as arsenic, iodine, bi-chloride hydrarg. and iodoform, which appear in many of them.

"I must confess that my success was a great deal more than I dared hope for, and though I firmly believe in the *vis medicatrix naturæ*, I also believe that a physician can be, and should be in the words of Lord Bacon, '*medicus naturæ minister et interpres.*'"

During the summer of 1886, and again within the last few weeks, I have seen the patient, and find him perfectly recovered.

4 Sixteenth Street.

THE PROFESSION AND PRACTICE OF MEDICINE

In Some of Its Relations to Human Society.[1]

BY S. M. HAMILTON, M.D.,

OF MONMOUTH, ILL.

This is a subject of great width, in its entirety. The history of medicine may be very appropriately included in the investigation, as well as an almost interminable biographical account of its representative members. But at present we will only try to give a few suggestions: first, as to the mutual relations between the profession of medicine, as a profession, and the public; second, as to the true *status* of the individuals who pretend to practice it.

The healing art, as it is sometimes called, is so old that no one can tell when it originated. It is quite probable that, with the exception of the priestly office, and those occupations and professions growing directly out of man's physical wants, it is the most ancient of all. I cannot tell whether it was from the first a part of the priestly office to minister to the ills of the body as well as the soul. But it is a fact that what we call the "historical era" found the profession and practice of medicine wholly in the hands of the priests. The Mosaic Law sets it down as a part of the priestly office, and the cure of disease through religious rites and ceremonies is a part of the Jewish creed. These rites and ceremonies, we are expected to believe, and do believe, were conditions to cure, enjoined by the Almighty. But curiously enough, coupled with them in all cases are certain things which the afflicted person must do for himself, to secure the result desired. There are instances, to be sure, of miraculous cure of disease, where the means employed seem to have no rational connection with the result. But, as a rule, there is laid down to the patient a set of rational sanitary laws, which he must observe just as rigidly as the religious rites of the priest.

The rite of circumcision was instituted as a sanitary necessity, beyond doubt; and it was made a part of the religious code of the Jews, merely to insure its observance. The evidence is conclusive that venereal and syphilitic disease existed to a prodigious

[1] Read before the Monmouth Medical Club, October 6, 1886.

extent among the ancient Jews. There cannot be found in the writings of Ricord or Hunter a more vivid description of these forms of disease than that set down in the Levitical law. Clearly this physico-religious rite was instituted for the purpose of controlling and restricting (as it does to some extent) the spread of this terrible disease, which we now call syphilis.

I do not know why the all-wise Creator did not reveal to his chosen people the knowledge of drugs useful in medicine and the different modern surgical appliances, for the relief of his suffering children. We only know that he did not. I presume that, in the plan of the universe, it was best that man should be required to do for himself everything which lay within the compass of his own powers of mind and body. Considering the status of the healing art in these far off days, and for many succeeding ages; the prominence which faith in mere forms, and otherwise meaningless ceremonies, held in the cure of disease, it is easy to discover the key to many problems in mental philosophy which have sorely puzzled some of us in modern times. Mental lopsidedness is a subject of heredity as much as an ill-shaped leg or a crooked nose. Mental characteristics of any and every kind descend in long lines from parents to children, quite as often as physical peculiarities of form. It is not wonderful, then, that exaggerated ideas of the power of "faith without works," charms and meaningless ceremonies, and superstitious rites, as agents in the cure of disease, should have been bred into the mental and moral texture of the race.

We see every day intelligent men, who manage their family and pecuniary interests, their political and religious affairs, with the utmost sagacity and good common sense. In these, as in every other thing touching their duties to God and man, they will be satisfied with nothing less than a good sound reason for the adoption of any proposed line of conduct. Not all, but many such men, when brought face to face with disease, in themselves or in their friends, are satisfied with nothing that looks like reason. Something supernatural, something outside the domain of human reason, alone will satisfy them. In their mind "the seventh son of a seventh son," no matter how ignorant or inexperienced, has peculiar adaptability to the cure of disease; that this or that individual is endowed by the Creator with the power of healing by touch of the hand; that faith, and not works, is the healing power for all earthly diseases. The "prayer cure" of disease is one of the delusions which seems to have fast hold of the convictions of many good ignorant people. If there is one thing clearly taught in revelation, and shown by the light of experience and reason, it is that God helps those who help themselves. He has given to mortals brain, bone, and brawn, by the proper exercise of which he is required to provide for his natural wants. Food and raiment come to him by the "sweat of his face." Every material good, every creature comfort, every intellectual pleasure or triumph, is obtained only in one way—by paying the price, in human effort or human anguish, which the God of nature and grace has set upon it. Even spiritual blessings, and all of the many things affecting the immortality of man, are no exceptions to this rule. All are obtained by the blessing of God upon human effort. "Faith without works" occupies the same contemptible place in the cure of disease, which it holds in the salvation of the soul. In both cases "faith without works is dead."

I do not lose sight of the fact, for it is a fact, as well authenticated as anything in history, that the God-Man, whilst on earth, miraculously healed the sick, and conferred the gift upon certain of his followers. Evidently it was the purpose to convince the wicked world of his divinity, and to show the depth of his sympathy for human suffering. But the Great Physician and his coadjutors have retired many ages ago, and left us to cure our own diseases, and even to work out our own salvation, with fear and trembling. I know of no promise of the salvation of the soul without the concurrent work of the soul itself.

The mission of the medical profession, in the minds of many good people, is to discover and present to the world a set of specific remedies for all the ills of the human body. That disease is a fixed and unvarying quantity, is assumed. The truth is that, even in most cases of what we call "acute diseases," the causes have been operating for months, perhaps for years, and the exact form of local manifestation was brought about by some seeming trivial and so-called accidental circumstance, such as exposure to cold, or great heat, or exhausting fatigue, although the remote cause had been operating in the general organization for months or years. In cases of death from local disease, post-mortem investigation often establishes the fact that not one, but several, sometimes all of the vital organs, were implicated, making it difficult to tell, even by careful examination, which was the original and which the secondary affection. Disease in general has been defined "a deviation from health." A good definition, as a short answer to an apparently plain question, but utterly worthless as an answer to an abstract question. It would have perfect mathematical correctness, if the term health could have a fixed, standard value. But it has not. Really, what is health in one, is a condition of disease in another; and as no two human faces, nor no two human voices, are exactly alike, so are there no two human organizations whose physical construction, or whose organic operations, are exactly alike. The definition is true, but it must be restricted to the single physical organization in question, and no other. So long as mankind is born into the world with diverse temperaments, and hereditary weaknesses and hereditary vigor peculiar to themselves; so long as some are rich and some poor; so long as vice and crime walk side by side with honesty and virtue; so long as ignorance and filth shall have their kingdom within the kingdom of intelligence and cleanliness—just so long will the treatment of disease by specific medication be a failure.

The natural sciences as applied to the investigation of disease are of immense value, but their usefulness is bounded by barriers which they cannot pass. As an illustration, take the human eye. It is a purely physical machine, for appropriating and condensing the rays of light, and transmitting to a background

the color, shape, and comparative size, of objects within a certain radius. Its construction can be exactly imitated. The form, size, and function thus far, can be produced artificially. At this point physical science halts, very far indeed from the goal of complete enlightenment. To all appearance it is an eye in form, size, color, weight, all perfect in reflection, refraction, and condensation of light, but it cannot see. What we call "vital force," "vital agency," in the animal economy, is beyond the piercing ken of physical science, and ever shall be, so long as the intellect of man is fenced in, and besmirched with the mire of this world, and its imperfect life. A great teacher (I believe Sir Everard Home), in lecturing to his class on the human stomach, says: "Some have called this organ a *retort*, some have called it a galvanic battery, and some have called it a *mill*. Gentlemen, it is none of these. It is a stomach." I know of no three lines in medical literature more suggestive of broad, comprehensive truth than these.

The operations of the stomach simulate in some degree all of these physical machineries; but, as in the case of the eye, above and beyond all these there is the vital power, so-called, which utilizes all, and without which they are but useless appendages to the human body. The machinery through which this vital force acts is of itself exceedingly complex. Most organs of the body have yielded to the anatomist and physiologist the secrets of their functional life. Others, after ages of painstaking investigation, are imperfectly understood, or not at all, to this day.

Let us be modest. Let us claim for ourselves just what is our due and no more, a place in the "republic of letters." Not a science, strictly speaking, but a department of human learning of which we may well be proud, gaining, ever gaining, in the strength and power which increased knowledge gives. The best work of the physician of to-day is to try to discover the causes of these deviations from health, make all possible efforts to remove or avoid them, and when his case is incurable, to alleviate what he cannot cure.

I had thought of saying something as to the claims of our profession upon the public. The old satire about the attorney pleading his own cause will no doubt suggest itself to you at once. But the pungent epigram loses its force, when applied to us. We have no beggar's petition to offer, and will not tax the benevolence of the "dear public" by asking gratuities. We ask the public to treat us as we try to treat disease, each one on his own merits. It is their right, and their duty, to scrutinize with the greatest care the conduct, professional and personal, of any man, presumably cultured, occupying a place of responsibility in which are wrapped up, very often, their nearest and dearest interests. It is their right and their duty to mark with the broad brand of condemnation every failure short of professional integrity and personal honor. As a profession, we have no right to demand favorable recognition at the hands of the public. Profession of angelic purity oftentimes covers from human eyes a heart and a secret life black with crime. In this great and beneficent profession of ours there are dark paths which, unhappily, do not always lack wayfarers to walk therein. But as honest practitioners of a legitimate calling, so long as we worthily represent that calling, we do not beg for, we demand, and generally get, respectful consideration.

It should not be a discouragement to the honest members of our profession, that we find in it many who are dishonest and unworthy. All professions have them; the clerical, the legal, the medical; and I have heard that there are a few bad men outside of all these. Humanity is weak, and imparts the odor of mortality to everything he touches with his foul and feeble hands. The contest between virtue and vice, in high places and low, is the business of the race, so long as it inhabits this planet. The contest is long, the progress slow, but sure. Our profession should do, and I believe is doing well its part toward the great result. Every one should add his mite, first in self-improvement and self culture to a higher plane of personal and professional position, and next to the improvement of our fellows. If we can do no more, let us put ourselves in the right, and *wait*. The great poet says:

"They also serve, who only stand and wait."

It is a maxim in political economy, that a demand for any article of commerce, good or bad, will create a supply equal to the demand. It is true of the moral as well as the political world. Create a demand in community for any species of crime, and criminals are ready at hand for their perpetration, for a "consideration."

I know of no deeper disgrace to the intelligence of the age, and the boasted Christian civilization of this nineteenth century, than the criminal disregard of human life which pervades society from top to bottom of the social scale. I do not allude to the nightly brawl over the wine-cup, or the midnight and stealthy murder for money or revenge, or the many ways in which men are done to death by knife, or bullet, or poison. These are bad enough and plentiful enough for thoughtful consideration, but not properly within the scope of this paper. The moral obliquity which ignores the responsibility of the parent for the lives of unborn children, is the most discouraging and alarming feature of this age. Unlike other crimes against God and society, it seems to grow rather than diminish with increasing intelligence and refinement. We hear a great deal of talk now-a-days about the restricted sphere of woman, the rights of woman, the little power she has, compared with what she ought to have, woman suffrage, etc. I am aware that this subject should be approached cautiously, as becomes the worldly wise, for these dear creatures, despite their own assertions to the contrary, have a mighty influence for good or evil, and they are not backward in their resentment of real or fancied injuries, and encroachments upon their rights. We will venture to suggest, very mildly and with the profoundest respect for true womanhood wherever found, that women would do well, first, to discharge the duties pertaining to the rights they already have, before demanding so loudly a more extended sphere. In the scramble for their own rights, so-called, let

them not forget the rights of their own children, which they, of all others, should be vigilant in preserving. And the first and most important of these is their right to be born. That the primary guilty party, in the production of criminal abortion, is generally the mother, cannot be successfully denied. Not always the first proponent of this measureless crime, but a consenting party to it, she is always. It is with unspeakable sorrow and regret that we are forced to the conclusion, after much observation, that she is, as a rule, guilty from first to last. The most humiliating and discouraging aspect of the case is, that this crime against God and nature is much more prevalent among the cultured and religious people of the country, than among the ignorant and depraved. As a rule, the uneducated mother, untrammelled by the bonds of fashionable life, and its dissipations, hearkening to the voice of God speaking to her through her maternal instincts, loves her offspring, and cares for it to the best of her ability. It is not held that mental culture, wealth, and high social position, are necessarily productive of the moral obliquity necessary to the commission of this great crime. Nor is the indictment against the class without exception. I do know that of these, there are very many of the best of mothers, who put first and foremost of all the duties of life the care and proper rearing of the children which God has given them, whose lives are blest each day by duties well performed to this end, who recognize in the home circle not only the widest sphere of action within the capacity of any human being, but one which secures to them the best possible field for a useful and happy life. Nevertheless, it must be conceded that to this class of people, namely, the educated, refined, religious and fashionable, a very large measure of guilt must be awarded.

While it is true that the impulse to this crime is often the offspring of ignorance of its true significance, and a plain relation of the facts is all-sufficient to convince the judgment and regulate the action of the deluded mother, I but state the facts in the experience of every physician, when I say that in an astonishing number of cases, his pleadings and demonstrations will be met by ears that hear not, and a mental vision which will not see, be the light ever so clear; and a perverted moral sensibility and recklessness frightful to behold. Reason and entreaty are thrown away upon such, and she invariably rewards her faithful medical adviser with undying hate and ceaseless persecution. She goes on in her evil way, stifling the pleadings of her own better nature, and the almost irresistible conclusions of her reason, deliberately taking upon herself a load of remorse and vain regret which will stick to her, like the shirt of Nessus, to her dying day. Reason with her as you may,

> "She is convinced against her will,
> And of the same opinion still."

This and other disgusting expedients, aimed at what is called very mildly, control of population, have already told disastrously upon the natural increase of this best class of society. It is so pronounced as to excite the alarm of thoughtful men all over the land. The bulk of our increase is from the poor and depraved classes, and from the foreign population. It is a shame to American civilization that our educated women must be outdone, in this highest of all moral duties, by their less favored sisters.

I suppose that the criminal jurisprudence of the civilized world cannot show anything more curiously absurd than the English law on this subject. Up to about ten years ago, the production of an abortion previous to the fourth month of utero-gestation, was in law merely a "*misdemeanor*," punishable by a ridiculously light fine. After that time (which they called the period of quickening), the same act was called "murder," and invoked the death penalty on proof of guilt. It may be that this absurd law, based upon imperfect physiological knowledge, had much to do with misleading all English speaking peoples as to the time when responsibility for human life begins. In the light of what we know now of the laws of life, it seems strange that any one should be misled in the matter, law or no law. Be the causes what they may, of a certainty the minds and consciences of our people are fearfully warped out of the straight in this direction. A large and steady demand for the services of the abortionist is created, and the supply to satisfy it is, of course, not lacking. It is hard, but we must admit the disgraceful fact, for it stares us in the face at every turn, that this demand is largely filled from the ranks of the educated practitioners of medicine. Is there any plea in justification, or even in palliation for such men?

Thus stands the case. He pretends to practice an honorable profession, stands well in society, perhaps well in the church. He has studied and understands the physiological principles involved. He knows that, from the instant of conception, the subject of it is just as much a human being as it ever is afterward; that it is, from that instant, as much the subject of responsibility as it ever can be, and that to interfere with the development just begun is deliberate murder, and if done or connived at by him, a sin against the clearest light and knowledge. In place of acting the part of an educator of the ignorant as to their duties, and refusing to be a copartner in their guilt, he assumes the position and function of a hired assassin for a pitiful sum of money.

It may be said by way of excuse, that many women who commit this dark crime, know not what they do. They are ignorant or thoughtless as to their true responsibility to an unborn child. But what excuse is there for the educated physician?

It is not just to arraign the medical profession as a whole, for the misdeeds of these unworthy members. From the American Medical Association down to the smallest local societies, the profession collectively has borne the strongest testimony and adopted the strongest official declarations against this crime. It must be confessed, however, that among the honest and true members of the profession there is a lack of courage in confronting this evil; a kind of moral cowardice which prevents him, for fear of losing patronage, from exercising his whole power and influence as an instructor and mentor to the ignorant and thoughtless. I do prefer to attribute a very large part of this

great crime to ignorance, rather than to out-and-out wickedness. And for this lack of information I hold the right-minded, honorable members of the medical profession largely responsible. They are the natural and proper teachers of the community on this and kindred subjects, and I honestly believe, and am sorry to believe, that they have but poorly discharged their duties.

We cannot dodge our responsibilities in this matter. We must be missionaries, devoted to the cause, until this heathenish darkness is dispelled, and this heathenish practice driven from our fair land. Above all, let us all do our best to educate the head and the heart of that fairest and most lovely of all God's creatures, the American girl, so that she may avoid this soul destroying crime against God and her own flesh and blood.

NOVEL METHODS OF TREATING DISEASES OF THE MIDDLE EAR.[1]

BY SETH S. BISHOP, M.D.,

OF CHICAGO.

ATTENDING SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY AND TO THE SOUTH SIDE FREE DISPENSARY, ETC.

In diseases of the middle ear, attended with increased and perverted secretions, the surgeon often feels the need of methods more effectual than the old ones for evacuating this cavity. Serum and mucus may be absorbed if they are not too abundant, but in frequently recurring attacks of sub-acute inflammation, such as occur in persons subject to naso-pharyngeal catarrh, nervous coryza, etc., the secretions are so profuse and attacks follow each other in such rapid succession, at certain seasons, that the middle ears contain mucus for periods of considerable length. Absorption may not occur after one attack before another supervenes. Unless these secretions can be removed, progress toward recovery is impeded, and the hearing is seriously impaired.

Instead of relying solely on the old methods of evacuation by injections into the middle ear, paracentesis of the membrana tympani and inflation, I have employed a treatment so simple that patients may practice it unaided. I have never seen such a method published, but I believe that its beneficial effects in a large class of cases entitle it to a place in aural therapeutics. This method is the reverse of the Valsalvian experiment. The patient closes the mouth and nostrils and exhausts the air in the naso-pharynx by a strong inspiratory act. This causes the ejection of the column of air and the secretions from the Eustachian tube and tympanum into the pharynx. The success of this practice becomes apparent in several ways. On evacuating the middle ear one experiences at first the subjective sound of rushing air, followed by the sensation of a movement inward of the drum head and ossicula. These sensations are accompanied with crackling sounds, comparable to fine mucous râles. After the discharge has entered the throat it may be seen on inspection with the rhinoscopic mirror, and sometimes without it, covering that portion of the wall of the pharynx corresponding to the side with the affected ear, if but one ear is diseased. When the patient clears the throat the evacuated secretions are forced into view upon the column of the fauces. Sometimes after expectorating the discharge a peculiar, disagreeable taste is left on the tongue. It has been compared to a metallic taste, when I have found a mixture of mucus and pus escaping from the tube. After removing the discharge the patient is directed to swallow, or practice the Valsalvian experiment, whereupon the air re-enters the middle ear and restores the equilibrium of atmospheric pressure on both sides of the drum head. A sense of relief from pressure, and increased hearing distance, follow. One should not inflate the middle ear too soon after practicing this method, else the tube and tympanum may not be emptied completely, and the entrance of air through the tube may force some remaining fluids back into the tympanic cavity, where they will be retained until the next treatment. That the discharge does not emanate from the nasal cavities is apparent from the rhinoscopic examination, and from the fact that it occurs when there is no concomitant naso pharyngeal catarrh, and the peculiar taste is experienced only after each evacuation of the ear. When the contents of the tympanum are of too great consistence, or too tenacious, to pass readily through the tube, we may liquefy them by injections of warm water solutions of salt or soda, so as to render their expulsion possible.

There are cases in which this method is impracticable owing to resistance in the tube. Its walls may participate in the tympanic inflammation and become so swelled as to close the passage into the middle ear, or the walls of the tube may be agglutinated together by adhesive secretions. Yet after ineffectual attempts, success has often rewarded repeated efforts, and a threatened rupture of the membrana tympani has been averted. A short, spasmodic effort may not suffice, when an inspiratory act, prolonged for the space of five or ten seconds, may succeed. If it does not, the surgeon may diminish the resistance to the passage of air through the tube by the use of astringent Eustachian bougies, or washes, when the occlusion is due to swelling of the walls. When the stoppage is attributable to the presence of secretions, the following method may be resorted to: A vulcanite syringe may be introduced into the Eustachian catheter *in situ*. Gentle traction may be exerted with the piston rod so as to suck the contents of the tube into the catheter. By this means the tympanic cavity, as well as the tube, may be emptied. The curve of the distal extremity of the catheter should be so adjusted that the axis of the beak shall correspond to that of the tube. Otherwise the part of the tube impinged upon might be drawn into the opening of the catheter, which would prevent the escape of fluids and occasion some irritation. The syringe should be easily manageable with the thumb and fingers of one hand, and the piston should fit the cylinder perfectly, to insure success. A Politzer air balloon, without a valve, may be substituted for the syringe. The air bag, exhausted by compression,

[1] Read at the Annual Meeting of the Illinois State Medical Society.

may be applied to the catheter and allowed to expand, thus causing a vacuum in the catheter, to fill which the secretions vacate the tube. After resistance in the tube has been overcome by this means the more simple method will probably succeed.

When the inflammatory process extends to the mastoid antrum and cells, and they are filling with secretions, it will be readily seen how much more rational these methods are than that of inflation. The latter practice forces the discharges in the direction of the mastoid cells, while the methods which I propose withdraw them from that locality. Indeed, when there is no concurrent mastoid disease, it need not be emphasized that the act of forcing the unhealthy secretions from the tympanum into the healthy mastoid cells is performed at the risk of inducing a grave complication. Either of the methods I propose is easily practiced, the one by the patient himself, the other by any surgeon who has had some experience in manipulating the Eustachian catheter.

The first method is also applicable to a different class of cases from those previously mentioned. It is serviceable in chronic catarrhal inflammation of the middle ear with proliferation of the mucous tissue, bands of adhesion between the tympanic walls and the ossicles, partial anchylosis in the chain of bones and retraction of the membrane. By repeatedly alternating this method with the Valsalvian or the Politzer method of inflation, the air is alternately rarefied and condensed in the middle ear. The effect of this practice is to cause, by rarefaction, a movement inward of the drum head and motion in the articulations of the ossicles with each other, and of the foot-plate of the stapes in the fenestra ovalis; and, by condensation, the reverse movement. It is evident that by this means the bands of adhesion are stretched, and perhaps divided, and stiffness of the joints is prevented or modified. I employ this treatment on the principle that motion prevents or overcomes anchylosis, as one sees demonstrated frequently in general surgery. It has an advantage over other methods in that patients are able to practice it unaided by a surgeon, and catheterism can be omitted. These are important considerations in the treatment of sensitive and fastidious or indigent patients. If they are unable to inflate the middle ear by the Valsalvian method, they can be instructed in the use of the air balloon. I have observed the hearing distance rapidly increase when no other treatment than this passive motion was employed. It is apparent that as the freedom of motion is restored in the sound-conducting apparatus it becomes possible for it to respond to sound waves, to the vibrations of which it was not before susceptible.

When this method is not successful, on account of an impermeable tube, I have resorted to another device which does not depend for its success on the condition of the Eustachian tube. I use a rubber tube of suitable calibre and length to fit into the patient's external auditory canal and extend to the mouth. By alternately rarefying and condensing the air in the external meatus he obtains the same movements in the conducting apparatus as were performed in the former experiment. To accomplish the same object I use Siegle's pneumatic otoscope. The advantage of this instrument is that the surgeon inspects the drum head during the treatment, and ascertains the degree of its mobility.

In closing, I will briefly describe one other method of treatment, which I have never known any other surgeon to use. I employ it for the purpose of applying various medicinal solutions to the walls of the external auditory meatus, tympanic cavity and Eustachian tube, without the aid of the Eustachian catheter. If the middle ear is discharging pus through the perforated membrana tympani into the external meatus, these cavities are thoroughly cleansed. Then, the patient's head being inclined to the opposite shoulder, the meatus is filled with the warm solution. The patient is then directed to exhaust the air of the middle ear by practicing the experiment I have already described. This effects the evacuation of the fluid in the external meatus through the middle ear and Eustachian tube into the nose or throat. In those cases where the Eustachian tube is patulous this is accomplished with little effort by the patient, and the tympanum and tube are thoroughly treated. In this manner I have used solutions of boracic acid, zinc sulphate, carbolic acid, mercuric bichloride, etc., with the happiest results.

719 West Adams Street.

MEDICAL PROGRESS.

A NEW MICROCOCCUS AS THE PATHOGENIC AGENT OF INFECTIOUS TUMORS; ITS RELATIONS TO PNEUMONIA.—DR. MANFREDI has recently made some researches in regard to the pathogenic agent of morbillous pneumonia in the case of two persons dead of measles complicated with pneumonia. No autopsy could be obtained, and the experiments were made with the saliva, the lachrymal secretion, and scrapings from the skin. The following is a résumé of the results obtained:

In the two cases the sputa contained constantly, and independently of the pneumococcus of Friedländer, a specific micrococcus endowed with very pronounced pathogenic properties, to which he gives the name "*micrococcus of lymphoma or progressive granuloma*," which, when inoculated on animals, gave rise to particular pulmonary lesions analogous to those of pneumonia. From the lack of necroscopic examinations and on account of the small number of cases on which the researches were based it is not yet possible to say what part this microbe plays in the pathogenesis of secondary morbillous pneumonia.

The micrococcus has an ovoid form, is often seen as a diplococcus, and measures about 0.5 μ. It develops tolerably well in all the common cultivating media, and the growth of the cultures is very rapid when air is freely furnished. On thick gelatin, on which typical cultures are obtained, the colonies are presented as discs, first thin and of a blue tint, then thicker and of a pearl gray color, with excavated borders and almost always a nacred reflex on the

surface. The growth and multiplication of this micrococcus causes a very marked rarefaction of the cultivating medium. In studying the influence of temperature and dryness on the cultures, it was found that the micrococcus develops in two distinct forms: a transitory and a more permanent.

Inoculation experiments were made on dogs, rabbits, guinea pigs, mice and birds. With the exception of the last, which succumbed to what seemed to be blood-poisoning, all the animals presented only one form of pathological manifestations, which was most clearly seen in the rabbits and guinea pigs. Of a total of 80 animals experimented upon only four were refractory and escaped fatal consequences from the inoculations. The micrococcus possesses very pronounced infectious power, which seems to be chiefly exerted upon the respiratory apparatus. This virulence is endowed with a capacity of resistance which is remarkable, persisting in the cultures for several months, and resisting successive passages through the animal organism, as was shown by series of inoculations on the animals. It resists dessication to a marked degree.

As a rule the animals died from the seventh to the twelfth day. At the autopsy there was enormous tumefaction of the parenchymatous organs, principally of the spleen and lymphatic ganglia. The tumefied organs were studied with gray or grayish-yellow nodules. Independently of the nodules the lungs contained the characteristic lesions of a more or less extensive pneumonia, even in the stage of hepatization, even when the inoculation was made in the subcutaneous cellular tissue. The nodules belonged to the class of granuloma, or infectious tumors with granulations. They usually go on to calcification, which begins at the centre; they contain the specific micrococci, and are infectious.

This new micrococcus usually leads an intracellular existence, and its pathogenic action consists in provoking caseous necrosis of the parenchyma of the cellule. More rarely they are found outside the cellular elements, and very exceptionally in the vessels. In the foci of degeneration and necrosis developed about it this micrococcus is not killed, for it can exist in a state of great rarefaction or dilution of the elements necessary for its existence.

The pathogenic action of this schizomycete is exerted principally on the lymphatic system, which represents at the same time both the port of entry of the infection and the most favorable medium for the development of the infectious agent. When the latter is inoculated into the subcutaneous cellular tissue there is formed, at the seat of the inoculation, a nodule which often grows very large, and which is made up of a plastic exudate on the way to caseation. It is in the centre of this nodule, which is the centre of a violent inflammation, that the lymphoid cells are penetrated by the micrococci, and thence transported to the lymph vessels in the vicinity. Along these vessels there are formed a series of small disseminated inflammatory nodules; and thus the whole system is infected.—*Gazette Méd. de Paris*, December 4, 1886.

Gaseous Rectal Injections in Respiratory Diseases.—M. Cornil read a communication on this subject at the meeting of the Académie de Médecine on October 19, 1886. The principles of the action of gaseous injections and their rapid elimination by the lungs, as given by Cl. Bernard, who showed that when sulphuretted hydrogen was injected into the recta of animals the gas was eliminated by the lungs; and he showed that it may be thus injected for a long time without causing accidents, while its introduction through the natural air passages causes serious results. This gas, however, is not well tolerated by the intestines. Carbonic acid gas, on the other hand, is well tolerated by the rectum and large intestine; it is rapidly absorbed, and eliminated by the lungs with the medicamentous gases which are incorporated with it.

In July M. Bergeon published the results obtained in the treatment of pulmonary phthisis by rectal injections of carbonic acid gas charged with medicamentous substances. He now gives his further results: Physicians of Lyons, Paris, Geneva, and Marseilles, who have treated phthisical patients by this method, have generally obtained the result of seeing the signs of pulmonary suppuration disappear, and the rapid downward course of the disease turned towards a state of health which promised cure. As regards the patients treated by me during the past two years, I can affirm that the results announced in July are confirmed and generalized. The phthisical patients whom I considered cured no longer have expectoration; and on auscultation there are only the dry stethoscopic signs of cavities or of cicatricial formations from old lesions. Some of these patients have to work very hard, and undergo excessive fatigue, but the improvement has been steadily maintained. The expectoration is very markedly diminished, in fact amounting to almost nothing now.

Whatever may be the action of these injections it is certain that they render hæmatosis more easy and more complete. They cause a sensation of well-being which is accompanied by an increased power. M. Bergeon gives the following directions for the use of carbonic acid gas for this purpose:

1. The gas should be as pure as possible, so as not to make a disagreeable impression on the intestine That which is obtained by the reaction of dilute sulphuric acid or bicarbonate of soda is always perfectly absorbed by the intestine without causing any disorder.

2. The gas should be collected in a receptacle previously completely freed of air; and the tubes of the apparatus should be so fixed that no air can enter the bowel, as it will cause meteorism and enteralgia.

3. The injection should be made before a meal, or three hours after. The instruments should be so made that the physician may accurately gauge the amount of gas thrown into the intestine, and the amount of pressure exerted on the intestinal walls.

Great care should be taken with regard to the medicinal substances used; turpentine, chlorine, ammonia, iodine, bromine and ether cause inflammation of the intestinal mucosa.

Dr. Chantemesse has used this method at the St. Antoine Hospital for three months, with the following results: Attacks of asthma cured by injections of carbonic acid gas charged with sulpho-carbonated vapors. In some of these cases the effect was quickly seen during an asthmatic attack. Pulmonary tuberculosis was treated with the same mixture, and with excellent results.—*Bulletin de l'Académie de Médecine*, No. 42, 1886.

TREATMENT OF PROLAPSUS ANI IN INFANTS.—DR. BETZ, of Heilbronn, relates in the *Memorabilien*, 1886, Heft 4, the case of an infant five months old which had been afflicted with prolapsus ani for five weeks. Cold water enemata, ice suppositories, dusting with pulverized alum, tannin locally and internally, opium, bromide potassium, and even injections of ergotine had been employed without benefit. The little patient was in a deplorable condition, greatly emaciated, covered with large and small boils, and intertrigo; it was incessantly straining and crying. The prolapsed bowel was a livid, conical plug, 5½ cm. in length; it was readily reduced, but pressure being removed it was shot out again by the straining of the child. Profiting by a knowledge of the treatment previously used, he at once determined to resort to nitrate of silver applications, but as the application of the stick caustic always acts unequally on the mucous membrane, and may result in ulceration, he made a solution of argent. nitr. 1.0, sulphuric ether 5.0, alcohol 25.0. This solution, though it gives rise to some smarting, can be evenly and equally applied and enters the tissues to a considerable depth. The prolapsus was thoroughly painted with the above solution, and even after a few minutes it became paler, began to shrink, and could be reduced more readily. To act on the upper portion of the mucous membrane a small piece of alum was introduced high up into the rectum. To prevent the bowel from slipping down, and to exert continued pressure on the anus, the nates were firmly pressed together and held in this condition by three broad strips of adhesive plaster, which were applied on either side, running from the anterior surface of a thigh across the seat to the opposite anterior surface of the abdomen. The next object was to stop the tenesmus and to prevent defecation, which was accomplished by keeping the child slightly under the narcotic influence of opium, and restricting its diet to small quantities of milk and water. The tenesmus stopped at once, and flatus was freely passed in twenty-four hours. The dressing was reapplied after two days. No prolapse occurred. The anus was cleansed with a wad of cotton steeped in carbolized oil, five per cent., and a piece of alum was again inserted. The anus was found drawn into folds and contracted. After three days a new dressing was necessary. The gut being slightly prolapsed, was treated with the stick caustic. Two days later the dressing was permanently removed. Stools came on without tenesmus. In order to insure contraction of the anus, he ordered it touched with alcohol for a few days. The cure was completed in eight days. Betz, though he is inclined to attribute much of the rapid success to the application of nitrate of silver, claims that the combined treatment carried out by him is entitled to the credit for the same, and would in a similar severe case not do without the adhesive dressing, the opium, the restricted diet and the alum suppository, in addition to the nitrate of silver application, while in a milder case nitrate of silver, opium and restricted diet would be sufficient for a cure. No relapse occurred.

REGENERATION OF THE SPLEEN AFTER EXTIRPATION.—A. ETERNOD reports an experimental case on a fox, four months old, from which the whole spleen was removed. It died 161 days after the operation, and the autopsy showed the following peculiarities: 1. Partial regeneration of the spleen, consisting in the new-formation of a splenic nodule, having anatomical connection entirely different from those which supernumerary spleens have under ordinary circumstances. 2. A new formation of ordinary tissue in the ganglia and Peyers's patches, in the adipose tissue of the mesentery, and even in the hepatic lobules. 3. Transformation of the ganglionic parenchyma, old and new, in the splenic parenchyma. 4. Diminution in the quantity of the blood. 5. Increase of the adipose of the mesentery. These results agree, in a general way, with those obtained by Tizzoni, Griffini, and others in experiments on the dog.—*Revue. des Sciences Méd.*, July, 1886.

TO BREAK UP A HYSTERICAL PAROXYSM.—RUAULT, of Paris (*L'Abeille Méd.*), has often employed firm and continuous compression of some superficial nerve. The supra orbital nerve is especially adapted for this purpose. The patient's head being firmly held between the hands of the physician, he places his thumbs on the inscisura supra orbitalis and makes gradually increasing pressure. The effect is said to be as follows: The patient begins to contract her facial muscles as if in pain, gives vent to short screams, makes four or five short inspirations, the thorax remains fixed in inspiration, the dorsal and nuchal muscles contract to hyperextension of the spine. Now a deep expiration takes place, the muscles relax, the paroxysm is over. The pressure may have to be repeated, as a new paroxysm may come on after a short time, and resorting to it early may intercept the attack. The sooner the paroxysm comes under treatment the more rapidly will it be broken up by the maneuvre.—*Memorabilien*, Heft 2, 1886.

NEW OPERATION FOR PROLAPSUS UTERI.—A Mexican medical journal gives an account of an operation practiced by Dr. Malanco for the purpose of forming a kind of false uterine ligament in cases of prolapsus. It consists in passing a trocar from the anterior vaginal fornix to the abdominal wall (taking care, of course, to avoid the bladder), and in applying the actual cautery to the track by means of a thermo-cautery inserted through the canula from the front. The proceeding, which was first proposed by Dr. Fenelon, of Mexico, is stated to have been employed several times with the most successful results.—*Lancet*, Nov. 20, 1886.

A NEW TREATMENT OF FEVERS.

M. ALBERT ROBIN, who so admirably combines a thorough knowledge of physiological chemistry with medical learning, has just published, in the *Gazette Médicale de Paris*, of December 25, what he calls "A New Therapeutic Method; or the Oxydizing Method in the Treatment of Fevers, and particularly of Typhoid Fever." In this communication he directly combats the accepted ideas as to the antipyretic treatment of fevers, and he does this in accordance with new grounds which are "more in accord with our knowledge of the state of nutrition in pyrexia." From the chemistry of nutrition in typhoid fever M. Robin lays down the three following propositions: 1. The elevation of febrile temperature does not depend on an increase of organic oxydations. 2. During fever there is retention in the organism of but slightly soluble waste, eliminable with difficulty, and generally toxic. 3. Organic disintegration is very much increased during fever. He now wishes to establish the *first therapeutic principle* to which the chemical study of nutrition in fever leads, and to show that so far from seeking to impede oxydations therapeutics should tend, on the contrary, to make them as active as possible, since, contrary to the classic opinion, the oxydations undergo a remarkable diminution in typhoid fever. Now perfect oxydation gives rise to soluble products, easily eliminated, and almost deprived of toxicity; while other chemical reactions give rise to only slightly soluble waste matter, which is eliminated with difficulty, and usually have considerable toxicity.

M. Robin next proposes to prove that oxidation is diminished in typhoid fever. "It has been believed, though wrongly, for a long time that the production of heat is subordinated to organic oxydation. But it it is now known that oxydation is not the exclusive source of animal heat and of febrile pyrexia; and it is also known that disassimilation is accomplished by the successive acts of which the first are hydrations and chemical combinations, which give rise to products which are only secondarily overcome by oxydation, and that animal heat results from the *ensemble* of all these reactions. And in typhoid fever, as the acts of oxydation are decreased the part played by oxydation in febrile pyrexia should be proportionally reduced. Now, in reality, the coefficient of oxydation[1] is less in typhoid fever than in the phlegmasiæ, and even less than in the normal state, since it is not above 74 per 100, while physiologically it is 85 per 100. Again, the proportion of urea is in inverse ratio to the gravity of the disease; and, thirdly, the excretion of carbonic acid of the typhoid fever patient is to that of the healthy man as 83, 8:100. It is therefore vain to attempt to restrain oxydation so as to lower temperature, since this would be assisting the disease. The aim of therapeutics in these cases should be to regulate organic disintegration, and thus to favor oxydations instead of hydrations and chemical combinations, so that the products of tissue waste, having undergone more perfect evolution, may be easily eliminated and rendered as little noxious as possible."

There are, therefore, according to M. Robin, two great therapeutic indications: 1. To eliminate from the treatment of typhoid fever all measures and medicines which retard oxydation. We must from this point of view, revise all our antipyretics. 2. The second indication is to favor, in every way possible, the organic oxydations which will diminish the formation of extractives, of ptomaïnes and leucomaïnes, and which, at the same time, attacking those products already formed, will assist in their elimination by oxydation, or in other words, will make them more soluble and less toxic. In regard to the first indication: sulphate of quinine retards disintegration without diminishing oxydation, provided it be given in small or broken doses; in large doses it lessens oxydation and the absorption of oxygen at the same time. It should therefore be given in small and broken doses. Antipyrin diminishes nitrogenous disintegration, but it at the same time diminishes still more the oxydation of disintegrated nitrogenous matters. It increases the amount of uric acid, and

[1] In excessive assimilation the quantity of urea is increased, and decreased in defective disintegration, according to Robin. To ascertain if the urea is increased it must be compared with the total quantity of urinary solids; and to express this relation he invents the term *coefficient of oxydation*.

diminishes the amount of urea; that is to say, it increases the amount of less soluble and not easily eliminated waste matters, while it lessens the vehicle which should carry them off. It increases the excretion of potash; which is to say, it demineralizes (as regards potash) the red blood globules. Other antipyretics have been tested, and will be treated of in a later communication. How is the second indication to be effected? 1. By maintaining in the air to be respired by the patient oxygen in sufficient quantity. 2. By keeping the respiratory apparatus, which is the port of entry of oxygen, in as perfect a state as possible. 3. By stimulating the nervous system, which exercises a direct influence on oxydation (cold spongings and baths increase the coefficient of oxydation, and regulate the proportion between the phosphoric acid and the urinary nitrogen, probably by the assistance of the reflex stimulation which they exert on the nervous system). 4. By choosing among the different drugs, those which cause increase of oxydation. As to the chlorine salts, while they furnish some oxygen to the system, they must be given in large doses for this purpose; and as these large doses are toxic, these salts should be rejected. The iodine and bromine salts are more easily reduced than those of chlorine, but the question of their toxic action on the red globules is not yet solved. We must therefore turn our attention to drugs which favor the absorption of oxygen or set free oxygen. Among the agents which will fulfil this indication are alcohol in small doses, common salt, the alkalies, the salts of organic acids, and the free ingestion of liquids.

As has been already said, the second therapeutic principle, derived from the chemical condition of nutrition during typhoid fever, is to favor the elimination of retained waste matters. This has already been made a special study, one of the conclusions of which is that a number of the so-called antipyretics, among which may be mentioned the salicylates, do not diminish intra-organic oxydation, but act on the temperature, and assist in eliminating in a soluble form, the slightly soluble extractives of the system. We may then speak of this new method as "the removal by solution of incompletely oxydized organic residue." The third principal, the restraining of the disassimilation which is so exaggerated in fevers, will be further studied by M. Robin.

COUNTY MEDICAL SOCIETIES.

Two weeks since we stated that the *ideal* plan of a complete and most efficient organization of the medical profession in this country, required the organization of the profession of every county or limited district of each State and Territory, into a Society with a constitution and by-laws providing for regular meetings for mutual acquaintance and professional improvement, and also for the election of one delegate for every five of their members to unite with a similar ratio of delegates from the other Societies in the same State to constitute the State Society, which should have its constitution and by-laws requiring at at least one meeting annually, at which *one* delegate for every ten of its members should be elected to unite with a similar ratio of delegates from all the other State and Territorial Societies in constituting the National representative organization of the profession of the whole country. It requires but a moment of reflection to perceive that a State Society composed of delegates thus chosen annually by the professional organization of each county or district, could not fail to represent correctly the social, scientific. and legal interests of the profession of that State; and that a National Society composed of delegates similarly chosen annually by each of the State Societies would be equally the true representative of all the interests of the profession of the nation. It is equally apparent that such a complete National professional organization would offer the greatest possible facilities for collecting and concentrating the influence of the profession for any great or important object, whether relating to the educational and scientific advancement of the profession itself, or the promotion of the sanitary interests of the whole people; and equally efficient for radiating the spirit of investigation, mutual respect, and generous emulation developed by the annual contact of the most active and enlightened minds in the National meetings, back through the State organizations to the remotest county and parish in our great Republic. It is hardly necessary to remind our readers that a representative National organization, capable of efficient work in the various directions here indicated, has for its foundation the primary organizations in each county or district. On the degree to which these can be made to include every active and intelligent regular member of the profession. and the activity with which their regular meetings are sustained, will depend, in a very great degree, both the permanency and value of the State and National Associations. It is here, in the incompleteness of the primary local organization of the profession in many parts of our country, that we trace nearly all the important defects in the practical working of our present State and National Associations. While State Medical Societies exist

in all the States, in only a very few do societies exist in all the counties or small districts, and only in a small number of the counties or districts in which societies exist, do such organizations embrace all the regular practitioners within their respective limits. Hence the most important and urgently necessary work in rendering the medical organizations of our country more complete and more permanently valuable, consists in active and persevering efforts to induce the formation of a medical society in every county containing five or more regular members of the profession, in which they can meet each other annually, semi-annually or quarterly, as they may find convenient. Here they would form each other's acquaintance, mutually increase each other's knowledge by reporting and discussing their more important cases, and their views of the local causes of such endemic diseases as they met with, and by securing the attendance of one or more of their number at the annual meetings of the State Society, where they would imbibe and bring back whatever was developed of value, whether it be new facts, improved practical methods, or increased zeal for investigation. Equally earnest efforts should be made to induce *all* the educated and reputable members of the profession to join the county or local society where one already exists. Experience has abundantly shown that no practitioner in any department of the wide domain of medicine and surgery can spend the same amount of time in any other way so profitably as in habitually attending the meetings of his professional brethren, and personally participating in their work. It softens his prejudices, multiplies his friendships, stirs his spirit of honest emulation, quickens and disciplines his thoughts, broadens the field of his mental vision, and furnishes him with abundant opportunities for making himself generally known and respected, which he could gain nowhere else. A careful study of the history of medical societies and those who have sustained them, especially in this country and Great Britain during the last half century, will demonstrate the advantages to which we have alluded as plainly as the sunlight at noonday. Why, then, do so many, especially of the younger members of the profession, stand aloof in apparently selfish isolation, while others are content to enter into social relations only with a few who are cultivating a narrow specialty—a mere half acre of the broad domain of medicine?. The answer we will try to give next week.

RESPONSIBILITY OF MEDICAL MEN IN REPORTING CONTAGIOUS DISEASES.

Many months since much interest was excited in medical circles by the prosecution of two highly esteemed physicians of New York for damages, by a lady who had been placed in the pest-house by the Health authorities on the strength of a certificate given by the physicians that she had an attack of small-pox, which she claimed was not true. It was not claimed that the physicians had intentionally or maliciously certified falsely, but simply that they had failed to make a correct diagnosis, in consequence of which she had been unjustly exposed to the atmosphere of a hospital for contagious diseases. Though the defendants showed that they had only given the certificate in obedience to the positive requirements of the law and in accordance with their best judgment; and that the Health authorities were the only parties responsible for the removal of the patient from her home, yet the trial resulted in a verdict of damages for a considerable amount. This decision of the court placed every physician in a dilemma. If, when called to a case of contagious disease in that early stage when, as is well known, the chief diagnostic symptoms are not sufficiently developed to admit of a positively correct diagnosis, the physician delays one or two days before he sends his report to the Health Department, and it proves to be a case of small-pox or scarlet fever, he renders himself liable to prosecution for not reporting it earlier; while on the other hand, if he yields a prompt obedience to the law which requires an immediate report, if he happens to err, the decision to which we have alluded makes him liable for full damages to the patient. This places every practising physician in a position so manifestly unjust, that the defendants appealed the above case to the Superior Court, which has recently reversed the decision of the lower court and set aside the judgment.

MULTIPLICATION OF MICRO-ORGANISMS.

In the *Proceedings of the Royal Society*, No. 245, 1886, Dr. Percy Frankland records some series of very interesting experiments on this subject, and shows that the pecularities of multiplication of micro-organisms have an intimate connection with the dissemination of infectious diseases. His experiments show that at the ordinary temperature of the air the micro-organisms show a decided tendency to become fewer after some time of storing; but the number of colonies is very greatly increased by exposure to an incubating temperature. In filtered river water the micro-organisms become multiplied at 20° C. with much greater rapidity than those in unfiltered water; and the organisms in deep well-water manifest but little tendency to multiply in the cold, but at 20° C.

their multiplication is in excess of anything observed with river waters.

With regard to these results Dr. Frankland says: "These tables show the enormous capacity for multiplication which is possessed by the micro-organisms present in this deep well-water. This is the more surprising, at first sight, when it is borne in mind that this water contains the merest trace of organic matter. It must, however, be remembered that this water is at the outset almost wholly free from micro-organisms, and that it has never before been inhabited by such living matters; it is only reasonable to infer, therefore, that those of its ingredients which are capable of nourishing the particular micro-organisms which flourish in it are wholly untouched, whilst in the case of the river waters the most available food-supply must have been largely explored by the generations of micro-organisms which have inhabited them."

We thus have an explanation of those cases in which infectious diseases are disseminated by well-water, examples of which, especially in the case of typhoid fever, are abundant. Dr. Frankland points out that the original source of the micro organisms should be regarded before the value of such investigations are estimated.

CHARLES JAMES FOX, M.D., of Willimantic, Conn., has been appointed Surgeon-General of the State of Connecticut, and entered upon his duties as a member of Governor Loundsbury's staff on the 7th inst. It is a deserved compliment to one of the most active and intelligent members of the profession in his State.

SEPARATING THE INCURABLE INSANE FROM RECENT CASES.—The desirability of doing this has been clearly pointed out by professional writers, and we are glad to learn that the importance of the subject received attention by Gov. Thayer, of Nebraska, in his recent inaugural address.

THE SACRAMENTO MEDICAL TIMES is the title of a new monthly journal, the first number of which will appear in March, under the editorship of James H. Parkinson, L.R.C.S., and Wallace A. Briggs, M.D., of Sacramento, Cal.

RETIREMENT OF PROFESSOR PAJOT.—Prof. Pajot, of the Paris Faculté de Médicine, recently attained his seventieth birthday, the time at which all Professors in French institutions must retire.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, December 20, 1886.

THE PRESIDENT, EDMUND J. DOERING, M.D., IN THE CHAIR.

DR. HOSMER A. JOHNSON read a paper on

PSEUDO-MEMBRANOUS BRONCHITIS.

(See p. 60.)

DR. N. S. DAVIS said: The disease which has been reported in the paper is one of rare occurrence. Having had occasion within the last two years to hunt up the literature on the subject, I found nothing more than has been stated in the paper, but I have no doubt that the disease is of more frequent occurrence than the reported cases would indicate. It is not always readily recognized, the question of diagnosis is not pursued with such closeness that the practitioner identifies it clearly, or gives it sufficient attention to recognize that it belongs to a rare form of bronchitis, and consequently the case is treated until the patient is well, or dead, and no record is made of it. In my own practice I think I have recognized at least four or five cases, and I remember some of them perfectly well, and the facts connected with them. I think the disease is more frequently met with in a chronic than in an acute form. The case that has just been detailed would come under the former class. In the majority of cases the disease attacks only a limited portion of the bronchial distribution. The cases that have been met with in an acute form, covering the greater part of the bronchial distribution, have been almost uniformly fatal.

The last case of this character that I treated was a young woman, a servant girl, who was attacked with general bronchitis. At first I supposed it was only a severe catarrhal bronchitis, but it created a cough unusually suffocating. There was but little expectoration for the first two days, subsequent to that she began to get, in the paroxysms of coughing, a little viscid, frothy mucus, and several times a day there came mingled with it well defined shreds of a membranous character. The patient belonged to a family that had marks of some specific influence of an hereditary character. In the progress of the case, during its acute stage, there were no complete casts, but shreds sometimes an inch and a half long, as though they were torn loose and thrown off. In the later stages the membranous discharges ceased and there was a suppurative condition. She expectorated a copious purulent matter as in ordinary cases of tuberculosis, but there were no cavities of the lungs, and the structure gave no evidence of having been invaded. She finally became exhausted and died. I have seen one other case that I regarded as an acute attack of this character; a child between 7 and 10 years old. That also ran an acute course, and the patient died from suffocation from the persistent obstruction. The other cases that I have seen have been of the chronic character and apparently involved

only a portion of the air passages. They would have attacks accompanied by feverishness and soreness which would go on to suffocating, violent paroxysms of cough, and in the midst of the cough would discharge more or less of the exudation. One case ended in the development of what has been called of late years fibroid phthisis. There was gradual contraction of one side of the chest, diminution of resonance, increased fremitus of voice, and purulent expectoration mingled with more or less mucus, and the patient died exhausted. The record of statistics shows that a large majority are of a partial character, involving but a limited portion of the bronchial surface, and these, though obstinate and apparently difficult to relieve, usually recover. I think that it is stated, also, that there is more than an ordinary tendency to involve ultimately the fibrous tissue of the lung and bring on that form of phthisis. If you examine the membrane under the microscope you will find in the fibrillated material some scant particles of fat granules and here and there a leucocyte, and when expectorated there is frequently an exudation of blood, but I think not often the amount reported in this case. I recollect very little, if any, blood following the expectoration of membrane in the cases I have had an opportunity of observing. Each layer of membrane tends to disintegrate, and when one has been thrown off another follows it, and this goes on, in the chronic form, indefinitely, unless there is a change of condition. In these cases, as in all true plastic exudations, there is some condition of the blood or of the vital properties that continues the existence and exudation of plastic material.

In regard to the treatment, I have nothing specially new to offer. I found that the chronic form was most benefited by ordinary anodyne expectorants combined with alteratives, especially of the mercurial class. In two instances of the chronic form the steady use of the alterative mercurial influence until there was a little swelling of the gum and a taint of the breath, then dropping it and using oxide of potassium with the more tonic class of expectorants, was followed with good results and ultimate recovery.

I remember one instance, I cannot say positively that it was of the true pseudo-membranous character, of a man whom I was called to see and who subsequently came to my office. He had an attack of the subacute character, involving apparently the whole of one bronchial distribution, which produced a very persistent and distressing cough with apparent suffocation. The man and his wife averred that in his coughing he threw off long pieces of a membranous substance several times, but as it was never saved I had no opportunity of examining it. In this case there was a well developed rheumatic diathesis, and I looked upon it as partaking somewhat of the nature of rheumatic bronchitis associated with plastic exudation. I put the man upon salicylate of sodium, dose 10 to 15 grains, accompanied at first by ordinary anodyne expectorants to help allay the severity of the cough. It acted favorably, and not only his bronchitis but his rheumatic troubles disappeared, and he made a fair recovery. The character of the cough and their description of the expectoration led me to look upon it as a case of pseudo-membranous bronchitis, and I questioned in my own mind when contemplating the subject, whether in the true plastic exudation that persistently forms, dislodges, re-forms and keeps on doing so, if the patients were put upon full doses of such remedies as salicylate of sodium or ammonium, sufficient to effect a decided change in the quality of the blood, it might not give better results than those ordinarily used.

Dr. Robert Babcock said. The paper is one of the most interesting I have listened to. It is needless for me to say, since such a man as Dr. Johnson has seen but one case, and such a man as Dr. Bowditch has never seen a case, that I have never seen one. In regard to the etiology, I would merely state that R. Douglass Powell says this form of bronchitis may be observed in all ages from childhood to old age. He differs from the author of the paper in saying that it is more frequent in females than in males. He mentions the probability that there is a hyperinotic condition of the blood. The line of treatment pursued by Dr. Johnson is interesting with regard to this point; after giving iodide of potassium and the mercurial salt in pretty full doses the character of the expectoration changed, becoming mucus and frothy, and it was not until these remedies had been given up and syrup of iron substituted that the plastic character of the bronchitis reasserted itself. May it not be that the exhibition of the potassium iodide and the mercurial salt did overcome to a certain extent the hyperinosis which may have existed in this man's case?

Dr. S. D. Jacobson: It has been my good fortune to see, besides this instance of the chronic form, which I saw through the courtesy of Dr. Johnson, one case which represented the acute form of this disease. It was a friend of mine, a man of about 47 years of age, who was accustomed to take great quantities of alcoholic stimulants. In the winter of 1871 he came to me and complained that for several days he had had some trouble with his pharynx, and he had expectorated a large amount of mucus. I inspected his pharynx and found a condition such as might be expected from a man who was out of doors a great deal, who was an inveterate smoker and a very convivial man. There were no symptoms of diphtheria; it was a case of pharyngitis or tonsillitis. Under the usual treatment it improved in a couple of days. About a week after he sent for me, and I found him with some fever and a very distressing cough. He expectorated great masses of mucus, and I recognized them as casts of bronchial tubes of the first and second order. At that time I had never heard of such a case. The next day I found him in great distress, and after a long and tiresome cough he brought up numerous quantities of matter like the first casts I had observed, which I found to be of the third and fourth order of bronchial casts, and after that he felt relieved, but died on the third day afterward. I then saw a report in the *Scandinavian Medical Archive*[1] describing a case exactly similar to mine, except that the man was 34 years of age. On

[1] Vol. iv, fasc. 4, 1872.

post-mortem it was found by incising the chest that it contained air over both lungs, and the bronchial tubes of the first, second and third order all contained casts. The lung contained air mixed with mucus and pus. The trachea contained casts which terminated on the under surface of the epiglottis. The physician questioned whether it was an ascending bronchitis or a descending fibrinous exudation from the pharynx downwards, because in this case, as in my own, there had been tonsillitis about a week before the alarming symptoms set in, but arrives at the conclusion that the disease was primary in the bronchial tubes. I have thus been fortunate enough to observe this rare disease in two cases, one representing the chronic, the other the acute form, and both of them conforming to the rule laid down by Dr. Davis, that the acute generally terminates fatally, while the chronic in many cases terminates favorably. Both of my cases were of the male sex, and both were rather given to alcoholic stimulants.

DR. E. FLETCHER INGALS said: I have had very little experience in these cases. It has never been my bad fortune to meet with a case of acute diphtheritic bronchitis except those growing out of ordinary diphtheria, which are unfortunately frequent. I have treated three cases of the chronic form of the disease, none of them very severe. In each case there was from time to time expectoration of the croupous deposit, but I did not see them at any time when they were very ill. The history of the chronic cases is that that they will have acute attacks from time to time for months or years, running from ten days to two weeks. They almost universally recover from these, though occasionally they die of phthisis. The acute cases, as a rule, die, though from 25 to 50 per cent. are said to recover. A friend in the country sent me last winter casts from a large number of the bronchial tubes. I should say there must have been five or six branches to these casts. They had been coughed up by a patient of his who subsequently recovered.

DR. C. M. FITCH said: Some eight years ago I had a case of this kind in a lady about to be confined. When I first saw her she was in an almost comatose condition, the face livid, and she was almost pulseless, the respiration fearfully obstructed, although air was entering all the larger bronchi. The woman died a few hours later, the child being born after she had become entirely unconscious. Four or five days later a child of the same family was taken with diphtheritic croup, the membrane passing down through the larynx, when Dr. Fenger performed the operation of tracheotomy. I have no doubt that lady's case was one of acute croupous bronchitis.

DR. H. A. JOHNSON, in closing the discussion, said: In reply to Dr. Babcock as to the influence of the potassium and mercurial salts upon the exudate, not only was the expectoration frothy, but after using these medicines for some time the casts became thin and evidently diminished in amount before they were thrown off. It was my opinion that the mercurial salts and the potassium had some influence in diminishing the amount of the exudate. You will remember, some time in December until February there were no casts thrown off. Some time before that the patient had been taking potassium and mercurial salts. In estimating the frequency of this disease I have excluded cases which seemed to be of diphtheritic origin. I have seen several cases where there have been well marked casts thrown off; in one case there were seven successive discharges from the bronchi ramifications of one lung. Those were diphtheritic and were from a child who was recovering from bronchial diphtheria. I do not say that this is not in its character anything like diphtheria, but I think there is a radical difference in the membrane and that which forms in diphtheria. It does not seem to me that we have the same tendency to disintegration that we have in diphtheritic forms of exudation, the exudate is more plastic. I have purposly not discussed the acute form as I have not had an opportunity to study such cases. The notes were made in the presence of the patient and they seemed to me worthy to be put on record.

DR. H. A. JOHNSON read a paper on

PNEUMATIC DIFFERENTIATION AND MEDICATION.

The question of pneumatic differentiation has been quite largly discussed by members of the medical profession during the last two or three years, but there seems still to be a good deal of mystification on the subject. I was unable to be present when the matter was brought before this society. I therefore beg permission to say a few words which I had intended to say at that time and also to exhibit a contrivance for medication by spray or vapor in condensed air. It is not my purpose to discuss the merits of pneumatic differentiation. The subject, if not the term, has been before the profession for many years, and various devices have been employed in its accomplishment. The manufacturers of pneumatic cabinets insist that the desired results can be realized only by placing a patient in a box with a tube, by means of which he breathes the air of the room, while the pressure on the surface of the body is either diminished or increased by pumping air out of the box or into it. It is claimed that the result upon the body must be quite different from that reached by the use of the Waldenburg apparatus or other similar devices, for the reason that in some way the movement of a body under the pressure of a force, we will say, of fourteen pounds against a resistance of thirteen pounds, in which the available moving force is one pound, must be quite a different process from that which is reached when the moving force is fifteen pounds and the resisting force fourteen pounds. They do not, it is true, state it in this form, but they do assert that, in case we will say of the patient breathing through a tube the external air while the air in the chamber has been partly exhausted, so that its pressure is one pound per square inch less than the outside air, a *vis a fronte* is developed, by which the fluids and gases of the body are moved in a manner quite different from that which takes place when the patient sitting in the room breathes from a tank air compressed so that the pressure of the air breathed is one pound per square inch greater than that of the air in contact with the

surface of the body. It must be evident that there is a fallacy in this claim.

We no longer use the phrase, *vis a fronte*, in the sense of an active force when we apply it to such phenomena as those which occur in the case of a vacuum filled by in-rushing matter. It is well known now that there is an active force from behind, a *vis a tergo*, which pushes into a partial vacuum sufficient matter to equalize the force, whatever it be, on the other side, or to produce an equilibrium of force. In the pneumatic cabinets there is therefore only another mechanical device for affecting the differentiation produced by the Waldenburg apparatus, and which has repeatedly been produced by breathing air from a tank into which it has been condensed by some means, such as air pumps, water pressure, etc. I am not alone in holding this opinion. Dr. Isaac Hull Platt in a paper read before the American Climatological Association at its third annual meeting, is led to conclude that the effects of breathing condensed air from the cabinet, the patient sitting in the room, are the same as those produced when the patient, placed in the cabinet and the air pressure reduced about the body, is allowed to breathe the air from the room. He says: "To put the matter beyond a doubt," that is the claim of a special value in the inclosure of the patient in the cabinet, "I have reversed the breathing tube of the cabinet, placing the patient on the outside and compressed the air within the cabinet. The effects produced upon the residual air and upon the pulse, as well as the subjective experience of the person operated upon, were found to be identical with those obtained when he was within the cabinet and the pressure reduced to the same degree."

I have made quite a number of experiments bearing upon the same question with results in no sense differing from those reached by Dr. Platt. The proposition to conduct medicated sprays into the alveoli of the lungs by the differentiation of air pressure has been also ably treated by Dr. Platt, but I do not desire to consider it in this connection. I presume all admit that to the upper air passages sprays may be applied with, in many cases, benefit. The use of sprays or vapors with condensed air is conveniently accomplished by the use of the cabinet, but this result can be and has been repeatedly reached, and just as easily, by other devices.

I have within the last twenty years resorted to several different contrivances for that purpose; an ordinary atomizing tube may be inserted through an opening in the tube from the tank, so that medicinal substances are thrown in the form of spray into the stream of condensed air inhaled. There are quite a number of ways of accomplishing this: That which I have more recently used and which I submit to the society as a sample of what may be done, consists of a glass tube (I employ an ordinary percolator such as pharmacists use) to one end of which a breathing tube is attached and to the other end through a cork the atomizing tube and also the tube from my tank of condensed air. I at one time used a double tank, or rather two tanks, with an air gauge and stop corks, so that I could maintain any required pressure in the tank from which my patient breathes. This tank may be a simple boiler such as is used in kitchens for heating water for circulation through the house, say eighty gallons or more, or it may be in any other form desired. As the pressure is never great, not more usually than one-half or at most three-fourths of a pound to the square inch, it may be made of wood. A strong, tight cask or barrel even will answer the purpose. The ordinary form of pneumatic cabinet—the New York cabinet or the Pine cabinet—may be used as a tank, but it is unnecessarily heavy and clumsy and expensive. As I have a Pine cabinet in my office, I use it as a tank, with an 8 inch air pump for compressing the air. A copper or sheet-iron tank that can be obtained of any plumber at a small fraction of the expense of the cabinet is quite as useful. Any physician who has a spray tube and glass vessel with two openings, a wolf bottle or even an ordinary wide-mouthed bottle, can provide himself with an apparatus just as useful as the pneumatic cabinet. By the use of a thin way stop-cock expiration may be made into a tank of compressed or rarefied air, or against a valve supported by a spring of any desired pressure, or through a narrowed opening, so as to regain force to expel the air from the chest. All these methods have been used to accomplish the same result, as expiration from the cabinet into outside air. The simpler the thing, provided it works, the better. The less mystery thrown around the whole subject, the better. I am quite confident that the physiological and therapeutical results obtained by the pneumatic cabinet are only such as may be reached equally well by the Waldenburg apparatus or by the still more simple means used some years since by the late Dr. Frank H. Davis, of this city. The apparatus is within the reach of anyone having a tank for condensed air for the purposing of atomizing or vaporizing medicinal substances, and requires no more skill or knowledge in its use than is required to administer narcotics, antipyretics or anæsthetics.

Dr. E. Fletcher Ingals asked Dr. Johnson if he thought the patient would get more of the medicated vapor into the lungs with the compressed air than with ordinary air.

Dr. Robert Babcock said: It has always been my opinion that pneumatic differentiation is essentially the same as the administration of compressed air, and I have not found reason to change this opinion. However, in justice to the inventor, I would like to ask Dr. Johnson what he thinks of Mr. Ketchum's assertion that the rarefication of the air around the chest of the patient by lessening atmospheric pressure allows the chest, and therefore the residual air, to expand, and with this expansion of the residual air lessens the resistance to the tidal air. In other words, that if the residual air did not expand the tidal air would meet with resistance from the residual air as from an air cushion; also, that this expansion of the residual air tends to force out any little plugs of mucus which may have obstructed the bronchials; that in this respect pneumatic differentiation certainly accomplishes more than could be done by the inhalation of compressed air.

DR. H. A. JOHNSON said: The claim of a special *value* in the cabinet as a means of differentiation is based upon a fallacy, viz., the assumption of the *vis a fronte*. If you take the pressure off from the outside of the chest there is a kind of force that drives the fluids to the surface of the body. Suppose you reverse the case, place the patient outside and let him breathe the rarefied air, is there a *vis a fronte?* It certainly seems to me that there is no such thing. It is a *vis a tergo* that pushes air into the lungs, and a *vis a tergo* that pushes the air out of the lungs, and the equilibrium is maintained. As to the effect of the rarefied air in the cabinet upon the residual air, it is about the same as going up and down in an elevator of one of our tall buildings. In answer to Dr. Ingals, it would seem to me that more spray may be carried into the bronchial tubes in the stream of condensed air than in air inhaled without differentiation of pressure. The discussion is simply upon the physiology and physics, not the value of pneumatic differentiation. Mr. Ketchum or some one connected with him, invented that term, but the thing itself, taking the name away, is by no means new.

DR. FRANKLIN H. MARTIN read a paper on

ELECTROLYSIS IN THE TREATMENT OF FIBROID TUMORS OF THE UTERUS,

with a description of Dr. Apostoli's methods.

He considered his subject under the following heads:

1. Consideration of the tumor.
2. Means of generating a current.
3. Electrodes, connections and other apparatus.
4. Electrolytic action of the current.
5. Cataphonic action of the continuous current.
6. The difference in the local action of the two poles with powerful currents.
7. Operation and details of application, with a description of Dr. Apostoli's methods.

He divided fibroid tumors of the uterus according to their position, into submucus, interstitial, and subperitoneal; according to their condition into hæmorrhagic and non-hæmorrhagic. Any means of generating a continuous uninterrupted current of electricity of 200 milliampère strength that is practicable will answer all the requirements for electrolytic treatment of fibroid tumors of the uterus. Dr. Martin uses a battery composed of 115 crow-foot gravity cells for this purpose, from which he can easily get a current of three or four hundred milliampères strength when properly charged. Storage cells and the dynamo were mentioned as possessing a future for this kind of work.

The very strong current that one now used in operations of this kind is made practicable by improvements in electrodes and conduction. Dr. Apostoli overcame the pain caused by high tension currents by using as a surface electrode a thick paste of potter's clay spread upon the abdomen with proper connections from a plate of soft metal upon its free surface. This answers the purpose perfectly, but has the objection of being very troublesome and very inelegant. Dr. Martin presented a decided innovation in this direction in the way of a surface electrode. From a soft plate of metal, the margins of which are bent so as to form a concavity upon one surface of an inch in depth, he has constructed an electrode by stretching loosely over this concavity an animal membrane, making the surface between the membrane and the metal water-tight. Through a stopper in the metal surface the inter surface is filled with a warm saturated solution of chloride of sodium. This contrivance, with its membranous surface upon the abdomen, with proper connections from the metal surface, possesses all the advantages of the potter's clay electrode of Dr. Apostoli, with none of its disagreeable features. The author has been able to use a current of 150 milliampères strength by means of the above electrode without producing the slightest discomfort. The internal electrodes include a uterine sound of platinum with the intra-vaginal portion insulated, a sharp probe of platinum and irridium with insulating sheath and a number of needles insulated with hard rubber to within an inch of the point.

The electrolytic action of the current was dwelt upon at length and given its due prominence.

The cataphonic action of the galvanic current was described, and to its action the author ascribed considerable prominence as aiding absorption of the fibroid growths.

Galvano-caustique is the name given to the local effect of the two poles when used intra-uterine in the form of metal probes. This effect is considered a great point of importance by Dr. Apostoli, and from which he expects to see a great advance developed in the treatment of the hæmorrhagic fibroid tumors of the uterus. The effect referred to is only obtained from a current of 100 milliampère strength concentrated by means of an electrode of unattachable metal. The local effect of the two poles upon the lining of the uterus are distinctly different. The effect of the positive pole is to coagulate and harden the tumor that it comes in contact with without changing the vitality of the tissue. The effect of the negative pole is to cause a liquefaction of the tissues in which it comes in contact, with considerable destruction of tissue.

The coagulating effect of the positive pole is utilized in transforming the hæmorrhagic surface of the endometrium into a dry, coagulated surface that will not allow of a hæmorrhagic exudate.

Three operations or methods of application of these powerful doses were described in detail.

1. Intra-uterine *galvano-caustic.*
2. Negative cervical galvano puncture.
3. Galvano puncture or needle operation: (a) extra-peritoneal; (b) intra-peritoneal.

The first operation (intra-uterine galvano-caustic) is employed for two effects: 1st, to check excessive hæmorrhage by the local effect of the positive pole upon the endometrium of the uterus; 2d, for the reduction in size of the tumor by the electrolytic action of the powerful current as it passes through the tissue of the tumor.

The second operation (negative cervical galvano puncture) is performed for the purpose of establishing an artificial channel into the substance of the

growth, to take the place of the cervical canal that has been distorted or obstructed to such an extent that it cannot be entered for the ordinary intra-uterine treatment. The effect sought here is the reduction of the tumor.

The third operation described by the author of the paper was the galvano puncture, or needle operation proper. This is for the treatment of large sub-peritoneal fibroids that can only be reached by means of needles, and the electrolytic action only of the current is expected.

The author offered the following summary of conclusions:

1. A means of generating a continuous current of electricity which can be increased from 10 to 250 milliampère strength is necessary in order to obtain all the effects of the electrolytic treatment of fibroid tumors of the uterus.

2. The most distressing hæmorrhages from fibroid tumors can be healed by the local coagulating effect of the positive pole if applied intra uterine.

3. The intra-uterine electrode when positive should be of unattachable metal and should conform as nearly as possible to the size and shape of the uterine canal, and have the intra vaginal portion insulated.

4. When the cervical canal cannot be entered a negative-galvano puncture should be made into the presenting part of the obstructing mass of the tumor, and an artificial channel created which is to take the place of the impenetrable uterine canal in all subsequent treatments.

5. The intra-uterine electrode should in all cases be negative, unless there is hæmorrhagia or excessive leucorrhœa, when the positive pole is required.

6. The strength of the current should be the strongest possible consistent with the desired therapeutic effect, and the toleration of the patient.

7. Cases of intolerance of high doses arrange themselves under the three following heads: 1, acute hysteria; 2, acute enteritis; 3, acute metritis, peri- or pari-metritis. The most tolerant are the deep uteri and profusely hæmorrhagic.

8. The ordinary duration of the séance should be about eight minutes.

9. The number of operations are necessarily dependent upon and influenced by the result to be accomplished. A severe hæmorrhagia can be checked in from four to five treatments, while a general reduction of the tumor necessitates many, varied, of course, according to the size and location of tumor. In many cases simply a restoration to health and a relief from the prominent and annoying symptoms must be accepted as the substitute for an actual cure.

10. The time of commencing treatment matters little if the tumor is not rapidly growing and no excessive hæmorrhage is present. The operation should be intra-menstrual, if possible, but if hæmorrhage is continuous, operate during flow.

11. Extra-uterine puncture should be regarded only as a last resort, but every means of reaching the tumor through the uterus being impracticable, seek, if possible, to make the operation extra-peritoneal; should this, in turn, prove equally undesirable, use as a final alternative the abdominal puncture.

12. Strict antiseptic precautions should be carried out in this treatment, as in all others.

Dr. H. T. Byford said: I wish to express my admiration of the mastery which Dr. Martin has acquired over this method of treatment. It will undoubtedly take an important place among the surgical remedies for uterine fibroids. But the usefulness of any remedy must be determined not only by its effect, but also by its safety and convenience of employment. For instance, the radical treatment, or removal of the tumor, is a frightfully severe measure, and is reserved for cases that cannot be cured in any other way, while removal of the appendages is attended with considerable risk of life, and is reserved for those cases which cannot be helped by less dangerous means. So also this electrolysis, which is difficult of application and capable of harm, must be reserved for cases which cannot be cured by remedies more convenient and less hazardous. But before this, the safest of surgical procedures, can become the usual treatment for such cases, it must prove more efficacious than the still safer medicinal treatment. Fibroid tumors with hæmorrhage are the ones also most benefited by ergot and tampons in the majority of cases, and after the hæmorrhage is thus relieved there is no hurry in resorting to surgery. As to the effect of this treatment on the tumor itself, the evidence is not all in. The success of Apostoli, whose persistence is very praiseworthy, has been somewhat limited with regard to the removal of the tumor. The success of the so-called electrolysis upon fibroids seems to be no better, if as good as that of ergot, and I doubt if it is produced in a very much different way. That electrolysis can break up the chemical constituents of a living tumor for any considerable distance from the electrode, without destroying the life and absorbing properties of the tissue in the course of the current, is a theorem that requires more than mere mathematical demonstration. We all believe, however, that it can stimulate the uterus to a contraction and partial strangulation of the tumor, and also stimulate the absorbents to remove it, and are prepared to have it proven to us that it will do so in many cases in which ergot fails. But it happens that the cases in which ergot is of the least use are those in which electrolysis is of most difficult application—the subperitoneal. And yet I have, as a rule, relieved the symptoms of the subperitoneal variety (excepting those immense neglected ones too large for anything but removal) by ergot, which, even when it cannot cause compression of the tumor, can diminish its blood supply. I hope and believe, however, that the methods of Apostoli will enable us to manage safely cases that must otherwise require a dangerous operation.

Dr. William T. Belfield said: Dr. Martin has conferred a favor upon us in bringing Apostoli's method before us. During the last twenty-five years various attempts have been made to reduce fibroids of the uterus by the galvanic current; yet none of them have been recognized as successful, because, doubtless, as Dr. Martin very properly says, the current has been used in an ignorant, inaccurate and bungling way. Apostoli's method is unique in the

strength of the current used, as well as in the accuracy of its application to the uterus; whether this method will produce satisfactory results remains, as I think, to be seen, for Apostoli himself has been guilty of the gross inaccuracy which necessarily impairs the confidence claimed by his statements. Through Dr. Martin's kindness I had an opportunity to read Apostoli's book in which are set forth his methods and the results of treatment on ninety-eight patients. The book bears the impress of perfect candor and truth, and yet, in looking through the ninety-eight cases which he records as fibroids of the uterus, most of which were benefited, it is evident that nearly all were not fibroids, but were cases of subinvolution. Many of them were women under 30 years of age belonging to the poorer classes, and who were unable to secure proper rest and care after confinement. The clinical history as well as the physical examination recorded by Apostoli shows that they were plain cases of subinvolution. That the electric current has a value in such cases is unquestionable and has often been demonstrated, but it is not accurate nor justifiable to apply the results obtained in treating subinvolution to the treatment of fibroids, for the distinction between subinvolution and myoma is as sharp anatomically and etiologically as it is clinically. It seemed to me that only four of Apostoli's cases were evidently and certainly uterine fibroids; it is possible that six others might be so reckoned, but certainly eighty-eight of the cases were, so far as can be judged from the record, cases of mere subinvolution. Yet the results secured in these four cases were most positive and decisive. In two of them the tumors were of enormous size. These two patients had been seen by Pean, whose opinion was sought as to the advisability of operation. In one case he declined to operate on the ground that the patient could not survive an operation; in the other he was ready to operate, but the patient declined. Yet both of these cases of undoubted and extensive myomata were rapidly and greatly improved and the tumors reduced under Apostoli's treatment. But four cases are not enough to justify a generalization, and I hope that Dr. Martin will soon favor the Society with the results of the method in his own hands, for we may be sure that he will avoid the sole error which can be charged against Apostoli.

DR. P. S. HAYES said: I have not given this matter a trial in fibroid tumors, but I have in the use of electricity generally. There are two factors in the treatment of fibroids by electrolysis—the chemical and physical and the physiological. How the physiological action of electricity operates is a question, but the chemical and physical produce their effect by the splitting up of compound molecules and the chemical and physical liberation of gases at the poles. Certainly this factor (the chemical and physical) can be measured by the amount of chemical work done which depends upon the strength of the battery, etc. It seems to me that a current even of 50 milliampère, is rather strong to use in the beginning. I have had quite an extended experience, and I can now call to mind six or eight cases in which even the slightest galvanic current would produce dizziness so that the patient would have to lie down for half an hour. I remember one case in which I used only half a dozen cells; the patient left my office staggering like a drunken woman, and finally had to go in some place and rest. Afterwards I was unable to treat her except by allowing the current to traverse a very minute portion of her body. An induction apparatus the helix of which consists of thick wires and in which the current is generated by a battery of very large surface, gives a current which resembles somewhat the interrupted galvanic current; it stands midway between the ordinary induced current and the interrupted galvanic current of eight or ten cells. This current, applied over a tumor sufficiently strong to produce vigorous contractions, will reduce the size of a fibroid when ergot has failed to do so, and apparently in the same way, by inducing forcible uterine contractions and contractions of the abdominal muscles, tending to astringe it and squeeze out the life-blood which enters into it. It seems to me, from my experience, that the injection of a few minims of 95 per cent. carbolic acid into the tumor would produce a very similar local result to that produced by either the positive or negative pole. In the *Medical Record* that I received to-day I saw an abstract of the last paper of Apostoli in which it states that, while he has reduced fibroid tumors in size, relieved the distressing symptoms and made the patient very much better, yet he does not claim that he has ever absolutely removed a fibroid so that it could not be detected. I think that this method of treatment offers a good deal of hope in many cases where other means have failed, and I should not hesitate to try it myself and recommend others to do so.

DR. FRANKLIN H. MARTIN, in closing the discussion, said: I cannot agree with Dr. Byford that this method of treating fibroid tumors should be reserved as a last resort. In careful hands it is entirely free from danger, pain, and (except in the last variety of operation described this evening) all disagreeable features, and it should not, therefore, be postponed until less efficient and more objectionable means have been employed, such as the hypodermic injection of ergot, its administration internally in large quantities, tamponing the vagina, cauterization of the uterine mucous membrane, and innumerable other less efficient means of relief. In my experience with the strong current I have never yet seen an untoward result, and I have employed currents varying in strength from 25 to 250 milliampères. Apostoli's method should especially be adopted early for the checking of hæmorrhage from the uterine cavity. I cannot agree entirely with Dr. Belfield's conclusion in regard to Dr. Apostoli's results as reported in 1884.[1] My

[1] That Dr. Belfield is in error in regard to this point will be made very apparent by the following summary of the cases reported by Dr. Apostoli and referred to by Dr. Belfield: 94 cases were reported; 15 of the cases had never borne children. Of the remaining 79 cases, where subinvolution of the uterus was possible, we find 4 pedunculated subperitoneal tumors in which error of diagnosis was not probable. Of the remaining 75 cases, 9 measured from 10 to 21 cm., and the accompanying descriptions of the cases can leave no doubt in an unprejudiced mind in regard to their being large fibroid growths. The full description in detail of the remaining 66 will convince any one who will take pains to peruse them that at least 44 are well defied fibroids. This leaves but 22 cases of the 94 reported in which there are not distinctive characteristics described, which definitely distinguishes them from simple subinvolution of the uterus.

own results have been such as to make me very sanguine in regard to the value of strong currents for the relief of these difficulties, but as the object of the paper is the discussion of the method, and not the results, I must postpone the consideration of the latter until another time. I have never seen troublesome dizziness occur in the use of these currents in treatment about the abdomen.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, December 2, 1886.

THE VICE-PRESIDENT, E. E. MONTGOMERY, M.D., IN THE CHAIR.

W. H. H. GITHENS, M.D., SECRETARY.

FIBROID TUMOR OF THE RIGHT LIGAMENT.

DR. W. CONSTANTINE GOODELL exhibited for Dr. W. Goodell the right broad ligament containing an enlarged ovary, and close by its side, but distinct from it, a fibroid tumor of the shape and size of the non-gravid womb. The left ovary was also greatly enlarged. It contained a cyst which burst into the cavity of the abdomen while the woman was being examined four days before the operation, which took place in Dr. Goodell's private hospital on June 22, and she recovered promptly. Her symptoms were painful and feeble locomotion, constant ovarian pains, menorrhagia followed by prolonged dribblings of blood, and a retroversion which could not be rectified on account of the tender and dislocated ovaries. She had been under treatment for several years, and without benefit; but since the operation she had greatly improved.

He also exhibited for Dr. W. Goodell an

INTRA-LIGAMENTOUS OVARIAN CYST,

with the following history: The girl, aged 18, had been growing large for two years, and her health also began to fail, but a tumor was not suspected until six months ago, when she was examined by Dr. Geo. H. Woods, of Pine Grove Mills, Pa. Discovering a cyst, he sent her to Dr. W. Goodell. The operation was performed on September 25, at his private hospital, and was a difficult one, because most of the cyst lay between the folds of the right broad ligament, and the rest of it was adherent at every point to intestines and abdominal wall. It was enucleated so completely that no pedicle was left to tie. He exhibited it mainly to show the greatly hypertrophied and dilated oviduct, the walls of which are very thick and were filled with pus. The left ovary being of the size of a goose's egg, was also removed. It contained pus, and also was enveloped in the broad ligament and had to be shelled out. In spite of the complications, this case recovered promptly. Dr. W. Goodell had had during the past year another case of intra-ligamentous cyst of the most formidable character. The cyst was attached to nearly the whole of the colon, to the small intestines, to the bladder, and to the whole surface of the womb, measuring five inches in length. The lower portion lay between two layers of the broad ligament, from which it was shelled out without a pedicle. The parts were so disorganized that the second ovary could not be found, nor was it possible to determine positively which ovary had been removed. But the presumption is that it was the right, because nearly the whole of the right ureter, fully ten inches of it, had to be carefully dissected off from the cyst wall and from between the layers of the broad ligament. Many ligatures were used, and very little blood was lost, but the patient died on the table from shock, while the wound was being closed. Before this death, Dr. W. Goodell had had twenty-two successive ovariotomies, all of which recovered, and he has had eight successful cases since, making in all thirty-one cases with but a single death.

DR. JOHN M. TAYLOR, upon invitation from the chair, remarked that the first case reported by Dr. Goodell had been originally under his care. He had attended her in labor and nothing abnormal occured in the puerperal period. He had examined her six weeks later, as is his custom, and found nothing wrong. Some months afterwards she had a miscarriage; there was some placental retention, and it was followed by ovarian tenderness and signs of inflammation which gradually increased, the ovaries became enlarged. Nine months after the miscarriage the operation was performed. An interesting question is, When did the tumor begin?

DR. MONTGOMERY remarked that there was a resemblance between the tumor and one horn of a uterus bicornus. Was there a distinct separation between the uterus and the tumor, or could it have been such a horn?

DR. W. C. GOODELL stated that the tumor was separated from the uterus by an inch. The tumor has greatly diminished in size since it was placed in alcohol.

DR. HOWARD A. KELLY exhibited a

PAROVARIAN CYST

weighing thirty-seven pounds. The patient, a young woman, multiparous, had noticed the tumor one year before. The character of the percussion wave and the evenness of the belly wall decided a correct diagnosis. A point of interest was the flatness of the anterior abdominal wall with more fulness in the flanks than the speaker had ever before observed in a cystic tumor. The tumor was removed through a two and a half inch incision. The fluid was viscid and yellowish. There were no adhesions. The broad pedicle was transfixed and tied, and over this a tie made embracing the whole. The wound was closed by silk-worm gut sutures, five to the inch, and the whole operation completed in thirty-six minutes.

It is two weeks to-day since the operation. The patient is sitting up in a rocking chair. She had no fever at all a pulse daily growing slower, and felt well. The cyst was one large cavity containing several cauliflower vegetations on its inner wall. The ovary lay intact on its outer wall and the tube about ten inches in length was drawn out over it.

REMOVAL OF OVARIES AND TUBES FOR SUBINVOLUTION AND CHRONIC METRITIS.

DR. KELLY considers the indications in this case so well-defined and new that he designs making it the subject of a more detailed critical communication. The patient, about 35 years of age, had raised five children, but for several years had suffered from constant soreness of the whole hypogastrium, a spot of intense burning pain to the left of the uterus, and a constant dark leucorrhœa. The menstrual congestions greatly increased her symptoms, which were again aggravated by several early abortions. She had been under excellent treatment before coming to Dr. Kelly, and had been carefully treated by him, but with only moderate, temporary improvement. Dr. Kelly then decided to stop the menstrual function, with a view to checking the periodical determination of blood to the uterus and finally bringing about complete involution of the organ. The operation was performed on the same day as that before described. The ovaries and tubes were removed through an incision two inches long. The ovaries were full of pea-sized follicles and were covered with a dense capsule, and were probably (not, however, in consequence of these appearances) diseased. The speaker insisted that the operation here had no reference whatever to any disease which might be found in the appendages, but the sole indication lay in the state of the uterus; the ovaries, whether diseased or not, were removed to correct that trouble. The recovery was as perfect and free from disturbance as any slight injury, and the patient was up in the next room on the fourteenth day, when the uterus was free from tenderness and already rapidly undergoing involation.

DR. CHAS. MEIGS WILSON considered oöphorectomy a resort of doubtful propriety as a remedy for metritis; for, as the menopause occurring physiologically would not stop such an intlammation, we would scarcely expect it to be of greater benefit when the result of an operatior.. He doubts the moral right of exposing the patient to the risks of abdominal section for such a condition.

DR. KELLY remarked that one reason for the operation for the relief of metritis was the exacerbation of all the symptoms at the menstrual period. Maternity could not again be accomplished in consequence of abortion; complete rest in bed had failed to stop them. He thinks these ovaries are diseased; ovaralgia has undoubtedly some anatomical basis, but he is not able to say how it is to be discovered; more microscopical research is needed. The history of this case excluded syphilis.

(To be concluded.)

DOMESTIC CORRESPONDENCE

RUMEX ACETOSA FOR REMOVAL OF MORBID GROWTHS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—In an adjoining county there resides a so called cancer doctress, who, like all of her class, professes to remove and cure cancers without the use of the knife. She uses a plaster which in from three to six applications will, so she claims, "kill any morbid growth and after a few hours poulticing remove it in one piece." That she does succeed in extirpating tumors there can be no doubt, but the means used by the members of the fraternity has, so far as I know, remained a secret which no reasonable amount of money would induce them to impart to the medical profession or laity. Their patients are numerous, owing to the fact that most people, seem to have an innate dread of the surgeon's knife, no matter how skilfully used; although it is far less painful than this local application. Four of my patients during the last few years have had growths removed in this manner, and when they were not of a malignant nature, have resulted successfully. Two of the most intelligent I requested to keep a sharp look-out and try to discover what it was that was used. One of them, with a sarcoma, (not benefited) felt certain that it was the juice of sheep-sorril, and procured the green plant, and after bruising it made the application to the sore twice a day, and had the satisfaction after the third day to notice the characteristic white appearance, which was the indication that its work was done, then with the poultice removed quite as much of the mass as did the quack doctress. The other one, having gone to her home to be treated, reported sheep-sorril as his discovery, having, unknown to her, found her gathering the plant in large quantities from which she extracted the juice, placing it in the sun until it had evaporated to the consistence of syrup when it was mixed with some excipient, and was ready for use.

Shortly after the reception of this information, a gentleman called to consult me about an ulcer on his nose. It had made its appearance about two years before in the form of a pimple, which in due time opened, but would never heal; a scab would form and in a few days come off, leaving an ugly looking ulcer, to be quickly covered and shed in the same manner; there was an uneasy sensation about it all the time, with, as he expressed it, "an occasional gnawing." He had tried every thing he could hear of and consulted a number of physicians without obtaining relief; it was slowly enlarging and this caused him much anxiety. I found the sore about one-sixteenth of an inch in diameter, the surrounding skin slightly indurated, the surface of the cup shaped sore very red, smooth, and filled with serum; he had been advised to consult this cancer doctress, but was undecided what to do. I told him that I was convinced that all she used was common sheep-sorril, and that if he would procure some, press out the juice saturate a piece of cotton and apply twice a day, keeping that put on in the morning in constant contact until renewed at night, until the skin around looked white and shrunken, then poultice, and he would have done all she could do and save 25 or 50 dollars. He "caught on" at once, made the application, and was gratified by the removal of a small hard lump, and the only evidence of its former presence, twelve months after, is a small depressed scar. Whether this result is due to the oxalic acid which is present in this plant I leave for others to determine;

but that the juice will cause the *painful* removal of morbid growths, and is the agent used by some, if not all cancer-quacks, I am fully convinced.

Eltinge, reports a case of epithelioma of the lip cured by the application of the inspissated juice of oxalis acetocella, (*Phil. Med. Times*, xii, 159). King, I believe, says, that it is reputed to possess the power to remove tumors and cancerous growths.

Yours truly,

AMOS SAWYER, M.D.

Hillsboro, Ill, Dec. 29, 1886.

REDUCTION OF INVERTED UTERUS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—The reading of Dr. W. W. Jaggard's interesting case of the reduction of a chronic inversion of the uterus by colpeurysis, in the last number of THE JOURNAL (Jan. 1, 1887), revived an old thought of mine, which I have had no opportunity of putting to a practical test, viz., that doubtless more certainty and promptitude as well as safety, in the reduction of inverted uteri, might be attained by the direct application to the protruding fundus and body of mere purely medicinal and dynamical, or physiological agencies, than by mere pressure or mechanical means alone, though they may be usefully combined. Thus, by the immediate application to the inverted fundus and corpus uteri of astringents and stimulants the *vis incita* and tonicity of the uterine tissues might be sufficiently increased to cause contraction, retraction, and reduction of the inverted organ more speedily and easily than by colpeurysis or mechanical measures exclusively. The most promising agents to be thus applied to the everted part are acetate of lead, common potassic alum or iron-alum, tannin, ergot, nux vomica, strychnia, hot-water douches especially, and electricity by current from fundus to sacrum or abdomen. As most of these agents are directly or indirectly active hæmostatics as well as astringents and stimulants, they are specially indicated in cases of hæmorrhages and other defluxions from the uterus. Even if not always sufficient of themselves for the reduction of the inversion, these agents could not fail to be more or less useful in connection with pressure by colpeurysis or otherwise. The same principles and remedies are efficient in relaxation, inversion, prolapsus, and paralysis of the bowels and other parts, and should be likewise effective in this similar abnormity of the uterus. Believing these agents will act effectively, in the speedy and easy reduction of inverted uteri in all degrees and stages, both acute and chronic, I present them suggestively for consideration and trial.

Respectfully,

GEO. J. ZIEGLER, M.D.

Philadelphia, 1887.

ASSOCIATION ITEMS.

THIRTY-EIGHTH ANNUAL MEETING AMERICAN MEDICAL ASSOCIATION.—*Section of Obstetrics and Diseases of Women.*—The following papers are announced for the June meeting in Chicago:

J. E. Kelly, New York, "Lithiasis in Pregnancy."

Charles Meigs Wilson, Philadelphia, "The Technique of Ovariotomy."

Hiram Corson, Plymouth Meeting, Pa., "The Treatment of Abortion."

Wm. T. Taylor, Philadelphia, "Eclampsia."

W. S. Caldwell, Freeport, Ill., "Intra-Uterine Therapeutics."

Geo. F. French, Minneapolis, Minn., "The Chief Source of Danger from the use of the Uterine Sound."

B. E. Hadra, Austin, Texas, "Hysteria and the Ovaries."

The following gentlemen have signified their intention of contributing papers, but have not yet announced the topics:

W. M. McPheeters, St. Louis, Mo.
A. McLaren, St. Paul, Minn.
John M. Keating, Philadelphia, Pa.
W. H. Wathen, Louisville, Ky.
W. H. H. Githens, Philadelphia, Pa.
Howard A. Kelly, Philadelphia, Pa.
W. P. Manton, Detroit, Mich.
A. H. Halberstadt, Pottsville, Pa.

F. M. JOHNSON, M.D., Ch'n.,
Kansas City, Mo.

W. W. JAGGARD, M.D., Sec'y,
2330 Indiana Ave., Chicago.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

THE PARIS ACADEMY PRIZES.—The Vernois prize has been awarded to M. Monod for a collection of works relating to Hygiene.

The Amussat prize of 1500 fr. has been given to Dr. Assaky for a work on "The Restoration of Sensibility by Suture of Nerves."

The accrued interest of the Morbinne Fund has been awarded to Dr. Charrin for a Report on the Epidemic of Cholera in the Department of Finistère.

The Desportes prize was not awarded, but M. Du

Castel received a recompense of 1000 fr. for a work on the treatment of Variola, and D. Moncorvo, of Rio de Janeiro, one of 500 fr. for his work on the treatment of Whooping Cough with Resorcin.

The Civrieux prize for a work on Migraine was divided between Dr. L. Thomas, of Paris, and Dr. Régeard, of Paris.

The Huguier prize was awarded to Dr. Charles Perrier for his ingenious treatment of inversion of the uterus.

The Godard prize was divided between Miss Klumpke, "Les Paralysies radiculaires du Plexus brachial," and Dr. Leon Perrin, whose paper was on "Cutaneous Sarcomatosis."

The "Prix de l'Hygiene de l'Enfance," "Relations of Syphilis and Rachitis in Early Infancy," was awarded to MM. Cazin and Iscovesco.

The Academy prize, of 1000 fr., on "Ruptures of the Urethra and their Treatment," was awarded Dr. A. J. Etienne, of Toulouse, with honorable mention of the paper of Dr. Drochon.

The Henri Buignet prize, 1500 fr., was awarded M. Lafon, of Paris, for his "Studies on Digitaline."

The Capuron prize, on the subject "The Relative Value of the Different Methods of Determining the Age of Intra-uterine Life at the Time of Birth; Its Medico-legal Applications," was awarded Dr. Bouillet, of Béziers.

The Fabret prize on the "Relations between General Paralysis and Cerebral Syphilis," is continued for 1887.

The Herpin prize, "Is there an Abortive Treatment of Confirmed Syphilis?" was awarded M. Marcel Crivelli, of Paris.

Louis prize, "Study of the Action of Mercury, Nitrate of Potash, and of Digitaline;" not awarded, but a recompense of 500 fr. given MM. Chautard and P. de Gennes, of Paris.

The Orfila prize, on "Serpent Venom," is continued for 1888.

The Portal prize, on "Exophthalmic Goitre," was awarded Dr. Liégeois, of Bainville-aux-Saules.

The Saint-Paul prize for a specific against Diphtheria; an encouragement of 1,000 fr. to Dr. Alfred Sass, of Paris.

SCHOOL HYGIENE IN AUSTRALIA.—In Australia, says the *Sanitary News*, the subject of school hygiene has received proper attention in the State schools for some years. The teachers are particularly instructed to be careful about the spread of infectious diseases, and the public health law is stringent enough to secure the exclusion of scholars and teachers from houses in which communicable diseases exist. In the State schools of Victoria, since 1879, a system of object lessons has been given with a view of imparting elementary instruction bearing upon the health of the people. These lessons generally include such subjects as food, clothing, ventilation, cleanliness, and the prevention of infectious diseases. There have also been given at stated times lessons for the treatment of snake-bite, for the resuscitation of the drowned, and for the first aid to the injured. The department of education requires some elementary knowledge on the part of teachers upon the subjects of sanitation and physiology, wisely substituting in this connection, the term sanitation for that older and less comprehensive word, hygiene.

IMPURE ICE.—The New York State Board of Health, in a report on the dangers of contaminated ice, draws the following conclusions: Ice formed in impure water has caused sickness; it may contain from 8 to 10 per cent. of the organic matter dissolved in the water, and in addition a very large amount of the organic matter that had been merely suspended or floating in it; it may contain living animals and plants ranging in size from visible worms down to the minutest spores, and the vitality of these organisms may be unaffected by freezing.

CHOLERA IN EUROPE.—The recurrence of cholera in fresh localities in Eastern and Central Europe, says the *Lancet*, is the most striking feature of the present phase of this year's epidemic. Large outbreaks are hardly to be expected in Europe at this season of the year, but it is most disquieting to learn that in certain parts of Austrian and Turkish Croatia, and in some districts of Hungary, fresh places are being attacked. The disease has also taken a fresh stride, in a south-eastern direction, Belgrade having been attacked. According to the latest intelligence, cholera broke out in one of the infantry barracks, and between the 21st and 27th of November there had been fifty cases and ten deaths. The King of Servia, on receiving the intelligence, returned to his capital and personally visited the sick; he at the same time stimulated the authorities to take ample precautions to prevent the spread of the disease. Typhus is also prevalent in Belgrade, so that there is doubtless ample room for sanitary progress.

THE LUMLEIAN LECTURES will be delivered on March 24, 29, and 31, by Dr. Priestley, on the "Pathology of Intra-uterine Death."

THE GULSTONIAN LECTURES for 1887 will be delivered on March 3, 8, and 10, by Dr. Macalister, of Cambridge, on "The Nature of Fever."

SANITARY INSPECTION OF PASSENGER CARS.—DR. R. HARVEY REED, now engaged in making an inspection of passenger cars on railways running in and through Ohio, has forwarded a copy of the blank used. Boards of Health engaged in such inspection would do well to obtain a copy.

KOCH'S RESEARCHES ON CHOLERA have been confirmed and extended by Drs. Tizzoni and Cattani, of Bologna, who have taken advantage of the recent epidemic of cholera in the north of Italy to study the subject.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 1, 1887, TO JANUARY 7, 1887.

First Lieut. H. I. Raymond, Asst. Surgeon, ordered for duty at Presidio of San Francisco, Cal. S. O. 127, Dept. Cal., Dec. 29, 1886.

ON DIABETES.

A Clinical Lecture delivered to the Students of the Western Pennsylvania Medical College, on October 29, 1886,

BY W. SNIVELY, M.D.,

PROFESSOR OF CLINICAL MEDICINE, PITTSBURGH, PA.

[REPORTED BY R. M. JONES.]

GENTLEMEN:—The case of the young man whom I present for your consideration to-day, affords us an opportunity to study a very interesting disease. I feel certain that many of you will make a correct diagnosis when I read you his clinical history. James G., æt. 25 years, laborer; married, and the father of two children, both living. Height 5 feet 4½ inches, weight 95 pounds. Family history good; father, mother, four brothers and one sister all living and in good health. Previous to eighteen months ago he had always enjoyed good health. Eighteen months ago he contracted a gonorrhœa, which lasted three months. He then weighed 150 pounds. About the same time he began to emaciate and grow weak, and he suffered from sharp pains in his body and limbs. Doctors told him that it was muscular rheumatism, and treated him for that disease, but without benefit. He continued to suffer progressive emaciation and weakness, until about three months ago, he noticed that his urine began to "dribble," wetting his clothing. About the same time it began to increase in quantity, and his thirst became enormous. He could not get enough to drink. His appetite also became proportionally increased, and he could scarcely get enough to eat. Notwithstanding the large amount of food and liquid ingested, he continued to emaciate. He also suffered from obstinate constipation. He took pills, and powders, and capsules, and salts, to physic himself, but without avail; they would not operate. The sharp pains from which he suffered have greatly diminished, but have not entirely ceased. His urine, which I show you, is highly acid; its sp. gr. is 1,030, and during the twenty-four hours ending at ten o'clock this morning he passed 273 ozs. It contains a large quantity of sugar.

You are now in possession of the clinical history of this case. What is the diagnosis? Diabetes. This young man presents *au grand complet*, the five fundamental symptoms, which by their union form the morbid complexus which we term diabetes. 1st, the presence of a notable quantity of sugar in the urine. This we call glycosuria; 2d, increase of the urinary secretion, or polyuria; 3d, increase of thirst, or polydipsia; 4th, increase of appetite, or polyphagia; 5th, emaciation, or autophagia. The four first phenomena are contemporaneous in their appearance; the fifth appears later; there is nothing definite in the period of its development.

The polyuria is the result of physical conditions, easy to comprehend. Glycosuria is not the effect of a pathological work, located in the kidneys; this primordial symptom is the direct consequence of the presence of sugar in the blood in abnormal quantity; there is glycosuria only because there is glycæmia, and this alteration of the blood holds under its immediate dependence not only the glycosuria, but all the other phenomena characteristic of diabetes. The presence of sugar in the blood increases the viscidity and the density of the liquid; in this condition, endosmotic absorption through the vascular walls becomes more active, and there is established a species of intra-vascular aqueous plethora, which is indispensable for the free circulation of the blood. Thus is produced a permanent increase of the intra-vascular pressure, and, in the kidneys, this abnormal condition translates itself by an augmentation of the excretion; this is the first cause of the polyuria. To this physical cause, another of a chemical order is added; the sugar, the elimination of which by the urine is always proportionate to the richness of the glycæmia, can pass through the renal filter only when diluted in a certain quantity of water; this superabundant water is abstracted by absorption from the peri-vascular tissues, and the polyuria is thus maintained at the degree necessary for the elimination of the sugar. This polyuria, the explanation of which has given rise to many different theories is merely the direct consequence of certain physical and chemical conditions. The first link in the pathological chain is the alteration of the blood by sugar, or glycæmia.

In order to make up for the abstraction of water to which his organism is subjected, the patient must ingest a proportionate amount of liquid; hence the polydipsia, the amount of which is always in exact relation to the polyuria. Frank, Christison, and other physicians once asserted that the amount of urine excreted exceeded the amount of liquid ingested. This could not be true, because it would be unphysiological, and it has been demonstrated as incorrect by Griesinger and other observers. This

paradoxical discordance between the amount of liquid rendered and the amount ingested, is quite exceptional and when it exists, is forcedly temporary.

The polyphagia explains itself; it results from the losses which the organism submits in materials, nitrogenous and otherwise; the analysis of the urine reveals at once the necessity and the amount, and permits us to understand the frequent modifications.

The fifth and last essential symptom of diabetes, the emaciation, or autophagia, is not less constant than the preceding, but it varies greatly as to the period of its development. The variations which the emaciation presents, in its appearance and in its rapidity, depends upon the source of the sugar lost by the patient. Take three individuals suffering from well characterized diabetes; their condition is in appearance the same, but a short time will show profound differences in the actual situation of each of these patients. You exclude sugar and starch from the diet of the first and in two or three days the glycosuria will disappear, and so long as the patient restricts himself to this rigorous regimen he has the benefit of this artificial cure.

Exclude starch and sugar from the diet of the second, and the glycosuria does not disappear; it merely diminishes, and this diminution may be quite temporary.

Put your third patient upon the same regimen and he continues to manufacture sugar as formerly.

Here, then, masked by an apparent similitude, are three conditions profoundly dissimilar. The interpretation is clear. The first patient makes the sugar which he loses out of the starchy aliments. The second, at the expense of the nitrogenous aliments. The third, at the expense of himself. What happens in regard to emaciation? The first patient does not emaciate. The second does not emaciate so long as his digestive organs can utilize the superabundant aliment which he ingests; in him polyphagia is a necessity—it maintains the nutritive equilibrium. Patients of this class can resist for months and years without emaciation, so long as the appetite and the digestion can satisfy this exaggerated activity; when the digestion and appetite fail, they emaciate rapidly. The third patient emaciates promptly and fatally, for subjected to a dietetic regimen, he makes sugar at the expense of himself. If you will permit me an alliance of words which render exactly the distinction which I have just established, I will say that the first patient has a starchy glycosuria, and that the other two have a nitrogenous glycosuria, the materials of which are furnished either by nitrogenous food or by the disintegration of their own tissues.

Here is a first point acquired, but this is not all; another condition, too often misunderstood, remains to be considered, if we wish to appreciate the signification of diabetic emaciation. So long as the excretion of urea is not increased, or so long as the increase can be imputed to polyphagia, this is not an additional cause of deterioration for the organism, the equilibrium is maintained by the integrity of the digestive functions; but when the aliments ingested fail to provide for the excess of urea lost, it necessarily follows that this urea has its source in the disintegration of the tissues; it is not only the glycosuria, it is the azoturia which weakens the patient. He lives at the expense of himself, he has autophagia. If we re-examine, from this point of view, the three classes of patients which we have established, we will find that these two causes of consumption are usually united in the same patients. Those who make their glucose but with the starchy aliments, do not present, usually, an increase of urea; they escape both causes of emaciation. But those who make their sugar with their nitrogenous aliments, necessarily draw from themselves a part of the urea which they lose, even when it is not in excess, since the vast proportion of the albuminoid materials which they ingest is viciously employed in making sugar. The precise experiments of Sidney Ringer establish clearly the reality of this autophagic consumption, in showing that the excretion of urea and of sugar continue when the patient is subjected to rigid diet. These are facts, not hypotheses, and must serve as a basis for the interpretation of the clinical differences presented by diabetes.

During the first period, the patient forms his sugar out of the starchy aliments; the nutritive aberration affects only the organic evolution of the starchy matters. Later, in the second phase of the disease, the aberration affects equally the nitrogenous matters, the patient employs the greater portion of them in forming glucose; if the polyphagia can repair the losses, the patient may remain plump, or fail but slightly; the organic budget is still in equilibrium, but it is an artificial equilibrium. In the third period, the equilibrium is broken, the patient employs his food and his own tissues to form sugar and urea in excess; the expenses exceed the receipts, and the bankruptcy of the organism is fatal.

In addition to these fundamental symptoms which we have just passed in review, diabetes presents some secondary symptoms which are subordinate to the primary. We will study them by grouping them according to the pathogenic mode; this method will have the advantage of instructing you, at the same time, of the existence and of the genesis of these phenomena.

Phenomena Dependent upon Glycæmia.—The blood cannot contain an abnormal element in notable quantity without all the liquids of the organism becoming impregnated with it. Griesinger and Semmola have demonstrated it in the perspiration. But perspiration is not often present in these patients; the skin of our patient has been persistently dry. Griesinger demonstrated a superabundance of sugar in the perspiration of patients in whom the urinary sugar had greatly diminished without corresponding amelioration in the general condition. The complementary elimination compensated for the diminution of the glycosuria; this teaches us that we must not judge the losses of our patient simply by the examination of the urine. The saliva often contains sugar, and it is to this alteration of the buccal liquid that the lesions of the gums and teeth, so frequent in these patients, have been attributed. Our patient has yet pretty sound teeth, but their preservation is perhaps due to his youth.

Impotence is another effect of glycæmia. In some cases the desires are preserved, the venereal act is possible, but it is sterile, for the spermatozoa cannot preserve their activity in a liquid containing sugar; this is sterility, not impotence, but in some patients true impotence exists, with or without anaphrodisia.

It is to the abnormal state of the blood, and to the modifications of the endosmotic exchange between the intra- and the extra-vascular liquids that we must attribute the peculiar predisposition of these patients to the cutaneous and visceral inflammations, and to gangrene. Of the superficial phlegmasias, the most frequent are furuncles and carbuncles. Some physicians, stricken with the frequency of this coincidence, have gone so far as to say that every individual attacked with furuncle or carbuncle, is necessarily the victim of glycosuria; this is erroneous; the frequency of the relation is great, the constancy is not a fact. Nevertheless, in practice we should examine the urine of every patient affected with this species of phlegmasia, and this rule is so much the more important because they are precocious accidents, and may lead to the discovery of a diabetes. The frequency of this complication is so common in Brazil that it is known to the common people, who reason invariably from carbuncle to diabetes. Our patient affirms that he has never suffered from these complications.

The most frequent of the visceral inflammations is pneumonia, which is characterized by its chronicity; often it is chronic from the beginning; besides, when it does present first in the acute form, resolution does not follow the fall of the temperature, the lesion persists and slowly submits the histological modifications proper to the regressive evolution of pulmonary hepatization. This pneumonia terminates quite frequently in gangrene, and this pulmonary gangrene, like the other visceral modifications sometimes encountered in the course of diabetes, have not the characteristic odor of common gangrene. This fact has been verified by a great number of observers.

Visceral gangrenes are not the only ones produced by diabetes; the carbuncles and furuncles of which I have spoken to you, have a marked tendency to sphacelus; in fact, so great, in this respect, is the pathogenic power of glycæmia, that we frequently observe gangrene of the inferior members, which was long considered spontaneous gangrene. The relation of these peripheric gangrenes to diabetes, is to day well known, and the knowledge of this important fact has given rise to an error, the inverse of that which was previously committed. Some observers think that senile gangrene always depends upon diabetes. This assertion is an exaggeration. I have seen, myself, two cases of gangrene of the toes without glycæmia, and these cases are not isolated. Remember the frequency of this relation, but do not believe in its invariability.

Phenomena Dependent upon Glycosuria.—The irritation resulting from the frequent miction of sugary urine is apt to cause redness of the meatus, and a pruritus sometimes insupportable; eruptions of prurigo and herpes often exist in this connection, and may become generalized. In the male, swelling of the prepuce, phimosis and balanitis are sometimes observed. None of these symptoms exist, or have previously existed in our patient; they have no signification from a prognostic standpoint but they have a very great signification for the diagnosis. When you observe these manifestations, you must always examine the urine.

Phenomena Dependent upon Polyuria.—Polydipsia, which we have already discussed, is not the only disorder dependent upon polyuria; to this cause we must refer the obstinate constipation and the dryness of the skin and mucous membranes. Our patient, as you already know, has suffered greatly from these conditions.

Phenomena Dependent upon Consumption.—Phthisis is one of the most common results of the diabetic condition; according to Griesinger, nearly one half of these patients succumb to tuberculization of the lungs. Clinically, diabetic phthisis is distinguished by the almost constant absence of hæmoptysis, by the rapidity with which excavations are formed, and the limited amount of the secretions. It is not rare to see patients with large caverns expectorate almost nothing at all. Our patient presents a striking example of this condition. Two eminent English observers, Wilks and Pavy, contend that the pulmonary caverns of these patients are due to the elimination of chronic pneumonic foci, and not to the presence of tubercles. The utilization of a large number of autopsies can alone settle this problem in pathological anatomy.

Visual troubles, as cataract, so frequent in these cases, are probably to be attributed to the consumption, or rather to the insufficiency of nutrition. Cataract occurs late in the disease, and operative treatment is rarely or never successful.

Diabetes is a condition of long duration. The reported cases in which death occurred in a few weeks are quite exceptional. Generally its progress is uniform and continuous; sometimes remissions occur, lasting a few weeks or months, which have probably been prematurely reported as definitive cures. According to Griesinger, who analyzed a total of 225 cases, the average duration of the disease is two or three years.

The diagnosis is to be based upon the discovery of sugar in the urine. This is a very simple matter when we are led to look for it; what is important is to be conducted to the presumption of the disease. The situation of the physician is the same as for Bright's disease. The affection does not reveal itself openly; it is necessary to suspect it. In order to make an early diagnosis of diabetes, you must be acquainted with the semiological value of certain phenomena which are indications sufficient to demand an immediate examination of the urine.

The polyuria, the insomnia which it produces, the increase of thirst, particularly if it coincides with that of the appetite, are symptoms the signification of which cannot be misunderstood; but there are other circumstances, less demonstrative, which are of real value; these are the pruritus, urethral or vulvar, the swelling and the eruptions of the prepuce or

of the labia, the generalized pruriginous or herpetic eruptions, the *fishy* condition of the linen and clothing. All these conditions, slight as they may appear to you, demand an examination of the urine. So with furuncles and carbuncles, you must think of diabetes and look for sugar.

But, when you have found sugar in the urine, in notable quantity, you are not justified in reporting it as a case of diabetes. Glycosuria is a symptom, and diabetes is a condition which has this for one of its symptoms; it is not constituted by this phenomenon alone. Prolonged observation may be necessary to prove the true character of a glycosuria. The glycosuria which sometimes follows cephalic traumatisms, or certain diseases of the spinal cord, are usually simple, although accompanied by polyuria and polydipsia, but this is not always so; a glycosuria of traumatic origin may become the point of departure of diabetes in an individual predisposed. The diagnosis must in every case be based upon the quantity of glucose lost, upon the other modifications of the urine, upon the constitutional symptoms, and upon the effect produced by diet.

The causes of diabetes are far from being completely elucidated; pathological anatomy has revealed no constant and characteristic lesion. Alterations of the kidneys, analogous to those of Bright's disease, are most frequent, and are probably due to excess of function, and to the irritating character of the excretion. Atrophy of the pancreas has been observed. Dilatation of the stomach with hypertrophy of the muscular coat, when it occurs, is probably due to polyphagia.

Hereditary influence must be a very unimportant factor, if we are to judge from the small number of cases adduced in support of it. I am cognizant of the case of a man, at present suffering from diabetes, whose son, a boy of 7, died a few years ago from this cause. Griesinger's analysis of 225 cases would seem to show that intermittent fever, gout, rheumatism, typhoid fever, pleurisy, scarlet fever, etc., may be probable causes. I am disposed to believe that psychical causes, and particularly worry and mental depression, may exert an exciting influence in an organism predisposed to it.

A short time ago, a young man was admitted to the Western Pennsylvania Hospital. He was suffering from diabetes, which ran a rapid course, terminating fatally in less than a year from the time of its supposed commencement. No reasonable cause could be assigned for the disease, but after his death we learned that he had been engaged to a young lady whose mother refused her consent to the marriage. He became melancholy, morbid and depressed, gave up his work, began to fail physically, and was admitted to the hospital in the condition stated. You are not to infer from this that every young man who fails to marry the object of his affections, will develop a diabetes. Our patient, as you already know, contracted a gonorrhœa about eighteen months ago; he has confessed to me that he suffered terribly, both in mind and body, from this cause, and that he was in terrible fear lest his wife should find him out; he attributes his present condition entirely to this cause. You are not to infer from this that every married man who contracts a gonorrhœa, and suffers from worry and mental depression in consequence, is going to have diabetes. In our ignorance we explain this by saying that these two individuals were *predisposed* to diabetes, and only required an exciting cause to stimulate into action the pathological work which forged the first link in the pathological chain, glycæmia. This morbid predisposition, we suppose, exists in the sympathetic nervous system. You may not consider this very valuable or practical information, but it is the best I can furnish you regarding the causation of diabetes.

I have said nothing of cephalic traumatisms, for the reason that they pertain to the etiology of glycosuria rather than of diabetes; the same remark is applicable to the ingestion of amylaceous foods in excess, to the poisons, curare and strychnia, and to chloroform.

When the famous experiments of Claude Bernard demonstrating the fact of hepatic glycosuria were given to the world, his conclusions were soon made the basis of a new theory of diabetes. But the clinic showed diabetes present with a liver perfectly healthy, and diabetes absent with livers variously diseased. You remember that at our last clinic, I tapped an ascites which was due to atrophic cirrhosis. That man has never had a symptom of diabetes. In addition to these clinical facts, the sixty-four autopsies of Griesinger show us the liver very often normal, sometimes atrophied, and very rarely congested or hypertrophied. Thus you see that pathological anatomy furnishes important evidence against the hepatic theory of diabetes. In addition, Prof. Schiff and others demonstrated the reality of the fact advanced by Pavy, that the production of sugar in the liver is a post-mortem phenomenon; that in a physiological condition, the liver does not make sugar. It fixes and contains glycogen, but the transformation of glycogen into sugar is a pathological or cadaveric phenomenon.

We now come to the most unsatisfactory part of our subject, the treatment. In the first phase of the disease, when the patient is making his sugar at the expense of the starchy foods, the treatment is to be dietetic and hygienic; benefit will be obtained by excluding the starchy, and the employment, to the greatest extent compatible with good digestion, of the nitrogenous foods. Rest, recreation and judicious bodily exercise must be enjoined also. But if he is making his sugar at the expense of the nitrogenous foods, or at the expense of his own organism, dietetic and hygienic measures will be as useless as drugs.

With the exception of pulmonary caverns, our patient presents absolutely none of the secondary symptoms which I have described to you, and you might be led to believe from this, that his case was still amenable to treatment. The absence of all these symptoms is not unusual; we are not dealing with a morbid species, but with an individual case, and, unfortunately, this particular patient is suffering from autophagia; he is making his sugar at the expense of his own organism. The prognosis is absolutely grave; nevertheless, we must not abandon him to death with-

out effort; we will submit him, as rigorously as is practicable, to a dietetic and hygienic regimen, we will endeavor with anodynes to relieve the suffering from insomnia, and we will employ the potassium bromide for this purpose. During the past two years, a preparation called *arsenite of bromine* has been highly recommended through the medical journals for its efficacy in the treatment of this disorder. It has received the endorsement of some of the leading physicians of the country; for this reason, we will give our patient the benefit of a trial of the drug, and I shall keep you advised of the progress of the case.

A word more, gentlemen, and I am done: When you go out into the world to practice your profession, you will probably write occasionally for the medical journals. Do not then, prematurely, report cases of diabetes, because if you do, you will probably report some cures, due to some peculiar method of treatment. These will likely be regarded by a majority of your readers as the result of mistakes in diagnosis, and you will be looked upon as incompetent observers. Observe your cases closely and patiently, and thoroughly investigate all the phenomena connected with them, before you decide upon giving your diagnosis, and the recommendation of a specific to the profession at large.

PARALDEHYDE AND URETHAN.[1]

BY H. B. WILLIAMS, M.D.,

ASSISTANT PHYSICIAN ARKANSAS STATE LUNATIC ASYLUM.

Every day sees a new remedy come to the front as a candidate for favor in the medical world. Some of them prove to be of value, and take their proper place in the armamentarium of the skilful, thoughtful physician. I desire to call attention to two new hypnotics which are awakening interest among neurologists more particularly, and which have been used in the State Lunatic Asylum.

The first is *paraldehyde*, a methylic ether, an exceedingly volatile liquid, somewhat resembling the compound spirit of ether of the Pharmacopœia; it has a pungent, penetrating odor, and its taste resembles that of sulphuric ether. In regard to its chemistry, method of preparation, etc., I quote from a letter of Prof. C. O. Curtman, of St. Louis, to Dr. P. O. Hooper:

"Paraldehyde is the condensation product of ordinary aldehyde and hydrochloric acid, hence $(CH_3, CHO)_3$. It is formed by adding to pure aldehyde a small amount of hydrochloric acid, when the condensation takes place with evolution of heat. (With even a small amount of sulphuric acid, the reaction occurs with explosive violence.) The product is cooled by ice till it solidifies, is then pressed to free it from acid, etc., filtered off and finally distilled. It boils at 253.7° F. It dissolves in 8.3 parts of water at 55.4° F., less in hot water. Distilling with sulphuric acid reconverts it into ordinary aldehyde."

Dujardin-Beaumetz says of it: In strychnia poisoning, delirium tremens, and uræmic convulsions, paraldehyde is superior to chloral. Cervello says: Paraldehyde affects the cerebrum, the spinal cord and the bulbus, successively abolishing the reflexes, causing anæsthesia and sleep by anæmiating the brain and cord. It is eliminated by the lungs. It is not a cardiac poison.

I may add, that in no instance have I seen interference with respiration result from its administration. At the Lunatic Asylum, we have used the drug as a hypnotic to allay excitement, and to control epileptiform seizures in one instance. The results obtained have been very gratifying. It is administered in doses of from 30 to 75 minims. I, however, usually give ʒj. A single large dose acts better than frequently repeated small doses.

In simple insomnia, in ʒj doses, it has acted for me like a charm, while in mania accompanied by great excitement, the results have been almost uniformly satisfactory. When the solution is freshly prepared and is administered without more than momentary exposure to the atmosphere, sleep, in nine out of ten cases, has been produced in from three to fifteen minutes. In the few instances in which no effect followed its ingestion, it was repeated in one hour and the desired result produced. The sleep produced is sound, refreshing, and to all appearances natural; it lasts from three to eight hours, and in my experience has never been followed by nausea, headache, anorexia, constipation, or any symptom of deranged function.

In recurrent mania attended with great excitement, restlessness, and persistent insomnia, it has seemed to me to shorten the duration of the paroxysms. In such cases it was administered nightly and sometimes had to be repeated, but in no instance has a tolerance been established. In one case of acute illness, where the patient was much emaciated, very weak, wildly delirious, and suffered from persistent insomnia which chloral failed to relieve, a single dose (ʒj) of paraldehyde produced a natural sleep of eight hours' duration, from which the patient awaked refreshed and improved. On the two succeeding nights he received the usual dose, and each time with like results. On the fourth night he slept soundly without a hypnotic of any kind, nor did he require one subsequently.

Again, in a woman, the victim of chronic mania, who was also in the last stages of pulmonary tuberculosis, paraldehyde produced sleep and quietude repeatedly and without untoward effect. I have used it but once to control the paroxysms of epilepsy. The history of that case is as follows: The patient, who has suffered from epilepsy for years, having two or three attacks weekly, suddenly had an increase in the number of paroxysms. For two days he had from one to three seizures hourly, and became totally demented. Potassium bromide in heroic doses had no influence over the seizures, while ʒj of paraldehyde caused a complete cessation in less than twenty minutes; this cessation was accompanied by a sound sleep of six hours' duration, from which the patient awakened improved in every respect

In epileptic mania in which paroxysms of epilepsy were not numerous, I have used paraldehyde for its

[1] Read before the Medical Society of Arkansas, April, 1886.

calmative and hypnotic effects, and in only one instance did failure result. In that case the patient was taking f. e. ergot and potass. bromid. for the epilepsy. In several instances, I have awakened the patient within a half hour or an hour after the ingestion of the drug, and found he would talk sensibly, but as soon as he was left undisturbed, he relapsed again into sleep.

In a case of chronic mania in a man who has a lesion of the mitral valve, compensatory hypertrophy of the heart having taken place, the paraldehyde gave most excellent results. I would state parenthetically that chloral has frequently been administered in this case without ill effects. Sometimes chloral produces a state of intoxication which forces the patient to occupy the recumbent posture, but neither allays excitement nor produces sleep. In this class of cases paraldehyde is invaluable.

The method of administering paraldehyde is important. It can be given in mucilage, syrup or whiskey, preferably in whiskey. At the Lunatic Asylum we give one part paraldehyde in three of whiskey. No difference in the action of the drug is perceptible when mucilage or syrup is used as the menstruum, instead of whiskey. Whiskey disguises the taste and in a great measure conceals the exhalation of the drug on the breath. This exhalation, when not obviated by whiskey, is almost intolerable and continues for several hours. I have noticed it twelve hours after the ingestion of the drug.

Paraldehyde must be kept in glass or rubber stoppered bottles, and must be taken as soon as poured out; otherwise disappointment will follow its use.

That paraldehyde will supersede chloral I do not believe, but that it will rank as a good reliable hypnotic, particularly where chloral and opium are contraindicated by personal idiosyncrasies, I am confident.

Another fact: paraldehyde is not an analgesic, and in insomnia due to pain is worse than useless.

Now, a few words on urethan, another hypnotic which promises to be as valuable as paraldehyde.

Urethan puriss. (NH_2, CO_2 C_2 H_5) is the ethylic ether of corbaminic acid; comes in white crystals, odorless, easily soluble in water, and has a sweetish bitter taste. Its hypnotic value has been tried in cases of rheumatism, gout, catarrh, neuralgia, skin diseases with irritation, general restlessness and sleeplessness. As a rule, the results were excellent, no unpleasant after-effects having been caused in a single instance. Urethan is an analgesic, as is shown by its action in gout, rheumatism, etc. Its action is chiefly on the cerebrum, and it has no influence on the medulla oblongata or cord. No interference with the action of the kidneys or bowels has been noticed.

The dose of the drug is 15 grs. I have used it only in insomnia of mania, and have found sleep result uniformly after the ingestion of the above-named dose. As toxic symptoms have never as yet been produced by the drug, I can tell you nothing of them, nor of the amount necessary to produce them. I have seen sleep, apparently natural, as the only result of the administration of urethan. If the promises which urethan holds out are fulfilled, it will prove an addition of very great value to our materia medica.

SHORTENING, BY OPERATION, THE BONES OF THE LIMBS IN THE TREATMENT OF INJURIES COMPLICATED WITH EXTENSIVE DESTRUCTION OF THE SOFT PARTS.

BY WILLIAM D. HAMILTON, M.D.,
OF COLUMBUS, OHIO.

In the issue of THE JOURNAL of August 14, 1886, page 176, appears an abstract from the *Gazette Médicale de Paris*, under the above title. Dr. Martel, of St. Malo, saw a patient June 2, 1885, with severe compound fracture of the leg. Anteriorly was a large wound, whose extent was due to actual destruction rather than to retraction of the skin and subjacent tissues. On February 25, 1886, he made an oblique resection of both bones of the leg. On March 25 union had occurred; April 25 consolidation was complete. August 3 two ulcerated spots remained, which soon healed. The author is only cognizant of a single case like his own: that of Karl Loebker, who, in 1884, resected the radius and ulna in continuity. My own case was reported to the Central Ohio Medical Association on the first day of last April, the patient being presented at the time for examination. I first saw her with Dr. Lewis Hoover, of Grove City.

L. S., æt. 10, was caught by the sickle of a reaper July 16, 1885. Her left leg was almost cut in two at the junction of the lower and middle third. The lower fragment was bent at right angles to the upper one. An ugly lacerated wound had been inflicted. It was irregularly rectangular in shape, the greatest length being at right angles to the axis of the limb. It was 2¼ inches broad in the continuity of the leg, and 5 inches long. It included at least two-thirds of the circumference and involved the anterior and outer aspect. The soft parts in this area were extensively destroyed to the level of the deeper posterior layer of muscles. Both bones were comminuted in their whole diameter. The periosteum was denuded from the upper fragment of the tibia for three-fourths of an inch. Nearly everything lying in front of a plane passing posterior to both bones was destroyed for 2¼ inches in the continuity of the extremity.

The wound was washed with a 1–3000 bichloride solution. To check the hæmorrhage, which was quite profuse, the divided ends of the anterior tibial artery were tied with gut. The periosteum was well retracted and a transverse, even division of the bones was made above and below the injury, and the intervening fragments were dislodged. It involved the removal of two inches of both tibia and fibula. Neat apposition was secured without wiring or suturing. Several layers of over and over gut stitching united the edges of the wound. A small opening was left in the lower angle for drainage. No tube was used. Thorough irrigation was followed by the use of iodoform gauze and other antiseptic absorbent dressings. A padded posterior splint with a bandage over-all, secured immobility. The temperature was normal, or nearly so, from the third day. There was no sloughing. On the 19th and 23d of July the dressings were changed. August 7 she sat

up and a plaster dressing was adapted. There was neither pain nor spasm during convalescence. Everything was taken off on October 19.

For several months the temperature of the limb was lowered. It had a dusky hue, its nutrition and innervation being seriously impaired. The complete division of the anterior blood vessels and nerves left everything to be done by the posterior group. When first seen, mortification seemed imminent. The operation had two things in view:

1. To prevent gangrene and save the limb by inducing prompt union throughout; the idea being to remove bone which occupied the gap, and which, being the focus of inflammation and suppuration, threatened the posterior blood and nerve supply. 2. Or to anticipate a probable long siege of periostitis, ostitis, necrosis or osteo-myelitis.

The accompanying cut shows the patient thirteen months after the injury. Both heels are on the floor, which gives a clear conception of the postural deformity. The following measurements are further explanatory of the result:

	Left. (injured)	Right.
Circumference over cicatrix	7½ in.	
Length of cicatrix	4 "	
Distance from head of fibula to outer malleolus	10¼ "	12⅛
Distance from upper ext. of fibula to internal malleolus	10⅛ "	11½
Circumference of calves	8¾ "	10⅞

Dr. Martel is to be congratulated on his good result. His operation was a *secondary* procedure; *this* was *primary*. It would not pay to try to generalize with these three cases for a text. They may be sufficient to raise a question, however, as to the propriety of exsection in certain bad cases of compound fracture.

No. 126 E. Long St., Columbus, O., Sept. 9, 1886.

LAPAROTOMY FOR REMOVAL OF MONOCYST OF OVARY.[1]

BY T. W. HURLEY, M.D.,
OF BENTONVILLE, ARK.

I saw for the first time, and examined Mrs. H. in consultation with Dr. Hartly Weems, of Rogers, in October, 1885.

Patient æt. 36, married nineteen years; no children, no abortions; physical condition fairly good; has had an abdominal tumor for very nearly two years. No cachexia. A tumor of considerable size was felt in the abdomen, reaching about six inches above the pubis, and mainly in left side. Bimanual exploration gave but little pain.

The character of the tumor was explained to the patient, and she was told that nothing short of an operation would afford any permanent relief. As the disease progressed it became more and more painful, and we were frequently importuned to operate. A puncture was spoken of, but the patient, on being told that the procedure would in all probability be only palliative, insisted on a radical operation. An operation was determined on and the patient put on preparatory treatment, mainly tonic and hygienic. Drs. Welch and Gray, of Fayetteville, were requested to meet us in consultation on January 18, 1886. After careful examination and consultation an operation—ovariotomy—was concurred in, and 10 A.M. the next day the time for the operation.

Ten o'clock A.M., January 19. The patient, seeming cheerful and in good condition, was placed upon the table, and Drs. Gray and Weems administered a mixture of chloroform and ether. The patient was one of the most difficult to bring under its influence, requiring an hour and fifteen minutes to properly anæsthetize her.

Assisted by Dr. Welch, abdominal section in the median line was made, and a large monocyst which had developed from the left ovary was exposed. The cyst was partially evacuated, drawn out as nearly as possible and cut off. There was no pedicle, and very little adhesion. The intra-abdominal wound was well constricted by silk suture with several threads, and left in the abdomen. The external wound was closed and dressed antiseptically. The toilet being completed, the patient was carefully taken from the table and placed upon the bed. The patient, at this time having returned to consciousness, did not seem to be in an unfavorable condition; but in about half an hour was observed by Dr. Welch to be in an alarming state—extreme pallor, cold surface, frequent pulse, and feeble respiration. In addition she showed a marked and unceasing restlessness, to which succeeded vomiting and painful eructations. These symptoms, with but one short respite—when the temperature rose to about 100°, and soon falling below 96°—presaging a fatal issue, which finally occurred from total collapse at 8 o'clock P.M. the 20th, about thirty hours from completion of the operation.

I think I may say now that the difficulties and

[1] Read before the State Medical Society of Arkansas, Eleventh Annual Session, April 28, 1886.

dangers in this case were largely due to the very extensive origin of the growth, there being no well-defined pedicle, and consequently a very extensive ligation of tissue. It is true that this should not ordinarily produce a disastrous result, and I have the report of a case in which a rapidly growing ovarian tumor—only having been noticed by the patient six weeks—in which the operation was prolonged from numerous adhesions and the bursting of a cyst, the pedicle broad, which was ligated *in sections* with shoemaker's thread, and yet the patient did well. I think that the very profound and almost immediately fatal shock, together with bad toleration of the anæsthetics used, the effects of which persisted to the last, were the chief factors in the fatal termination of this case.

That an operation was justifiable there can be no doubt, as the patient repeatedly solicited it, and no other procedure could have with any certainty given a hope of prolonged life. And I may say the above opinions are fully concurred in by Drs. Welch and Gray, to whom Dr. Weems and myself are under many obligations for the valuable assistance rendered in the case.

PERMANGANATE OF POTASH IN THE TREATMENT OF ECZEMA.[1]

BY W. B. LAWRENCE, M.D.,
OF BATESVILLE, ARK.

In the *Medical and Surgical Reporter*, of July 11, 1885, I read the following in regard to "Permanganate Potash Baths:"

"In June, 1879, a well-developed child, of two years of age, was brought to Dr. Hüllman *(Archiv. für Kinderheilk*, Band vi, Heft 3), covered with eczema and impetigo. He had been sent from Berlin to Halle to try the baths there, but after three weeks he was worse instead of better. He was therefore prescribed an immersion-bath of permanganate of potash of the strength of fifteen grains to a pail of water, the child to remain in it until the fluid began to turn brownish. Fourteen days afterwards he was cured. Since then Dr. Hüllman has used the remedy both in adults and in children, and mostly with good effect. He has not confined its use to eczema, but has also employed it in prurigo, intertrigo, and the desquamating stage of measles, scarlatina and varicella. When the skin is much covered with scales or scabs it should first be well brushed with soap and water. For convenience of use he keeps a concentrated solution made of hot water."

At the time I saw this short article I had under treatment a very stubborn case of chronic eczema. I say chronic, because it was of almost three months' duration. It covered nearly the entire surface of all the fingers on one hand. The patient, a married lady, and in perfect health otherwise, had a hereditary predisposition to eczema. I had about exhausted all of the remedies generally used in this disease, so far as my knowledge goes. I had prescribed the tar ointment, citrine ointment, and others, besides nitric acid, with which I have cured similar cases heretofore; and in addition to the local remedies the patient had been taking liq. pot. arsenitis, 6 to 8 drops after each meal.

Under this treatment my patient's malady did not improve in the least, but gradually grew worse. Anxious to try anything reasonable, and remembering the good effects claimed for this drug in the treatment of some forms of foul ulcers, I ordered the following:

℞ Potassii permanganas..... grs. x
Aquæ..... ℥ j

The solution to be applied freely daily with a camel's-hair brush. Under this treatment the disease entirely disappeared in about twelve days. Of course the new skin remained somewhat tender for some days. She left off the arsenic when she began the potash.

I think it was in September that I treated another case of eczema. The patient was a young lady, and in other respects her health was perfect; no hereditary tendency, so far as I was able to find out, of any form of skin disease. The disease was on the face, in the region of the mouth, in fact almost covering both lips. She had used iodine and carbolized cosmoline, but with no good effect. I ordered

Pot. permangs..... grs. v
Aquæ..... ℥ j

The solution to be applied freely daily with a camel's-hair brush. Under this treatment the patient was cured within fifteen days.

In December I saw another case. The patient, a child one year of age, a male, well developed, and with the exception of this skin disease in perfect health. The disease was situated in the external ear and extended to some little extent down on the jaw. I ordered same formula as last, to be applied in the same manner as in the two previous cases, and within a week's time the disease had entirely disappeared.

NARCEINE IN WHOOPING-COUGH.[1]

BY LLEWELLYN ELIOT, M.D.,
OF WASHINGTON, D. C.

Whooping-cough is one of the most distressing diseases of childhood, although it has been observed in adults. It seldom occurs before the sixth month of life, nor is it frequent after the eighth year. Second attacks are exceedingly rare. Barthez and Rilliet mention a case occurring on the day after birth, the mother having had the disease four weeks previously. Bouchet mentions a case infected on the second day of life, developing on the eighth. Keating records a case of a child born with the disease. Steiner has seen it between the second and third weeks.

The pathology of the disease is unsettled, but it appears to be a catarrh of the respiratory organs, combined with an affection of the respiratory nerves, rather than a pure neurosis. This unsettled pathology has led to the employment of remedies without

[1] Read before the Medical Society of the District of Columbia, December 8, 1886.

number. Among them may be mentioned hydrocyanic acid, potassium bromide, ammonium bromide, hyoscyamus, digitalis, alum, lobelia, ipecac, potassium bicarbonate, belladonna, atropine, opium, morphine, musk, sodium et aurum chloride, cocaine, tartar emetic, insufflation and inhalation of quinine. Success and failure have followed the use of each.

In the *Medical Record*, of July 17, 1886, is an editorial on the treatment of whooping cough, and among the remedies mentioned is narceine. This alkaloid was introduced as a remedy for this disease by Laborde, as far back as 1869, but the physicians of Philadelphia who employed it about ten years ago failed to obtain the results which were claimed for it. The recent visitation of the disease has afforded me a peculiar experience.

It was my intention to thoroughly test this treatment; my reasons for not doing so will be seen from what follows. On July 12, W., born July 3, showed symptoms of whooping-cough, his mother having contracted the disease five days before his birth. He was given on the 19th the following prescription, other remedies having failed to afford relief:

R. Narceine..... 0.133 gm. (gr. ij).
Aq. destillat..... 8 c.c. (℥ij).
Syr. acaciæ..... 40 c.c. (℥x). M.
Sig. Teaspoonful every three hours.

This would make the dose .0110 gm. (gr. 1/6) the minimum, but to insure safety only 1/4 of a teaspoonful was given three times a day. Following the second dose there was a decrease in the quantity of urine; the dose was then lessened to 5 drops with the following results: entire suppression of urine, great drowsiness, refusal to nurse, constipated condition of the bowels and great restlessness. The urine not being voided from 4 in the evening till 6 in the following evening, he was given .0016 gm. (1/60) podophyllin every three hours until the bowels were freely moved; 5 drops of spirits of nitre every two hours, and hot poultices to encircle the entire abdomen. This continued until 12:30, when the bowels were acted upon freely and the urine voided; at 8 he again passed urine; the nitre was then continued at four-hour intervals. The whooping-cough was not benefited in the least. Possibly, had the narceine been continued, the effect might have been different, but with such a state of affairs as here presented I could not have the hardihood to do anything which would tend to increase the unfavorable outlook.

This is one experience with narceine. The dose may have been too large, .0025 gm. (gr. 1/24), if so, the condition should have altered when it was lessened. I have no intention of doubting the results obtained by other observers, nor of questioning the reports made concerning the use of "Narceine in Whooping-cough," but I cannot refrain from making known the unfavorable result which followed at my hands. After the effects of the narceine wore away, the child did as well as one so young could be expected upon alum and syrup of wild ginger, to finally have violent convulsions and die on August 2.

510 E. St. N. W., Dec. 8, 1886.

HOSPITAL REPORTS.

MYOFIBROMA UTERI.

CLINIC OF PROF. ROKITANSKY, OF VIENNA.

[Reported by HORATIO R. BIGELOW, M.D.]

G. H., 48 years old, married fourteen years. For over one year has had the menses every fortnight, but not very abundantly. Has had four difficult labors, the last one ten years ago. Three weeks ago had a strong hæmorrhage. On the right side of the abdomen there is an ulcer. She is anæmic, small and thin. The lower half of the abdomen is vaulted out by a solid, elastic, circumscribed, movable tumor, not painful, the walls of which are flat and extending out of the pelvis. Vagina of normal length. The vaginal portion of the uterus is long and broad. The anterior lip is thickened. The posterior lip is flat and thin. Bi-lateral cervical laceration. The interior surface of the anterior lip is soft and swollen; bleeds easily. Through the anterior vaginal roof the enlarged fundus can be detected easily. Circumference around abdomen, four fingers width under navel, 80 ctm.; uterus 27 ctm.

On account of violent hæmorrhage she was at once received into the hospital, but was soon after discharged, as the bleeding stopped and as she did not wish to be operated upon. On November 18, 1885, the patient returned to the hospital. After she left the hospital the hæmorrhage returned, and was profuse for five days. Since this time the patient complains of violent pains throughout the abdomen. Examination *per vaginam* shows a soft, œdematous vaginal portion, and the tumor is more painful than formerly. The bladder is distorted toward the right side, and has a peculiar form. On the right side the probe passes easily up in a vertical direction over the anterior superior oss. il. to a level with the navel; on the left side the probe was only about 3 ctm. over the sym. pubes, and through the uterine walls could be felt in the linea alba. On November 21 the patient complained of violent pains in the right side. There was a painful spot over the ninth and tenth ribs, but she had no other signs of pleuritis.

On November 23 the pains ceased entirely, but the patient was unable to lie on the right side. Early on this morning the patient took a hip bath, then the mons veneris was shaved, and the patient had another bath. The abdominal parietes were covered with a linen cloth, moistened in a two per cent. carbolic solution, which was left *in situ* 20 hours. Temperature 37° (R), pulse 100.

On November 20 temp. 37°, pulse 105. Carbolized sitz bath.

Operation.—Chloroform. The primary incision, made with great care to avoid wounding the bladder, extended from the navel to within 3–4 ctm. of the sym. pubes. Parietal adipose 2 ctm. thick. Arteries caught with forceps. When the tumor was disclosed it was found to be smooth, and not adherent to the anterior uterine wall. The incision was found to be too short for its enucleation, so it was extended to a total length of 25 ctm. In the peritoneum was a

little ascetic fluid. As the tumor extended so deeply into the pelvis it could only be partially enucleated, the adhesions having been separated. The bladder was adherent to the tumor and was distorted, as already described. The peritoneum for about 3 ctm was separated from the floor of the bladder by the Paquelin cautery, and the bladder freed. The broad ligament was ligatured with silk in three parts, and divided between with the Paquelin. The tumor was drawn out as far as possible, and at the height of the cervix was ligatured with the elastic tubing. The anterior uterine wall was now incised in a medial line, from the fundus to the ligature, and the tumor enucleated down to the ligature. It was found that this intra-mural fibroid extended down to the anterior cervical lip. All above the ligature being removed with the knife, the upper angle of the fundus was provisionally sewed up, and the wounded edges of the uterus were seized with hæmostatic pincettes. Under the elastic ligature a Chaunenac chain was thrown, and the rest of the tumor was enucleated. Drainage *per vaginam*, by means of a thick trocar with a drainage tube drawn after it. The elastic tubing was now entirely removed, and after trying in vain to apply the chain, which tore through, a thicker and permanent elastic tubing was applied, and the uterus amputated. The stump was transfixed with two long straight needles and secured in the lower angle of the wound (extra-peritoneally). Rapid peritoneal toilette. Sublimate silk ligatures used. Duration of operation, two hours. Iodoform powder and iodoform gauze and sticking plaster were used in external dressing.

The stump was painted every day with a concentrated solution of ferr. sesquichl. A one per cent. sublimate irrigation was used in the vagina for several days. For the first few days the urine contained a considerable quantity of phenal. Vagina then packed with iodoform gauze. On the ninth day the stump was cut off with scissors, the cavity cleansed and treated with iodoform. On January 3, 1886, forty seven days after the operation, patient was discharged as cured.

MEDICAL PROGRESS.

LEPROSY.—The Hawaiian Legislature, in its determined efforts to try to control the spread of leprosy in the islands, was fortunate in securing the valuable services of DR. EDWARD ARNING for purposes of special research. He found the bacillus lepræ plentifully in all nodules and diffuse swellings of the tuberculated cases and in similar lesions of the mucous membrane of the mouth, throat, nose, rectum, and large intestine, and in the discharges from the ulcerated lesions. He recognizes a diarrhœa arising from the leprous ulceration of the bowels closely simulating a true dysentery, and thinks that the deaths usually ascribed to intercurrent pneumonia, tubercular phthisis, and dysentery should be more correctly ascribed to breaking down of leprous infiltrations of the lungs and bowels. He failed to find the bacilli in the early bright red patches of vaso-motor congestion due to nerve lesions, in the anæsthetic patches of the so called "anæsthetic cases," and in the chronic sores of necrotic parts of skin tissue and bone, but they were present in the nerves supplying the mutilated parts. There were none in the urine and none in the blood, nor could he discover by culture or otherwise the existence of any spores in the latter fluid. All attempts to obtain an independent and pure growth of the bacillus lepræ failed, nor were inoculations of animals of various ages in different parts of the body succeeded by a general infection. Arning inoculated a condemned criminal, but fourteen months later no definite results had followed, though a few bacilli could still be detected in the scar. Lastly, he demonstrated a vitality persisting over several months of the bacillus lepræ in putrefying tissues. On the clinical side, researches in electro diagnosis convinced him that the anæsthesia and paralysis are due to leprous disease of peripheral nerves, but he does not regard the muscular crippling as so characteristic of the disease as the bone affections. Coming to therapeutics, we notice that Arning administered iodide of potassium without any good effect, also hyposulphite of soda, creasote, carbolic acid, and arsenious acid; and with some good effect salicylic acid and hypodermic injections of corrosive sublimate. He observed the efficiency of electrical treatment in anæsthetic cases, and insists on the value of salicylic acid in a 10 per cent. paste or ointment or solution in oleic acid, and also of pyrogallic acid in a 10 per cent. ointment or strong solution in traumaticine. Arning declares that, for one reason or another, he found it impossible to obtain from questioning the natives reliable statistics on which to base proofs for the hereditary or congenital transmission of leprosy; but we note from other reports that amongst the cases of advanced leprosy at Molokai sterility is almost universal, and the majority of the offspring, where either one or both parents are diseased, have been still-born or have died within a short period after birth, and of those who have survived many have not yet developed leprosy. No congenital cases have been observed, but Arning saw two well-marked lepers aged respectively 3½ and 4 years. Dr. Mouritz points out that, whilst it is perfectly true that healthy people may live with tuberculated lepers for years without contracting the disease, many on the other hand do not escape, and he especially refers to the remarkable percentage of the non-leprous assistants, or kokuas, on the settlement who contract the disease. Of 178 kokuas, 17 developed leprosy between February 1885 and 1886.—*Lancet*, Dec. 4, 1886.

SARCOMA AND CARCINOMA OF THE BREAST.—In a lecture on this subject TILLAUX gives the following as the differential diagnosis between these affections:

The course of sarcoma is much more slow than that of carcinoma, and may extend over twenty-five years.

Confirmed sarcoma is uneven and rough, and the indentations are larger than those of carcinoma. Sarcoma is not adherent to the thorax, while carci-

noma is. Sarcoma may attain an enormous size—as much as 12 or 15 pounds.

In carcinoma the skin rapidly becomes adherent (orange skin); adhesion is late in sarcoma.

There is retraction of the skin in carcinoma (*peau capitonnée*); in sarcoma the skin is distended.

The skin in sarcoma is glistening, shiny and purplish; in carcinoma there are white and lactescent lines.

In carcinoma the nipple is markedly retracted; in sarcoma it stands out so that its form is easily made out by running the hand over the skin.

Both diseases tend to ulceration: in carcinoma the skin melts away; the edges of the ulcer are hard and continuous with the wound. In sarcoma, on the contrary, it recedes from the distension exerted on the inner face by the sarcomatous nodules; the borders are thin, soft and free. The ulceration of carcinoma may be compared to that of hard chancre, and that of sarcoma to that of chancroid.

In carcinoma the consistence is firm, and often hard and sensibly uniform. In sarcoma it is less firm; and there may be soft spots due to cysts.

Carcinoma fuses rapidly with the mammary gland; sarcoma always remains distinct.

Carcinoma quickly adheres to the subjacent tissues, particularly to the pectoralis major muscle; sarcoma glides over the subjacent tissues almost to the end of the disease.

The lymphatic system is invaded almost at the beginning of carcinoma; Sarcoma almost never attacks the lymphatics.

Carcinoma returns much more fatally than sarcoma; it returns at a distance from the original seat; sarcoma returns in the same place.

In carcinoma cachexia is rapid; sarcoma almost always remains localized.

Carcinoma is painful; sarcoma is indolent.

In operating in either case cut around the tumor into sound tissue, and try to obtain immediate union. *Gazette de Gynécologie*, October 15, 1886.

Urea and its Relation to Certain Morbid Conditions.—The question whether urea is furnished equally by all the albuminous constituents of the body, or whether it only represents the decomposition of one particular tissue or organ, has long been a puzzle to physiologists. The exclusive view, however, which regarded urea as derived only from one source, such as from the excess of nitrogenous food taken into the system but not employed, or from disintegration of muscular tissue, or from nitrogenous metabolism taking place in the liver, have given place to wider ones, and most physiologists are now disposed to admit that the sum total of urea eliminated in the twenty-four hours is derived from many sources. Such a belief would enable us to account for many anomalous circumstances attending on urea excretion in disease. Among the many possible sources of urea formation, Dr. Noel Paton (*Journal of Anatomy and Physiology*), has recently drawn attention to the destruction of blood-corpuscles in the liver, under the agency of certain hæmolytic agents, as leading to the increased discharge of urea and urinary pigment. Indeed, these researches have led Dr. Locke, in the *Practitioner* of September, 1886, to explain the diuretic action of mercury as exhibted by the action of the preparation known as "Guy's" pill. Dr. Oliver, of Newcastle-on-Tyne, has recently considered the subject from its clinical side, and has arrived at she same conclusion that Dr. Noel Paton has from the experimental—viz., that the destruction of blood-corpuscles forms an important source of urea; and he has shown that in diseased conditions in which chronic anæmia was present the daily discharge of urea was small, but that where the anæmia was quickly progressive the disappearance of blood-cells was always followed by a marked rise in the daily discharge of urea. Also in a paper on "Functional Albuminuria" communicated to the *Lancet*, Oct. 23, 1886, Dr. Ralfe observes that the albuminous element of the blood-corpuscles brought to the liver under ordinary circumstances, no doubt undergoes transformation into urea; but that when the destruction is considerable, and the process takes place suddenly, probably, whilst there is a decided increase in the formation of urea, a large proportion of this effete albumen is at once got rid of by the kidneys, giving rise to what is known as functional albuminuria. In a more severe form, however, the number of blood-corpuscles destroyed is so great that the conversion of all the effete hæmoglobin into bilirubin cannot be effected, so that a portion of the undestroyed hæmoglobin appears in the urine. In this manner Dr. Ralfe explains the relationship that exists between certain forms of albuminuria and hæmoglobinuria, and the increase of urea elimination that occurs in them. As we have already stated, the belief in the multiple sources of urea enables us to explain many anomalous circumstances attending urea excretion in disease. Thus, for instance, in phthisis with rapid wasting of tissue we should naturally expect a considerable increase of urea elimination if urea were solely derived from tissue metabolism, but no such increase can be definitely established, even when high temperature exists; and Dr. Oliver has shown, from the observation of numerous cases, that when the ureal excretion in phthisis is augmented it is always accompanied by distinct evidence of the increase of the anæmia.—*Lancet*, Dec. 4, 1886.

Reducing Dislocations of the Fingers.—Dr. J. W. Macfarlane, of Philadelphia, says: While demonstrating to a class on minor surgery the appliances used to reduce dislocations of the fingers, some difficulty was experienced in keeping Levis's instrument in position, even with a wet bandage applied to the part. Having of late been obliged to wear some of the gum finger-stalls of the shops, to avoid poisoning in a cut, and recognizing how they adhered when once in position, the idea suggested itself that one of these would be an excellent covering for the finger, over which Levis's instrument or a clove-hitch could be secured if desired.

A close fitting gum finger-stall was then applied, and, upon grasping with the right hand the finger so covered, we found that we had such a power and perfect control that further appliances were unneces-

sary—slipping being out of the question with a finger so covered, especially if the operator's hand is warm.

This simple suggestion may, perhaps, not have the merit of originality, although I have never come across it before; but it seems to me that much more accurate and judicious traction can be made when the dislocated finger is in the firm grasp of the fingers of the right hand, while the thumb of the right and the whole of the left hand are free to manipulate with, than in the customary method of procedure. Or, if desired, the gum finger-stall can be used as a fixation-point for Levis's instrument or the application of a clove-hitch.—*Philadelphia Medical Times*, Jan. 8, 1886.

TREATMENT OF CONSTIPATION WITH UTERINE DISEASE.—The *Gazette de Gynécologie*, of Oct. 15, 1886, gives the following as useful formulæ for the treatment of constipation associated with uterine disease:

In cases of intestinal paresis, with faulty secretion of the intestinal mucosa:

Extract of physostigma.....	
Extract of belladonna.....	
Extract of nux vomica.....aa	30 centig.

Make 12 pills, one to be taken on rising from bed.

In cases of hæmorrhoids the constipation may be advantageously treated by administering 10 to 30 grm. of the following:

Sulphur, washed and sublimed.....	50 grm.
Pulverized senna.....	20 "
Essence of citron.....	0.30 centig.
Simple Syrup.....	Q.S.

M. Huchard frequently uses the following:

English magnesia.....	25 grm.
Cream of tartar.....	13 "
Bicarb. soda.....	2 "
Oleo-saccharate of anise.....	1 "

Make 40 powders. One at the beginning of each meal.

Podophyllin.....	
Extract of hyoscyamus.....	
Medicinal soap.....aa	30 centig.

Make 10 pills. One or two at bed time.

Tincture of rhubarb.....	10 grm.
Tincture of nux vomica.....	6 grm.
Tincture of badian (Illicium anisatum)..	4 grm.

Ten drops in a little water 5 or 10 minutes before meals.

Cascara sagrada may be used either in the form of the powder or the tincture. Should it cause colic it may be administered by the following formula:

Powder of cascara.....	0.25 centig.
Extract of belladonna.....	0.01 "
Powder of lycopodium.....	0.10 "

In any case treatment should be continued for several weeks, or until the desired result is obtained.

HYDRASTIS CANADENSIS.—DR. WOLTERING, of Münster, confirms, in a paper published in the *Allgemeine Medicinische Central Zeitung*, No. 47, 1886, the favorable results obtained with hydrastis canadensis by Fellner and other therapeutists of note.

The styptic virtues of the drug, especially in uterine fibromyomata, are very pronounced. Thus, Woltering saw cessation of the hæmorrhages in three cases of fibromyoma with a uterus-length of 9 and 8 ctm. In one of the cases the uterus-length had at the end of one year decreased 2 ctm. True, besides the drug, the patient had had the benefit of long-continued self-tamponage and warm washes. The remedy was ordered in pill form on account of its unpleasant taste. Ten grammes of the fluid extract can conveniently be evaporated down to about three grammes of a dry extract, furnishing an excellent pill mass. Woltering orders usually as follows:

℞ Extr. hydras. canad. sicci.....	6.00.
(To be prepared from fluid extr.....	20.00).
Extr. secal. corn.,	
Ferri. redacti,.....aa	3.00. M.

F. fil., No. 120.

S.—Two to 5 pills every three to four hours.

Of course morphine, aloes, or any other indicated remedy could be incorporated with this styptic. The above pills are taken readily and well borne, especially when taken during or after the meal. Woltering claims that neither wine, aromatics, nor liquorice cover the taste of hydrastis canadensis sufficiently.

In simple hæmorrhagic endometritis the remedy renders also excellent service. In profuse bleeding from the lungs and stomach, however, a teaspoonful of oil of turpentine appears to be preferable.—*Therapeutic Gazette*, December 15, 1886.

LANOLIN MERCURIAL OINTMENT.—DR. BERNARD BRANDIS, of Aachen, in his work, "Principles of the Treatment of Syphilis," writes as follows: "I must also mention the mercurial ointment brought forward by Professor O. Liebreich, of which lanolin forms the basis. It is thus prepared: 100 parts of mercury, 25 of lanolin, and 5 of (grey) mercury-ointment are rubbed together thoroughly till all the mercury disappears, which very quickly happens, and then mixed with 50 parts of mutton-suet, to which, in the melted condition, 175 parts of lanolin have been previously added. An elegant and smooth preparation results, without any disagreeable odor, and the trials of it here mentioned speak most emphatically in its favor. Those who use it upon patients boast of the ease with which it is "rubbed dry," and we may presume that the mercury is rapidly taken up by the skin."—*London Medical Record*, Nov. 15, 1886.

RUPTURE OF BLADDER CLOSED BY SUTURE.—DR. GARRÈ reports the case of a young man whose bladder was ruptured. Petarseris colporynteur was inserted into the rectum and a median longitudinal incision made over the pubes. The peritoneum was uninjured, but there was a vertical tear 2–3 cm. long in the anterior vesical wall. Its edges were stitched to those of the external wound, thus forming a urinary fistula, which was healed in five weeks.

Rupture of the bladder with fracture of the pelvis, says Garrè, can only occur when the abdomen is full and the parietal muscles passive. The fact that the bladder contains a considerable amount of urine shows that the rupture is in the anterior wall, for if the posterior wall be torn the urine will most probably escape from the bladder.—*Centralbl. für Chirurgie*, Nov. 7, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

OBSTACLES TO THE FORMATION OF PERMANENT COUNTY MEDICAL SOCIETIES.

In THE JOURNAL of last week, we called attention to the necessity for more complete and universal organization of the profession, in all its departments, into County or small District Societies, as the basis of efficient and truly representative State and National organizations. It was further stated that we have already such societies in nearly every county of some States, in a majority of others, and in only a few of the remainder; but that in all those existing, there is need of having the active membership embrace more nearly all the regular members of the profession within their limits, and still more need for the prompt formation of new societies in all the counties where none now exist. Experience has shown the existence of three chief obstacles in the way of the complete voluntary organization of the profession in a country embracing so vast a territory as ours. The first is the lack of appreciation of the advantages to be derived from such organization, on the part of a large class of practitioners. Without due consideration they let the comparatively trifling expense and time required for attending a County Medical Society, once or twice a year, deter them from making any movement in the matter. This class, though numerous, only require to have the real advantages of active membership in such medical associations fairly brought to their attention, to secure their coöperation. The members of every learned profession need some method by which its working members are, at stated intervals, brought in contact with each other and more or less before the public. This is secured for the clerical profession by the stated meetings of their conferences, synods, conventions, etc., and their weekly ministrations before the public. The same end is obtained substantially for the members of the legal profession by their frequent contact and open intellectual encounters at the bar of the several courts. But, for the great mass of the members of the medical profession, the local organized and actively sustained medical society affords the only opportunity to meet one another on common ground, each contributing something to the common stock, and each mentally imbibing something of value to himself and his patients, while the emulation or ambition for closer study and higher attainments, is more or less excited in all. To the younger members of the profession especially, the opportunities of active society work are of inestimable value. He who embraces them with a fair degree of diligence rarely fails to advance in his attainments and reputation, while he who neglects them, soon loses his habits of study, early lapses into a mere routine practice and is seldom known beyond the limited circle of his patients.

The second obstacle consists in attempts to make the machinery of these organizations too complicated and therefore difficult of execution. Many a social organization has come to an early death through vain attempts to enforce the details of its elaborate and ingenious system of rules and regulations. The more simple and brief the constitution and by-laws of a local medical society can be made, having for their paramount object the mutual improvement of the membership, the more efficient and durable will they prove to be.

The third obstacle in the way of effecting and maintaining a general and harmonious organization of the profession is difficult to define, and still more difficult to remove. It seems to have its origin in the undue development of the selfish tendencies of the human mind, and may generally be recognized in one of the three following forms: It has not required fifty years of personal observation to find in every populous community one or more medical men who make large pretensions to education and professional skill, who are prominent in social clubs and places of amusement, but when asked to join the local or county medical society, promptly tell you to "go to the dogs with your medical society. Do you think I want to go there and listen to an essay from that young upstart Dr. C., who has not had half a dozen patients since he left college, or to hear old granny D. relate a case of hysterics?" This may be styled the *pompous* form. Still more easy is it to find members of the profession fairly well educated and

gentlemanly in their deportment, but whose ready answer to all solicitations for them to sustain any general organization of the profession of a county or State, is: "Oh! I do no general practice—attend only to ophthalmological or gynecological cases, and cannot possibly find time to attend any medical societies except those devoted to my own specialty." This may be called the form of *exclusiveness*, manifested by a large class who never lack time to attend to every paying case sent to them by the general practitioner, but who never think of devoting an hour to the interests of the profession as a whole; or if they do occasionally come in to a general meeting, it is sure to be improved in generously instructing the general practitioners how most readily to diagnosticate such cases of disease as should be sent to the *specialist* for treatment. In most of our large cities may be found a small group of most influential and for the most part really eminent men, some of whom occupy positions on the staffs of public hospitals or in the faculties of medical colleges, and others are earnestly engaged prosecuting scientific or literary work. As a rule, the members of this class give no attention whatever to the city or county organizations of the profession, and only at long intervals to those of the State or of the Nation. More than any other equal number of members of the profession are they capable of giving efficient support and scientific character to the medical organizations of all grades—County, State and National; yet, by their almost total neglect, they strongly influence many others to follow their example. If you solicit them for papers and personal attendance, the almost uniform reply is, that they either have no time, or they are so much worn out by their labors they must make a trip to the mountains or the sea-side, or more likely across the Atlantic, to restore their energies, and very likely look in upon some medical society meeting on the other side. The latter step has, indeed, been so frequent with some during the last two or three decades that their writings show them to be more familiar with the society work and medical literature of some of the countries of Europe than they are of their own.

Widely different as are the three groups we have just described, they all agree in practically ignoring all obligation to personally sacrifice either time or thought in establishing and maintaining such local, State and National Medical Associations as are necessary to advance the educational, scientific and practical interests of the whole profession.

ABSCESS OF THE PANCREAS.

If there be one well established principle of modern surgery it is that suppurating cavities must be treated by incision and drainage, wherever this cavity may be located. The great strides made in the surgery of suppuration of internal organs warrants us in saying that at no distant day abscesses of the pancreas will be treated on the same principles as abscesses elsewhere. "Asepsis and effective drainage," says Dr. Senn, in the valuable monograph to which we called attention in the last issue but one of THE JOURNAL, "are the two cardinal points upon which we have learned to depend in the treatment of abscesses in important organs or cavities. If we can secure and maintain these two essential conditions, we can attack with immunity and a fair hope of success, any abscess wherever it may be located, and whatever its immediate surroundings may be." As the case now stands surgical literature shows no case in which abscess of the pancreas has been treated surgically. One reason of this may be its rare occurrence; and another that there are many difficulties in the way of recognizing the condition. The difficulties will, however, be removed by improved methods of examination, and greater skill in operating.

In looking at the pathology of abscesses of the pancreas we, of course, must remember that suppuration here, as elsewhere, is only one of the terminations of inflammation, and that the abscess, like the inflammation, may occur primarily in the pancreatic gland itself, or it may begin in the para- or peripancreatic tissue. When endo pancreatic, or in the gland, it "may be bounded and circumscribed by the proper investment of the gland; if, on the other hand, it commences primarily outside the gland it appears as a diffuse abscess, which extends to the pancreas by contiguity; in other words, we speak of the abscess as a suppurative pancreatitis, or a suppurative peri- or para-pancreatitis."

As there now seems to be no doubt as to the causative relation between pus microbes and suppuration, it must be taken for granted that suppurative pancreatitis, of whatever kind, is caused by the presence of these microbes in the tissues. The suppuration always begins in the interstitial tissue, either within the gland or in the connective tissue around it. Peri-pancreatic suppuration usually begins in the adjacent lymphatics; the pus surrounds the lymph glands or forms a small abscess. These peri-lymphatic abscesses are sometimes met with near the pancreas in pyæmia. The abscess may begin on the outer surface of the gland, and the pus separate the

gland from its attachments. Gendrin records a case in which it was lying loose in the abdominal cavity. In some cases the pus burrows in the region of the mesocolon and the retroperitoneal space, and may thence find its way into the peritoneal cavity or the alimentary canal. Again, a calculus in the pancreatic duct may be the indirect cause of an abscess; or one may originate in a preëxisting cyst, as in a case described by Kilgour. "As primary, idiopathic, uncomplicated, purulent inflammation of the pancreas is an exceedingly rare affection, it is of great practical importance in the surgical treatment of such cases to determine, if possible, the predisposing cause or causes, and to remove them, or render them inert at the time of the operation."

There are not always characteristic or positive symptoms of the presence of pus within the pancreas or in its immediate vicinity; in fact, the symptoms always point to the stomach or liver as the seat of disease. Nausea, vomiting of a clear greenish or viscid fluid, thirst, anorexia, constipation, progressive emaciation, and distension of the epigastrium are the more prominent and constant symptoms. In the recorded cases the patients as a rule, were very anæmic, and presented a sallow, cachectic appearance. In a number of cases ascites and œdema of the lower extremities were present; and in some cases there was biliary retention from extension of the inflammatory process to the bile-duct, or from stenosis of the bile-duct from compression. Fever is neither a conspicuous or a constant symptom of the condition. If the abscess be large palpation and deep percussion will show a tumor in the epigastric region. Inflammation of the stomach will often serve a useful purpose in the differential diagnosis of tumors in the epigastric region; and manual exploration of the rectum may give important or decisive information. Most of the recorded cases were in persons more than 40 years of age, and often of persons of intemperate habits. "In all cases where a tumor can be felt in the epigastric region, and a probable diagnosis can be made regarding its benign character, an exploratory laparotomy should be resorted to for the purpose of making an accurate anatomical diagnosis." This is important from a prognostic point of view, as the prognosis in abscess of the pancreas is always unfavorable. Progressive emaciation and inanition, or septic absorption, or secondary lesions in adjacent organs are usually sufficient to cause death. In cases of acute diffuse pancreatic abscess death may take place in a few days. A very great danger of these abscesses is the number of important veins in the immediate vicinity; these may become involved by extension of the suppurative process, leading to suppurative thrombophlebitis. The most favorable spontaneous termination of these cases is perforation of the abscess into the stomach or intestinal tract; and in one case this has resulted in cure. Perforation into the peritoneal cavity would of course hasten death by setting up a rapidly fatal septic peritonitis.

The treatment of pelvic and abdominal abscesses has been, and is now, so successful that the hope is justified that before very long the same treatment, and possibly the same success, will be extended to and gained in abscesses of the pancreas. It must be admitted, however, that there are greater difficulties in the way of operating in this region than in other portions of the abdominal cavity. "Multiple abscesses, disseminated throughout the entire organ, and especially its head, are not amenable to successful surgical treatment. Circumscribed endopancreatic abscess in the peripheral portion of the body or tail of the pancreas should be treated by partial excision of the pancreas in all cases where the isolation of that portion of the organ can be accomplished without inflicting serous injury to adjacent important organs. When extirpation is impossible, as when the abscess is located in the head of the organ, it must be treated by incision and drainage. This is accomplished in the same manner as in the treatment of a pancreatic cyst. In some instances the access is rendered difficult by distension of the stomach, the dilated organ overlapping the pancreas. In such cases the stomach must be pushed upward, and subsequent distension guarded against by ordering an absolute diet until the external fistula has been established. The external incision must, in all cases correspond to the most prominent part of the swelling, as it is of the greatest importance to incise the abscess at a point where the distance between the surface of the abscess and abdominal wall is the shortest. Incision of the great omentum will be required in all cases. In making an external fistula it is essential to protect the muscular and connective tissues of the external incision against contact with pus by lining the margins of the wound with the parietal peritoneum before the serous covering of the anterior wall of the abscess is stitched to the margins of the wound." A great difficulty in this operation will be the approximation of the peritoneal surface of the abscess with the margins of the wound; a difficulty which increases in proportion to the prominence of the swelling. The external incision should be large, as the margins of the wound can then be turned in, which facilitates suturing of

the anterior wall of the abscess to the margins of the wound. There is but little danger of puncturing the abscess-cavity with the needle, as the anterior wall of the abscess is generally covered by peritoneum and is of considerable thickness. Evacuation of the abscess by aspiration, before the operation, will cause recession of the abscess wall, and thus render approximation difficult; but it may be done if the swelling is so prominent as to render this a secondary matter. The sutures of the peritoneal surfaces should be of silk, should be placed close together, and grasp the tissues so that tearing out will be impossible; for the object of the sutures is to prevent escape of pus into the peritoneal cavity, and to secure permanent adhesions of the abscess wall to the margins of the wound. Incision and drainage should follow immediately upon the suturing.

"The remaining steps of the operation will depend upon circumstances. If the abscess is endopancreatic or peripancreatic, simple incision, drainage, and disinfection will answer all indications. If, however, the purulent cavity is located behind the peritoneum and occupies the connective tissue space behind the pancreas, it would appear rational to drain the abscess posteriorly through one of the lumbar regions above the kidney by pushing a long closed forceps in a proper direction through the posterior and lateral wall of the abscess until its point can be felt under the skin externally. A small cut in the skin over its point will enable the operator to push the instrument clear through, and, by dilating its blades, widen the canal sufficiently to permit the insertion of a large drainage tube. In this manner the most desirable method of drainage—through drainage—could be established, which would render subsequent disinfection and evacuation of the abscess a comparatively easy task. In cases where an anterior pancreatic fistula cannot be established on account of the distance between the abscess and the anterior abdominal wall, we might resort to lumbar drainage and closure of the incision in the anterior wall of the abscess by carefully inverting and approximating the peritoneum over the wound with fine silk sutures. The abscess found and located by abdominal section should be removed by partial extirpation of the pancreas when it is endopancreatic and located near the splenic end of the pancreas. When extirpation is impossible, or when it is located in the head or on the anterior surface of the pancreas, it should be treated by the formation of an anterior abnormal fistula; when located behind the pancreas, by through drainage, or lumbar drainage performed through the abdominal cavity."

"THE CHICAGO CINCHONA COMPANY; OFFICE, PALMER HOUSE."

We have received from a physician in a neighboring State a printed circular, marked by its author "private and confidential," setting forth the formation of a company by the above title, and with a capital stock of $500,000, for the purpose of manufacturing and selling "D'Unger's Cinchona Cure for Drunkenness." The company claims to have purchased the formula and all details of its preparation from Dr. D'Unger; and while setting forth in the usual style its virtues as "a certain cure for drunkenness and the morphine habit," this "private" circular shows the real nature of the speculation in the following paragraph:

"The capital of the company has been fixed at $500,000, the price of each share being $20. Of this sum, $250,000 has been placed by the former owner of the formula in the treasury, to be *allotted* to *such physicians* as may desire five or ten shares of it at *twenty-five* cents *on the dollar*." This offer is made to physicians *only*, and is rendered more tempting by the strong assurance that after the remedy is fairly introduced to the profession, it will yield "annual dividends of at least 25 per cent. to the stockholders." The circular is signed by E. S. S. Kemp, President, and Henry Plowman, Jr., Secretary.

As the so-called "D'Unger's Cinchona Cure for Drunkenness" has been advertised (and sold by its "former owner") in the daily papers of this and other cities for five or ten years past, until its worthlessness is as well known as is that of all the other advertised *cures* for *drunkenness*, etc., it is hardly necessary to caution the most credulous member of the profession against wasting even a postage-stamp on inquiries concerning it.

SECTION OF OBSTETRICS AND DISEASES OF WOMEN, OF THE AMERICAN MEDICAL ASSOCIATION.—In THE JOURNAL of last week we published a preliminary programme of work for this Section as furnished by the President and Secretary of the Section, for the coming meeting in June. The number and character of the parties named in the list affords a guarantee of an excellent meeting. We now are requested by the Secretary to add to his list the name of another eminent writer, Dr. H. F. Campbell, of Augusta, Georgia. Which Section will follow next with an equally good showing?

THE NATIONAL CODE OF MEDICAL ETHICS.—Our cheap Reprint edition of the Code of Ethics of the

American Medical Association is ready. Physicians or others wanting single copies should send a *two* cent postage stamp to pay the cost of the reprint and a *one* cent stamp to pay the postage. One hundred copies can be sent for $2.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, November 24, 1886.

The President, C. H. A. Kleinschmidt, M.D., in the Chair.

H. M. Cutts, M.D., Secretary.

Dr. D. S. Lamb presented for Dr. J. Taber Johnson the specimens and read the histories of

THREE CASES OF OVARIAN DISEASE.

Case 1.—On the 18th of Oct., 1886, I saw Miss L., at the request of Dr. B. B. Adams of this city. She was unmarried, age 31, and had been well up to three months ago, except attacks of typhoid fever and jaundice, which she had four years ago. Her sisters first noticed her change of form which progressed with unusual rapidity, until she reached the size of a woman eight or nine months pregnant. Her condition attracted the attention of friends and neighbors, and though quite able to do so, she reluctantly appeared in public. Her disease so preyed upon her mind that she lost flesh rapidly and was fast becoming an invalid. Upon my advice she took a private room in the Providence Hospital, and on the 23d of October, 1886, I made a two inch incision and removed what proved to be a parovarian cyst, weighing twelve pounds. She has up to this moment, had no unfavorable symptoms. She left the hospital on the 20th day, perfectly well.

Case 2.—Mrs. C., white, age 24, married for three years; has been subject to most dreadful attacks of menstrual or ovaro-epilepsy, for the past ten years. She was sent to me by Dr. J. W. Bayne. Mrs. C. had been under the care of at least twelve different physicians, including Dr. Hammond, of New York. She had been told repeatedly by Dr. Hammond and others, that the cause of her trouble was ovarian, and believed to be incurable, except by removal of those organs. During these ten years the patient had worn out the endurance of as many doctors who had passed her on to the next, and of several hospitals, which had discharged her, after exhausting their nurses and drugs to no purpose. She had tired out relations, friends and neighbors, in watching and holding her. While her periods were less than normal and irregular, the menstrual molimen occurred with painful regularity, and before it, during and afterwards, she had the most active and distressing clonic spasms. She would, on some occasions, remain unconscious for half a day or more at a time, except when in an attack, when she would require the strength of a number of women to hold her, including those in the house and what neighbors would come in, until her husband could be sent for. She has been much worse since marriage than before. The patient was unable to do much, if any useful work about the house. She complained of almost constant pain in the pelvic region; and was losing ground mentally as well as physically. When I was asked by Dr. Bayne to see her, I was informed of her previous history and present condition. A vaginal examination caused much pain and brought on convulsions. I did not then feel her ovaries. Though requested by the attending physician, the patient and her family, to remove the uterine appendages, her case did not seem to me, at that time, to be one which held out a very strong promise of cure by this operation, and not wishing to have a failure, I declined to do it. Two months later their importunities were so great, and also their anxiety to take the risk of a cure, as well as the risk to life, which *were fully explained to them all.* I made another examination under ether. I found the ovaries atrophied and adherent to the tubes and surrounding structures. Believing that cause enough existed for the production of her symptoms, I agreed to operate. I had the patient take a private room in the Providence Hospital, and on the 27th of October I removed her uterine appendages. It is now five weeks since the operation, and barring her use of opium, which is an old habit, her present condition is all that one could expect or wish. I anticipate that she may have slight spasms for a while, at the time when her periods are due, but hope they will grow less and less severe until they finally disappear. Her change of life, produced by the operation, may not be any more sudden, than when it occurrs in the usual way. If at the end of two years she is free from her old troubles, I shall feel that the operation is a success, and was properly done. If she is no better I shall regret it. The evidence in recent medical literature is not conclusive on this question. Even Sir Spencer Wells in the recent symposium, in the *American Journal of Medical Sciences*, does not decide against it. He says he thinks every thing else should be done first, and well-done and continued for several years, and that all the risks of the operation should be explained to the patients and their friends; and so do I. But what shall we do with those patients who resist all treatment, marriage included, for years, and are growing worse? This operation must continue to have a limited field of usefulness in nervous diseases where all other treatment has failed. Battey in his part of the recent symposium above referred to, produces unimpeachable evidence of the beneficial and lasting effects of the removal of the uterine appendages in both nervous and mental diseases. I join those who cry out against the abuse of this operation, but I am in favor of it after other means have failed, rather than allow this class of patients to die or to repeatedly go over the same dreary old ground without benefit.

Case 3.—Mrs. W., white, age 49, married, the mother of five children; passed her menopause seven

years ago, she was without her periods for five years. During the past two years she has had some irregular bloody discharges, which were supposed to be a return of her menses. Being a patient of Dr. B. B. Adams, she sought his advice and treatment. Some of her peculiar symptoms he attributed to her rather irregular change of life. As her abdomen enlarged the question of pregnancy arose, and finally when she had clots of blood discharged, and especially when it was accompanied by a bad odor, it was supposed that she was carrying a dead fœtus, and that there had been an hydatidiform degeneration of the membranes. She was supposed at one time to be in labor, and these symptoms continued for about ten days. I was asked to see her and to assist in delivering her. Sponge tents had been introduced, and efforts had been made to rupture the bag of waters. I found her in an acute peritonitis. Her abdomen was so tympanitic, tender and distended, that an accurate diagnosis was impossible. I decided two points, however: 1. That the uterus was empty and not enlarged; 2, that she had a tumor of some kind. She grew rapidly worse for several days, until one night I was telephoned for to see her die. As she had a septic discharge, and as I had other abdominal cases on hand, I declined; but requested them to arrange for a post mortem, which they did. She had a pulse of 160, cold clammy skin, and a subnormal temperature. She rallied from this condition, and in ten days was sitting up and anxious for an operation. Dr. Busey was invited to see her at my request. He was uncertain as to whether the tumor was ovarian or cancerous, but agreed with me as to its presence, and that the uterus was empty. We decided to make an exploratory incision and remove the tumor if it appeared feasible. She at once arranged for a private room in the Providence Hospital. On the 10th inst., I opened the abdomen in the presence of Drs. Busey, B. B. Adams, Reyburn, Cutts, Cuthbert and others. The abdominal wall was at least 2.5 inches thick in fat. When the tumor was exposed it had the dark appearance of an ovarian tumor, with a twisted pedicle. Some dark extravasated blood escaped. The recent and still uncured peritonitis had caused the tumor to be everywhere adherent. These adhesions were easily broken down and I decided to proceed. After separating the tumor as much as I could I tapped it and drew off half a bucket full of what appeared to be dark red blood. It was difficult to turn the tumor out of the abdomen as it was very friable and tore when much traction was made upon it. I finally succeeded, and reaching the pedicle, transfixed and ligated it, cut away the tumor, the solid part of which was estimated to weigh at least five pounds. The bleeding from the torn surfaces soon ceased, and I was not compelled to wash out the abdominal cavity as at one time I thought I should have to do. After crowding several large sponges into the cavity, the last of them coming out clean and dry, I concluded to close the wound and put in a glass drainage tube. The operation lasted just an hour; fully a third of this time was consumed in putting in the sutures and applying the dressings. The unusual fatness of the abdominal wall was a source of difficulty and delay. I think all the gentlemen present expected the patient to die, myself among the rest, on account of the nature of the tumor and the extensive adhesions. The tumor was thought from its appearance to be cancerous. The patient has made an uninterrupted recovery; her only drawback being a troublesome cough, produced by the ether, and from abscesses along the track of the sutures. It is now two weeks since the operation and the patient is feeling perfectly well, has a splendid appetite and is anxious to sit up and go home.

DR. P. J. MURPHY presented the following history, and a bottle of thick, pinkisk-white fluid removed by laparotomy from the patient, of a case of

CHYLOUS ASCITES.

Maggie M., æt. 19, white, single, nativity D. C. Admitted to Columbia Hospital for Women, Nov. 7, 1886.

History.—Puberty at 16 years. Menses are regular, painful, scanty, light in color, and last three days. Father died of phthisis pulmonalis five years ago; and a sister died of the same disease one year later. Two children died of diphtheria and one of heart trouble from rheumatism. Family history otherwise healthy. Last summer she was a chambermaid at a hotel in the Catskills, and had to work very hard. While there she went frequently to balls, sometimes walking as far as ten miles, and being perfectly exhausted next day. Now suffers from "swelling" of the abdomen, which began about three weeks ago after an attack of "chills." When the swelling began she had a severe pain in the right inguinal region, which lasted about a week. Since then has had no pain. Bowels constipated. Appetite poor. Has dyspepsia. Has never been strong. Is now pale, emaciated and very nervous. Last menses Nov. 1st to 4th.

Examination.—An exploratory incision was made in median line of abdomen and a creamy colored fluid gushed out, 9 pints of which were saved and fully twice as much lost. Bi-manual examination (one hand inserted through the wound and the other per vaginam), showed the uterus and appendages to be normal in size and position. There was no sac present, but the fluid was clearly loose in the abdominal cavity. There was no glandular enlargement discovered or other evidence of local disturbance. A glass drainage tube was inserted, but there being no further discharge the tube was removed on the fourth day and the wound closed.

Examination of Fluid. — Color, fresh cream (slightly pinkish from blood). Reaction — alkaline. Specific gravity—1,023. Albumen—about 70 per cent. by bulk after heating.

Microscope.—A number of red and white blood corpuscles and a large number of irregularly outlined, globular bodies, having a diameter of 8 to 20 m. m., that are thought to be *lymph globules.* On standing the fluid separates into layers—the lowest being nearly white.

DR. S. C. BUSEY said the specimen just exhibited by Dr. Murphy was one of the most interesting he

had ever seen. He supposed the case was one of chylous ascites, and it was possible that the chyle had escaped through a puncture of some chyle vessel by this *filiaria sanguinis hominis*. Most of the distinctive characteristics of chyle were, however, not present, certainly not given, no fat was reported present in the milky fluid. (Dr. Murphy explained that the examination had been hasty and very likely much had been overlooked.) The pinkish color might be due, as Dr. Murphy says, to admixture with blood from the wound, but such a color may be derived from other sources. If the fluid be chyle it must have been discharged from some chyliferous vessel or escaped by transudation. In the latter event the quantity would have been small and would have gradually diminished instead of continually increasing, as in case of rupture of some chyle-conveying vessels. Only about thirty cases of chylous ascites have been reported. Most of the cases have occurred in Germany. America, England and China report a few cases.

There have been also a few cases of chylous hydrocele reported. The first in this country was by Dr. Mastin, of Mobile. Vidal was the first to suggest, but Mastin was the first to demonstrate, that the milky fluid found in these cases had escaped from dilated and ruptured lymph vessels. Having discovered the milky fluid previously by tapping the scrotum, he subsequently, after its refilling, cut down upon the sac and discovered the network of dilated and ruptured lymph vessels, ligated it, and the patient recovered. Mastin, Jr., had had a similar case, in which he found the same condition. It was treated in like manner, and also recovered. Other cases had been reported cured, one by the injection of iodine.

Lymph scrotum and chyluria are now believed to be due to the presence of the filiaria, but, as yet, only two or three cases of chylous ascites have been proven to be due to the puncture of this pariete. The escape of chyle into the peritoneal cavity in large quantities is due to the rupture of some large vessels, thoracic duct, lacteals or receptaculum chyli. Most frequently the rupture is found in the lacteals. Any condition which may interrupt or impede the flow of chyle into the subclavian vein will cause stasis, repletion, dilation, and may cause rupture, either of the duct, but more frequently of the receptaculum. or lacteals. Certain pulmonary and heart diseases have produced such results. The presence of cancerous, aneurismal and other tumors and other conditions, by occluding or obliterating the thoracic duct either at or about its terminus or along its continuity, have caused rupture of the duct or other large chyle-conveying vessels. Several cases have been ascribed to some violent and sudden effort, and at least one to congenital defect.

The diagnosis of chylous ascites can only be made by microscopic examination of the fluid. The accumulation of a fluid can be recognized and it can be determined whether free in the peritoneal cavity or in a cyst. Acute anormia, with great and sudden prostration, a loss of appetite and rapid diminution of the quantity of urine, associated with the rapid accumulation of a fluid in the peritoneal cavity, might suggest the presence of chyle.

Dr. Busey believed the treatment in this case was correct, but the fluid would probably reaccumulate, and the patient finally, as is usual, die of pulmonary disease. The fluid in chylous ascites is chyle, but in the cases of chylous hydrocele it was lymph transformed into a milky or chyle-like fluid in consequence of disease of the intima of the lymph vessels.

Dr. A. F. A. King suggested that Dr. Murphy obtain, if possible, a thorough history of the antecedents of the patient and of all points pertaining to her. He said that it is supposed that the filiariæ are spread by mosquitoes. These insects suck the embryos with the blood of the person. The embryos grow and burst open the mosquito and then fall into our food or drinking water. A peculiarity of the filiaria is that it cannot be found in the blood in the daytime.

Dr. Busey said that it was either Lewis or Manson who confined persons in a room filled with mosquitoes. Before their confinement careful examination proved the absence of the filiaria. Shortly after this confinement with the mosquitoes filiariæ were found in the subjects of the experiment. Manson was the first to discover the relation between the elephantiasis and the filiaria. He found in every case the fileria.

Meeting of December 8.

The President in the Chair.

The case of

CHYLOUS ASCITES

reported two weeks previously came up for continued discussion.

Dr. S. C. Busey said that he had recently seen the case and could add some points to the history. The girl had begun menstruating at 16, and the menses had always been in every way normal except that on one occasion she had "missed" one month. She had been otherwise healthy, and last summer she had been a chambermaid in a summer hotel in the mountains. She had been accustomed when off duty at night, to take long walks, go to parties at a distance, etc. It was after one of these long walks that she suddenly felt a violent pain in her abdomen on the right side. Her abdomen then began to swell, the pain still continuing. She had good appetite and ate heartily, but lost flesh, and color and strength. Since the operation by Dr. Murphy the pain has disappeared and she has regained, somewhat her weight and strength. Before the lower end of the wound, which had been a large one, had closed, there had been some oozing of a chylous fluid. He said it looked as if some chyle duct had been ruptured by violence. Dr. Nickerson, of Lowell, reports such a cause in a man upon whom he operated several times before he obtained a cure. Another case is reported by Viniwarter, in a child. The large abdomen was supposed at first to be due to a congenital cyst. Two operations cured this case. Several other cases are reported, notably one by Bessieus in a girl due to exertion in raising a child.

DR. BUSEY replied to Dr. King that he thought the cause of pain was the rupture of the duct or receptaculum chyli, and to Dr. Cook that there was no special desire on the part of patients suffering with escape of chyle for fat. If the chyle escaped only slowly through a small opening the peritoneum readily reabsorbs it, and patient suffers no very great emaciation. In cases where there has been a large and sudden escape of chyle there is much loss of weight and symptoms of collapse. The person is probably here also kept alive by reabsorption by the peritoneum. There is a case reported by Poncy which he tapped twenty-two times in six months, removing 285 litres of chyle. Here the color and smell of foods given could be recognized. Usually there is a good appetite and the food is enjoyed.

DR. KING said that he thought that the odor of some foods, as onions, could be detected in all fluids of the body.

DR. E. CARROLL MORGAN presented a specimen of

NASAL POLYPUS,

and said he thought it instructive by reason of the beauty, freshness, and unusual dimensions of the tumor.

The history of his patient, briefly stated, is as follows: John K., white, male, aged 18 years, born in Ohio, now a resident of Washington, D. C. The patient first noticed the polypus in August, 1882, in the right naris. It grew slowly, giving little trouble. In November, 1885, he was operated on by Dr. Blank, of Columbus, Ohio, who clipped off a small portion of the tumor. Patient breathed freely for about one month, when the tumor rapidly increased in size. He was much affected by cold in the head, and by changes of temperature, and the tumor often protruded as far down as the lower lip. When the cold was relieved the tumor retracted within the nose. I operated on him at 3 P.M. to-day, Nov. 24, 1886, when the tumor was just even with the anterior nasal orifice. The polypus was removed in the presence of Drs. Thos. A. Taylor and Frank Chamberlain, is of the mucous or gelatinoid variety, weighs 265 grs. (℥ivss), measures four and a half inches in length and one inch in its greatest breadth. The attachment was apparently to the posterior extremity of the lower turbinated body, and the wonder is that there was not regurgitation of the polypoid mass into the pharynx, for it was not adherent anteriorly, allowing the wire loop to be passed freely over its entire length. The operation was done with a Douglas snare and by the aid of reflected light.

The polypus was extracted through the right anterior naris. There was slight bleeding and nasal respiration was completely restored. It is, however, not certain that the entire polypoid mass has been removed, and a second operation may be required, as in other cases.

DR. J. L. ELIOT read a paper entitled

NARCEINE IN THE TREATMENT OF WHOOPING-COUGH.

(See page 92.)

DR. S. C. BUSEY asked the cause of the convulsions, as it is very important to find out the pathological conditions present in these rare cases of whooping-cough which prove fatal by convulsions. Is it a defect of the respiratory centre or thrombosis of the cerebral sinus?

DR. G. B. HARRISON said that it is frequently stated that a second attack of whooping-cough is rare. It seemed to him that a second attack was not uncommon, and he knows of several persons who had had three attacks.

DR. A. F. A. KING said he was aware that the exanthemata attacked the child in utero, but he failed to see how whooping-cough would reach it before birth. If a child presents the symptoms of pertussis on day of birth it must have had the prodromal symptoms in the womb. As children born after having had small-pox in utero are to some extent exempt from it in after life, he does not see why the same should not be true of pertussis. He mentioned a case of twin birth where only one child had small-pox, and stated that Morrison, the obstetrician, was born with small-pox pustules, though his mother did not have it at the time, but was only nursing a son with the affection.

DR. BUSEY said that he had never heard of a case of congenital whooping-cough.

DR. KING said that he did not mean to imply that the child actually coughed in utero, but if born with whooping-cough when did the catarrhal process in the lungs begin?

DR. J. L. ELIOT said that he did not think, at any rate, that the narceine was the cause of the convulsions, as the dose was small and the effects had passed off several days before.

DR. S. S. ADAMS questioned the diagnosis made by Dr. Eliot. He said that it was extremely difficult to tell at that age what is the matter with a child. The pathognomonic symptom of pertussis is the whoop, and even that may be produced by simple laryngitis. He did not think that narceine would produce convulsions, but congestion of the kidneys following its use might. He said that there was no specific treatment for whooping-cough.

DR. BUSEY objected to the statement that pertussis could not occur without the whoop. For instance, all of several children of a family cough; all present the same phenomena except that one does not whoop. If this was an isolated case the diagnosis would be uncertain. But if whooping-cough was epidemic and the others undoubtedly had it, he thought it fair to say that the child who did not whoop had it also. Usually the cough and whoop are associated, but the latter varies in degree and intensity, and may only occur once or twice, or not at all, during the attack. He thought that there was no medicine which could stop the disease, but it could be cut short by treatment. The epidemics also vary in severity and contagiousness, and the remedies successful in one will fail in another. The season had its effect. In autumn and winter attacks were less controllable. Climate and hygienic surroundings were elements to be considered. He has seen one death preceded by convulsions, and thrombosis of the cerebral sinus was probably the cause. The case just reported may have had pneumonia or ate-

lectasis. The narceine narcotism would have helped bring about the former. Of course he does not censure Dr. Eliot for having given narceine. The child also must have been badly nourished, which condition would predispose to cerebral thrombosis.

Dr. Adams said he was still unconvinced that pertussis could be diagnosticated without the whoop.

Dr. T. E. McArdle said that the mere fact of a laryngitis or a bronchitis occurring in a child in a house with several cases of whooping-cough did not prove that the child had pertussis. For his part he knew of no way to tell the disease without the whoop.

Dr. Briscoe said that about six years ago he caught the disease from his children. His paroxysms of coughing and theirs were alike, but he whooped only once or twice during the attack.

Dr. G. W. Cook said that the whoop was only an inspiration after a violent attack of coughing, and might happen after such a paroxysm from any source.

Dr. G. B. Harrison said that he had diagnosticated endemic cases before the whoop appeared. There was a characteristic peculiarity in the paroxysm of coughs.

Dr. Adams asked how the diagnosis was made without the whoop?

Dr. King replied that there were a series of short expirations which cut off the air supply and the person gets blue in the face.

Dr. Adams said that he had seen the same in bronchitis.

Dr. Busey said that there were paroxysms of cough which increased in their intensity up to a certain point when they began their decline. They have, as Dr. Harrison says, a peculiarity of their own. If the chest be examined before the paroxysm we will hear coarse and moist râles which disappear after the fit of coughing, and this occurs in no other condition with which he is familiar.

Dr. Adams said that we can make a diagnosis in most diseases if we wait long enough, it may be at the autopsy. Bronchitis has usually been associated with his cases of whooping-cough, and the râles he has found both before and after a paroxysm.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, December 2, 1886.

The Vice-President, E. E. Montgomery, M.D., in the Chair.

W. H. H. Githens, M.D., Secretary.

(*Concluded from page 82.*)

Dr. Joseph Price read a

REPORT OF THIRTY-ONE CASES OF INTRA-ABDOMINAL OPERATIONS DONE WITHOUT ANY SELECTION IN PRIVATE HOSPITAL; BY R. STANSBURY SUTTON, OF PITTSBURGH, PA.

October 27, 1883, Mrs. B. Ovariotomy, large cyst; recovered.

November 18, 1883, Mrs. O. Ovariotomy, large cyst; recovered.

December 28, 1883, Mrs. C. Ovariotomy, large cysts, extensive adhesions, tapped frequently; recovered.

February 2, 1884, Miss T. Supra-vaginal amputation of uterus, with both ovaries and tubes; recovered.

February 20, 1884, Miss P. Supra-vaginal amputation of uterus, with both ovaries and tubes; large fibroids of uterus; recovered.

March 20, 1884, Mrs. K. Ovariotomy, left ovary large and cystic, developed under the broad ligament and roofed over by it. The ligament was opened up to get at it. On right side a fibro-cyst of the uterus, with adhesions, existed. Performed supra-vaginal amputation of the uterus with the remaining ovary and tube, and split the broad ligament of the left side; recovered.

April 22, 1884, Mrs. S. Ovariotomy, large cysts, extensive adhesions, especially to the liver, had been often tapped. Liver was burned with cautery iron over strip one inch broad by four or five inches long to stop bleeding. Incision in abdominal wall seventeen inches long; recovered.

May 12, 1884, Mrs. D. Large sarcoma of left ovary, general chronic peritonitis with ascites, tumor fed by enormous vessels. Pedicle tied and dropped as in ovariotomy. Pulmonary clot occurred on fourth day suddenly with temp. 99°; died.

May 29, 1884, Mrs. G. Ovariotomy, large cyst, adhesions; recovered.

June 24, 1884, Mrs. S. Pelvic abscess. Tait's operation (the pus was stinking); recovered.

July 12, 1884, Miss M. Removal of sub-peritoneal fibroid, anterior wall, pedicle short; recovered.

July 12, 1884, Mrs. L. Supra-vaginal amputation of uterus with 16 pound fibroid; extensive enucleation, adhesions numerous; died.

September 16, 1884, Mrs. R. (insane), removed both ovaries and tubes, cured; recovered.

September 22, 1884, Miss J. Both ovaries and tubes removed. Died of septicæmia on fifteenth day. (Consultants pronounced it typhoid fever.)

September 24, 1884, Mrs. W. Supra-vaginal amputation of uterus and both ovaries, with 15 pound fibroid, extensive enucleation, vast adhesions; tetanus; died.

December 4, 1884, Mrs. C. Supra-vaginal amputation of uterus for large fibroids; extensive intestinal and mesenteric adhesions, and in the presence of peritonisis, very bloody operation. Shock was too great; died.

December 17, 1884. Resection of small intestines at two points for cure of artificial anus and extensive adhesions of gut, fatal on seventh day from renal hæmorrhage. Five stones, one an inch long, were found in the kidneys post mortem. The points of resection were found with difficulty, the sutures were all covered. (My first and only other resection of intestine recovered and is living, three and one-half years since operation.)

March 7, 1885, Mrs. J. Ovariotomy, large cysts, extensive adhesions; had often been tapped; recovered.

April 7, 1885, Miss S. Exploratory incision; recovered.

June 10, 1885, Mrs. L. Double ovariotomy, dermoid on right side; recovered.

June 27, 1885, Miss H. Both ovaries and tubes removed; recovered.

July 30, 1885, Miss D. Ovariotomy, large cysts, extensive adhesions, came in a dying condition, had been tapped very often; died.

November 18, 1885, Mrs. B. Ovariotomy, incomplete small cyst, size of cocoanut. As it was impossible to remove the cyst on account of adhesions, it was emptied, dried out, and lining well mopped with a five per cent. carbolic solution. Recovered and cyst has not refilled.

November 19, 1885, Mrs. M. Oöphorectomy, right ovary and tube; recovered.

November 24, 1885, Mrs. W. Double ovariotomy, large cysts, bad adhesions, patient very anæmic and feeble, had been tapped often; recovered from operation, but died from peri-nephritic abscess three months afterwards.

January 9, 1886, Miss N. G. Oöphorectomy, pyosalpinx; recovered.

March 23, 1886, Mrs. R. Oöphorectomy, right ovary and tube; recovered.

April 3, 1886, Mrs. N. Oöphorectomy, both ovaries and tubes; kidneys contracted, uræmic poisoning a week after operation, coma, death.

October 1, 1886, Miss S. Oöphorectomy, right ovary and tube, chronic ovaritis and salpingitis; had to dig the ovary and tube out of a mass of adhesions; bad case; recovered.

November 20, 1886, Mrs. N. Double ovariotomy, removed large parovarian cyst and cystic ovary on left side and cystic ovary on right side; recovered.

This list of thirty-one abdominal sections are all I have made in my private hospital during the three years of its existence. I have never used spray over a wound, and only occasionally in my earlier cases I used 2½ per cent. carbolic solution over the instrument. Long ago I quit this and have used no chemical during the operations. After closing the wound I dress it with iodoform gauze. Our wounds all heal by first intention. A great many of these patients have neither health, strength, or money when they come to us. Rich or poor, all have had the same chance for life. All the provisions of cleanliness known to science and art are practiced in my institution. With our present good condition, I believe we can save 98 per cent. of ovariotomies sent within a year or eighteen months from the time the disease begins, and without having been tapped. We never lose a case if in fair condition, and if no trocar has been previously introduced into the cyst.

In this list there were thirteen ovariotomies for large cysts, and in one case a supra vaginal hysterectomy was also done. Of these thirteen cases two died, one of the two three months after operation, and the other was in the last stages of exhaustion when she was brought in on a stretcher.

Of the cases of supra-vaginal amputation of the uterus and both ovaries, there were six. In one an ovariotomy was also done for large cysts. Of these cases three recovered and three died.

The Tait operation for large pelvic abscess recovered.

The intestinal resection was not lost through the operation. The removal of the uterine appendages shows a mortality of two cases; one was due to operation, I think the other was not.

I am sure that, as we gain experience in further operative work and exercise more care in rejecting cases with bad kidneys, our results here will compare favorably with others. Thus far we have refused no patient willing to enter the list for operation, and I am sure that no operator, East or West, is likely to meet with worse cases than are contained in this list. Summary:

Ovariotomies, McDowell operations	13
Oöphorectomies, Hegar-Tait operations	8
Laparotomy for pelvic abscess, Tait operation	1
Resection of intestine	1
Removal of large solid sarcoma of ovary	1
Supra-vaginal amputation of uterus and both ovaries	6
Exploratory incision	1
Removal of sub-peritoneal fibroid of uterus	1

(One case is counted twice, first as an ovariotomy for large cysts complicated with supra-vaginal amputation for fibro-cyst of uterus; second, as a supra-vaginal amputation of uterus complicated by ovariotomy.)

In looking over my ovariotomy cases who have recovered during the last ten years, I find that eight children have been born to them. My last laparotomy (46th) for all diseases yet attacked by operation, by me, was a large parovarian cyst, with both ovaries cystic. The cyst and both ovaries were removed through a two inch incision, the dressing completed, and the woman in bed, in thirty minutes, without any haste. She has taken no drugs, not a drop of anything. Temperature on the fourth day was normal and the pulse 76. Wound completely healed. Experience with honest precautions, coupled to a possibility of earlier operations and a discontinuance of tapping, will result in as good statistics in this country as abroad.

DR. H. A. KELLY remarked that Dr. Sutton's account of his cases is very interesting, and in many particulars instructive, and better results for general work, handling all classes of cases without selection, certainly can not be found in our country. He, Dr. Kelly, called especial attention to the note by Dr. Sutton, that his ovariotomy patients have borne eight babies within the past ten years. This fact is significant as deciding a question which has been discussed in terms of vague generalization and sentimentality, "The Other Ovary."

About a year ago, when writing a paper upon ovarian cysts of large size, Dr. Kelly found facts in Sir Spencer Wells's table which determined this question for him upon a solid scientific basis. Of Sir Spencer Wells's 1000 cases, 768 recovered; and deducting from these 343 over 40 years of age, as beyond the child-bearing period, we have left 371; again deducting twenty more, which was about the number of double ovariotomies, under 40 years, recovered, we have left about 351 women survivors with one ovary and in a child-bearing condition. As an actual fact, 117, or about one-third, did bear children to the number of 228, or a fertility of about 65 per cent. to the total number of survivors. This is

then clearly the advantage of leaving one ovary in 351 women, to-wit: 228 children. Now what are the disadvantages? Obviously a return of the tumor in the other ovary, and death from the second operation,

In seven of these 351 women a second operation was necessary, and one of the seven died of a tumor, doubtfully uterine.

Here, then, is the status of "the one ovary" case. *One doubtful death* of a woman seven years after her first operation, against *two hundred and twenty-eight children born.*

Dr. Kelly could not accept the diagnosis of death from typhoid fever in a surgical case within three weeks of operation, in the absence of careful post-mortem examination. The typhoid condition is so common in all cases of peritonitis tending to a lethal end, and true typhoid fever so extraordinarily rare, that he rejected the diagnosis not subsequently confirmed. It savors too much of the many cases of women coming to my office week after week who tell me they "have never been well since their last confinement, when they had typhoid fever." Dr. Sutton, however, does not himself make this assertion.

Dr. Coffee, of Pittsburgh, drew attention to a case under his own observation in which typhoid fever of distinct character followed close upon a surgical operation.

Dr. M. Price spoke of a case in which typhoid fever followed immediately after an attack of small-pox.

Dr. Joseph Price reported a case of

HYSTERECTOMY FOR MYOMA.

The patient had applied to Dr. J. R. Haynes on account of menorrhagia, with hypogastric discomfort. Uterus about the size of a three months' gravid uterus. She became very much prostrated, and suffered from sciatica in the right leg. The tumor grew rapidly, and seven months after first seeing her the tumor was found to extend from the umbilicus to the perineum, resembling in shape and position the gravid uterus at seven months. Two inches below the umbilicus and to the left a bruit was distinctly heard. Fœtal heart-sounds could apparently be distinctly heard beating 125 per minute, but they were syncronous with the patient's pulse. The lower portion of the tumor extended into the vagina almost to the perineum, and resembled very much a fœtal head surrounded by a small quantity of fluid. The os uteri could be felt, only with the utmost difficulty, behind the centre of the os pubis.

November 19 Dr. J. Price performed abdominal section; before operation her pulse was 150 and temperature 100°. Six syringefuls of brandy were given hypodermically. The operation lasted about an hour. The patient slept well that night and improved in condition for a few hours, after which vomiting occurred, followed by great restlessness, pain, and increased frequency of pulse. Peritonitis developed and the patient died at 7 A.M., about thirty-one hours after the operation. Post-mortem examination showed nearly a pint of bloody serum in the peritoneal cavity.

Dr. Price remarked that in reviewing the operation he felt that, with one exception, he had nothing to regret, but he did regret that he had not introduced a drainage-tube. His reason for not using it was the complete absence of bloody stain in the last abdominal washings; but it is his rule to use a drain whenever there have been adhesions to separate; he had three tubes in use in other patients at that very time. He feels assured that if he had used a drainage-tube in this case the woman would have recovered.

Dr. H. A. Kelly considered the important error in this case was the neglect to insert a drainage-tube, and gladly made this subject the text of a few remarks. Operators at large should by this time have reached a common understanding as to just how and when the drainage-tube should be used. In the *first* place: whenever there is any denuded area as large as the palm of the hand, or smaller if there be a tendency to weep, a tube should be introduced, and sometimes when least expected several ounces of serum will well up through the tube daily, and the absorptive powers be saved a severe tax. *Second: Whenever in doubt, use the tube;* no harm ever comes from it when guarded with the antiseptic precautions now in common use.

His own plan is as follows: Pass all the silkworm sutures as if the whole length of the incision was about to be closed, slip in the drainage-tube (he prefers a straight glass one under ordinary circumstances), and run down the shot and close the wound to the tube, but the two sutures passing through the track of the tube are left long, to be used after the removal of the tube. He then, once or twice a day, draws out all serum accumulated in the pelvis by means of a long nozzle uterine syringe. When all discharge has ceased, provided it has been but sweet, clean serum, he withdraws the tube, and running the shot down on the two unused sutures, closes the wound perfectly, leaving only a linear cicatrix instead of a deep pit at the lower angle to be filled up by granulations and a large plug of scar tissue; this is also safe after suppuration, provided all suppuration has entirely ceased.

He does not like Koeberle's clamp, which had been used by Dr. Price in this case, and considers it far more dangerous, in every way, than the elastic ligature. Sänger's device, just announced, combining an extra- and intra-peritoneal treatment, promises much, and is certainly destined to repeated trial.

Dr. Montgomery thought the case one of extreme interest in point of diagnosis and treatment. The pressure of the tumor on the ureters causes changes in them, and also sacculation of the kidneys. He had operated in a similar case some years ago, and subsequent examination revealed sacculated kidneys, and pus in one; even if no knife had been used, the patient would have died from the ether. He thinks, with Dr. Price, that the drainage-tube should have been used in his case.

Dr. Joseph Price remarked that he had no fear whatever of the drainage-tube, and thought it might be used in every case. Tait's rule: "When in doubt, use the tube," was a good one. Dr. Price made some remarks upon his methods of using drainage-tubes of

glass, using cotton wick in some cases to remove accumulations of serum and to clear the openings of the tubes, using a sucking bulb with gum tubing to draw out fluid accumulations, and introducing a smaller gum tube through the glass one before withdrawing the latter.

DR. M. PRICE exhibited specimens from a case of

PYOSALPINX OF GONORRHŒAL ORIGIN.

Is pyosalpinx not generally or always the result of gonorrhœa? His cases have, without exception, followed attacks of gonorrhœa. Can such a sequel be anticipated and prevented?

DR. MONTGOMERY remarked that Dr. Noeggerath initiated the idea of latent gonorrhœa as the cause of salpingitis and pelvic peritonitis.

DR. M. PRICE remarked that his patients had been in robust health; they were generally women who had borne but one child, and the labor had been followed by repeated attacks of peritonitis.

DR. LONGAKER read a report of a case of

LAPAROTOMY FOR PYOSALPINGITIS.

Maggie T., aged 33, was admitted to Lying-in Charity Hospital November 13, 1886. She had one child eighteen years before, after a difficult and prolonged labor. Unmarried, and has a history of specific disease. During the last four years her periods have been accompanied by intense suffering, and in the intervals she was never free from distressing aches in the pelvis. Lately she had used opium to some extent. In addition to the evident enlargement of the appendages on both sides, the patient has a perineo-recto-vaginal fistula and a stricture of the lower end of the rectum. A diagnosis of pelvic cellulitis was made by him in this case two years ago. *Operation* November 18. The left tube, a sausage-shaped tumor, and the ovary, a fluctuating mass the size of a walnut, were easily removed; a small amount of pus escaped from the end after ligation, but this was arrested by pressure forceps. The ligature was necessarily passed over the uterus, but owing to friability of tissues, troublesome oozing continued and delayed closure of the abdomen. On the right side the ovary and tube formed a large abscess the size of a goose-egg. It was impossible to separate and remove this without rupture. It was filled with pus and altered blood. Adhesions were dense and firm. There was also some oozing on this side, but it gave rise to comparatively little trouble. The peritoneal cavity was irrigated with hot water; 1 to 5,000 bichloride solution sponges. Abdominal walls sutured with silk over which was placed an impervious coat of iodoform collodion. Convalescence uneventful. She is now free from pain.

DR. M. PRICE inquired about the source of hæmorrhage. He had seen severe hæmorrhages due to the fact that the tube was cut by the ligature. He thought it important to tie straight across the tube and not obliquely. He ligates by double ligature and ties back. He considers it right to open up at once if hæmorrhage is at all free; he does not think it right to trust to sponges and hot water.

DR. JOSEPH PRICE had seen very free hæmorrhage from adhesions to the bowels, large sinuses being laid open and pouring out blood. In several cases he had used iron as a styptic.

DR. LONGAKER explained that the hæmorrhage came from the opening up of the broad ligament.

DR. H. A. KELLY read a paper embracing

NOTES ON PALPATION OF THE FEMALE URETERS,

which will be published in full with diagrams.

DR. JOSEPH PRICE read an interesting letter from Dr. Joseph Eastman, summarizing the features of McDowell's early operations, showing how perfectly antiseptic his work was.

DR. COFFEE spoke of Dr. Sutton's work as being pioneer work. He gave up good practice and went to Europe to work up this field.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Antiseptic Treatment of Summer Diarrhœa—Officers of the Academy—Hospital Saturday and Sunday Fund.

At the last meeting of the Academy of Medicine Dr. L. Emmett Holt read a paper on the "Antiseptic Treatment of Summer Diarrhœa," which seems likely to have a marked effect upon the manner of dealing with this affection in the future. As he truthfully remarked, an examination of even the most recent text-books on the diseases of children will show that practically the same methods of treatment are inculcated which were in vogue fifty years ago; so that there would certainly appear to be some "room for improvement."

Dr. Holt said that he made use of the term summer diarrhœa as designating an affection with which all were familiar, but which did not involve any points of pathology about which there might be differences of opinion. While acknowledging the prime importance of suitable hyygienic conditions in the treatment, it did not come within his province on the present occasion to discuss these. With the exception of instances of pure cholera infantum, all cases of summer diarrhœa are, in his opinion, due to fermentation or putrefaction in the intestinal tract. Among the factors entering into the causation of the trouble he mentioned heat, improper feeding, and bad hygienic surroundings. The affection was evidently not due to heat alone, or else we should find the greatest mortality among infants under six months of age; which was not the case. During the first six months a much larger proportion of infants were wet-nursed than at a later period, and it was after this age that the greatest number of deaths was noted.

In treating of the influence of heat he spoke of its effect not only upon the child, but upon its food, and referred to an instance at the New York Infant Asylum in which no less than twenty-three children became affected with diarrhœa from the use of tainted milk. In tenement-houses all the conditions were

especially favorable to the contamination of this article of food, and it was only a wonder that more children did not suffer from this cause than was actually the case. In this connection he spoke of the development of poisonous ptomaines from food, and alluded particularly to the investigations of Professor Vaughan, of the Michigan State Board of Health, in regard to the principle which he had designated tyrotoxicon. Brunton's researches had also, he thought, furnished the solution of many hitherto insoluble problems. Cerebral symptoms had been generally supposed to be due to the sudden stoppage of the diarrhœa; but Huchard had shown that poisonous ptomaines were evolved from human fæces even in a state of health, and this was the case to a much more marked extent in such diseases as summer diarrhœa.

In this affection, Dr. Holt went on to say, the inflammatory changes are almost entirely confined to the large intestine. A specific microbe having a causative relation to the disease had not as yet been demonstrated; though numerous bacteria, of various kinds, were always found in connection with it. The indications for treatment were as follows: 1, clear out the bowels; 2, stop decomposition; 3, restore healthy action to the bowels; 4, treat the consequential lesions.

In the first place, it was necessary to clear out the bowels for the same reason that the surgeon thoroughly cleanses a wound before applying his antiseptics. In nearly all cases, Dr. Holt said, he began his treatment with a cathartic, in order to remove the altered secretions; and if the stomach was not very irritable, there was no purgative which was to be compared to castor-oil for this purpose. If the stomach was irritable, he was in the habit of using large injections of water by means of a fountain syringe. By experiment he has found that it takes almost a pint of fluid to reach the ileo-cœcal valve, and at least this quantity, he thinks, should be used. In many cases the castor-oil was all the medicine that was required, as a suitable dietetic and hygienic regimen would complete the cure. In cases in which the passages, consisting of pure serum, were odorless and alkaline in reaction, no preliminary cathartic was required.

In order to arrest decomposition and restore healthy action to the bowels, the most efficient agent that he had met with was salicylate of sodium. If there was much vomiting, it was better to withhold food altogether for from ten to twenty-four hours; employing carbonic acid water, or thin barley water, for allaying thirst. In children under 2 years of age no milk whatever should be allowed; though peptonized milk was less likely to do harm than either condensed or ordinary cow's milk. He had known many relapses to be brought on by the use of milk.

The treatment of the consequential lesions, the fourth point considered, consisted in, 1, appropriate dietetic treatment; 2, the continuation of the antiseptic; and 3, the washing out of the whole large intestine every day with pure water or a weak antiseptic or astringent solution. The medicinal agents which he preferred for these injections were benzoate of soda and nitrate of silver. It was a fact, he said, that all the drugs which had hitherto proved of service in the treatment of summer diarrhœa, with the exception of opium (in regard to which there had been much discussion), were of a more or less antiseptic nature. He then proceeded to give a *résumé* of the history of the use of antiseptic remedies proper in this affection, from the year 1846, when creosote was first employed for its relief.

In order to find out what is the present practice in New York institutions, Dr. Holt has written to the physicians of fourteen of these, including the Nursery and Child's Hospital, the Foundling Asylum, St. Mary's Hospital for Children, the Demilt Dispensary, and a number of other prominent hospitals and dispensaries, in which upwards of 40,000 children — 25,000 of them for diarrhœal diseases—are treated annually. He ascertained, among other facts, that opium was used in all, bismuth in all, chalk mixture, with paregoric and astringents, in quite a number, castor-oil as a preliminary medication in six, castor-oil emulsion, with equal parts of the oil and of paregoric, in three, calomel in three, ipecac in three, pepsin in one, iodoform in one, morphia and atropia hypodermically in one, and astringent injections in three.

In his own experience Dr. Holt found that with the use of opium, bismuth and astringents, 50 per cent. of cases are cured, and 7 per cent. died; the remainder being classified as improved and unimproved. A year ago last summer he first commenced the use of salicylate of sodium. In about two-thirds of the cases in which he employed it he gave castor-oil as a preliminary to the treatment, and out of 81 cases, 60 were cured, 14 improved, 6 unimproved, and 1 died. He also treated 44 cases with naphthaline, 22 with resorcin, and 28 with bichloride of mercury. The comparative results of the different remedies were as follows: Cured by opium, bismuth and astringents, 50 per cent.; cured by salicylate of sodium, 84 per cent.; cured by naphthaline, 67 per cent.; cured by resorcin, 55 per cent. He, therefore, considers the salicylate of sodium the most efficient remedy; and next to this comes naphthaline.

Having related an illustrative case in which the sodium salicylate, administered after a preliminary dose of castor-oil, had effected a cure in an apparently hopeless case, he stated that he is in the habit of giving this remedy in doses of from 1 to 3 grains, in aqueous solution, every two hours; and recommended that it should be administered with the food or drink. It did not produce vomiting, but, on the contrary, often allayed irritability of the stomach. Naphthaline could be given in doses of from ½ grain to 5 grains, and resorcin in doses of from ½ grain to 2 grains. Bichloride of mercury, which should be given in doses of from $\frac{1}{120}$ to $\frac{1}{100}$ of a grain, was sometimes apt to produce vomiting. Dr. Holt said that he did not undervalue the efficiency of opium in other forms of diarrhœa.

In conclusion, he stated that the use of evacuants constituted an essential part of the antiseptic treatment of summer diarrhœa, and that he considered the latter especially valuable because it was aimed at the cause of the trouble in the intestinal canal, and not simply at its effects.

In the discussion which followed the reading of the paper Dr. Wilcox related his experience with naphthaline in the treatment of diarrhœa; stating that he had employed it in thirty-two cases, though nearly all of them were in adults. In his hands it had proved so efficient that he had come to regard it of the same value in diarrhœa as mercury in syphilis, or quinine in malarial trouble. In order to secure its full effect the patient should take at least 60 grains a day, and in some cases as much as 120 grains was required. He gives it chiefly in starch capsules, with some oil of bergamot to conceal its odor. Occasionally he has found that the urine becomes smoky under its use, but he has never been able to detect any albumen or casts in it. In one case of twenty-four years' standing, in a man 61 years of age, a cure was effected by the use of 90 grains a day. In two cases he has employed it successfully in the diarrhœa of typhoid fever. The patients were in the third week of the disease, and took from 60 to 90 grains a day; which reduced the stools to two in the twenty-four hours, and rendered them perfectly odorless. Naphthaline has also an antipyretic effect in these cases, and Dr. Wilcox regards it as quite as safe as antipyrin, thallin, or any of the other agents of this class now in use. He has also tried resorcin to some extent, but with very indifferent results.

Dr. Andrew H. Smith remarked that it had been his idea for some time that the cause of summer diarrhœa could be best treated by the aid of antiseptics. The essential oils which were in common use in domestic practice were really antiseptics, and the same was true of the pennyroyal, spearmint and peppermint teas so often resorted to in the country.

Dr. Van Santvoord said that Dr. Holt was no doubt correct in considering the disease primarily dyspeptic in character. He thought bismuth was of service not simply from its mechanical effect, but because it was a true antiseptic. The inflammatory changes were largely located in the large intestine, and he was in the habit of employing large astringent injections, in which he combined an alkali with the astringent, in order to remove the mucus which covered the parts.

The President, Dr. Jacobi, said that he quite agreed with Dr. Holt as to the antiseptic character of remedies long in use. As regards bismuth, which he never considered simply as an inert mechanical substance, he had published an article twelve years ago in which he distinctly claimed that it was an antifermentative. He also agreed with Dr. Holt as to the importance of appropriate dietetic treatment, and particularly in regard to the danger from milk, which it was often necessary to withdraw for a number of days. For twenty-five years, he said, he had taught that the disease could not be cured unless milk was given up as a food; but there were plenty of things which could be temporarily substituted for it. He himself generally used the white of egg, raw, mixed with barley water.

Dr. Peabody said that he had come to look upon naphthaline as a very valuable addition to our therapeutical resources in a number of intestinal complaints. For some time past he had been using it in all the earlier cases of typhoid fever which came under his care at the New York Hospital, and in several instances the disease had apparently been aborted by the remedy. He referred particularly to a case which came under treatment on the second day of the disease. By the thirteenth day the fever was gone and convalescence was established, although the patient had had the usual prodromal symptoms of typhoid, and the characteristic eruption and enlargement of the spleen had been well marked. All his cases of typhoid fever, he said, were given a preliminary full dose of calomel. In conclusion, he mentioned some obstinate cases of chronic diarrhœa which had been promptly cured by the use of naphthaline.

In bringing the discussion to a close Dr. Holt stated that Dr. Caldwell, who had expected to be present, had used salicylate of sodium with much success in twenty cases of the diarrhœa of phthisis.

At this meeting the following officers of the Academy were elected: President, Dr. A. Jacobi; Vice-President, Dr. Wm. H. Draper; Treasurer, Dr. W. F. Cushman; Member of the Board of Trustees, Dr. Everett Herrick.

The amount thus far reported from the annual Saturday and Sunday Hospital collection is about $40,000, and there is reason to suppose that the grand total will exceed that of last year. P. B. P.

BOOK REVIEWS.

WÖRTERBUCH DER BACTERIENKUNDE. Bearbeitet von DR. W. D. MILLER, Professor am Zahnärztlichen Institut der Universität Berlin. Stuttgart: Verlag von Ferdinand Enke. 1886.

DICTIONARY OF BACTERIOLOGICAL SCIENCE. By DR. W. D. MILLER, Professor in the Dental Department of the University of Berlin. Sm. 8vo. Stuttgart: Ferdinand Enke. 1886.

To Professor Miller the Profession in general and bacteriologists in particular should be grateful for this Dictionary of Bacteriological Science, which he has so carefully and laboriously compiled. In this, his own country, and in Germany, Prof. Miller is well known through his writings, not only concerning dentistry, but also concerning those microörganisms which represent the lowest forms of life, and which are so near the border line that biologists had much discussion whether they should be classed in the vegetable or the animal kingdom.

Prof. Miller is the first and only American who has been raised by the German Government to the honorable position of Professor in the University of Berlin. He has discovered, described and named several microörganisms, perhaps the most important of which are those which cause dental caries, and the Miller bacillus. The latter is a comma bacillus found in the human mouth, and which, though for a long time recognized as morphologically similar to that ascribed by Koch to cholera Asiatica, and to that by Finkler and Prior to cholera nostras, yet was so re-

sistant of isolation by the efforts of all bacteriologists, that it remained for Prof. Miller to obtain pure cultures of it only after repeated attempts.

The Dictionary describes not only a long series of different kinds of microorganisms carefully selected from the great mass of literature on this subject, and scattered through the different modern languages, but also the various technical expressions which have been recently coined to meet the needs of the bacteriologist, who, together with the practicing physician, has appreciated the want of just such a work. The former will look herein to find the nomenclature, description and source of those microörganisms with which he may chance to be less familiar, and the latter can obtain ready reference to the bacteriological names and expressions which appear in the course of his general reading.

It may be expected that an edition in English will soon appear.

Milk Analysis and Infant Feeding. By A. V. Meigs, M.D. 8vo, pp. 102. Philadelphia: P. Blakiston, Son & Co. 1886. Chicago: W. T. Keener.

In this little book Dr. Meigs attempts to show that the great majority of analyses of human milk made by various chemists are wrong. He claims to have discovered that the caseine of human milk amounts to seldom more than one per cent.

Dr. Meigs has evidently undertaken to work in a field where he is not at home. This subject has been thoroughly discussed years ago, and by men who are well known as thoroughly trained chemists. Their conclusions do not agree with those of Dr. Meigs.

In the part of the book relating to infant feeding, the author presents a number of practical observations from the experience of himself and others, and makes suggestions as to what is the proper food for infants of different ages.

MISCELLANEOUS.

Hot Springs Water.—A circular recently issued by the War Department says, in regard to the water of the Hot Springs of Arkansas: Relief may reasonably be expected from the use of the Hot Springs water in the following classes of diseases, viz., gout and rheumatism in their various forms, after the acute or inflammatory stage has passed; neuralgia, peripheral or central, especially when depending upon gout, rheumatism, specific infection, or metallic poisoning; paralysis, if not recent, progressive, or organic; locomotor ataxia, or tubes, if not in advanced stages, and especially if traceable to specific infection; Bright's disease of the kidneys, only in the early stages; diseases of the bladder and urinary organs; functional diseases of the liver; dyspepsia; chronic diarrhœa and catarrhal diseases generally; chronic skin diseases, especially of the squamous or scaly forms; chronic conditions, resulting immediately from specific infection, either syphilitic or malarial; chronic alcoholism.

In general terms, it may be stated that the Hot Springs water acts by stimulating all secretions and organic functions, increasing appetite, promoting digestion and assimilation; favoring tissue change and excretion of waste products, relieving internal congestions, and stimulating the blood-making function.

In the following classes of diseases the use of the Hot Springs water is contraindicated: All acute, inflammatory diseases; tuberculosis; organic diseases of the heart and brain; aneurism; cancer; and all diseases in which stimulation of the circulation is to be avoided.

Collective Investigation on Centenarians.—The late Dr. Farr has shown, in his "March of an English Generation through Life," that one million children born in England live forty million, eight hundred and fifty-eight thousand, one hundred and eighty-four years, that two hundred and twenty-three live to the age of one hundred, and that finally at the age of one hundred and eight, one solitary life dies.

In the supplement to the *British Medical Journal* of December 11, Prof. Humphry has analyzed the returns from reliable medical men regarding fifty-two centenarians tabulated from the results of a form of inquiry issued by the Collective Investigation Committee of the British Medical Association. In only eleven was the age confirmed by any official record, but the others were naturally assumed to have at least reached nearly the age of one hundred, the informant, in each case, being competent to estimate the value of the evidence, and in most of the cases being intimately acquainted with the individual.

In eleven the intellect is stated to have been high, and low in only five; twenty were reported strong, sixteen of average strength and twelve feeble. Thirty-six were women, sixteen men—a fact explained by Mr. Humphry partly by the fewer exposures of women, notwithstanding the dangers incidental to childbearing and the diseases associated with the varying demands made at different periods upon the organs connected with that process; and partly also by the greater inherent vitality in the female.

Of the thirty-six women, twenty six had been married, eleven had large families, and eight married before they were 20, one at 16 and two at 17. Many of the centenarians were members of large families, there being but two designated as only children. Forty-one of the fifty-two had been married. Twelve were first children. The parents of one centenarian were first cousins.

The average centenarian qualities were a good family history, a well-made frame of average stature, spare rather than stout, robust, with good health, appetite, and digestion, capable of exertion, good sleepers, of placid temperament, and good intelligence, with little need of, and little consumption, of alcohol and animal food, although one man always did and "always will" drink to his utmost capability.

Three were affluent, nineteen poor, and twenty-eight in comfortable circumstances.

Twenty-four of the centenarians had no teeth, and the average number retained was only four or five.

Twenty-eight used glasses, but thirty-five, including many who used glasses, were reported to have been in the enjoyment of good sight. Hearing was good in twenty-two, indifferent in seventeen, bad in nine, one was deaf.

The majority were moderate or small eaters, but maintained an average pulse of 70 and respiration of 22—a fact explained by the diminished elasticity of the circulatory and respiratory apparatus. The arteries had become less capable of accelerating the blood-stream, and the vital capacity of the chest was much reduced, as shown in the slight difference in the chest-girth between the state of inspiration and that of expiration. The hours of sleep averaged nearly nine, the extremes being twelve and four.

The brain held out as well as the other organs, perhaps better; two only were demented. The weakness or failing, generally, seemed to have been about equal in the several great organs.

The majority had suffered little from illness at former periods, yet some had recovered from severe diseases. The habits of life were generally such as conduce to health, necessitated in a measure, at least, by some from their occupations. Thirty-two did not use tobacco; twelve were total abstainers from alcohol, twenty-two took little, eight drank moderately, one drank to excess, on festive occasions, one was a free beer-drinker, and one "drank like a fish all his life" when he could, but said also that he could not get much.—*Boston Med. and Surg. Jour.*, January 13, 1887.

ASEPTOL: A NEW DISINFECTANT.—This substance is orthophenol-sulphuric acid, and has been known since the year 1841. It has been lately brought forward in France as a disinfectant, and Dr. Huppe (*Centralb. f. d. Med. Wiss.*, No. 50, 1886), has made experiments with it, which have led him to the opinion that it possesses advantages entitling it to rank beside carbolic acid and bichloride of mercury. Commercial aseptol is a syrupy liquid, having a faint odor of carbolic acid. It is soluble in all proportions in water, alcohol, and glycerine, and even in a 10 per cent. solution has no caustic action upon the skin. Such a solution kills spores of anthrax in thirty minutes, whilst a 5 per cent. carbolic acid solution requires at least twenty-four hours to produce the same effect. A 3 or 5 per cent. solution of aseptol is a true disinfectant for spore-free microorganisms, or for such as do not form endogenous spores. A 3 per cent. solution was found quite sufficient to disinfect the (previously cleansed) hands. Solutions of aseptol in alcohol, glycerine or oil (in the last named no permanent solution takes place) showed no disinfectant power. By heat it is changed into the corresponding para-combination.

DEATH OF DR. JOHN SCOTT.—John Scott, M.D., M.R.C.S.I., of San Francisco, died of acute pericarditis on December 24. He was born in Ireland, and was about 58 years of age at the time of his death. In his early professional life he was in India for a number of years. When he came to New York in 1865 he spent several months in the study of gynecology under Dr. Emmet, and afterwards went to San Francisco and organized the California State Woman's Hospital, of which he was chief surgeon. Though not a voluminous he was a good writer, a genial companion, and a honor to his profession.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—The next meeting of this Society will be held at Crab Orchard Springs, Ky., in July, 1887. There is every prospect of a large attendance, and the papers to be presented give promise of being of unusual value. Physicians having cases to report should communicate with Dr. J. L. Gray, corner Wabash Avenue and Sixteenth Street, Chicago.

THE INDIANA STATE BOARD OF HEALTH.—The Governor of Indiana says in his annual message: The State Board of Health recommends several amendments to the present law to increase its efficiency, to extend its jurisdiction over diseases of domestic animals, and to create the office of State Veterinarian. The Board states that as the people become more familiar with the operations of the various organizations, and the objects to be attained, the more popular the law becomes, and the more readily the rules and regulations of the Board are observed.

PORT PHYSICIAN OF PHILADELPHIA.—The *Sanitary News* says: A lively scramble is being made by Philadelphia politicians for the position of Health Officer of the port, which is an office in the gift of the new governor. A singular and noteworthy fact is that not a solitary name has been suggested for the position which stands for a sanitary worker. They are all political workers. May none of them get there!

SANITARY ASSOCIATION IN MONTREAL.—A much needed Sanitary Association, with 125 members, has been organized in Montreal.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 7, 1887, TO JANUARY 14, 1887.

Lt.-Col Jos. C. Baily, Asst. Medical Purveyor, ordered from Dept. East to New York City, to take charge of the medical purveying depot in that city, relieving Capt. Henry Johnson, Medical Storekeeper, from duty as acting assistant medical purveyor. S. O. 9, A. G. O., Jan. 12, 1887.

Major Harvey E. Brown, Surgeon, granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Div. of the Missouri. S. O. 9, A. G. O., Jan. 12, 1887.

Capt. J. K. Corson, Asst. Surgeon, ordered to Ft. Coeur d'Alene, I. T.

Capt. C. E. Munn, Asst. Surgeon, ordered to Ft. Canby, W. T.

First Lieut. J. M. Banister, Asst. Surgeon, ordered to Ft. Coeur d'Alene, I. T. S. O. 227, Dept. Col., Dec. 31, 1886.

Capt. Richards Barnett, Asst. Surgeon, leave of absence further extended six months on account of sickness. S. O. 9, A. G. O., Jan. 12, 1887.

First Lieut. Geo. F. Wilson, Asst. Surgeon, leave of absence extended twenty days. S. O. 9, A. G. O., Jan. 12, 1887.

First Lieut. H. I. Raymond, Asst. Surgeon, ordered for duty at Presidio of San Francisco, Cal. S. O. 127, Dept. Cal., Dec. 29, 1886.

First Lieut. F. J. Ives, Asst. Surgeon, granted one month's leave of absence, with permission to apply for twenty-three days' extension. S. O. 1, Dept. Platte, Jan. 3, 1887.

ORIGINAL ARTICLES.

THE OSTEOPLASTIC RESECTION OF THE FOOT, as Devised by Wladimiroff and Miculicz.

Read in the Section on Surgery of the American Medical Association, May, 1886.

BY CHRISTIAN FENGER, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; SURGEON TO COOK COUNTY HOSPITAL, THE EMERGENCY HOSPITAL, CONSULTING SURGEON TO THE GERMAN HOSPITAL; FELLOW AMERICAN SURGICAL ASSOCIATION, AMERICAN MEDICAL ASSOCIATION, OF THE GERMAN SURGICAL ASSOCIATION, OF THE BRITISH GYNECOLOGICAL SOCIETY, ETC., ETC.

One of the characteristics of aseptic surgery is conservatism; this is especially seen in the hesitancy with which, in certain cases, modern surgeons resort to amputations, and in their endeavors to devise less mutilating operations. At the present day joints are excised, partially or totally, and portions of the tarsus or carpus are removed in cases where, in former days, nothing short of an amputation would have been thought of.

The osteoplastic resection of the foot has lessened, and is destined still further to lessen, the number of cases in which amputation of the foot above the malleoli is called for. The operation is indicated when the soft or osseous structures of the heel are destroyed so extensively that there is not sufficient skin or bone left on which the weight of the body can rest. It will thus be had recourse to in certain cases in which Pirogoff's operation or Sédillot's *évidement* cannot be performed, *e. g.*, where there is tuberculosis of the body of the os calcis, with or without fistulous openings, or where there is extensive loss of cutis on the heel. In such cases Pirogoff's operation is impracticable; for to be successful, the posterior half-inch or inch of the calcaneum must necessarily be healthy, and the skin of the heel must be reasonably well preserved. Cicatricial tissue, as is known, is of low vitality; it is unable to endure the pressure and friction incident to walking; it is thinned by "usure," becomes necrotic, and the omnipresent pus microbes gain admittance to the denuded tissue.

Sédillot's *évidement* also has its limitations. Where the operation leaves large cavities, in a patient older than 10 years, the cavities will, as a rule, never fill with bone. If the greater part of the spongy substance of the calcaneum be removed with a gouge; if, as Sédillot says, a mere shell of bone be left, the calcaneum will, in many instances, be unfit to walk upon; it is too weak, its spongy substance is but imperfectly reproduced. In such cases the only operation by which, formerly, the patient could be relieved, was amputation above the malleoli.

In 1872 a Russian surgeon, Wladimiroff, read before the Medical Society of Kasan, Russia, a paper on several new osteoplastic operations which he had performed on the lower extremity. Among them he described an operation by which he formed, according to his phraseology, an artificial *pes equinus*. He had had a case where there was chronic destructive disease of the astragalus and calcaneum, with loss of skin on both sides of the lower astragalus joint. The cuboid, scaphoid and remaining bones of the foot were sound. Being desirous of having the patient walk on his foot, of preserving the sound parts of the member, and of obtaining a clean wound which would be likely to heal by first intention, he conceived of the following operation, which he carefully studied and practised on the cadaver:[1] He removed the astragalus and calcaneum with the skin covering the heel, and united the cut surfaces of the scaphoid and cuboid bones with the tibia and fibula; the last two bones he cut just above the malleoli. Wladimiroff operated March 2, 1871, and published the case on February 11, 1872. He stated that his patient, a boy of 15, could walk without a cane, and that he walked well with a cane. As this case was published in the Russian language, it was almost as good as lost to the medical profession in all countries except Russia.

In 1881 Miculicz, of Vienna, having no knowledge of Wladimiroff's case, devised an operation similar to, or rather identical with that of the Russian surgeon.[2] As the profession became acquainted with the operation through Miculicz, his name has been attached to it. At the Eighth International Congress in Copenhagen, however, Professor Sklifossoffsky, of Moscow, stated that Miculicz's operation had been known in Russia for some years past, and that the idea of forming an artificial pes equinus was due to Wladimiroff. Miculicz's case is as follows:

A man of 22 years suffered from a serpiginous ulcer which, destroying the skin, had extended from the malleoli around the heel to the anterior half of the sole of the foot. The skin on the dorsum of the foot remained intact. Miculicz incised the ankle joint, removed the astragalus and os calcis with the integument, and sawed a disc off the scaphoid and

cuboid bones. The steps of the operation were as follows: An incision was made across the sole of the foot from the tuberosity of the scaphoid to a point a little posterior to the tuberosity of the fifth metatarsal bone. From the ends of this incision he cut upwards and backwards on both sides of the foot as far as the malleoli, and made a fourth incision between these two points posteriorly to the joint. He then disarticulated at the ankle, cutting from behind, and brought the foot into dorsal flexion; the astragalus and os calcis were detached from the soft parts on the dorsum of the foot and Chopart's joint opened from above. Having obtained with a saw cut surfaces at the ends of the tibia and fibula above the malleoli, and cut surfaces at the posterior parts of the cuboid and scaphoid bones, he brought these surfaces into apposition, and thus placed the foot in the position of a pes equinus. The wound healed in two months. In four months his patient walked without a cane in a boot constructed for the purpose. A few weeks later he walked without the boot and was able to bear his whole weight on the resected foot.

In order to illustrate the operation I will give the history of my case, and later I will discuss the indications for the operation, the method of performing it, and its results:

Synopsis.—Traumatic injury to the right heel resulting in chronic progressive osteo myelitis and periostitis of the os calcis and the talus of ten years' duration. Osseous ankylosis of posterior talus joint and of Chopart's joints, fibrous ankylosis of ankle-joint. Ulcerative destruction of the skin on the posterior surface of the heel. Repeated local operations on the calcaneum without permanent benefit. Abscess and subsequent intractable fistulas on the dorsal side of the talus, leading to diseased bone in the sinus tarsi. Osteoplastic resection of the foot in accordance with Miculicz's description. Consolidation of the foot in good condition. No relapse of the disease in the bone; forcible extension of the toes into the equinus position. Rupture of skin at the base of the first phalanx of the hallux. Subsequent inflammation of the scar. Excision of the scar and transplantation of skin from the planta pedis. Healing by first intention. Patient is able to walk without cane, and can bear the whole weight of his body on right foot.

Christian Jebsen, æt. 28, laborer, gives the following history: *His father* was troubled for many years with annually recurring attacks of facial erysipelas; his mother suffered from a chronic pulmonary disease and varicose ulcers of the left leg. Patient's health was good up to his 18th year. At that time patient followed the occupation of a sailor. On board ship he received an injury in his right heel from a pointed iron rod which was thrown at him by the captain of the vessel. The point of the rod entered the os calcis posteriorly and passed forward and downward for about one half inch. The wound suppurated one year, during which time patient was in poor health. He was confined to his bed most of the time. Two months after closure of the wound the cicatrix opened; this, together with swelling and tenderness around the os calcis and its articulations, rendered patient an invalid for three years. The wound again healed, and swelling and tenderness diminished so far as to enable patient to wear a boot and to walk without suffering much pain. Six months later a sinus showed itself, through which a probe could be passed into the bone. This sinus closed after several months. Patient then came to America. He had been here but five months when again a fistula began to discharge. In 1883 he was admitted to the Cook County Hospital, where the sinus and a cavity which was found in the posterior part of the os calcis, were scraped with a sharp spoon and gouge. In three months the cavity filled and the wound closed. Patient was discharged in November, 1883. He was able to walk some, but movements of the foot were limited and painful. Swelling and tenderness remained. In the spring of 1884 he returned to the hospital with a running sinus. Dr. Verity removed part of the os calcis, excised the cicatrix and united the skin over the remainder of the bone. The wound did not heal; six months after the operation an abscess formed on the dorsum of the foot over the astragalus.

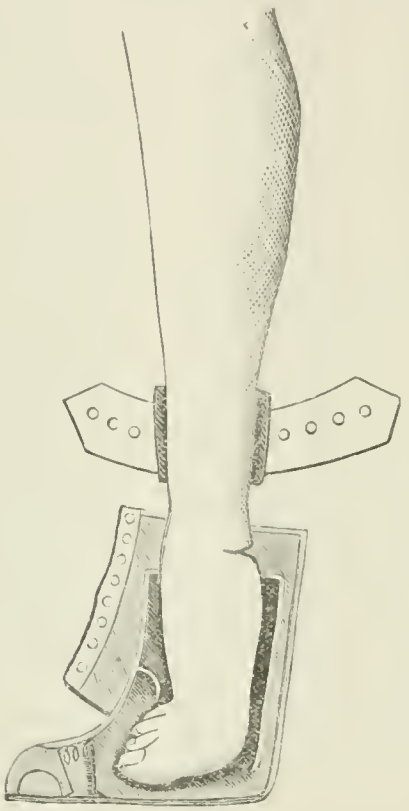
Patient now passed into my care. I found him pale and poorly nourished; lungs, heart and abdominal organs healthy; urine normal. The right foot was fixed in plantar flexion at an angle of about 30°. There appeared to be complete ankylosis in all the joints from the ankle to Chopart's articulation. On the posterior and inferior surfaces of the heel there was an adherent cicatrix, roundish in shape and about 1½ inches in diameter. The centre of this cicatrix presented a granulating spot where a probe could be passed to the roughened surface of the calcaneum. The soft parts around the ankle and on the dorsum of the foot were swollen and indurated. An abscess on the dorsal side of the astragalus was opened and about a tablespoonful of pus evacuated. The probe discovered roughened surfaces of bone in the sinus tarsi. I drained the abscess, placing a tube transversely behind the flexor tendons; scraped the granulating spot on the heel and applied an iodoform dressing. The wound was treated for four months with injections of tincture of iodine and of a solution of iodoform in ether. As the condition remained the same it became necessary to decide whether the foot should be amputated above the ankle or resected according to the method of Miculicz. The loss of skin on the heel and the diseased condition of the bone put Pirogoff's operation out of the question. As the patient wished to retain as much of his foot as possible, I determined on Miculicz's operation, which I performed upon him December 31, 1884.

After thorough disinfection of the foot and leg as high up as the knee, patient was anæthetized, turned over on his stomach, and Esmarch's elastic bandage applied. As there had been an abscess on the dorsal side of the astragalus, and as there remained considerable infiltration of the tissues around the flexor tendons and in the neighborhood of the arteria dorsalis pedis, I dared not rely upon this artery alone for the blood-supply of the foot. I desired to pre-

serve the posterior tibial artery as far down as I possibly could; at all events down to its division into the internal and external plantar arteries. I was consequently compelled to make my incisions somewhat different from those made by Miculicz. I began my internal incision in the planta, three-fourths inch from the inner margin of the sole, and three-fourths inch posterior to the tuberosity of the scaphoid. From this point I curved my knife, cutting down to the bone, backwards and upwards over the internal surface of the os calcis, below the sustentaculum tali, to the inner border of the tendo Achillis; thence upwards along the tendon to a point posterior to the ankle joint. In making my external incision I commenced one inch behind the tuberosity of the fifth metatarsal bone in the margin of the foot; I then cut upwards and a little backwards, running the incision half an inch anterior external malleolus, over the external surfaces of the processes anterior calcanei and the body of the astragalus to the ankle joint. Between the upper and lower ends of these incisions I made transverse incisions across the sole and behind the ankle joint respectively, cutting down to the bones. The superior transverse incision dividing the tendo Achillis, gave a ready access to the ankle joint. The soft parts of the dorsal flap were detached from the subjacent bones with a periosteal elevator, which was kept between the periosteum and bone in order to avoid injuring the vessels. The disarticulation at the ankle joint was accomplished with some difficulty, as a complete osseo-fibrous ankylosis was found to exist between the astragalus and the tibia. Having disarticulated, I pushed the heel downwards and further detached, with the periosteal elevator, the anterior soft parts from the astragalus. From inactivity and the proximity of a suppurative inflammation, the bones had undergone fatty atrophy (adipose osteoporosis); they were so friable as to break in or near Chopart's joint, which was completely ankylosed. The posterior parts of the scaphoid and cuboid bones were now gouged away as far as diseased; after healthy bone was reached a thin disc was sawed off each bone in order to obtain even and smooth bony surfaces. The ends of the tibia and fibula were sawed off half an inch above the joint. The sinuses that existed in the dorsal flap were scraped with the sharp spoon. Esmarch's bandage was now taken off and the hæmorrhage stopped. After this the cut surfaces of the scaphoid and cuboid were brought into apposition with the corresponding surfaces of the tibia and fibula, and held in place by means of two silver wire sutures. The wound was lightly dusted over with iodoform, the soft parts were united with deep catgut and superficial silk sutures, and the necessary drainage was provided for. The foot and leg, half way up the thigh, were enveloped in an iodoform-Lister dressing and immobilized with plaster of Paris bandages.

The soft tissues on the inner side of the foot naturally formed a bulky mass. I preferred to leave this and to allow it to undergo atrophy in the future. By diminishing its size I should have run the risk of losing important branches of the posterior tibial artery. The circulation in the distal portion of the foot was perfect; after removal of the elastic constrictor blood was seen to ooze from all parts of the peripheral side of the wound.

The wound healed (definitively) in four months. During this time a few small abscesses formed in the just-mentioned mass of soft parts on the inner side of the foot. One also appeared behind the tibia. These abscesses being promptly opened and drained, caused no further trouble.



MICULICZ S BOOT.

As the toes of the foot were fixed in semiflexion, and as they possessed but little mobility, it became necessary to effect their complete dorsal flexion in order to enable the patient to walk on the balls of the first phalanges. Two months after the operation, in June, 1885, the patient was again anæsthetized and the toes were forcibly extended, *i. e.*, flexed on the dorsum of the foot. The flexor tendons, as well as the metatarso-phalangeal joints had (from non-use) almost entirely lost their mobility; the skin covering the plantar surfaces of the joints was contracted. As a consequence of this condition the skin gave way beneath the first and second metatarso-phalangeal joints, and the first phalanx of the great toe was fractured just anterior to the joint. The wounds resulting from these ruptures of skin were irrigated with an antiseptic solution and packed with iodoform gauze. An extensive Lister dressing was put on and the dorsal flexion of the toes maintained by a plaster cast. These small wounds healed in about a month. Patient was

TABLE OF OPERATIONS.

No.	Operator.	Year.	Age.—Sex.	Disease.	Course.	Death.	Result.
1	Wladimiroff.	1871	Boy. 15.	Tuberculous caries of talus and calcaneus; tuberculous ulcers on both sides of the joint.	Recovery.		After 12 months walked well with a cane, able to walk without cane. Lengthening.
2	Miculicz.	1880	Man. 22.	Serpiginous ulcer (syphilis) on calf of leg, on heel and posterior half of plantar surface of foot. Bones and joints healthy.	Wound healed in two months.		In 4 months walks without cane and without boot. In 6 months does hard work; can walk one hour. Lengthening 1½ ctm.
3	Socin. (Reported by Burchart.	1881	Girl. 22.	Caries.	Healed rapidly.		In 2 months walks with cane; later she works in the field; 2 years later no fistula. Lengthening 1½ ctm.
4	Miculicz.	1881	Woman. 27.	Tuberculosis of posterior astragalo-calcaneal articulation. Evidement and removal of a sequestrum of no avail.	Healing by first intention.	6 mos. later, of tub. pul.	In 2 months commenced to walk. Lengthening 1½ to 2 ctm.
5	Sklifossoffsky (Moscow)	1882	30.	Caries.	Recovery.		When reported in 1882 did not walk very well.
6	Lümniczer (Reported by Haberern).	1882	Boy. 18.	Tuberculosis of the talus, calcaneus, and malleoli and the joints from ancle to Chopart's articulation. Fistulæ and fungous ulcers on the skin of the heel. Syme's and Pirogoff's operations impossible.	Relapse of the tuberculosin the wound.		Amputation above the malleoli: recovery 5 months after the operation.
7	Miculicz.	1883	Boy. 16.	Tuberculosis, traumatic, of the posterior astragalo-calcaneal articulation. Numerous fistulous openings through skin of heel. Evidement of cuboid and scaphoid bone at the operation.	Healing by first intention under two dressings.		In 4 months walks with boot and cane fairly well. In 6 months solid ankylosis. Can walk without boot, but must use cane. Can walk in boot without the cane. Lengthening 1½ ctm.
8	Lauenstein.	1883	Woman. 32.	Tuberculosis of the talus, calcaneus —upper posterior part—and internal malleolus. Evidement. Relapse in ankle and posterior astragalo-calcaneal articulation.	Healing of wound in three months.	8 mos. later, of tub. pul.	The stump was painless and could bear some weight.
9	Lauenstein.	1883	Man. 25.	Tuberculosis in posterior astragalo-calcaneal articulation. Evidement. Relapse in ankle-joint. Abscess in plantar side of foot.	Healing in one and one-half months.		In 2 months can walk without pain. In 3 months works as a plasterer, in boot. Lengthening 3 ctm. Five months later walks 4 hours without pain.
10	Miculicz.	1883	Man. 50.	Tuberculosis of talus and calcaneus.	Healing.		Walks fairly well with cane; no difference in length visible when he walks.
11	K. Roser.	1883		Caries.	Recovery.		Good functional result.
12	Kümmel.	1883	Woman. 38.	Tuberculosis of the calcaneus. Extirpation. Relapse. Extirpation of the talus and malleoli. Relapse.	Healing of wound; relapse four months later, removal of the rest of the tarsus, part of the metatarsus, and an additional piece of tibia and and fibula.		In 7 months after last operation can walk with a plaster cast. Lengthening 6 ctm.
13	Schattauer.	1884	Girl. 10.	Tuberculosis of ankle-joint and swelling of posterior part of the foot; fistulas below the external malleolus. Tuberculosis pulmonum incipidus; fever; emaciation.	Healing by first intention.		In 5 weeks walks in plaster cast In 5 months walks in a common shoe for hours without pain; both legs of equal length.
14	Schattauer.	1884	Boy. 9.	Tuberculosis of ankle and posterior astragalo-calcaneal articulation and along the tendo Achillis.	Relapse of the tuberculosis.		Amputation above the malleoli. Recovery.
15	G. Fischer.	1884	Girl. 18.	Tuberculosis of posterior astragalo-calcaneous articulation. Fistulas. Evidement. Relapse.	Relapse of tuberculosis after 8 months. Removal of cuboid and 2d and 3d cuneiform bone.		Six months after last operation; can walk slowly without boot. Walks well with boot and cane. Mounts stairs.
16	Ranke. (reported by W. Reussen.)	1884		Cicatricial contraction of the foot in the position of equino-valgus, subsequent to a badly treated suppurating fracture above the malleoli.	Healing in 3 months.		7½ months after the operation walks very well with boot. The leg operated upon is 3½ ctm. shorter than the other.
17	Sordina.	1885	Man. 20.	Caries of the tarsus involving the ankle joint.	Gangrene of the foot on the fourth day.		Amputation above the malleoli. Recovery.
18	Sordina.	1885	Girl. 11.	Caries of the talus. Evidement. Relapse in the talus and calcaneus. Tuberbulosis around the extensor tendons.	Healing in 7 weeks.		In 7 weeks able to walk without cane; walks almost without limping.
19	Chr. Fenger.	1885	Man. 28.	Chronic traumatic osteo-myelitis for ten years. Ankylosis of the joints from ankle to Chopart's articulation Fistulas leading to suppurating bone in the sinus tarsi. Ulcerating cicatrix on posterior and lower surface of the heel. Evidement and plaster operations twice. Relapse.	Healing definite in 4 months. In 6 months toes dorsalflexed; 12 months after the operation plastic transplant of skin from plant healing in 4 weeks.		Fifteen months after the operation can walk without boot and cane, and bear the whole weight on the foot. Solid ankylosis. Lengthening 5 ctm.

then allowed to step on the foot. He was furnished with a boot made according to the plan designed by Mikulicz, and discharged from the hospital.

He gradually learned to bear some weight on the foot. But the cicatrix on the plantar surface of the great toe, where the skin had broken in making dorsal flexion, soon began to ulcerate; either because patient's boot did not fit, or because the cicatrix was insufficient to bear his weight in walking. In January, 1886, he had an attack of facial erysipelas, for the treatment of which he returned to the hospital. After his recovery from the erysipelas I ordered him disinfected for the final trifling operation which the case required. I had his whole body shaved and sponged with a weak sublimate solution. I then excised the cicatrix beneath the metatarso-phalangeal joint of the great toe, and transplanted to the wound a flap of skin from the sole of the foot. The dimensions of the cicatrix were one inch transversely and three-fourths inch antero-posteriorly; those of the flap were three inches by one and one-half inches. The flap, which had been loosened from the plantar fascia, and to which the adipose tissue was left adherent, was united to the skin of the great toe. The wound remaining in the place from which the flap had been cut, was packed with iodoform gauze and left to cicatrize. A cicatrix thus situated could do no harm, as it would be one and one half inches above the ball of the great toe, on which the patient must rest his weight. The flap grew to its new surroundings in two weeks, and by this time patient is beginning to walk in his Mikulicz boot.

The parts which I removed by the operation were exhibited at a meeting of the Chicago Medical Society. The specimen shows the following points: On the skin covering the calcaneum is seen a cicatrix about two inches long and between one-half inch to an inch wide; it curves around the heel from below upwards and backwards, half of it being situated inferiorly and half of it posteriorly. A sagittal section through the astragalus and os calcis presents a complete osseous ankylosis between the two bones, which are separated only by the sinus tarsi. On the tibial surface of the astragalus the cartilage has disappeared and a rough osseous surface is seen, which had been united with the tibia by osseous ankylosis. The bone is found to be in the same condition on the anterior surface of the head of the astragalus and on the anterior process of the os calcis. Osseous ankylosis here also existed (at the time of the operation) between these portions of the two bones and the scaphoid and cuboid bones respectively. The latter two bones, as I stated above, were partially removed with gouge and saw. The other piece of the specimen shows the malleoli united by a thin disc of the tibia, from which subsequently an additional disc was sawed off.

I furthermore called the attention of the Society to two plaster casts which had been taken of the foot after patient had recovered. The shortened foot is seen to be in the axis of the leg, in the position of an extreme pes equinus. The dorsum of this artificial pes equinus is slightly convex; the planta is flat and almost in direct continuation with the surface of the calf. In place of the internal malleolus a bony prominence has formed, which closely resembles the malleolus; it probably grew from the periosteum of the malleolus. The mass of soft parts which was left on the inner surface of the foot, has undergone almost complete atrophy. The superficial tissues lie almost as close to the bones as on the fibular side of the foot. The external malleolus is replaced by a small process of bone; about one inch posterior to this, and half an inch inferior to it, the tuberosity of the fifth metatarsal bone may be noticed.

The first and second toes are flexed on the dorsum of the foot almost to a right angle; the third and fourth toes are flexed in the same manner, but to a less degree. We must remember that the cast was taken while patient was lying in bed; when he is in the upright position the flexion of the toes exceeds that seen in the cast.

A solid osseous union has taken place between the cut surfaces of the bones. The foot still possesses some active and passive mobility in the remaining joints of the tarsus and in the joints between the tarsus and the metatarsal bones. This mobility, however, is so limited as not to impair the necessary stability of the foot. The toes move actively, the first, second and third toe through an angle of 25°; passively the great toe can be moved through an angle of 40°, and the second and third toes through one of 80°. The circumference of the walking surface of the foot, the toes included, is 10½ inches. Across the foot this surface is three inches wide, and from before backwards, beginning at the bases of the toes, it is 1½ inches. The active mobility of the toes gives a certain degree of elasticity to the gait. Measurements of the two extremities show that the limb operated upon has been lengthened by two inches. The measurements were made from the anterior superior spine of the ileum to the lowest point of the heel on the left, and to the ball of the great toe on the right side.

Indications for the Operation.—The operation is indicated in cases in which there is an extensive loss of substance or an intractable disease of the bones and skin of the heel. In Mikulicz's first case there was extensive destruction of the skin only. In four cases out of the nineteen cases published there existed tuberculous ulcers of the skin together with disease of either the calcaneum or astragalus. Of the remaining cases, in but one was the operation done for widespread destruction of bone with implication of one or more of the joints between the ankle and Chopart's articulation. In Ranke's case the bones and joints were sound, but a cicatricial contraction of the skin and malformation of the foot disabled the member.

Mikulicz enumerates the indications as follows: 1. Extensive injuries of the heel and the parts surrounding it. 2. Caries, *i. e.*, tuberculosis of the astragalus and os calcis with implication of a neighboring joint. 3. Extensive destructive ulceration of the skin on the heel.[3]

[3] Mikulicz. Zwei Falle von osteoplastischer Fuss-resectionnach eigener. Methode, 1883, pp. 36, 37. Centralbl. fur Chirurgie, No. 1, 1884, p. 12.

As to the first indication it is to be remarked that the operation, as far as we know, has not as yet been performed in a case of acute traumatic injury of the heel.

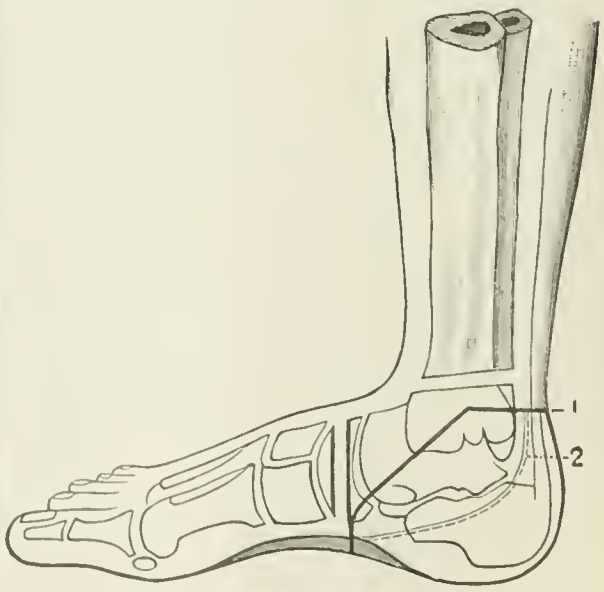
The second indication has most frequently led to the operation; it being present in thirteen out of the nineteen cases reported. As the skin of the heel was intact in these cases, the question arises whether it would not have been preferable to make an extensive atypical resection of the tarsus. The latter operation does not alter the position of the foot; it allows the patient to walk on the planta. Opinions differ in regard to this question. Most of the older writers, as Hueter, Koenig, Czerny and Billroth, advise against resection of the tarsus. Lately, however, Kappeler in Germany and Connor in America have taken up and, in able papers, revised the subject of resection of the tarsus; both come to the conclusion that a good functional result may be obtained after removal of the tarsus, even when the operation is combined with a resection of the ankle joint, *i. e.*, with a removal of the lower ends of the tibia and fibula. It may thus be doubted whether such cases as the thirteen mentioned call for Miculicz's operation, and whether his second indication is not better met by a partial, or even a total resection of the tarsus.

Miculicz's third indication is the only one which, as appears to me, must be indisputably accepted as good. Where there is extensive ulceration of the skin covering the heel, nothing but a cicatrix will form, and a cicatrix under the heel cannot bear the weight of the body, and will always ulcerate under the pressure it is subjected to in walking. As both Syme's and Pirogoff's operations require that the skin on the posterior flap be healthy, the osteoplastic resection of the foot is the only operation by which a supra-malleolar amputation can be avoided.

If, in the course of time, the osteoplastic resection of the foot should prove superior to excision of the tarsus, to Syme's and to Pirogoff's operations, in its functional results, the indications for the operation will be viewed in a different light.

Steps of the Operation—1. Incisions.— Miculicz made a transverse incision across the sole from the tuberosity of the scaphoid to a point a little behind the tuberosity of the fifth metatarsal bone. Schattauer cut one-fourth to three-fourths inch anterior to this, running his incision over the cuneiform and cuboid bones. From the ends of the transverse cut incisions were made on the tibial and fibular sides of the foot, upwards and backwards as far as the malleoli, between which two points the knife was carried around the ankle joint posteriorly. The tibial incision from the tuberosity of the scaphoid to the internal malleolus inevitably divides the posterior tibial artery, or rather its plantar branches. This leaves but the anterior tibial artery to supply the foot with blood. Miculicz, before he did his first operation, doubted that the blood-supply of the foot would be sufficient. He was, however, relieved of his anxiety when, after the removal of Esmarch's bandage, he saw the cut ends of the plantar arteries bleed freely. As I said above, I likewise feared for the safety of my patient's foot, in which there existed fistulous openings, hard induration, and infiltration of the soft tissues surrounding the anterior tibial artery. That such apprehension was well founded may be seen from Sordina's case, in which, four days after the operation, gangrene of the foot necessitated its amputation. It is, therefore, necessary to preserve some branches of the posterior tibial artery. This can be done by altering the incisions of the operation in the following manner:

Instead of cutting clear across the planta, the anterior transverse incision may be begun three-fourths inch external to the tibial border of the foot. The tibial incision may then be made from this point, not upwards to the internal malleolus, but almost horizontally backwards over the tibial surface of the os calcis, below the sustentaculum tali, to a point one inch posterior to the sustentaculum; then it may be continued upwards along the tibial border of the tendo Achillis to the posterior side of the ankle joint. By this incision we may hope to save the internal plantar artery, whose assistance in supplying the foot with blood seems essential. This low incision is somewhat inconvenient to the operator; he meets with greater difficulties in getting at the ankle joint and Chopart's articulation than he does when Miculicz's incision is made. This difficulty, however, is overcome partly by separating the soft parts subperiosteally from the calcaneum and astragalus with a periosteal elevator (flat gouge), partly by bringing the external or fibular incision more upward toward the dorsum of the foot, so as to have it terminate about one-fourth inch anterior to the external malleolus. This incision does not imperil the safety of the anterior tibial artery. The upper and lower transverse incisions will be about of the same lengths as they are when Miculicz's directions are followed; there will be sufficient working space to get at the joints.



1. Miculicz's line of incision. 2. My line of incision.

2. *Disarticulation.* — The disarticulation at the ankle had better be done first. Wladimiroff disarticulated first at Chopart's joint. By beginning at the ankle we gain more room for separating the dorsal flap, with the extensor tendons and anterior tibial artery, from the neck of the astragalus. Besides, disarticulation of Chopart's joint is more readily accomplished from above than from below, on account of the process of bone which, at the *posterior tibial* extremity, projects from the inferior surface of the cuboid under the neck of the calcaneum.

3. The step in the operation following disarticulation at the ankle joint, should be the *separation of the dorsal flap from the astragalus.* This should be done subperiosteally with a periosteal elevator. By keeping close to the bone, all injury to the anterior tibial artery and to the extensor tendons is avoidable. Preservation of the extensor tendons is of importance, because active mobility of the toes facilitates walking by rendering the gait more elastic.

4. Next, the ligaments of the calcaneo-cuboid and talo scaphoid articulations are cut through from above, and the heel is removed.

5. After this the malleoli, the articular surface of the tibia and the articular surfaces of the cuboid and scaphoid bones are taken off with a saw. If the cut surfaces should be found to be diseased, more of the bone must be removed. Miculicz (case 17) made *évidement* of the cuboid and scaphoid bones; Fischer (case 15) removed the cuboid and the second and third cuneiform bones. Kümmel, in one of his cases in which there was a relapse of the tuberculosis, was compelled to remove the remainder of the tarsal bones, part of the bases of the metatarsal bones and additional pieces of the tibia and fibula. In all of these cases the functional results were satisfactory.

In case the tuberculosis extends along the sheaths of the tendons, these should be scraped with the sharp spoon; or, better, the sheaths should be dissected out with scissors and forceps (Schattauer, case 14).

6. The cut surfaces of the cuboid and scaphoid are brought into apposition with the cut surfaces of the tibia and fibula. In order to prevent dislocation of the foot and to facilitate bony union, Haberern proposed suturing of the bones. Examining the specimen of Lümniczer's case, in which the foot was amputated five months after the operation, he had found the foot dislocated forwards and rotated outwards, and one-third only of the cut osseous surface in contact with each other. Sklifossoffsky united the bones with silk; Fischer with catgut; Kümmel used silk and a steel nail; in my case silver wire was employed.

That a solid osseous union may be obtained without bone suture is proved by one of Miculicz's cases (No. 7), where he made *évidement* of the cuboid and scaphoid and consequently had irregular osseous surfaces. Nevertheless, the bone suture or the nail must be regarded as valuable helps in holding the bones in exact apposition and in bringing about osseous union.

7. The soft parts are united and drainage is provided for in the usual manner. There is, however, in these cases, a peculiarity which must be mentioned. Where a considerable amount of bone is removed, the dorsal flap is so long that a large fold is formed when the foot is brought up to the tibia. A similar folding and bunching occurs at the tibial side of the wound in cases where the internal incision is made horizontally to save the posterior tibial artery, as in Sordina's case (No. 18), and in mine (No. 19). In order to prevent the formation of dead spaces in this abundant tissue and separation of the coapted bones in cases where no sutures are used, Miculicz employs deeply placed quilled sutures or Plattenvähte. These quilled sutures are undoubtedly of service in cases like Lauenstein's first case (No. 8), where he was obliged to go as high as 7 centimetres above the ankle. In ordinary cases, however, the terraced catgut suture, which is left in place for absorption, serves equally well; besides, it is less apt to interfere with the circulation than is the quilled suture. The superabundant tissue in the anterior flap gradually disappears; it atrophies from non-use.

8. Subcutaneous tenotomy of the flexor tendons of the sole was resorted to by Miculicz in order to facilitate the backward flexing of the toes. If, as in Fischer's case, the toes, before the operation, are sufficiently movable, tenotomy is, self-evidently, superfluous. In most of these cases, however, the toes will be found to be flexed and rigid, probably from non use. As such a foot requires that the toes be flexed dorsally at least to a right angle with the foot, an operation to obtain this position must be done, and it had better be done at once, as thereby time is saved and a secondary operation avoided.

It is doubtful whether, in cases of long standing like mine, tenotomy in the planta will prevent rupture of the skin, or even a fracture through the base of the first phalanx. The latter accident was due, probably, more to stiffness of the metatarso-phalangeal joint than to retraction of the tendon. In the next case which comes into my hands, I shall perform tenotomy and then either extend the toes at once, or, at a later date, after the wound has healed, try gradual, elastic extension. It is of importance to avoid rupture of the skin and fracture of a bone; not because this latter wound does not heal readily under antiseptic dressings, but because the cicatrix will be so situated as to be subject to greater pressure in walking than any other part of the walking surface. The cicatrix will ulcerate, and this will necessitate transplanting of skin from the planta, lest the foot be useless. Such an operation should, of course, be avoided.

9. Over a heavy antiseptic dressing extending from the toes beyond the knee, a light plaster cast should be applied. This should include the knee to insure perfect immobility of the foot. Posterior (Lauenstein, Fischer) and anterior (W. Reussen, Ranke) splints have been used for the same purpose. In cases where there is danger of gangrene, splints may be preferable during the first week, on account of the ease with which they are removed, for in such cases the foot should be inspected daily.

After-Treatment.—The foot is liable to be displaced in any direction, especially in cases where the bones are not held together by sutures. Miculicz says that such displacements can be corrected as late

as four or six weeks after the operation, and that they do not compromise the final result.

A far more serious occurrence, during the after-treatment, is a relapse of the tuberculosis, either in the bones or in the soft parts, but especially in the sheaths of the tendons. The tuberculous tissue must at once be removed. That an extensive secondary operation may be done and the final result still be good, is learned by Kümmel's case. Four months after a typical Miculicz operation, Kümmel took away the tarsus, part of the metatarsus, and additional pieces of the tibia and fibula. The wound healed by first intention. In five weeks his patient was able to walk in a plaster cast, and in five further weeks he walked in a shoe for four hours without suffering any pain. In Fischer's case the tuberculosis returned eight months after the operation. He removed what remained of the cuboid and the second and third cuneiform bones. His patient walked in a boot, with the aid of a cane, in six months. It is also stated that he could walk up and down stairs. The duration of the after-treatment in the different cases, from the time of the operation to the time when the patients began to walk, was as follows: In one (13), five weeks; one (17), seven weeks; three (2, 4, 9), two months; three (2, 7, 19), four months; three (12, 15, 16), six to seven months.

Prognosis and Results.—As yet there has been no death attributable to the operation. Two patients died of pulmonary tuberculosis, one six and one eight months after the operation (cases 4 and 8). Both of these patients had walked on the foot, and, consequently, the operation may be said to have been successful. Three of the operations published were failures, as amputation above the malleoli became necessary. In two of these cases the disease relapsed (6 and 14), and in one gangrene of the foot set in (17). The patients, however, did not die.

It is thus seen that the osteoplastic resection of the foot is not attended by greater danger than the other operations in this locality. As the nineteen operations published were done with antiseptic precautions, it would, of course, be rash to conlude that the mortality of Miculicz's operation is less than that of excision of the tarsus, or of Pirogoff's or Syme's operations. The statistics of the latter operation undoubtedly owe their death-rate to pre-antiseptic surgery.

It cannot be said that the final, functional result of the operation has, as yet, been well ascertained; most of the cases were published a relatively short time after recovery from the operation, and Fischer rightly remarks that we cannot judge of its value before we have a large number of cases before us. The object of the operation is to enable the patient to walk on his foot without any pain; to enable him to bear the whole weight of his body on the walking-surface. This object was accomplished to perfection in three cases (2, 3, 13), and fairly well in nine. In this respect the results of the operation are far superior to those of supramalleolar amputations. It is Fischer's opinion that Miculicz's operation gives better results than Pirogoff's, because after the former the walking surface is at least one-third larger than after the latter, and because the toes give a certain "elasticity" to the gait. Closer comparison of the results of the two operations is as yet needed to confirm the correctness of this opinion. Miculicz did not intend his operation to take the place of Pirogoff's or Syme's, although it seems that in some of the nineteen cases reported the question might have arisen whether excision of the tarsus, or Pirogoff's or Syme's operations were not respectively indicated.

From the facts which I have collected and stated above I think it is justifiable to draw the following conclusions:

1. The osteoplastic resection of the foot, as devised by Wladimiroff and Miculicz, has a legitimate place in the surgery of the foot. It gives functional results superior to those of supramalleolar amputation.

2. Destruction of the soft parts of the heel is an indisputable indication for its performance.

3. In tuberculosis of the ankle joint with tarsus atypical excisions may be done, as advised by Connor and Kappeler, or Pirogoff's or Syme's operations. It is doubtful whether these operations, in cases permitting the choice, should be abandoned in favor of the osteoplastic resection. This question can be answered only after further observations have been made as to the permanent cure of the disease by the operation, the duration of its after-treatment and its final functional results.

4. The results so far recorded allow of a choice between the osteoplastic resection and the operations mentioned, for the purpose of determining its value as compared with that of the older operations.

THE ETIOLOGY AND CURE OF ASTHMA.

Read before the Chicago Medical Society, January 3, 1887.

BY EDWIN J. KUH, M.D.,

SURGEON TO THE MICHAEL REESE HOSPITAL, CHICAGO.

The work of Wilhelm Hack on the radical treatment of migraine, asthma, hay fever and other neuroses, has received very inadequate recognition in this country. By writers on hay fever he is frequently quoted in an offhand manner together with a string of other authors; so that one derives the impression that few of those who quote him have read him. And if his specialistic colleagues do not do him justice, the large class of general practitioners ignore him almost altogether. His work is—taken altogether—of even greater interest to the physician than to the specialist, and it is a deplorable consequence of specialistic exclusiveness, that the results of his work have not yet received wider recognition among us. He teaches us that the rhinoscope must forthwith be as indispensable an instrument for all physicians as the thermometer and stethoscope.

The value of Hack's discovery, that asthma nervosum is a reflex disease with, usually, the nose as a starting-point, can best be appreciated by one who himself, for many years, struggled against the disease and fumed at the utter impotence of medical art to stave off the attacks. If I, therefore, in the course of this paper, class myself among my own patients, I shall do so with the view of bringing the subject within closer range. It is foreign to my subject to consider the isolated publications, from Voltolini downward, on the dependence of asthma upon polypous growths in the nose. Such cases are infrequent enough to be almost considered curiosities (Michel, for instance, reports 135 cases of polypus without asthma); and as Hack shows, polypi have rather a tendency to prevent asthma than to cause it. It will also simplify our subject, if we omit hay fever from our consideration.

The form of asthma of which I wish to treat exclusively is that perennial form which is more or less independent of the seasons, namely: asthma nervosum, or "Essentielles Asthma" of the Germans. Some persons never get beyond a slight hint of asthma. They will from time to time make a heaving, sighing motion, or complain of præcordial fulness with or without palpitation, or of sudden drowsiness, or dream heavily at night and complain of dulness, lassitude and headache in the morning. This latter condition has many gradations, the culmination of which is nightmare. In the future we must, therefore, learn to distinguish between an incubus of gastric and of respiratory origin. Other half-asthmatics complain only of a fleeting, leaden heaviness in the limbs amounting almost to pain; the same sensation of which so many true asthmatics complain after an asthmatic night. The typical asthma nervosum is known to us all as a neurosis occurring in paroxysms.

The patient may or may not feel an aura. He will generally, towards evening, or when he lies down, or awakes in the night, begin to wheeze. This wheezing may be associated with itching in the nose, or sneezing, or coughing; the attacks last an indefinite time, and generally end with the expectoration of a transparent glassy mucus. Such patients are often free from asthma during the day. Physical and chemical irritants, such as dust, sudden changes in temperature, the inhalation of certain gases, and a long series of idiosyncrasies which we find enumerated in text-books, can induce an attack. But the recumbent position is the most uniform exciting cause of the single paroxysms. Such patients may be free from chronic bronchitis, chronic emphysema, heart-, kidney-, intestinal- and uterine disease: hence the term "Essentielles Asthma."

When we read authors whose contributions to the study of asthma antedate the last few years, we are struck by the uniformity with which they cling to a pet theory, each of which seems to give satisfaction to its upholder. It is merely an evasion to say that asthmatic paroxysms are induced by bronchial spasms, or by hyperæmia of the bronchial lining, or by the presence of Leyden's crystals, or by phrenic spasm, or by bulbar irritation, or by exudative bronchiolitis. For any one of these presumable causes would demand a first cause, in order to merit etiological dignity.

A true etiology of asthma had therefore to be discovered, and Hack did it in the following manner: He knew, of course, of the occasional rôle of nasal neoplasms. Schäffer and B. Fränkel had also indicated that the sensibility of the nasal lining could be so heightened through chronic catarrhal conditions, as to be a starting point for reflex disturbances. Then Hack found that he could experimentally produce glottis-spasm by touching the turbinated bodies of a sensitive individual with a probe. He then reasoned as follows: A nasal mucous membrane which shows merely slight affection, and which is not deadened in its sensibility by thickening and hypertrophy, is perhaps a better surface for exciting reflexes than one which shows evident signs of disease. And if this were the case, he reasoned, then perhaps the importance of nasal reflexes had been formerly overlooked just because of the insignificant abnormities of such a sensitive nose.

The very frequency of certain conditions may have given rise to an under-estimation of their significance. And so Hack systematically examined the nose of every patient who, for whatever ailing, came within his reach. He learned to make one distinction very rapidly, namely: that what is usually termed hypertrophic nasal catarrh is a twofold condition, which in its effects is quite opposite. In the anatomically true rhinitis hypertrophica the mucous membrane is really thickened, hypertrophied through chronic inflammation. Pressure with a probe meets with a certain

unyielding resistance, and there is a purulent, crusty secretion. This form does *not* give rise to reflex disturbances.

But there is another form, a pseudo-hypertrophy, the importance of which it is Hack's merit to have pointed out. It is that transitory swelling of the cavernous tissue of the inferior and middle turbinated bodies, which has of late been so often described that I spare you a repetition. In this form the nose may either have a very dry, itchy sensation, or show copious watery secretion. Compression with a probe gives the air-pillow reaction. Such individuals show fleeting alternate or synchronous obstruction of the nasal cavities. Often, when examining the nose of patients, we notice sudden engorgements and collapse, so that Hack's term erectility is not an exaggeration. These cavernous bodies with their frequently anæmic covering form a link in certain morbid reflexes, and when this link is destroyed through operative intervention, the reflexes cease. No symptom is more frequently overlooked by patients than transitory nasal obstruction. Most patients will positively deny its existence, until it is demonstrated to them. Therefore the assurance of an asthmatic that his nose has always appeared healthy is of no value.

Other asthmatics, if conscious of nasal trouble, consider it simply concomitant with their asthma, and it is characteristic of them that they will often resist the inquiries of the physician who attaches so much importance to rhinoscopic examination and nasal symptoms, when all their trouble seems located in the chest. It is interesting to observe how such people become gradually convinced, and how uniformly they marvel at having forgotten or overlooked most constant symptoms. Only recently I succeeded in showing an asthmatic half a dozen rapid openings and closings within barely more than a minute or two.

The theory of Hack is a simple one, and although it does not cover all the ground, is a very satisfactory one. He says that the turbinated bodies become engorged through various irritants, and that this vasodilatatory disturbance is transmitted to the bronchial tubes in asthma. The turbinated bodies act as accumulators for reflexes, store them up, as it were, and then transmit them to other parts. A destruction of the nasal swelling removes the reflexes. The experiences of numerous writers since 1883 corroborate the correctness of Hack's discovery.

By way of illustration I could not, I believe, select a better type of asthma of long standing than that of my own person. Twenty years ago, when I was 8 years of age, I became subject to so called colds in the head and on the chest. They increased in severity and frequency from year to year, so that my surroundings were often puzzled to find an explanation for each outbreak. Presently nightly dyspnœa began to set in, in the following manner: During the day my respiration was quite free, but as soon as my head touched the pillow, the first wheeze set in; the paroxysms were very severe. They ceased, after lasting throughout the night, in the morning, with the usual expectoration of glassy mucus.

During the day there was never any difficulty, except when occasioned by laughter. Laughter would infallibly cause itching under the chin and between the scapulæ, then I would cough convulsively and the attack was upon me. But the recumbent position was the surest exciting cause. During the first years I also suffered from that form of conjunctivitis which is now known to arise from nasal disorder.

I must give Dr. Abram Jacobi, of New York, under whose treatment I was at the time, credit for having already then, even without the use of the nasal speculum, laid stress upon a nasal trouble. But the aggravation of my troubles which followed upon the introduction of weak nitrate of silver solutions into my nose, made the memory of him a less pleasant one in those years than it is at present. The greater part of 1870 to 1875 I spent in the Swiss mountains, where I was entirely well. The attacks ceased from the day on which I reached the mountains, and infallibly returned on the very day I left them. Once during harvest season in Bavaria (1872), while I sat in a meadow, I was suddenly overtaken with convulsive sneezing, coughing and asthma. It lasted hours before I could reach the neighboring village. During that same period I developed a peculiar idiosyncrasy towards dinner. In the midst of the meal I would invariably for weeks be seized with a convulsive cough, so severe that it threw me to the ground. Asthma was never absent in these attacks. Then, at other times, one or two or three sneezes would initiate an asthmatic attack; or sometimes, especially after traveling, I would sneeze sixty or seventy times without intermission. In those years I had the sensation as if the asthma were brought on by a swelling, which seemed to begin above and behind the palate (it was associated with intense itching, which I attempted to relieve by rubbing my tongue against the hard palate), and traveled downward to the posterior pharynx, then seemed to skip the larynx and continued from the trachea downward. This phenomenon lasted a few seconds, and then the attack began. Railroad travel would invariably cause a night of asthma. One hotel, at which I was frequently obliged to stop in Germany, adjoined a stable, and was regularly the cause of some of the severest attacks.

The few years which antedated my acquaintance with Hack's writings were comparatively easy ones, because the inhalation of Kidder's asthma pastilles —the only palliative I ever used successfully—gave me very great relief. They not only immediately terminated an attack, but also prevented their occurrence for the next hours.

As soon as I became acquainted with Hack's articles in the *Berliner klin. Wochenschrift*, of 1882, and with his monograph in 1883, I commenced stricter self-observation, and found the following:

As soon as I lay down my nose would become obstructed. The occlusion corresponded to the side on which I lay. By turning over, the occluded side would open and the other close. To have any part of the nasal mucous membrane touched by a probe gave such intense pain that I could not suppress an outcry. I could bring on an attack of asthma by rubbing my ala nasi against the septum.

Never did I feel the slightest dyspnœa when nasal respiration was free, and never was nasal respiration obstructed but what I felt asthmatic distress.

Under these circumstances there could be no hesitation; Dr. Jefferson Bettman (now of New York) and Dr. Henry Gradle, performed the galvano caustic "destruction" of both inferior turbinated swellings. When I say galvano caustic "destruction," I should like to put the word destruction in quotation marks; for I have found the radical obliteration of the entire inferior turbinated bodies almost an impossibility. Hack demands, and my experience confirms the correctness of his view, that the radical cure of asthma demands the radical destruction of the cavernous erection. But a longer and closer observation of such patients in whom the extirpation seems complete will almost invariably show relapses, which must again be subjected to operative interference.

In my own case fourteen cauterizations, performed with both a flat and furrow electrode in the manner described by Hack, have not succeeded in permanently clearing the nose. The asthmatic attacks have, to my unspeakable relief, ceased. Sleep is now a function of which I have lost all dread. But during the daily occurring fleeting occlusions, there is a feeling of heaviness on the chest and of excessive fatigue in the limbs, which do not pass away until the nose is free.

What is it that causes nasal occlusion? I have observed myself so closely in this regard, and have so many corroborative observations of intelligent patients, that I can make these positive statements:

Firstly, the fullness of the turbinated bodies is regularly influenced by gravitation, and corresponds to the position of the head.

It is furthermore influenced by the temperature, and probably much more so by artificial warmth than cold; an over-heated room will almost invariably cause swelling in such patients. But the most dangerous and permanent cause of nasal obstruction is the inhalation of dust.

The time is, I hope, not far distant when our views on the etiology of respiratory diseases will undergo a radical change. The superstition of catching cold has lived too long. The light which mycological research has thrown on the etiology of most infective diseases must soon influence us toward a conviction that respiratory diseases are *inhaled*, not caught, and that suppuration in the respiratory tract is as impossible without the presence of micro-organisms, as it is on a wound. The superstition of "catching cold" is so pernicious because it diverts attention from the entrance-way of disease-generators. It is as impossible to contract an acute bronchitis through temperature influences alone, as it is to contract tuberculosis through a cold.

It is therefore of the utmost importance to warn asthmatics that as perfect an avoidance of dust inhalation as is possible in our contaminated surroundings is necessary to prevent a recurrence of their trouble. Not only the dust in the streets, but also that in our houses, is to be avoided as much as possible. Carpets and curtains are great receptacles of dust; and a strict regulation of street sprinkling will in the course of years, when the true etiology of respiratory diseases will have been recognized, be considered as important a municipal regulation as the regulation of sewerage.

When are we to operate on asthmatics? The more recent the asthmatic trouble and the more pronounced the nasal symptoms, the better the prognosis. When complicated with chronic bronchitis and chronic emphysema, the outlook is generally bad. A most thorough examination of heart, lungs, kidneys and intestines should precede any operative interference. In cases of cardiac and nephritic asthma with nasal complications, I have *never* cauterized. Firstly, because it has seemed to me irrational; and secondly, because I feel so much gratitude towards Hack's discovery, that I shun any risk which might discredit it.

In some cases it is very difficult to decide whether an operation should be performed or not. For instance, in cases of long standing, say fifteen or twenty years, in which in the first years the nasal symptoms were very pronounced, but in later years have almost or entirely disappeared, in such cases cauterization is sometimes successful, but generally it is unsuccessful.

Cases in which the asthma is more or less constant and has lost its paroxysmal nature, give a doubtful prognosis. It has been a matter of experience with me, that those patients to whom the inhalation of Kidder's pastilles, or the application of cocaine to the nose (four per cent. solution on cotton), gives relief, afford a much better prognosis than others.

In asthmatics in which coughing precedes the attack and all nasal symptoms are missing, nasal cauterization will cure, if the cough is a so-called nasal cough.

There are a number of asthmatics, fortunately a minority, who seemingly offer a good prognosis, but with whom, for unknown reasons, the operation will fail. There can now be no doubt that there are other starting points for reflexes in the respiratory tract, besides the nose. The works of Trautmann and Tornwaldt have already added the vault of the pharynx to this list.

The bronchial tubes themselves can act as a starting point, as I can demonstrate on myself when I walk against a piercing wind, or inhale vapors of sulphurous acid with my nose plugged. So that, as Hack himself warningly says, we must not over-estimate the applicability of his discovery.

We must accuse the nose *per exclusionem*. Examine every patient thoroughly in every direction, and examine the nose *last*, is what I should like to advise.

About the operation itself, little is to be said. It is, as far as we know, absolutely harmless. I have performed many hundred cauterizations without any noteworthy complications. I have never had any traumatic infection. I insufflate iodoform or iodol upon the wound, introduce a pledget of cotton for a a few days, and keep my instruments aseptic.

The results are, on the whole, extremely gratifying. Asthma of many years' standing is sometimes broken after the very first cauterization. Almost all patients are relieved and many cured in the strict

sense of the word. Some have relapses, which additional cauterization will remove. Others again may relapse with a new reflex sensitiveness in other parts.

But on the whole the subject, still so new, still so capable of growth, broadening and development, is one of the most pleasing contributions to medical knowledge, and the name of Hack will be, I am sure, not soon forgotten.

A CASE OF ANTE-PARTUM HÆMORRHAGE AT TERM. RECOVERY.

Read before the Chicago Medical Society, January 3, 1887.

BY AUGUSTUS V. PARK, M.D.,
OF CHICAGO,
MEMBER OF THE AMERICAN MEDICAL ASSOCIATON, ETC.

On the morning of August 5, 1886, I was called to see Mrs. S., age 37 years, a large and powerfully-built American-born Irish woman, cultured and intelligent for one in her station of life; she gave me this history:

This was her ninth confinement, she had also suffered six miscarriages. Professor Daniel T. Nelson, her family physician, was compelled to use instruments on one occasion; the child was large and healthy and she made a good recovery; she had received no falls or injuries since carrying this child, to her knowledge. There was no history or evidence of specific disease. Before I finished questioning she remembered a few evenings since of running against some obstruction in the back-yard; this gave her a slight shock just at the time, but she paid no attention to it. The evening previous to my call, just as she had retired for the night, she said she was taken with a severe hæmorrhage which lasted for some time, and the amount of blood frightened her, and she called in a physician. The hæmorrhage soon stopped and her pains were nothing to speak of. There had been some propulsive efforts throughout the night, and in the morning they were simply teasing and prevented her from securing any rest. She suffered no real or hard labor pains and not a particle of hæmorrhage during the night.

I made a careful examination of the bedding and of the soiled clothing which had been removed the evening before, and found them wet and heavy and blood-stained, but was unable to find clots of arterial blood or any evidence of a severe or continued uterine hæmorrhage. The pulse was regular, the volume and strength good, respiration and temperature normal; vaginal examination revealed a rigid os uteri and situated high in the pelvis, and directed backward so it pointed toward the cavity of the sacrum; the os uteri in this situation would have escaped any ordinary examination; there was no dilatation. I was satisfied that the pains were not true labor pains and I gave tinctura opii deodarata in fifteen minim doses, and to repeat in an hour or two if necessary.

3 P.M.—I was sent for in great haste, and upon my arrival found that there had been expulsive efforts during the past hour, but she was again quite easy and free from severe pain. I again examined the os and found it more soft and was enabled to insinuate my index finger, and by careful pressure with my left hand over the fundus uteri I could distinguish the head presenting. To satisfy myself as to the true character of the pains I remained at the bedside; the pains were irregular, sometimes severe, again they would be but slight. I examined the condition of the os uteri during the period of the pain, and found that the pains had no effect upon the cervix which remained undilated and flaccid, and the membranes did not become prominent or tense. The bowels had moved early in the day and a light meal taken at 12 M. Advised the continuance of the anodyne at once and again in two hours. This would control the severity of the pains and would lessen the rigidity of the os.

11 P.M.—Found the patient suffering true labor pains, pain in the back, the os soft and dilated to the size of a twenty-five cent piece; the head at the brim of the pelvis; the edges of the os thinned; the cervix rigid with each pain; there was no bag of water to act as a cushion. 12, 1 and 2 o'clock the labor was much the same, and was what would be termed a tedious labor; the liquor amnii having all escaped with the so-called hæmorrhage and each expulsive effort accomplished but little.

2:30 A.M.—The pains are more regular, the patient is warm and perspiring; the face is flushed and the carotids stand out round and full with each parturient effort; everything seemed favorable for an early termination of labor. Soon I noticed that the pains were not as propulsive, yet they were equally as painful; complained of great thirst, constantly calling for water; she became uneasy and restless, the face losing its ruddy color and the lips bleached; the pulse feeble, rapid and easily compressible. For the first time in nearly four years of active obstetric practice I was brought to the full realization of the great danger of concealed or ante-partum hæmorrhage. There was but one thing to be thought of, and that was to deliver at once and in the shortest time practicable. I placed the patient across the bed, the head and shoulders without bolsters, the nates drawn forward over the edge of the bed, the knees well flexed and held by assistants. With the first pain I ruptured the membranes; this was followed with a gush of blood, a small amount however. I applied the forceps; the head was at the superior straight, and with the second pain I made gentle and careful traction, observing the well-known law which governs the obstetricians in the high forceps operation, and delivered a still born child which bore all the evidences of having been dead at least six hours; gave child to the nurse and applied my left hand over the fundus uteri and made gentle pressure; soon the uterus commenced to contract and expel its contents; the blood and blood-clots that were thus forced out filled a common wash basin. The placenta was high up and normally situated on the posterior wall; with my left hand still on the fundus I experienced no trouble in reaching and removing the placenta; with this accomplished, all hæmorrhage ceased, ergot was given and gentle

pressure continued over the fundus uteri for a short period, stimulants given and patient made as comfortable as possible; pulse 140 to 145, weak and compressible, thirst continued for a few hours.

Complicating this case we had hæmorrhoids with prolapse of rectum and during the real labor pains it was nearly impossible to retain the hæmorrhoids within the sphincters; after delivery they were cleansed and returned with the replaced bowel within the sphincters and retained with a T bandage and compress; suppositories of opium and tanic acid gave quick relief. Patient made a rapid and easy recovery; was sitting up on the tenth day after confinement.

From all the phenomena observed I believe that the hæmorrhage was caused from a partial separation of a normally situated placenta. I also believe that the head of the child acted very like a ball valve and prevented the escape of the blood externally. I further believe that the blood or a portion of it found its way within the amniotic cavity, this would account for the amniotic fluid being colored with blood, also for the slight hæmorrhage that followed the mechanical rupture of the membranes previous to delivery. There must have been a rupture of the membranes high up and out of reach that allowed the escape of all the liquor amnii, for the membranes were intact, at least those presenting as far as they could be reached by a digital examination previous to delivery.

From statistics published by Churchill I find that out of 218 cases of accidental hæmorrhage thirty-two proved fatal, or one in six.[1]

I quote from Lusk's third and last edition:[2] "The circumstances under which concealed hæmorrhage takes place are given by Goodell[3] as follows: (a) When the placenta is centrally detached and the blood accumulates in the cul-de sac formed by the firm adhesion of its margins to the uterine wall. (b) When the placenta is so detached that the blood escapes into the uterine cavity behind the membranes near the fundus. (c) When membranes are ruptured near the detached placenta and the effused blood mingles with the liquor amnii. (d) When the presented part of the fœtus so accurately plugs up the maternal outlet that no existing hæmorrhage can escape externally. I have had a case where after labor I removed at least a basinful of firm clots from the uterine cavity, and yet both mother and child survived. In my own case to which I have referred, the Barnes dilator acted capitally, not only enabling me to expand the cervix, but exciting the uterus to contract vigorously.

"The serious symptoms set in after the membranes were ruptured and compelled me to deliver with forceps. In another case I should certainly first dilate, and, after rupture of the membranes should chose version and speedy extraction, and should avail myself of a skilled assistant, whose duty it should be to compress the uterine walls externally during the act of delivery.

"In case of internal hæmorrhage occurring during the progress of the labor the treatment will depend upon the stage of the labor and the amount of blood lost, judging by its effect. If the patient be in danger of sinking, and the os uteri dilatable but the head within the uterus, there can be no doubt that we must deliver by turning; but if the loss be moderate we may perhaps afford to wait until the head descends into the cavity of the pelvis, and in all cases where it is within reach of the forceps they should be used for immediate delivery, if the case be mechanically suitable. But little hesitation need be felt on account of the child in deciding upon the mode of delivery as it is lost in almost every case of extreme hæmorrhage.[4]"

We know from experience that a diagnosis of this condition is not easily made, yet the symptoms are so evident that one can only think of an internal hæmorrhage. The prognosis for the child is very bad, because, as a rule, it dies unless delivery be very speedily accomplished by nature or by art. For the mother the prognosis also is unfavorable and much more so than in placenta prævia.[5]

MEDICAL PROGRESS.

A Practical Hint for Tracheotomy.—Mr. W. Leonard Braddon says: The operator is usually recommended, standing preferably on the right side of his patient, after first determining the exact relation of parts, to fix the trachea with the left hand, the fingers on one side and the thumb on the other, at the same time stretching the skin at the site of incision. The direction is at least distinct, but the manipulation is usually in effect very different. In all of many cases which I call to mind, there has been a little (the only) trouble in the operation, and in some, considerable danger, delay, or anxiety, consequent upon the way in which the attempt is made to keep the windpipe steady, as customarily taught and performed: Four fingers on the left side and the thumb upon the right side of the larynx, press with more or less force immediately backwards to hold the organ in place, with the effect of considerably aggravating the dyspnœa (especially if an anæsthetic is not being employed), of flattening the pipe against the vertebral column to some extent, of in all cases increasing the depth at which the part to be incised can be reached, and frequently of failing to secure fixity of the larynx, which, likely to move with the slightest change of pressure, is pushed still more out of reach by the increased pressure made to secure it. Any or all of this inconvenience is the result of pressing backwards with the fingers placed upon the skin immediately on either side of the windpipe.

The suggestion I have to make, and which, I have

no doubt, many surgeons have long ago thought of or adopted, although hitherto I have never seen it noticed, is so simple as to provoke a doubt as to its value, but any one who tries it will, I think, find it so effectual in practice as to have no more doubt than I have as to its advantage. Let the surgeon place his left hand, as widely expanded as possible, over the neck of a child in the position for tracheotomy; then resting the fingers upon one and the thumb upon the other side firmly upon the skin, as far to the side of the neck as they will reach, gradually draw in the thumb and fingers, and the skin (and loose tissue underneath) with them, towards the median line; as the sides of the windpipe are approached, a little more pressure, made in a backward direction, will place the ends of thumb and fingers in a position in which they almost meet behind the larynx, which is thus firmly held by the encircling hand in a position in which all the great blood vessels, etc. (which *have* been wounded) and the vertebral bodies (which, it is recorded, have *blunted a knife-point*) are far out of harm's way, the windpipe itself starting forward and standing out prominently under the skin, which is yet fairly stretched (and can be stretched more tightly) over the site of incision, and lying both as superficially as could be desired and as perfectly under control as possible. Lastly, and this I think is not altogether unimportant, this procedure may be adopted without producing more than the very slightest degree of discomfort in any ordinary child—the younger the more easily; and one is still able to make the skin as tight as possible; now, however, the necessary pressure is distributed all round, instead of acting directly backwards upon the tube so as to flatten or displace it. I have even been able without much trouble to make the thumb and fingers feel each other behind it by this means; while by the older method I have seen the production of undoubtedly a dangerous increase of dyspnœa. I may have overrated the danger, or underrated the utility of the usual method of fixation, but it has always seemed to me to be the only difficulty in an operation, which of course has none for experienced surgeons, but to others presents often some trouble, chiefly in consequence of the fact that the means adopted for fixing the part to be incised, being ill-devised though time-honored, are not only not to be relied on to secure that end, but, as I have tried to show, they directly tend to increase the depth of the wound of the trachea from the surface and the distress of the patient; and in all the accidents I have read of, and some that I have witnessed, this method has shown itself marked sometimes by danger, often by inutility. As to the barbarity of the *hook*, is it not an insult to the fingers of the surgeon?—*The Lancet*, November 20, 1886.

NEW POSITION FOR OPHTHALMIC OPERATIONS.—MR. G. M. GILES, Indian Medical Service, says: The supine position is, as most must have felt, by no means a convenient one for eye-operations. It is, however, the only practicable one when chloroform is used as an anæsthetic. The discovery, however, of a local anæsthetic, in the shape of cocaine, leaves us free to adopt any position that may be found most convenient for patient and operator.

For the last fifteen months I have been employed with an exploring party in the regions lying beyond our North West Indian frontier. Transport difficulties have rendered it necessary for us to fly very light. Hence, as may be well imagined, an operating couch formed no part of my equipment. A good deal of surgery of all sorts came to my hands, much of it ophthalmic, and I was often at a loss how to improvise a couch of some sort. Not unfrequently even the low country bedstead was unobtainable, so that one had to operate on the ground. Now, even to operate on a low bed is most difficult in ophthalmic cases, the surgeon's position being so constrained that all steadiness of hand is lost. Hence, after adopting cocaine, which I came to do very early in our travels, I began to try various positions with the view of finding one suitable to the peculiar exigencies of camp life, and finally hit upon the following position, which has been found so entirely convenient that I feel sure it is well worth a trial, not only by such as have to operate under difficulties, but even as a position of election.

The operator sits on an ordinary chair, with the knees well separated so that the patient may be able to sit on the ground between his feet. The position of the latter varies according to the nature of the operation and the side operated on. In ordinary cases, such as iridectomy, removal of pterygia, etc., he is seated with his back nearly to the operator, but with the face turned slightly to the left for the left eye, or to the right for the right. Seated thus, between the operator's feet, he throws back the head so that the occiput rests firmly on the surgeon's thigh; the left thigh in operations on the right eye, and *vice versâ*. This position answers equally well for cataract-extractions on the right side. For left cataract, however, unless the operator actually prefers to use the left hand, the following modification is necessary. Seated as before on the ground, between the operator's feet, he faces quite to the surgeon's left, then throwing back his head, and turning it slightly so that the chin points to the surgeon's hip-joint, he rests the occiput firmly on the operator's right knee. With the patient in this posture, it will be found perfectly easy to operate with the right hand.

The method is, no doubt, specially suited for dealing with Orientals, who are accustomed to sit on the ground; but for the limited time required for an operation, I do not think it will be found too constrained for Europeans. Primitive as it may seem, I feel sure that any one who will give it a fair trial will find the position much more convenient than either an ordinary operating couch or a dental chair. —*British Medical Journal*, Dec. 11, 1886.

FORMIC ACID AS A DISINFECTANT.—DR. VOITOFF, who has made a number of experiments on cultures of pyogenic microörganisms, says that formic acid is a specific against their success, and so may be considered as an excellent disinfectant.

PROPHYLACTIC MIDWIFERY.

There still seems to be some who do not recognize the difference between a "Lister dressing" and "Listerian principles." It does not seem sufficient to say that the dressings may change but the principles cannot, as this has been repeatedly pointed out during the past four years, or more. Nor does it seem sufficient to say that all the principles of aseptic and antiseptic surgery and medicine are comprehended in the one word "cleanliness," as this has been repeatedly done, even by Sir Joseph Lister himself. Again, there are many who, seemingly, cannot understand the value of circumstantial evidence in medicine; they insist upon proof—absolute and incontrovertible, and question the pathogenic influence of dirt and germs in much the same way that the Rev. John Jasper disputes the movement of the earth about the sun. Those who, without any special knowledge of bacteriology and the etiology of disease, insist upon writing papers ridiculing more recent methods of investigation and the principles of antisepsis, should first learn that "antisepsis" is not synonymous with carbolic acid, with iodoform, corrosive sublimate, or any drug or drugs; that Listerian *principles* may be strictly adhered to without the use of drugs.

In the *Transactions* of the Medical Association of Georgia, for 1886, is a paper entitled "A Review of Modern Antiseptic Midwifery," by Dr. Eugene Foster, of Augusta, who attempts to "demonstrate that the antiseptic system is founded upon speculation pure and simple; and, furthermore, that this antiseptic system, as a routine practice, is, in its essential features, unscientific, unsuccessful, unnecessary and frequently harmful to the lying-in woman." And "the facts upon which the argument is based are taken almost exclusively from writers who are, or have been, advocates of the antiseptic system." In opening the argument on this question he first proposes to consider the theories as to the essential nature of puerperal fever, each one of which, he says, "is a matter of unadulterated guess-work." He does not discuss the question from the stand-point of labor in hospitals, but in private homes; for he says: "There is no analogy whatever between puerperal fever in private practice and hospital experience as to the modes of infection and the necessity of prophylaxis." If this be true, why apply hospital statistics to those of private practice? Why reason in private practice from hospital experience? If filth can cause disease in a hospital it can do the same thing in a private house; if it cannot cause disease in a hospital it cannot in private practice. If, as Dr. Foster says, labor is a purely physiological process, it is as much so in private practice as in a hospital, and *vice versâ*. It need not be said that private homes are in better sanitary condition than hospitals; for if antiseptic principles be unscientific then filth has nothing to do with the matter. If there be no analogy between puerperal fever in hospitals and that in private practice there can be none between amputations, compound fractures, typhoid fever or any other disease or affection in the two places. But to refuse to admit hospital statistics in this question practically shuts out argument, and reduces the whole matter to one of (simple individual opinions). However, the author of the paper under consideration does "not shrink from the task of attempting to demonstrate that even in hospitals the antiseptic methods have been unsuccessful"

Before witnessing this attempt it may be well to ask, why, in enumerating and commenting upon the theories of puerperal fever Dr. Foster, after quoting the masterly work of Lusk, should have wholly ignored his consideration of the "Nature of Puerperal Fever as regarded from the Standpoint of modern Investigation?" He gives what he calls Semmelweis's theory, Fordyce Barker's theory, Pasteur's theory, and Dr. Kinkead's theory of puerperal fever; but singularly enough he omits any mention of the facts contained in Lusk's work (Edition 1885, pp. 654–668), in which all the evidence in the case has been most carefully, and in a most masterly manner, collected and interpreted. Dr. Foster claims "distinctly that in epidemics of puerperal fever there are occult epidemic constituents of atmosphere, either local or general, which produce these epidemics in

recurring cycles." Where do these "occult constituents of atmosphere" come from; who has seen them; have they been isolated, cultivated, injected into mice and produced symptoms and lesions identical with those of the original disease? If not, we may as well attribute puerperal fever to volcanic eruptions or a shower of meteors.

The attempt to prove "that even in hospitals the antiseptic methods have been unsuccessful" may be attributed to a confusion of terms; to the idea that antisepsis, or asepsis, consists in carbolic sprays and injections of solutions of certain disinfectants or germicides. Where asepsis is complete antisepsis is unnecessary. Obstetricians will no doubt be surprised to learn that the author takes the statistics of the Rotunda Hospital and the Vienna Maternity to prove that antiseptic methods are unsuccessful; but, on investigation, it is found that he does not recognize that absolute cleanliness is *the* great antiseptic precaution. He does not mention the fact that the Rotunda Hospital is one of the best ventilated hospitals in the world; nor does he seem to realize that good ventilation is an antiseptic precaution. He declares that antisepsis has had nothing to do with the good results at the Preston Retreat, under Dr. Goodell, and then quotes Dr. Goodell: "I am governed by four golden rules—cleanliness, ventilation, rotation, and isolation!" Are not these antiseptic precautions? As against antiseptic principles he quotes *some* statistics from the New York Maternity Hospital (from 1875 to 1882, inclusive). He then says that in the autumn of 1883 Dr. Garrigues overhauled the Maternity, and instituted new antiseptic measures (which may be found in Lusk's Midwifery, p. 689, footnote); but he does not tell us that "in the following 162 confinements there were no deaths, and from October to July inclusive, of 409 patients confined, though many operations were performed, five died; but of these, only three were from septic causes, and they, Dr. Garrigues believes, were the results of the neglect of certain of the prescribed details." Lusk says (p. 693): "The great improvement in the condition of maternity patients in recent years has been due to the application of Lister's antiseptic principles in obstetric practice." He does not say that it has been due to vaginal injections, to carbolic acid, to corrosive sublimate, cheese-cloth, or iodoform, or to the application of Lister's *details*, but of his *principles*. Certainly it is no argument to quote statistics of a hospital which used details and neglected first principles, as does Dr. Foster in the case of the Philadelphia Hospital.

Obstetricians are familiar with the paper relating to this subject read by Dr. T. Gaillard Thomas before the New York Academy of Medicine about three years ago. This paper was admired and criticised by the leading obstetricians of the country at the time; and Dr. Foster now takes up the rules therein laid down *seriatim*. He ridicules the proposition to disinfect the lying-in room before labor, for the remarkable reason that if there are any germs they must have come from the atmosphere, and that it is impossible to disinfect the atmosphere of an occupied room. With regard to the rule that nurses and physicians should take care that all their clothing is free from exposure to the effluvia of septic infection, such as typhus fever, erysipelas, etc., Dr. Foster says: "To this rule I have no objection, so far as it is intended to protect the lying-in woman from zymotic diseases. If, however, it is intended to contend or intimate that the poisons of scarlet fever, measles, variola, etc., can produce puerperal fever, I most unhesitatingly deny the proposition." So far as the woman is concerned it is perhaps immaterial with her whether she die of puerperal fever or scarlet fever; and the fact (if it be a fact) that scarlet fever cannot produce puerperal septicæmia is no argument against antiseptic precautions and principles. The rule which prescribes that the physician should wash his hands in soap and water and scrape the nails, and afterwards use a solution of bichloride of mercury, is criticised by quoting the experiments of Förster, which showed that solutions of carbolic acid, boracic acid, zinc and iron chlorides do not sterilize the hands; but in the same paragraph he quotes Förster to the effect that the hands *were sterilized* by the use of a solution of corrosive sublimate of 1–1000 (the solution recommended by Thomas).

It is needless to follow this paper to its conclusion. Had the author used the word *details* instead of "system," "methods," and "principles," his paper would not present such a prominent mark for legitimate adverse criticism. Many good obstetricians, and many good surgeons, may be found who do not follow the minute details of antisepsis as laid down by others, because they think they are unnecessary; but those who have given the *principles* intelligent study and thought both believe and act upon them. Furthermore, while all the intelligence of the profession is not centred in those members who have hospital positions, it only needs a moment's reflection to see that such men have the advantage of others in experience. Intelligence without opportunity will not show the usefulness or worthlessness of principles or details. The fact that an Indian woman

who is confined by the side of a purling brook at the foot of Mt. Hood, does not have puerperal fever is insufficient proof that a woman confined in the Vienna Maternity can not have it; nor does the fact that a woman may be injured by repeated vaginal injections show that she cannot possibly contract puerperal fever when confined in a filthy room, attended by a careless physician. Among other honored members of the profession Sir Joseph Lister comes in for a large share of Dr. Foster's ridicule. Lister's contribution to medicine does not lie in the fact that he invented a spray for throwing carbolic acid vapor; not in the fact that he once used cheesecloth; that he made a metallic case for keeping surgical needles in carbolized oil—but in his system, his principles, of antiseptic surgery; which principles, not details, have been successfully applied to midwifery. The truth of principles is not proved by any one set of details; but Lister's principles have been shown to be true because they hold good under any and all details in which the principles are adhered to. Even the once hated and despised, but now honored Semmelweis comes in for a share of the ridicule which Dr. Foster attempts to heap upon members of the profession who have worked, and are now working for the good of humanity.

INTERNATIONAL COLLECTIVE INVESTIGATION OF DISEASE.

During the session of the Eighth International Medical Congress in Copenhagen, 1884, an International Collective Investigation Committee was organized, composed of representatives of Sweden, Norway, Denmark, Finland, Russia, Germany, Austria-Hungary, Switzerland, France, Great Britain, India, the United States, and South America. The two representatives on the Committee for the United States were Professors A. Jacobi, of New York, and N. S. Davis, of Chicago. Under the personal supervision of Prof. Jacobi a large number of the blanks for making returns adopted by the International Committee were printed in a neat and convenient form, and distributed to members of the profession in different parts of this country. Those receiving them were requested to fill up the blanks in due form with such cases of the several diseases as should come under their observation, and return the same to Professor Jacobi, on or before the 1st of January, 1887. A few weeks since he gave notice, through the medical journals, that he had resigned his position on the Committee, and requested those interested to make their returns to the other American member of the Committee, N. S. Davis, M.D., 65 Randolph street, Chicago. As it is very desirable to derive as much benefit from the expense and time already bestowed in printing and distributing the collective investigation blanks, and equally desirable that the work in this country should not prove a failure, we wish to add to the request of Prof. Jacobi by urging that all those who have blanks with recorded memoranda would return them as promptly as possible to the address already given above.

PRESENTATION TO DR. N. S. DAVIS.

On Thursday, January 20, the fiftieth anniversary of the entrance of Dr. N. S. Davis into the medical profession, he was presented by the students of the Chicago Medical College with a magnificent arm chair and a valuable and beautiful revolving set of reference shelves. The presentation was made by Professor W. W. Jaggard, in behalf of the students, and Dr. Davis responded in a most graceful manner. It has been but a few weeks since Dr. Davis's seventieth birthday was celebrated at his house by a large number of his friends.

It is peculiarly fitting that the students of the College of which Dr. Davis is practically the founder, the College which represents the principles of higher medical education for which he did so much before its foundation, and has done so much since, should have taken some note of his fiftieth birthday into the profession. Indeed, the American Medical Association is the outgrowth of Dr. Davis's earnest endeavor to raise the standard of medical education in this country. E.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, January 3, 1887.

THE PRESIDENT, EDMUND J. DOERING, M.D., IN THE CHAIR.

DR. E. J. KUH read a paper on

THE ETIOLOGY AND CURE OF ASTHMA.

(See p. 121.)

DR. J. A. ROBISON, in opening the discussion, said: The facts, which are indeed facts, that have been related in this paper are of interest not only to the specialist but to the general practitioner. It has been a fact long known to specialists that obstruction of the passage of air through the nares will give rise to asthma, and a great number of articles have been written on this subject. It has also been demonstrated that when operations have been per-

formed that cleared away these obstructions the relief from the asthmatic attacks was complete. This can be easily demonstrated by any physician. Cases of nasal polypus are quite frequent and they do not always fall under the care of a specialist. The operation is generally a very simple one, almost any physician, without special training, can remove nasal polypi, and it is really wonderful to find how many cases of asthma are thus cured. As to asthma being due to other causes, I have no doubt of the truth of the observation made by the author, that is that transitory swelling which takes place in the turbinated bodies in cases of mild irritation. I presume we have all noticed that when we are affected with an acute coryza and go to bed at night the narium of the side on which we lie becomes obstructed, and if we turn over the other side will become obstructed. This is undoubtedly due to the force of gravitation in a great many cases where the mucous membrane is especially sensitive. There is no doubt that in a great many cases by the irritation of a probe, or the inhalation of dust, coughing can be produced resulting in asthmatic attacks. Therefore this demonstrates that reflex irritation of the nares is one of the causes of asthma, and it points out very clearly the method of treatment which should be instituted. The author has rendered a service in showing that there are such a large number of cases in which by destroying the turbinated bodies we can prevent the occurrence of reflex asthma. It would have been an interesting question to solve whether, in the case of the author's personal experience, a respirator worn over the nose so that the air could not pass through the nose unless filtered, would have been of any benefit in preventing the recurrence of the asthma.

DR. H. MARTYN SCUDDER: About five years ago, when practicing in India, where I had to ride on horseback a great deal in the sun and breathe a great deal of dust, I suffered frequently from acute attacks of coryza, accompanied occasionally by bronchitis and slight asthma. The nose was not much obstructed, and when an attack of coryza came on fifteen minutes sleep would often cause it to pass away. Gradually the attacks became more severe and were accompanied and followed by some obstruction. When in London more than three years ago, Dr. Mackenzie wanted to cauterize my nose, but it was before the days of cocaine and I decidedly objected as I thought the remedy worse than the disease. Since coming to Chicago I have been troubled less than when abroad. Quite recently I had my nose cauterized by Dr. E. Fletcher Ingals, and it has certainly relieved the trouble to a very great extent. My experience, however, was somewhat different from Dr. Kuh's as the cauterization gave me considerable trouble for a week or two. It was followed by soreness and even by slight chills, and it made me feel out of sorts for about a fortnight, but it was successful in relieving the obstruction and I have had no more asthma or bronchitis, although once in a while I still suffer from coryza.

DR. JOSEF ZEISLER said: Professor Schnitzler, of Vienna, has published a number of cases in which decidedly polypus of the nose has caused asthma, and where by the use of the polypus the asthma was cured. I can confirm what Dr. Kuh has said in regard to the effectiveness of the galvano-cautery. I had a case of a boy 12 years old, who had nearly all his lifetime had chronic eczema of the hands and asthma. Believing that the asthma was in causal relation to the eczema, I referred the patient to Dr. Kuh for treatment of the former trouble, while I prescribed local applications for the hands. Very soon both affections were cured and have remained so for the last year.

DR. H. N. MOYER asked what the author means by the term essential asthma, whether he means reflex asthma or something different?

DR. KUH, in closing the discussion, said: By essential asthma, I, of course, mean, as I have been attempting to explain all the evening, reflex asthma; the same asthma which textbooks classify as idiopathic or nervous or essential asthma. In lieu of these clouded expressions we have now, fortunately, a term by which we express an etiological meaning; namely, nasal asthma. It teaches us again, that the term neurosis always smacks of the hypothetical; and that when we speak of any pathological condition as a neurosis, we do so in order to cover ignorance. An asthmatic individual is not necessarily a "nervous" one, although I, of course, am not blind to the fact that some unknown factor must come into play in order to affect disease through nasal reflex. In regard to Dr. Zeisler's remarks on the connection between polypi and asthma, I did not know that Schnitzler, of Vienna, had published forty cases of nasal polypus with asthma. I am greatly surprised that such a publication should have escaped my notice. I quoted Michel, of Berlin, as having reported 135 cases of polypus without asthma. There is no doubt that sometimes nasal polypi cause asthma, but as far as I am aware, only exceptionally so. Hack found that when a patient had polypus with asthma and he left the polypus untouched and cauterized only the turbinated bodies, the asthma disappeared, although the polypi remained in the nose. I think there can be no better evidence of the relative innocence of polypi than that experiment. I have been asked whether, if I had worn a respirator, I would have been free from asthma in traveling. I found that to be the case. For when I plugged my nose with cotton while traveling, I remained free from asthma. Dr. Scudder said that nasal cauterization gave him trouble for weeks. This could only have been through wound complication. An asthmatic may have very severe trouble for a week or less after cauterization, on account of the eschar.

In order to show how careful one must be in diagnosis I should like to interpolate the following description: A patient with the mildest form of asthma, namely, the occasional involuntary deep, sighing inspiration, consulted me. The examination was negative with the exception of slight tympanites (the abdomen should always be carefully examined in such cases) and slight swelling of the inferior turbinated bodies. I treated his mild constipation for

weeks, without any benefit to his respiratory trouble. Then I cauterized, also without effect. At last I discovered that his alæ nasi were so pliable that when he inhaled through the nose they collapsed and occluded the nares. In regard to the claim that injections of boracic acid solution into the nose will relieve asthma, I should simply refer to the uniformly condemnatory verdict of all specialistic practioners against the use of the nasal douche in such cases.

Dr. Elbert Wing, Pathologist to Cook County Hospital, showed

A HEART SHOWING ATHEROMA AT THE BASE OF THE AORTA AND IN THE MITRAL VALVE,

and a condition described by the Germans as *prior chronic endocarditis*. The last mentioned lesion itself in the distribution of grayish streaks or patches on the endocardial surface, lying irregularly distributed over it. When this lesion has proceeded far enough fatty degeneration follows, shown by patches which appear slightly yellowish to the eye. The patches upon the valves are upon the anterior segment of the mitral. They are simply interesting and would cause no symptoms whatever. I do not know that such a case has any further interest than that these things very frequently exist, and in my experience more than a majority of cases present lesions of prior chronic endocarditis.

Dr. Wing also exhibited

A LUNG SHOWING ONE OF THE POINTS OF DIFFERENTIAL DIAGNOSIS BETWEEN A CAVITY RESULTING FROM TUBERCULOSIS, AND ONE RESULTING SIMPLY FROM DILATATION OF A BRONCHIAL TUBE IN BRONCHIECTASIS.

That point is the persistence of bands, or stumps of bands, of the more resisting tissues which remain, sometimes passing across the cavity. As the fibrous tissues are more resistant than the others in the lung they are the last to disappear in the necrotic process. In this specimen there are a few cavities in the apex, some of them large, and the tubercular infiltration extends entirely to the base of the lower lobe of the right lung. There was extensive adhesion of the two layers of the pleura over the lung.

Dr. W. T. Belfield asked for a repetition of the diagnosis distinction between cavities due to tuberculosis and bronchiectasis.

Dr. Wing said: A cavity resulting from bronchiectasis has a smooth pyogenic membrane, and upon washing it, no stumps of these bands can be seen upon its floor, but in a cavity resulting from tuberculosis there are always some of these stumps or bands present. Sometimes they are very short, at other times long, and at times, as in this case, they are easily seen and demonstrated.

Dr. A. V. Park read a report of

A CASE OF ANTE-PARTUM HÆMORRHAGE AT TERM. RECOVERY.

(See page 124.)

Dr. A. V. Park reported

A CASE OF PYELITIS OF NINETEEN YEARS' DURATION, CAUSED BY A RENAL CALCULUS. RECOVERY.

(See No. 6, Vol. viii.)

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 12, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. H. A. Wilson read on behalf of Dr. John B. Roberts the report of

A CASE OF SUPRAPUBIC LITHOTOMY, FOLLOWED BY DEATH FROM PERFORATING ULCER OF THE STOMACH.

The following case of removal of stone from the urinary bladder by the suprapubic or high operation, is reported as proving the position which I have so long insisted upon, that this operation is easily accomplished, and is free from many of the dangers of the lateral perineal operation.

C. H., aged 63, applied to me for relief from frequent urination, and other bladder symptoms, and was sent to the wards of the Pennsylvania Hospital. Upon the introduction of the lithotomy sound, it was easy to discover the presence of a stone. When the catheter was used, the stone was struck before any urine was drawn from the bladder, apparently proving that the calculus lay close behind the prostate gland. The patient was a very fat man, with poor circulation, and evidently a bad subject for etherization or operation. The urethra was large and easily distended. It therefore seemed to me proper to attempt the removal of the stone by the rapid crushing method.

With this object in view, I had him frequently dilated with large bougies, in order that the urethra and bladder might become tolerant to the contact of instruments. Subsequent to this preparatory treatment, I made an attempt to crush the stone with a lithotrite, expecting to evacuate the fragments by the ordinary method of Bigelow. Repeated efforts proved the impossibility of seizing the stone, either because it was too large to fall into the grasp of the blades of the instrument, or because it was encysted behind the prostate gland. Even with a finger in the rectum, and with the jaws of the lithotrite turned downward, seizing the stone was impossible.

As the man's perineum was deep, and as I believed that the perineal operation was inferior to the suprapubic one, because of the liability of hæmorrhage, of injuring the seminal ejaculatory apparatus, and also because of the supposed size of the stone, and its possibly encysted character, I determined to perform the suprapubic operation.

After etherization, a rubber bag, to which was attached a long tube, was placed in the rectum, and filled with about twelve ounces of warm water. The bladder was afterward filled with 6 or 8 ounces of a weak solution of bichloride of mercury. A three-inch incision was then made in the median line through the skin and a depth of nearly two inches of adipose tissue. The muscles were then separated, and the tissues torn through with my finger until I came upon the distended bladder. By means of a curved needle I passed a string through the top of the bladder, and brought both ends out of the wound to serve as a

handle by which the bladder could be held up close to the surface. A longitudinal incision of about an inch in length was then made in the anterior wall of the bladder from above downward. The water immediately escaped from the bladder, and on the introduction of my finger I felt a large flattened stone lying in the lower portion of the organ, but not encysted. After some little difficulty the calculus was seized in ordinary lithotomy forceps and drawn out of the bladder, the wound in which was then closed with interrupted catgut sutures. The muscles were brought together by buried sutures of catgut, and the integument subsequently closed in the same manner. A drainage-tube was carried in at the middle of the incision, and pushed down into the space between the anterior wall of the bladder and the pubic bone. The edges of the wound were finally sprinkled with powdered iodoform, and the ordinary antiseptic dressing of gauze and corrosive sublimate applied. A hard-rubber catheter was left in the urethra in order to drain the bladder. At the end of twenty-four hours it was found impossible to keep the catheter in the bladder because of the pain which it gave the patient. Accordingly, his urine was drawn at frequent intervals by means of a catheter similar to that originally introduced, but it was very difficult to keep the dressings properly applied and avoid their becoming soiled by the urine.

Three days after the operation the wound seemed well united along the surface, and a couple of days later the drainage-tube and two of the sutures were removed. Dribbling of the urine soon began to occur through the opening left by the withdrawal of the tube. This continued until eight days after the operation, upon which day the last suture was removed. On the evening of the same day the patient vomited about six ounces of blood, and during the straining of the vomiting on that day, or on account of the sitting up in bed a few days later, the wound became gaping throughout its entire length. The edges of this reopened wound were again brought together by sutures of silkworm-gut and shot.

From this time forward the man's general condition was bad, although the wound gradually closed, except superficially, and all dribbling of urine from the wound ceased. In fact, he seemed to have recovered from the local effects of the operation, and to have left merely the deep wound through the skin and superficial fascia. Here the granulations were sluggish, and the repair of the opening in the fatty tissues and skin very inactive. He was, however, able to pass his urine normally through the penis, and, so far as urinary symptoms were concerned, was in a very comfortable condition. There persisted, however, nausea, a dull, uncomfortable feeling of pain in the epigastric region, and a total want of appetite. I was unable to make any definite diagnosis as to the meaning of these symptoms. Disease of the liver or stomach were the suggestions which came to mind.

Two months after the operation he suddenly suffered intense pain in the epigastrium, and immediately went into a condition of profound shock, from which he never reacted. A few days before this time he had been sitting up in a chair every day, and the wound in the abdomen was almost closed. He had no trouble in urinating, and was very comfortable, except for the epigastric pain and the great weakness.

The post-mortem examination showed a large gastric ulcer the size of a silver dollar, which had caused perforation of the walls of the stomach, and had allowed its contents to escape into the peritoneal cavity. The cause of the vomiting of blood, of the impaired nutrition, and of the constant pain which he suffered for many weeks before his death, was, therefore, shown to be a gastric ulcer, probably present before the time of operation, but latent in regard to symptoms.

The ease with which the suprapubic operation can be performed, due largely to the distension of the rectum and bladder by the fluid forced into them previous to making the first incision, was clearly demonstrated in this case. The facts that union of the bladder wound and early restoration of the functions of the bladder in regard to urination readily occur after the high operation for stone, and that wounding of the peritoneum is easily avoided, make this method of removing vesical calculi very satisfactory. The unfortunate death of the patient from disease of the stomach does not in any way vitiate the results of the operation; for, although the patient had not recovered sufficiently to be discharged from treatment, still the operation had effected the results which I sought.

THE PRESIDENT presented

A SERIES OF THREE EPITHELIAL OR PSEUDO-MEMBRANOUS CASTS OF THE TONSILS AND PALATINE FOLDS OF A CASE OF DIPHTHERIA.

The patient is an adult, and has exhibited no symptoms of a constitutional infection. The local disease was limited to the tonsils and palate: one tonsil became parenchymatously enlarged and underwent suppuration. The abscess was opened twice. At present there is an additional abscess in the upper portion of the palate. There has been no complication in the case except from difficulty in deglutition, so great that for forty-eight hours the patient had to be nourished mainly by the rectum. Two days ago there was brought to me a thin sheet of false membrane, which was an accurate mould of the tonsil and palatine fold. Yesterday a similar mass of desquamation, having much the same shape, was brought; and this morning a third mould has been thrown off. The appearance of the second cast closely resembles a cast of the interior of the larynx and trachea, and could readily have been mistaken therefor had there been any laryngeal complication. Manipulation, however, demonstrates that it has sheathed the tonsil and one of the palatine folds.

The point to which particular attention is called, is the physical resemblance of these patches to the desquamated epidermis in scarlatina.

DR. J. H. BRINTON made some remarks

ON THE USE OF WHALEBONE BOUGIES IN THE TREATMENT OF URETHRAL STRICTURES.

I propose, for a few moments, to ask the attention of the Society to some points in the application of

filiform bougies to the treatment of urethral stricture, although it is not my purpose to institute any comparison between other modes of treatment and that of which I shall speak. I wish merely to refer to the process of rapid dilatation, effected in the course of a few minutes, by the introduction of stretching instruments, the employment of which is preceded and accompanied by the use of filiform bougies. When these latter were first introduced they were warmly welcomed, but I think that of late some disappointment has been felt in regard to their efficiency, a disappointment which, however, I do not share. I believe that in these instruments we have an efficient mode of treating stricture, provided they be properly constructed, and skilfully manipulated.

As I have never been quite satisfied with the whalebone filiforms of the shops, I have for some years been in the habit of making my own, and with these I have experienced comparatively little difficulty in treating stricture, and in relieving obstinate cases of retention. My experience has convinced me that all organic urethral strictures of non-traumatic origin are pervious to the filiform bougie, patiently and systematically essayed, and this is the essential and starting-point in the treatment which I prefer.

In making my bougies I purchase the material from a dealer in New York. These long, slender, rounded whalebones of various thicknesses are articles of commerce and are used for many purposes in the arts. They are rounded through a drawplate, and come in lengths of twenty-seven to twenty-eight inches, costing about two dollars a gross. Each piece will make two bougies. In preparing them I first cut off the end transversely, so as to get rid of any tendency to split. I then round the end by rubbing it lightly on a sheet of emery-paper gummed upon a board. I then make the extremity bulb-shaped. I am told that the bulb is usually produced by the action of a file. This, I think, is objectionable, as it impairs the fibre of the bone, and renders it liable to break or cut when metallic instruments are slid down over it. I make the bulb extremity by placing the end of the whalebone in a groove on the board, and shave or scrape it from the end with a very sharp knife. I then shave down the shank and neck in like manner in the opposite direction, until I have formed a conical neck from three to four inches long and of almost capillary thickness as it approaches the bulb. The shaping of the bulbar end demands some dexterity in handling the knife, and to insure accuracy I do this under a lens of low power. Having shaped the filiform with the knife, it may, if desired, be yet more smoothed by being rubbed laterally on the emery board. In case cylindrical whalebone cannot be obtained from the manufacturers, the irregular strips may be readily rounded by being passed through a watchmaker's drawplate, or wire gauge. As the filiform bougie is the guide upon or over which metallic instruments are to be passed, each one should be carefully fitted. This can be done by frequently passing it upward and downward through the tunnelled perforation in the beak or extremity of each and every instrument in conjunction with which it may in future be used. This may seem a small matter, but, in fact, the harmonious action of the guide bougie and its metallic companion has much to do in effecting a ready passage of a stricture point. [The speaker here illustrated the process of constructing the bougie.] After using one of these instruments, should the neck become bent or twisted, I place it for a moment in hot water, and then press it between the leaves of a book.

In endeavoring to pass a stricture I make the first attempt with a single whalebone; if it passes, well and good. If it does not go through, I follow it with others, perhaps five or six, until the follicles or folds of the mucous membrane near the stricture are occupied. Then by patiently essaying the inserted filiforms, I almost always succeed in getting beyond the stricture at the first sitting. Sometimes, although very rarely, and in non-urgent cases, if great difficulty be encountered at the first trial, and the patient be frightened and irritable, it may be advisable to desist for the day, and to make a subsequent second attempt. Success at the first trial is, however, the rule, if the instruments be well made, and the efforts be gentle. There is, however, a caution to be observed as to the time of making use of filiform instruments. Their application in cases of tight stricture should be primary—I mean that one cannot expect to succeed with them if they have been preceded on the same day by the attempted introduction of round-ended instruments, the tendency of which undoubtedly is to obscure or close in some way the narrow opening of a resisting stricture, and thus to render its detection more than usually difficult. I may add here that I always use the straight filiform.

The whalebone, when once introduced, serves as a guide to the metallic catheter, or stretching instrument. This may be the tunnelled catheter, or any of the various forms of ditators or divulsors; preferably, I think, that of Sir Henry Thompson, followed by the powerful and most efficient instrument designed by Professor S. W. Gross, and which registers from 16 to 40 of the French scale.

In using metallic instruments in conjunction with the filiforms, there is one point to which, I think, attention has not been directed. We are ordinarily told to slide the metallic instrument over the whalebone through the stricture into the bladder; in so doing, the whalebone may be cut at the seat of stricture. I have often heard of this accident, and I have seen it happen. I avoid it in this manner: Having passed the whalebone into the bladder, I carry the metallic instrument—threaded on it, as it were—down until I reach the stricture, the point of resistance. I then cease to push the metallic instrument along the filiform, but slightly withdrawing the latter to gain a little by its conicity, I grasp firmly both instruments between my thumb and finger, and carry them on together. In this way I am almost certain to pass the resisting point, and, if the stricture be single, to reach the bladder. I speak on this matter somewhat positively, since I have used these instruments largely, and cannot, for many years, recall a case which I have failed to pass in the manner described.

In employing the stretching instrument I usually

separate the blades as far as No. 30 or No. 35 of the French scale, and on its withdrawal, introduce a steel bougie of about the same calibre, to see that all is right and that the urethra is clear. The bougie is then removed and is not reintroduced until the third or fourth day. The after-treatment consists in the hypodermic use of morphia, etc., full doses of quinine, and in a milk diet.

In retention dependent upon tight and irritable stricture, not readily overcome by the catheter, I have often succeeded by simply passing a whalebone into the bladder and leaving it *in situ*. The urine will readily pass along the filiform by capillary action, and the steady dribbling thus established will in a short time empty the bladder. The presence of the whalebone serves also to render the stricture less tight, and so facilitates the after-passage of metallic instruments, should their use be considered desirable.

DR. S. W. GROSS said: I take it that Dr. Brinton has confined his remarks to the treatment of very tight strictures. I think that the younger members of the profession, who are not much accustomed to the use of filiform bougies, ought to be told not to put too much confidence in them. The filiform bougie does not pass with a great degree of readiness through a small stricture, or even through a large one in all cases. I differ from the speaker in regard to the usefulness of the twisted bougies. In the great majority of strictures the orifice is eccentric. A twisted bougie will often pass after we have failed to pass a straight bougie, although the urethra has been packed with them.

We know that in cases of stricture not the result of traumatism, the obstruction does not arise from the organic stricture itself. A man may have been suffering with stricture for some time, and the calibre of the urethra have been gradually narrowing until the stream of urine becomes very small. In this condition he exposes himself to cold and wet, and in the course of a few hours is unable to pass urine. In such a case the obstruction is not due directly to the organic stricture, but there is a superadded spasm of the muscles of the urethra, and it is spasm which we have to overcome rather than the coarctation itself. In such a case, the patient being under the influence of an anæsthetic, I carry a medium-sized instrument, say one whose shaft measures No. 16 and whose point is No. 13 of the French scale, down to the stricture, supporting, if necessary, the curve of the the instrument with the finger on the perineum or in the rectum. In the majority of cases gentle pressure for a few minutes will enable the instrument to pass into the bladder. I have succeeded in this way in cases where I have failed to introduce a filiform bougie. A convenient way of passing the filiform bougies is first to pass into the urethra to the seat of stricture a short metallic tube, and then carry the whalebone bougies through this tube.

I have met with the difficulties referred to in the manufacture of the whalebone bougie. The cutting of the bougie is often due to the instrument which passes over it. The eye is at times so sharp that it strips up the whalebone. Care should be taken to see that the opening is well rounded.

In the operation described by Dr. Brinton, which is the one to be used if it is so desired in these cases, it is always well after passing the coarctation and relieving the retention, to bring the urethra up to a certain calibre, and that is another point in the treatment of stricture. How shall we know to what extent we shall divulse or excise a stricture? The operation described to night is really that of divulsion. I had to day at my clinic a case in point. It was that of a young man from a distance. He was etherized, and in order to determine to what extent the stricture should be cut or dilated, I introduced into the urethra the urethrometer, with which we can measure the capacity of the urethra. In this case there were two strictures. Immediately in front of the first, which was six and one fourth inches from the meatus. the urethra had a capacity of No. 31. In such a case, as the stricture always shows a tendency to contract, it is well to cut or rupture it to No. 34 or 35, to allow for the subsequent contraction.

The instrument to which Dr. Brinton has referred, I had made more particularly for the purpose for which he has used it. At the time that I invented this instrument, I was a rather firm believer in the treatment of stricture by divulsion. I do not employ this method now, although I would use it in a case of retention of urine. It is no more dangerous than cutting, and cutting is no more dangerous than divulsion. The cutting can be more accurately limited than the divulsion. With the latter method we tear not only the stricture, but also the mucous membrane at some distance in front of and behind the stricture. In a specimen in my possession where divulsion was employed, there were no less than nine rents in the mucous membrane, and the rent in the stricture was oblique and had not gone completely through the stricture. This method will do in superficial strictures, but in hard fibrous strictures we have to supplement this operation with urethrotomy. It is for this reason that I have given up divulsion for internal urethrotomy, and I do not resort to this latter operation so frequently as I formerly did. When the patient is within convenient distance, I much prefer, in ordinary cases of inflammatory stricture, and in recent cases more particularly, to resort to gradual dilatation. I have reached the firm conviction that the cases in which radical cure is produced by divulsion, internal incision, or external incision, are so rare that it is rarely worth while to resort to these operations.

DR. CHARLES B. NANCREDE said: While agreeing with most of that which has been advanced by Dr. Brinton, I am rather more in accord with the last speaker. When I intend to do any radical operation, I prefer incision, for then I know exactly what I am doing. My experience teaches me that filiform bougies are not always easily passed through a stricture, even when it is of comparatively large size. Where I have failed to pass the filiform bougie, I have frequently succeeded with a metallic instrument of fair size. I have never had to tap a bladder for retention, but have always succeeded, sooner or later, in getting into the bladder with a filiform bougie.

Although well aware of the eccentric position of

the orifice of most strictures, I was particularly struck with the usefulness of recognizing this fact some years ago, in a case of organic stricture in which the urethra had ruptured. Dr. Packard had made several incisions to relieve the infiltration of urine, and when the patient was turned over to me as a hospital case, the larger part of the urine was passed through an opening at one side of the root of the penis. I tried, on a number of occasions, to pass filiform and other bougies, but always failed. I then called a consultation, intending to perform external urethrotomy. Under ether, I again failed to pass any instrument. I asked Dr. Packard to try. Passing the bougie down to the stricture, he carried it transversely to the left, at a right angle to the course of the urethra, passed it in this direction for about half an inch, and then again by a right-angled turn passed the instrument on in the normal direction of the urethra through the stricture, which was not tight. The instrument was tied in, and the patient eventually recovered. In like manner, a twisted filiform bougie may do good service in a tight stricture. I do not think that the filiform instrument is entirely free from danger in the hands of a tyro. There are cases in which the extremity has been caught in a crypt behind the stricture, a false passage made, and this erroneous route has been followed up with other instruments. Whalebone filiform bougies are, however, of the utmost value when skilfully used, and I should feel completely lost without them to fall back upon in a difficult case. Like Dr. Brinton, I have found it necessary to make them myself. I heartily endorse his method of procedure after the tunnelled catheter or sound has entered the stricture, and have for years resorted to it myself, with invariable success.

Dr. Brinton said: The remarks which have been made only show that every surgeon operates according to the habit of his own mind and hand. While I do not claim that the method which I have described is better than that of others, I can only say that it is one which I have followed for many years, which has yielded me great success in the past, and to which I look forward with confidence in the future. I believe, too, that uniform success in this procedure can only be secured by the use of properly constructed filiforms, and by the observance of the cautions to which I have referred.

STATE MEDICINE.

A PROPOSED PHARMACY LAW,

Adopted by the Legislative Committee of the Nebraska State Pharmaceutical Association.

AN ACT

To Regulate the Practice of Pharmacy and Sale of Poisons, and to Prevent Adulterations in Drugs and Medicinal Preparations in the State of Nebraska.

Whereas, The safety of the public is endangered by want of care in the sale of poisons, whether to be used as such for legitimate purposes, or employed as medicines, and dispensed on the prescriptions of physicians.

And Whereas, The ability of physicians to overcome disease depends greatly upon their obtaining good and unadulterated drugs and properly prepared medicines.

And Whereas, The persons to whom the preparation and sale of drugs, medicines and poisons properly belong, known as apothecaries, chemists and druggists, or pharmacists, should possess a practical knowledge of the business and science of pharmacy in all of its relations; therefore,

Be it enacted by the Senate and House of Repesentatives, of the State of Nebraska, and it is hereby enacted by the authority of the same:

Section 1. That there shall be established in the State of Nebraska a Board to be styled the Nebraska State Board of Pharmacy, said Board shall consist of the Attorney General, Secretary of State and Auditor: And said Board shall appoint and choose three examiners or secretaries who shall be skilful retail apothecaries of seven years' practical experience, actually engaged in said business in the State of Nebraska; and said Secretaries shall assist said Board in conducting all examinations hereinafter provided for, and in the performance of any of its duties.

Each of said Secretaries shall receive a compensation of five dollars per day for each days service actually and necessarily performed, and such necessary expenses, as shall be audited and found just and reasonable by said Board for attending the meetings thereof

Provided, that all such services and expenses, and all the necessary expenses of said Board shall be paid out of the moneys received by said Board for fees, all moneys received in excess of said per diem allowance, and other expenses above provided for shall be paid into the State Treasury at the end of each year, and so much thereof as shall be necessary to meet the current expenses of said Board shall be subject to the order thereof, if, in any year the receipts of said Board shall not be equal to its expenses. The Board shall make an annual report and render account to the State Auditor and to the Nebraska State Pharmaceutical Association, of all moneys received and disbursed by it pursuant to this Act. And the State of Nebraska shall in no case be liable for any such compensation or expenses.

And Provided further that said Board shall have the power to discharge any of said Secretaries at any time and to fill any vacancy in the position of Secretary whenever from any cause such vacancy exists.

Sec. 2. The said Board shall within thirty days after its appointment, meet, and organize by the election of a President and Secretary, from its own members, who shall be elected for the term of one year, and until their successors are elected, and shall perform the duties prescribed by the Board. It shall be the duty of the Board to examine all applications for registration submitted in proper form; to grant certificates of registration to such persons as may be entitled to the same under the provisions of this Act;

to investigate complaints and to cause the prosecution of all persons violating its provisions; to report annually to the Governor and to the Nebraska State Pharmaceutical Association upon the condition of Pharmacy in the State, which said report shall also furnish a record of the proceedings of the said Board for the year, and also the names of all Pharmacists duly registered under this Act; the Board shall hold meetings for the examination of applicants for registration, and the transaction of such other business as shall pertain to its duties, at least once in four months, said meeting to be held on the first Tuesdays of March, July and November in each year; and shall make By-laws for the proper fulfilment of its duties under this Act, and shall keep a book of registration in which shall be entered the names and places of business of all persons registered under this Act, which book shall also specify such facts as said persons shall claim to justify their registration. The record of said Board or a copy of any part thereof, certified by the Secretary to be a true copy, attested by the Seal of the Board, shall be accepted as competent evidence in all Courts of the State. Two members of said Board shall constitute a quorum.

SEC. 3. Every person who shall, within three months after this Act takes effect, forward to the Board of Pharmacy satisfactory proof, supported by his affidavit, that he was engaged in the business of a Dispensing Pharmacist on his own account in this State at the time this Act takes effect, in the preparation of physicians' prescriptions, or that at such time he had been employed or engaged three years or more as a Pharmacist in the compounding of physicians' prescriptions, and was at said time so employed in this State, shall, upon the payment to the Board a fee of two dollars, be granted the certificate of Registered Pharmacist: *Provided*, that in case of failure or neglect to register as herein provided, then such person shall, in order to be registered, comply with the requirements provided for registration as a licentiate in pharmacy hereinafter described.

SEC. 4. No person other than a licentiate in pharmacy shall be entitled to registration as a pharmacist, except as provided in section three. Licentiates in pharmacy shall be such persons not less than 18 years of age, who shall have passed a satisfactory examination touching their competency before the Board of Pharmacy. Every such person shall, before an examination is granted, furnish satisfactory evidence that he is of temperate habits, and pay to the Board a fee of three dollars. *Provided*, that in case of the failure of any applicant to pass a satisfactory examination, the money shall be held to his credit for a second examination at any time within one year. The said Board may grant certificates of registration without further examination to the licentiates of such other Boards of Pharmacy as it may deem proper, upon payment of a fee of two dollars.

SEC. 5. The said Board may grant, under such rules and regulations as it may deem proper, at a fee not exceeding one dollar, the certificate of registered assistant, to clerks or assistants in pharmacy, not less than 18 years of age, who at the time this Act takes effect shall be engaged in such service in the State, and have been employed or engaged two years or more in the practice of pharmacy, but such certificates shall not entitle the holder to engage in such business on his own account, or to take charge of or act as manager of a pharmacy or drug store.

SEC. 6. Every registered pharmacist, or registered assistant, who desires to continue the practice of his profession, shall annually, after the expiration of the first year of his registration, during the time he shall continue in such practice, on such date as the Board may determine, pay to the said Board a registration fee to be fixed by the Board, but which shall not exceed one dollar for a pharmacist, or fifty cents for an assistant, for which he shall receive a renewal of said registration. Every person receiving a certificate under this Act shall keep the same conspicuously exposed in his place of business. Every registered pharmacist, or assistant, shall, after changing his place of business or employment, as designated by his certificate, notify the Secretary of the Board of his new place of business. If any pharmacist or registered assistant shall fail or neglect to procure his annual registration, or to comply with the other provisions of this section, his right to act as such pharmacist or assistant shall cease at the expiration of ten days from the time notice of such failure to comply with the provisions of this section shall have been mailed to him by the Secretary of said Board.

SEC. 7. All or any registrations obtained through false representations shall be void, and the Board of Pharmacy may hear complaints and evidence, and may revoke such certificates as it may deem improperly held.

SEC. 8. Any proprietor of a pharmacy who, not being a registered pharmacist, shall, ninety days after this Act takes effect, fail or neglect to place in charge of such pharmacy a registered pharmacist, or any such proprietor who shall by himself, or any other person, permit the compounding or dispensing of prescriptions, or the vending of drugs, medicines, or poisons, in his store or place of business, except by, or in the presence, or in and under the supervision of a registered pharmacist or registered assistant; or any person, not being a registered pharmacist, who shall take charge of or act as manager of such pharmacy or store, or who, not being a registered pharmacist or registered assistant, shall retail, compound, dispense drugs, medicines or poisons, or any person violating any other provision of this act to which no other penalty is herein attached, shall be deemed guilty of a misdemeanor, and for every such offense, upon conviction thereof, shall be punished by a fine of not less than ten nor more than one hundred dollars, and in default of payment thereof, shall be imprisoned not less than ten days, nor more than ninety days, or both such fine and imprisonment, in the discretion of the court.

SEC. 9. Nothing in this Act shall apply to the business of any retail dealer engaged in business at a distance of not less than five miles from the limits of any incorporated village or city, except physicians' prescriptions, or with the vending of the patent or proprietary medicines by any retail dealer, nor with the selling of, by any person, of drugs, medicines,

chemicals, essential oils or tinctures which are put up in bottles, boxes or packages, bearing labels securely affixed, which labels shall bear the name of the pharmacist or druggist putting up the same, the dose that may be administered to persons 3 months, 6 months, or 1 year, 3 years, 5 years, 10 years, 15 years and 21 years of age, and if a poison, the name or names of the most common antidotes; of coperas, borax, blue vitrol, saltpetre, pepper, sulphur, brimstone, Paris green, licorice, sage, senna leaves, castor oil, sweet oil, spirits of turpentine, glycerine, glauber salts, cream tartar, bi-carbonate of soda, sugar of lead, and such acids as are used in coloring and tanning, nor with the selling of paregoric, essence of peppermint, essence of ginger, essence of cinnamon, hive syrup, syrup of ipecac, tincture of arnica, syrup of tulu, syrup of squills, spirits of camphor number six, sweet spirits of nitre, laudanum, quinine, and all other preparations of cinchona bark, tincture of aconite, and tincture of iron, compound cathartic pills, or quinine pills, when such cathartic or quinine pills are compounded by, or put up in bottles or boxes bearing the label of registered pharmacist, with the name of article and directions for its use on each bottle or box, nor with the exclusively wholesale business of any dealer. Nothing in this Act shall prevent a physician from compounding his own prescriptions.

SEC. 10. No person shall add to or remove from any drug, medicine, chemical, pharmaceutical preparation, any ingredient or material for the purpose of adulteration or substitution, which shall deteriorate the quality, commercial value or medicinal effect, or which shall alter the nature or composition of such drug, medicine, chemical, or pharmaceutical preparation, so that it will not correspond to the recognized tests of identity or purity. Any person who shall thus wilfully adulterate or alter, or cause to be adulterated or altered, or shall sell, or offer for sale any such drug, medicine, chemical, or pharmaceutical preparation, or any person who shall substitute, or cause to be substituted, one material for another, with the intention to defraud or deceive the purchaser, shall be guilty of a misdemeanor, and be liable to prosecution under this Act. If convicted he shall be liable to all the costs of the action, and for the first offense be liable to a fine of not less than ten dollars nor more than one hundred dollars, and for each subsequent offense, a fine of not less than twenty-five dollars nor more than one hundred and fifty dollars. On complaint being entered, the Board of Pharmacy is hereby empowered to employ an analyst or chemist, whose duty it shall be to examine into the so-called adulteration, substitution or alteration, and report upon the result of this investigation; and if said report shall be deemed to justify such action, the Board shall duly cause the prosecution of the offender, as provided in this Act.

SEC. 11. All suits for the recovery of the several penalties prescribed in this Act shall be prosecuted in the name of the people of the State of Nebraska, in any court having jurisdiction, and it shall be the duty of the prosecuting attorney of the county where such offense has been committed, to prosecute all persons violating the provisions of this Act, upon proper complaint being made to him.

SEC. 12. The pharmacist of every house dispensing and compounding medicines, registered under this Act, shall be exempt and free from all jury duty in the courts of this State.

SEC. 13. All acts and parts of acts in conflict with the provisions of this Act are hereby repealed.

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Frisch's Report on Pasteur's Method.

La Semaine Médicale, of January 1, has published a report of Professor von Frisch, of Vienna, on the researches of M. Pasteur on the rabic virus and his method of prophylaxy against rabies, and as the subject is of the highest importance, I reproduce here the conclusions of the Vienna Professor, giving the results of his own researches:

1. In animals which have died from rabies the virus exists in its most concentrated form in the central nervous system (brain and spinal marrow). 2. Small quantities of the cerebro-spinal substance of animals which have died from rabies, injected under the dura mater by trephining, provoke with certainty the same disease in animals infected after a latent period of from fourteen to twenty-one days, which disease may be transmitted from these to other animals. 3. The same disease, with the same symptoms and after the same period of incubation, may be produced in animals by intra-cranial injection with particles of the spinal marrow of human beings who have died of rabies, thus proving the identity of the affection in man and in the lower animals. 4. By the subcutaneous injection of the cerebro-spinal subtance, infection is less sure, and the period of incubation longer, than by intra-cranial infection. 5. The quantity of virus injected under the skin appears to be in an inverse relation with the duration of the period of incubation: the less the quantity injected, the longer is the period of incubation. 6. By the continual intra-cranial transmission of the rabic virus contained in the cerebro-spinal substance of rabbits, one obtains, after a series of generations, a shortening of the period of incubation, irregular at first, but more regular and always increasing later on. 7. The "fixed virus" of a period of incubation of seven days, which M. Pasteur obtains by inoculation from rabbit to rabbit in from forty to fifty generations, surpasses, in intensity, the virus of "street rabies," not only by the more precocious appearance of the disease, but also because the animals, without exception, die from rabies, as well after the subcutaneous injection as by inoculation under the dura mater. 8. The fixed virus does not seem to undergo by ulterior transmissions a notable shortening of the period of incubation, the malady sometimes commencing after six days. On the other hand the period of incubation of seven days is not constant, as it is sometimes prolonged to eight, ten, and even twelve days. One

may also obtain a period of incubation of from eight to twelve days, and consequently a virus of the same virulence as that of the fixed virus, by the transmission of street rabies, and that occasionally from the second or the third generation. 9. The procedure indicated by M. Pasteur to obtain a fixed virus of a period of incubation of seven days, is perhaps not the only one, as the said virus may sometimes be obtained much earlier, independently of the transmissions, and this virus is constant in its effects and in its period of incubation. 10. The virulence of portions of the spinal marrow diminishes from one day to another by dessication at 20° centigrade over caustic potash, and is completely destroyed after a dessication of twelve or fourteen days. 11. Animals that have been subjected to subcutaneous injections of a series of attenuated inoculations (by more or less lengthened dessication), are rendered refractory to the stronger virus by the previous inoculations with the weaker virus, if the stronger virus have not been used in too rapid succession. 12. Animals which have been inoculated subcutaneously during ten days with virus of progressive virulence (spinal marrow from ten days to one day) have not been refractory to infection with the fresh virus of "street rabies," and have only exceptionally escaped after intra-cranial infection. 13. Rabbits and dogs infected after trephining with the virus of street rabies of sixteen days' incubation have, without exception, succumbed, notwithstanding the preventive treatment already described. 14. M. Pasteur attributed to *the method of slow vaccinations* the unsatisfactory results obtained previously by M. von Frisch, and recommended a more rapid procedure. The experiments carried out conformably to M. Pasteur's instructions have given no favorable results whatever; all the animals died of rabies. 15. These experiments have demonstrated a very important fact: that is, that by the rapid procedure, the weaker spinal marrows do not confer the same certainty of immunity against the stronger ones of a series of dogs and rabbits, which have served as a control experiment, referred to in the preceding paragraph, and in which the rapid process was carried out without previous infection, most of the animals died of rabies. 16. Most of the animals which were submitted to the preventive treatment after subcutaneous inoculation with street rabies, died of the disease, even when the period of incubation was thirty-four days.

M. von Frisch asserts that these experiments show that M. Pasteur's method of rendering animals refractory to rabies is, as yet, not quite certain. There is not yet a sufficient scientific basis for the application in man of a preventive treatment after the bite of a rabid animal. Moreover, it is quite possible that by the preventive treatment itself, at any rate by the rapid procedure recently recommended by M. Pasteur, the malady itself may be transmitted. In taking a glance over what precedes, it will be seen that the conclusions 1, 2, 4, 5, 6, 7, and 10 only concord with those of M. Pasteur. A. B.

DOMESTIC CORRESPONDENCE

COCAINE IN MINOR SURGERY.

Dear Sir:—I desire to give my experience in the use of injections of cocaine in minor surgery, for producing complete local anæsthesia by injecting into the part, through a fine needle, one or two drops of a four per cent. solution of cocaine. For this purpose I use the thinnest steel needle procurable—a very delicate needle sold by Tiemann & Co., which they bill as "Green's."

My experience leads me to think that some of the surgeons using cocaine for local anæsthesia inject more than is necessary. Its local action, as I have observed it, is anæsthetic and anæmic. When injected it causes much more local congestion and irritation of the integument than morphine. It greatly aids morphine to relieve any form of neuralgia, especially facial, and migraine. Is it the hydrochloric acid that chiefly causes the local irritation? Is the plain drug *cocaine* less irritating than the hydrochlorate, benzoate, etc.? I cannot answer from experience. A full dose hypodermically—gr. ss–j, often much less—will cause quite free sweating, and frequently a momentary sense of painless dilatation of the heart, a peculiar feeling, like that sometimes felt in the beginning of syncope. I believe its effects are toxic in most cases when more than one-half grain is given hypodermatically, although the dose, as of other drugs, varies in effect according to temperament, use, state of system, etc.

During the last half year I have several times used, on my own person, for the relief of intense neuralgic pain, Magendie's solution of morphine, to which a four per cent. solution of cocaine was added, the medicine being injected under the skin, as usual. For five minutes or so after each injection an area of two to four inches surrounding the puncture appeared to be quite devoid of sensibility.

On January 2 my partner, Dr. W. A. Cottle, was suffering agonizing pain and inflammation of his forefinger, which he had pricked slightly, with a needle, during an amputation of a gangrenous finger the day before. It was decided to incise the finger, freely, to the bone, to relieve tension, and he sat there dreading the knife, as doctors do, yet too proud to inhale ether. I suggested cocaine, only to be laughed at, but on mentioning my experience was permitted to try it.

Accordingly I injected, near the centre of the ball of the finger, into the skin only, two drops of the cocaine and morphine solution. A moment later the doctor deliberately plunged his bistoury down through the periosteum and cut outwards, making a gash in the skin eight lines in length. He cut as deliberately as he could have if I had been the victim instead of himself, never wincing in the least, and exultingly exclaimed that it did not hurt at all.

With the fine implement above named scarcely any pain is caused by the puncture, which may go through the skin or into it, so that it reach the absorbent vessels. The opening of abscesses and felons, too often postponed from sheer dread of the knife, may thus

be relieved of its terror. It is now known that a small member may be amputated painlessly, without general anæsthesia, by injecting cocaine in two or three places around the limb near the line of incision.

For relief in extracting teeth, cocaine applied to the gums has been generally voted a failure. I would suggest a trial of it by injecting a drop or two into the gum on each side of the tooth, believing it will greatly diminish the pain. Use only the very thin needle named above, for one might as well suffer the operation as the use of such *crow bars* as I have seen physicians employ.

I venture the hope that cocaine may soon be more generally used in this way.

Very respectfully,

ALMON CLARKE, M.D.

Sheboygan, Wis., January 6, 1887.

LOCAL ANÆSTHESIA.

Dear Sir:—In an article in THE JOURNAL of October reference is made to a suggestion of Dr. Franklin H. Martin, of Chicago, who utilizes the properties of the galvanic current discovered by Haertner, who ascertained the valuable fact that particles in solution would, under the influence of a galvanic current, pass through permeable bodies from the positive toward the negative pole of the battery. This important fact caused the writer to experiment on the best mode of applying it so as to produce local anæsthesia and other influences. I think my plan superior to that adopted by Dr. Martin, although the same principle is involved in both.

I draw on the part to be experimented upon a hard-rubber cup of any size, under which I put a piece of light rubber cloth, pierced by a small brass wire, to which is attached, on the under surface, a brass button. Around this I wind cotton-wool, which, being saturated with a ¼ per cent. solution of muriate of cocaine, I place under the cup, and on producing suction the whole appliance is drawn to the part. The rubber cloth, being held by the rim of the cup, makes a nice pressure upon the part to which it is applied. The blood is drawn to it by the suction, and the tissue is thereby made more permeable. The wire is united with the negative pole and the current turned on.

I have in this way produced the most satisfactory results, and at the same time most permanent. Air being excluded from the solution, no evaporation takes place. The appliance is hard to explain without diagrams, but I trust my suggestion will be sufficiently explicit for those who may wish to utilize it. The cup and rubber appliance referred to can be used in many ways in local and surface medication.

Very truly yours, J. W. HARVEY, M.D.

Indianapolis, Ind., December 20, 1886.

MISCELLANEOUS.

TENNESSEE STATE BOARD OF HEALTH.—The Governor of Tennessee pays a well deserved tribute to the State Board of Health. In his annual message he says: "It is my pleasure to call your attention to this important and steadily-growing valuable branch of the State service. During the past two years, under its auspices, there have been organized eighty-two county boards of health, besides securing to each of the large towns in the State an efficient municipal health board, thus bringing the people of the entire State practically under the most intelligent sanitary supervision and administration, which contemplates the remedy, if possible, of all those causes which produce human sickness, and which intensify and facilitate the ravages of all epidemic diseases. Through instructive circulars, which have from time to time been extensively circulated over the State, the State Board of Health has offered to the people valuable suggestions and advice, based upon the latest developments of science, regarding the most approved methods of preventing or restricting the spread of those domestic plagues which in the past have annually left desolate so many homes in Tennessee. Besides which the Board has issued monthly a 'Bulletin' giving the influence of climate upon diseases, together with the prevailing diseases of the State, month by month, and the death-rate per 1000 population so far as under existing law it can do so. In this connection it is not inappropriate to suggest that there is no law in our State now looking to the continuance and proper connection and preservation of the 'vital statistics' of Tennessee. This Board of Health has done, and is calculated to do, much scientific and practical good, and is most efficient as it is now organized."

TOOTH POWDERS.—Prophylactic medicine is of greater value to the public than curative, although they are slow to give it its due; hence the subject of tooth powders may be of some interest. The necessity of keeping the teeth clean, with a view to the prevention of future trouble, is overlooked by too many, even in the higher classes, sometimes from carelessness, sometimes from ignorance. Now, cannot the medical attendant do a great deal to combat this state of things? The dental surgeon is often asked, "How soon should the first tooth-brush be used?" "As soon as there are teeth to use it upon" should be the reply. An ideal tooth powder should be alkaline, since acids dissolve the tooth substance; finely pulverized, that it may not mechanically abrade; antiseptic, to prevent decomposition of food lodged between the teeth, and perhaps to destroy the microbes which are always found choking the tubules of carious dentine; it should contain nothing irritating to the gums; and, lastly, it should be pleasant to the taste, or it will not be used. Fluid dentifrices do not, as a rule, clean the teeth effectually, unless they contain some ingredient which acts upon the enamel itself; and those preparations which are eulogized as making teeth white or preventing the deposit of tartar, should be avoided. Charcoal was at one time a very popular form of dentifrice, and is even now largely used, but from the amount of silica it contains it will rapidly wear away teeth that are not of exceptional hardness; and, moreover, the gums in

some instances become tattooed in a curious manner from absorption of minute particles. Pumice powder, again, is too gritty; and camphorated chalk is said to make the gums spongy. Precipitated chalk forms the best basis for a tooth powder, to the base of which may be added pulv. saponis and ol. eucalypt., a drachm of each; and, if there is no objection to the taste, half a drachm of carbolic acid.—*Lancet*, January 1, 1887.

NECROLOGICAL.—The members of the Council of the New York State Medical Association, while humbly submitting to the decrees of Providence, realize with much grief that the year now closing is made notably sad in the loss by death of so many of their Fellows whose labors have largely contributed to the honor, dignity and usefulness of the medical profession. They now mourn the loss of the second President, Dr. John Perdue Gray, whose aid, wise councils, and personal work have been of such signal service. In common with all the Fellows of the Association, and with the medical profession at large, they sorrow for the death of one who had rendered himself so useful to the State in the guidance of the charitable work in the department of medicine in which he had become a shining light. The Council, therefore, resolved, that the above be published in the forthcoming volume of the Transactions of the Association, and in the medical journals, and that a copy thereof be transmitted to the family of the deceased.

E. D. FERGUSON, Secretary.

January, 1887.

DISINFECTION OF CABS.—At the meeting of the Society of Medical Officers of Health, on Nov. 19, the Council advised the following method of disinfection: The cushion and as much of the internal fittings as are movable should be taken out of the cab and put in a disinfecting oven, where such is available; if there is no disinfecting chamber, the cushions, after having been taken out, if movable, well beaten and dusted, should be replaced, putting them on end so as to expose both surfaces to the action of the chlorine gas which is subsequently used. All exposed woodwork on the inside of the cab should be washed with carbolic acid soap; and carbolized oil should be smeared over the metal work, with the view of disinfecting it, and protecting it from the action of the chlorine. Chlorine gas should be evolved inside the cab, and the cab shut up and kept exposed to the fumes for one hour.—*British Medical Journal*, Jan. 1, 1887.

DR. CHARCOT.—George Augustus Sala says: Dr. Charcot is surely one of the most ingenious of medical mankind. He is a specialist in hysteric and hypnotic cases, and I read that, having satisfied himself as to the practicability of transferring paralysis, nervous contractions, and cataleptic symptoms from one patient to another, he is now about to extend his experiments to hysteric dumbness. "A female patient affected in this manner was placed back to back with a women who had been for a long time cataleptic. By means of the magnet the dumbness was transferred from one patient to the other with the same regularity as marked the experiments in paralysis. By continuing these tests, Dr. Charcot hopes to be able completely to restore speech to tongue-tied patients." The mention of Dr. Charcot's name reminds me that he has written an editorial preface to a book which, artistically, is one of the most extraordinary on which I have ever set my eyes. You know what Sir Charles Bell, what Lebrun, what Darwin and Lavater have done in delineating the passions and emotions of the face; but for a series of terrific pictures illustrating the passions of the body, let me commend you to the "Etudes Cliniques sur l'Hystérie-Epilepsie ou Grand Hysteric," by Dr. Paul Richer, one of Dr. Charcot's pupils. Dr. Richer is an accomplished draughtsman, and his bulky and most appalling volume is embellished with a large number of etchings and woodcuts portraying every conceivable variety of hysterical attitude.

DR. THOMAS E. MCARDLE has been compelled, on account of ill health, to resign the position of Professor of Surgery in the Medical Department of the National University, Washington, D. C., and Dr. Philip T. Harvey, U. S. Army, has been appointed to fill the vacancy.

RUSSIA AND PATENT MEDICINES.—The Russiau Government will prohibit the importation of patent medicines, and the published prohibited list contains more than eight hundred items.

REPORTING OF CONTAGIOUS DISEASES.—The Mayor of Columbus, Ohio, has given notice that for every violation of the law requiring physicians to report contagious diseases he will fine and imprison the offender.

WEEKLY MEDICAL REVIEW.—Dr. B. J. Primm succeeds Dr. Robert Luedeking as associate editor of this journal.

THE BUILDING OF THE COLLEGE OF PHYSICIANS AND SURGEONS, New York, has been sold to an ice-cream firm.

AN ITALIAN HOSPITAL.—The wealthy Italian residents of New York are raising funds for establishing a hospital for Italians.

DR. RAYNER, in the London *Times*, advocates the treatment of mental diseases at general hospitals.

THE UNIVERSITY OF BOLOGNA will celebrate its seventh hundred anniversary in the spring.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 15, 1887, TO JANUARY 21, 1887.

Major W. H. Forwood, Surgeon, ordered for duty at Ft. Meade, Dak. Ter. S. O. 5, Dept. Dak., Jan. 14, 1887.

Major John Brooke, Surgeon, ordered for duty as Post Surgeon at Ft. Monroe, Va. S. O. 10, Div. Atlantic, Jan. 14, 1887.

Major W. H. Gardner, Surgeon, ordered for duty as Post Surgeon at Ft. McHenry, Md. S. O. 10, Div. Atlantic, Jan. 14, 1887.

Major B. F. Pope, Surgeon, ordered for duty at Ft. Clark, Texas. S. O. 15, A. G. O., Jan. 19, 1887.

FRACTURE OF THE ANATOMICAL NECK OF THE SCAPULA.

BY H. B. HEMENWAY; A.M., M.D.,

OF KALAMAZOO, MICH.

Early in the evening of December 28, 1885, I was called in haste to see Dr. R. J., American, temperate, aged 51 years, lympho-sanguineous temperament, five feet seven inches in height, and weighing 200 pounds. A few minutes before, the doctor had started out of his house to walk down town. He was eating an apple at the time, which perhaps tended to make him more careless. In his right hand he carried a heavy walking-stick. He was hardly off from his front steps before he slipped upon the sidewalk. He tried to regain his equilibrium. After stumbling along a few feet he fell, striking his left arm, just below the shoulder, heavily upon the edge of the raised sidewalk. His body was twisted, for in the fall he hit his head and right hip.

When I arrived at his residence I found him seated in a chair, holding his arm so that the elbow was about five inches from the side of the body. He stated that that was the most comfortable position he had found. Upon removing his clothing it was easy to see that the head of the humerus was absent from its usual place. On account of the thick clothing which he wore at the time of the accident, there was no indication of bruise apparent. I made no measurements, but I thought the injured arm was slightly longer than normal. The acromion and coracoid processes were very prominent. Under them was a cavity. The upper extremity of the humerus did not stand out further than, if as far as, a perpendicular from the tip of the acromion process. I passed my finger down the spine of the scapula without discovering any abnormality. The clavicle was in place and entire. I could feel the head of the humerus in the axilla. There was no tumor under the coracoid process, nor under the spine of the scapula. I could find no crepitus anywhere. Though the elbow did not stand out prominently, and though it could be brought to the chest, I diagnosticated the case as one of simple subglenoid dislocation of the head of the humerus.

I first tried to reduce the dislocation by manipulation, but without success. Since the patient was well and strong and not relaxed by drug or drink, I anticipated some little difficulty in the reduction of the dislocation. I accordingly placed him upon a lounge. To protect him from the cold while we were working at him, I drew his flannel undershirt over the shoulder. I am now sorry that I did this, for it hid the shoulder from view, so that I did not know when the dislocation was reduced.

I next placed my left foot against the side of his chest, below the shoulder, as a counterbrace. I afterwards assisted this foot by grasping the acromion process with the toes of my right foot. First alone, and then with the aid of a neighboring gentleman, I made side extension upon the arm, at right angles to the body. I did not hear nor feel the slightest thud or jerk, so familiar in the reduction of dislocations. Then I changed and put my heel in the axilla. I made downward traction on his arm, and, using my foot as a fulcrum, I passed the lower end of the humerus gently but firmly toward the patient's chest. Again meeting with no apparent success, I announced that I must give an anæsthetic. Before proceeding to do so, however, I examined the shoulder. To my surprise, there was no cavity under the acromion. I removed the covering and made a careful examination of the shoulder, both by touch and sight. I could discover no abnormality of shape or position. Though voluntary motion was in a degree lost, the left arm could be placed in any position into which the right one could. The motions of the arm revealed no sign of fracture. Now, however, I found what I had not found before, namely: that *pressure just below the end of the coracoid process gave crepitus*. Pressure upon the coracoid process did not produce crepitus. I therefore changed my diagnosis from simple dislocation to *fracture of the anatomical neck of the scapula*, and directed that the elbow be bound to the chest and that the forearm be carried in a sling.

That night the arm was not bound to the chest as directed. In the morning the patient found his shoulder not quite so easy, but thought it not strange. He thought in the night during his sleep he turned and lay for a time towards his injured side. He had a dim memory of something of the kind. After getting up he happened to sneeze, and at that time he felt a slight jar of the shoulder. Immediately thereafter his joint became more comfortable. Two days later he had a repetition of the uncomfortable feeling in the morning, relieved by sneezing.

January 14, 1886.—I found some ecchymosis of the left arm and chest. Arm doing well. The head

of the humerus seemed to me a very little forward and below its natural position. No special soreness in the shoulder joint. Pressure towards the body upon the head of the humerus did not produce pain. Pressure below the tip of the coracoid did produce pain. Voluntary motion was returning. The doctor reported that it was improving rapidly. When the elbow was raised to the level of the shoulder, pain was felt along the track of the musculo-spiral nerve.

Fracture of the anatomical neck of the scapula is very rare. Gray, in his "Anatomy," does not mention the possibility. Stephen Smith in his "Operative Surgery," Hamilton in his "Surgery," Ranney in his "Surgical Diagnosis," do not mention it. F. Hamilton, in his work on "Fractures and Dislocations," says that it is very rare. Its existence "uncomplicated by comminuted fracture of the glenoid cavity is denied by Sir Astley Cooper, South, Erichsen, and others." No specimen is in any of the museums of London, and Hamilton has not been able to find one in any of the museums in America. Gross, in his work on "Surgery," says: "It is not improbable that the edges of the glenoid cavity may occasionally be broken off, either by direct force, or by sudden and violent propulsion of the head of the humerus. It is remarkable, however, that the existence of such a lesion has never been demonstrated by dissection." The "International Encyclopædia of Surgery" mentions the case reported by Assaky to the Société Anatomique, in which a stellated fracture of the glenoid cavity was found, but that was accompanied with other fractures.

Such being the opinions of our distinguished surgeons, men recognized as authorities on the subject, it is incumbent upon me to give my reasons for diagnosticating the case as I did. When the accident occurred, I did not think of the case being unique, or I should have called on other surgeons to verify my diagnosis. I give, therefore, my argument.[1]

The case was not one of simple subluxation, because:

1. Before reduction the upper extremity of the humerus, instead of being more prominent, was less prominent. A ruler laid along the external border of the arm, while the elbow was by the side of the chest, would touch the acromion process.
2. Reduction by manipulation did not occur.
3. Crepitus was discovered after reduction.
4. The head of the humerus could be felt in the axilla.
5. There was no "thud" on reduction.

It was not a simple subglenoid luxation of the head of the humerus, because:

1. Crepitus was present.
2. The elbow did not stand out prominently from the thorax, but the axis of the arm was nearly parallel to the chest wall.
3. Of the ease with which it was reduced by traction.
4. Of the absence of the "thud" on reduction.

It was not a subclavicular nor a subcoracoid luxation, because:

1. Crepitus was present.
2. The elbow could touch the chest.
3. The elbow was not drawn backward.
4. It was reduced easily.
5. The arm was slightly lengthened.
6. Communicated motion forwards and outwards was not greatly restricted.
7. The head of the humerus was felt in the axilla, and not under the coracoid process.
8. The coracoid process was prominent.
9. No "thud" was heard or felt on reduction.

It was not a subspinous dislocation, because:

1. There was crepitus.
2. The depth of the shoulder was not increased
3. The tumor was felt in the axilla and not on the scapula.
4. The elbow could touch the chest.
5. No "thud" was heard on reduction.

It was not a fracture of the surgical neck of the scapula, because:

1. The acromion and coracoid processes moved together, with the scapula, and not with the humerus.
2. There was a marked depression and space, between the acromion and coracoid processes above, and the humerus below.
3. I could discover no crepitus before reduction.
4. When reduced there was no great or marked tendency towards a return of the deformity.
5. Pressure on the scapula posteriorly did not produce pain. Nor was the break through the spine of the scapula, for that was entire so far as I could discover by palpation.

It was not a fracture of either the anatomical nor surgical necks of the humerus, because:

1. The limb was lengthened rather than shortened.
2. Movements of the humerus at no time produced crepitus.
3. The acromion was very prominent, and the depression below it deep.
4. Reduction was permanent.

I do not think there was a comminuted fracture of the glenoid cavity, because, in that case, there would be a greater tendency towards the return of the deformity after reduction. With a comminuted fracture of the head of the scapula there would be too little resistance to the sinking in of the head of the humerus. Moreover, pressure from the side upon the shoulder would tend to separate the fragments, and would therefore produce greater pain than was present in this case. The greatest pain upon pressure in this case was caused by pressure backwards just below the coracoid process. Further, in a fracture into the joint, we should expect more indications of synovitis than were present in this case.

The fracture may have entered the glenoid cavity. The slight change in the shape of the shoulder after reduction may be due to such a fracture, but not necessarily so. If the fracture did enter the glenoid cavity I think it must have been a simple fracture, and by far the greatest portion of the head must have been broken off. A study of the shape of the scapula strengthened by the ligaments will indicate that probably if much of the head is broken off, the fracture would be one of the anatomical neck.

[1] This paper was read to the patient, in order to make sure that it contains no errors of fact.

What should we expect to find in a fracture of the anatomical neck of the scapula?

1. There would be downward dislocation, with possibly dislocation either forward or back. This dislocation would be caused by the blow received, and when once displaced the broken bone would catch in the muscles. The coracoid and acromion processes would stand out distinct. There would be a cavity below the acromion.

2. In proportion to the amount of dislocation it would be difficult to obtain crepitus.

3. In so fleshy a man the only way to obtain crepitus would be pressure from in front back, just below the coracoid process, and possibly by pressure from the side on the shoulder.

4. The arm might be slightly lengthened, though not as much so as in the simple subglenoid luxation.

5. Since the humerus would move freely on the broken head of the scapula, and the latter would be caught in the muscular tissues surrounding, movements of the arm would not produce crepitus, and would only produce pain, when it was raised to such a position as would stretch the injured muscles.

6. Since the head of the humerus would not be caught on the edge of the head of the scapula, though the axis of the same might not be parallel to the chest, unlike a subglenoid luxation the elbow might touch the chest.

7. When reduced the abnormality would not show a marked tendency to return. Such a tendency would be in proportion to the obliquity of the fracture.

8. Reduction by manipulation would not occur, but reduction by lateral traction would be comparatively easy, and without a noticeable "thud."

9. The arm would be neither rotated inwardly nor outwardly.

10. The elbow would neither be prominently thrown backward, forward, nor outward; but

11. The arm would be most comfortable with the elbow a few inches from the chest.

12. Paralysis of voluntary motion might be present.

In such an injury, there would remain to hold the bones in place after reduction of the dislocation:

A. To hold the humerus up: 1. The coraco humeral ligament. 2. The deltoid, coraco-bracialis, short head of the biceps, triceps, supra-spinatus, and the superior fibres of the pectoralis major muscles.

B. To prevent backward dislocation: 1. Coraco-humeral ligament. 2. Pectoralis major, and short head of the biceps muscle.

C. To prevent forward dislocation: The latissimus dorsi and scapular muscles.

The points in treatment are: First, reduction by lateral extension. Secondly, to keep the bones in place. The head of the humerus must be kept up, and quiet. To accomplish this the elbow should be bound to the chest, and a bandage should be passed under the elbow and over the shoulder. The bandage around the chest should not extend too high up, as that would tend to crowd the injured pieces together, and cause them to slide on each other. Were I to treat another case I should use an ample axillary pad to act as a fulcrum, and take off the lateral pressure.

Since writing the above I was called in consultation to see another case, the record of which I will here give for comparison:

Late in the evening of August 18, 1886, I was requested by my friend, Dr. W. H. Schaberg, to go with him into the country and see a case of luxation of the shoulder joint.

The patient, Mrs. B., aged 40, was a farmer's wife. Since girlhood she had been subject to epileptic seizures. Six times, during these spells, she had fallen and dislocated her left shoulder. Once, although a physician was promptly summoned, the luxation was not reduced for a week.

Upon this day the family came down to Kalamazoo to visit the Soldiers' and Sailors' Reunion, and to witness a sham battle. The long ride and excitement of the day quite exhausted Mrs. B. After reaching home she was sitting alone in the bed room, getting the baby to sleep in her arms. Hearing a noise, the family ran in and found her lying on the floor. She said that generally she had a little warning, but this time she fell without any premonition. In falling she struck on a crib by the side of her chair.

Upon examination we found a thin, nervous woman, of bilious temperament, and in feeble health. She was quite the opposite of Dr. J. She was seated in a chair. Her left arm hung parallel to her chest, with forearm and elbow supported on a pillow. She said it looked and felt different from other times, but she regarded it as a simple dislocation. All motion, and even the weight of her arm, was very painful. Arm shortened. Acromion prominent, with cavity, though not deep, below it. Elbow could easily touch the chest. With hand on right shoulder elbow touched the chest. The coracoid process moved with the scapula, not with humerus. The acromion was cracked off from the spine of the scapula about an inch and a half from the tip of the process. No unusual point of motion in humerus detected. Could not feel the head of the humerus in the axilla. The pain was intense in the joint only, not in hand. There was very little swelling, though it was then four hours after the accident.

To facilitate examination we administered chloroform. We could not reduce the luxation by manipulation, either before or after using the anæsthetic. Rotation of the arm, when the elbow was raised forward to the level of the shoulder, and the head of the humerus was pressed against the scapula, produced crepitus. Crepitus was not produced by backward pressure below the coracoid process. With very little force I could reduce the luxation by lateral traction with slight rotations, but as soon as I relaxed my hold the luxation returned.

Dr. Schaberg was inclined to think it was a fracture of the anatomical neck of the scapula, with fracture of the acromion process. I diagnosticated it a fracture of the anatomical neck of the humerus, probably impacted, with fracture of the acromion.

The case was treated as above recommended. Three days later we removed bandages and substi-

tuted adhesive plasters, much to the comfort of the patient. Since then I have not seen the patient, but am informed that she made a good, though slow, recovery. Dr. Schaberg tells me that a callus can be easily felt just external to the coracoid process. Deformity is slight, and motion not greatly impaired.

A CASE OF CONCEALED PLACENTAL HÆMORRHAGE

BY VIRGIL McDAVITT, M.D.,

OF QUINCY, ILL.

Mrs. L. T., aged 24, of German descent, and of good form and constitution, having previously borne two healthy children at term, the labors being natural and easy, was badly frightened while driving on August 3, 1886, being then, as she thought, about four months pregnant, and believing that she had repeatedly felt motion in the child. After the ride, although not feeling well, she had no serious symptoms until the forenoon of the next day, when a sense of nausea, faintness, and dull pain in the left side came on, and gradually increased until such alarming prostration occurred that medical aid was sought.

I saw her first at 1 P.M., when her condition was as follows: Very pale and faint; breathing rapid, and anxious; feels as if suffocating; pulse feeble almost to extinction; has a feeling of great distress in left side of abdomen, reaching from crest of ilium to hypochondrium. At this point there is much tenderness to pressure, which increases the distress and faintness. Abdomen generally soft, with some sense of fulness on the left side, as from accumulated fluid. Cannot by palpation make out any uterine tumor.

Per vaginam.—Os high up. No apparent dilatation, no hæmorrhage or discharge of any kind. Beyond the os and cervix cannot detect the expanded body of the uterus, as it should be found at this stage of normal pregnancy. Diagnosis uncertain, but that of concealed hæmorrhage best comports with the conditions of the case; caused either by extra-uterine pregnancy with rupture of cyst, or utero-placental rupture. Treatment: ergot, opiates and astringents, with free alcoholic stimulation, cold, and tight bandaging to the abdomen.

August 4. Still has spells of great faintness and difficult breathing, attended by profound exhaustion. Find more marked sense of fulness in left side. Can not yet make out any definite uterine tumor, or clearly detect the locality of the fœtus, probably on account of the increase of faintness and extreme flaccidity of the tissues. Treatment continued.

August 5. Condition much the same as on yesterday, but the bad symptoms not so extreme. Treatment continued.

The sense of faintness and nausea gradually abated under the influence of occasional doses of bismuth and morphine, added to the specific remedies above stated, and the uterus gradually gathered itself into the hypogastrium about and after the third day, as an indistinctly outlined soft mass, but there was no relish for food, and the sense of faintness attended with nausea, and slight uneasy pains recurring frequently during every twenty-four hours, made the life of the patient miserable and led to a feeling of great insecurity and danger on the part of the physician. The pain had never been severe, but of an uneasy, sinking, unendurable character.

From the first the external os was soft and patulous, so that a finger could easily enter to the depth of the internal os, which was firmly closed. The child, which had shown previous signs of quickening, as the mother thought, was quiescent, and no sign of life could be detected from fœtal motion or heart sound. This condition continued, with occasional aggravations, until about September 12, when the symptoms of nausea, faintness, pallor and indefinable pain, uneasiness and exhaustion, became so much aggravated as to call imperatively for relief for the sake of the mother's safety.

In the meantime there had been perceptible growth in the abdomen, but no definite signs of life in the child could be made out, and at this time again, as at all times since the inception, when there was much faintness, the uterine tumor disappeared to the sense of feeling, and the fœtus, which could now be distinctly located through the exceedingly lax abdominal walls, appeared to wander indifferently about the abdominal cavity, was apparently lying along the right side of the abdomen, reaching high up near to the under surface of the liver.

I requested counsel in the case, which was not secured until the following day, when Dr. G. W. Edison was called, at which time the condition was much the same, viz.: great pallor, pulse very feeble and frequent, frequent faintness and nausea with sickening, sinking pains, and rarely one approaching a labor pain in appearance. Abdomen very much relaxed, child still lying on right side, reaching high up, os patulous externally; internal os closed. It was concluded as best to use ergot and opium in small and frequent doses, hoping gradually to promote uterine action with dilatation of cervix, and thus bring on labor, and also to use alcoholic stimulants very freely. Ext. ergot (Squibbs), gtts. v, tr. opii. deod., gtts. v, were given every two hours.

The day following there appeared to be some relaxation of the internal os, but so much nausea had been caused by the medication that some change in it was demanded, when ext. belladonna and ext. nux vomica, each ½ drop, were added to the dose of medicine, with enough of ess. cinnamon to disguise the disgusting flavor of the ergot. Next day the pulse was better, faintness less, internal os so dilated that two fingers could be passed within the cavity; but the fœtus kept high up, no part presenting at internal os. I endeavored by dilating with the fingers to force labor, but, aside from a few pains induced by the direct irritation, no labor pains followed. Some show of bloody mucus appeared during the day. This general treatment was followed for two or three succeeding days, the condition of the os remaining much the same, no farther dilatation taking place, the show of blood and mucus subsiding, and her general appearance, pulse, color and everything apparently improving, the uterus having resumed its globular form and distinct motion in the fœtus having be-

come manifest, I thought it best to partially suspend the treatment and await the indications of nature.

On making my visit on the morning of September 21 I found that true labor pains had been felt with some regularity during the preceding night, and on examination found the os soft and pliant, the internal os dilated so that two fingers could easily pass and detect a vertex presentation. Everything now indicated a speedy termination of the labor. I left about 8 A.M., with instructions to call me if the pains became frequent or severe. I was called at noon and found the pains recurring every five minutes. Found but little progress in the dilatation of the os, but for the first time the membranes were pouching in the cervix. Waited two hours, and the head not engaging in os, ruptured the membranes to hasten delivery, as the os was dilating so slowly and the woman was much exhausted.

I left her after 3 o'clock until 5 P.M., when labor was found to be making slow progress, the os dilating with provoking deliberation. I again left her at 6 P.M. for an hour, and on returning found some progress made, but the case lingered until 10:15 P.M., when she was delivered of a very small male fœtus. Sexual apparatus very rudimentary. It made occasional respiratory efforts for five or ten minutes, when they ceased. The after-birth was delivered partly by the Créde and partly by the old method, after a delay of twenty-five or thirty minutes. Following its expulsion was much blood, in large clots, which were red and fresh-looking, as having just escaped from the vessels, with a good deal of darker colored fluid blood. There was probably altogether between two and three pints of blood, possibly somewhat more. She was much exhausted during the later hours of labor, but was sustained with wine and the ergot mixture before spoken of. After delivery the uterus showed signs of relaxation, and fearing any additional loss of blood, ice was applied to hypogastrium, with the effect of causing speedy firm contraction. After a few intermittent applications of ice and doses of the ergot mixture and wine, she remained comfortable.

The placenta presented extravasations of dark blood, effused through its meshes, over a large part of its uterine surface, and in some of the sulci, imbedded in the tissue, were seen larger quantities, as though walled within a sinus, through the coats of which it had percolated into the surrounding tissues. The placental tissue was soft and easily broken down, but, except for these extravasations, appeared healthy. The extravasated blood appeared nowhere to pass beyond the thin border surrounding the placenta, none appearing in the layers of the membranes.

The gravity of the symptoms in this case appeared greatly to exceed what might have been supposed to result from the apparent quantity of blood found extravasated within the placental meshes, which was of a decidedly dark color, showing that it was not of recent origin, and was doubtless the result of the first hæmorrhage. The clots of blood passed at the expulsion of the placenta appeared altogether too bright in color to have been cast out of the vessels long anterior to the closing period of labor, and could hardly have contributed to the first serious onset of the trouble seven weeks before. How much of the fluid blood passed at the time of delivery, and which seemed darker, might have been pent up and now first appeared externally, cannot be told, but no place was found upon the surface of the placenta showing marks of long separation from the uterus, and all the abnormal appearance of dark blood about the placenta was that found spread through its tissue and in one or two of the sulci. If the amount of blood lost from the vascular apparatus, and forming the concealed hæmorrhage, was not sufficient to cause the profound symptoms noted as existing in this case, what was the cause? Was it the nervous element of shock? If so, why was it delayed so long after the fright she received, which occurred on the day before my first visit?

Authors tell us that in concealed uterine hæmorrhage the uterus is more *tense;* but here, during the greatest gravity of the symptoms, no uterine body could be felt by most careful palpation, leading at first to the strong suspicion of extra-uterine pregnancy. Nor did the uterus contract so as to be clearly mapped out by the hand, until she had been under the continued influence of ergot and opium, with abundance of alcoholic stimulation, for two days.

This form of hæmorrhage, according to Playfair, is diagnosticated from ordinary syncope by the severity and persistence of the symptoms. Uterine pain, he says, is generally present, of a tearing or stretching character, but true labor pains may be entirely absent. Goodell estimates the mortality in this class of cases at fifty-four in the 106 cases noted. Galabin reports them as extremely rare, only one case of concealed hæmorrhage having occurred in thirty-one cases of puerperal hæmorrhage in the wards of Guy's Hospital. Cazeaux speaks of a class of cases in which the blood is effused into the placental tissues as placental apoplexy, but passes them as cases in which the woman's life is never compromised, but in which the death and premature expulsion of the fœtus is apt to occur. Here, for forty-eight hours, and to a less extent during the interval and including the third day, the woman's life hung as by a thread, requiring the most powerful stimulation, local application of cold, tight abdominal bandaging, and the free use of ergot and opium to save her life, while the fœtus, greatly enfeebled, showed no signs of life until the sixth week from the onset, and at the seventh was born alive, dying within a few minutes because too immature to sustain life.

A CASE OF PYELITIS OF NINETEEN YEARS' DURATION CAUSED BY A RENAL CALCULUS. RECOVERY.

Read before the Chicago Medical Society, January 3, 1887.

BY AUGUSTUS V. PARK, M.D.,

OF CHICAGO.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, CHICAGO MEDICO-LEGAL SOCIETY, CHICAGO MEDICAL SOCIETY, ETC.

The case I have to present to the Society is that of William P., aged 30 years; of slight physique, medium height; temperament exceedingly nervous,

disposition retiring. I saw patient first on May 12, 1885; I found him in great agony—indeed his suffering was excruciating in the extreme. I found the temperature 101 F., pulse 120, respiration 20; complained of severe and distressing pain in the region of the left kidney, a dull aching pain in the lumbar region; sometimes the pain would be sharp and stabbing and radiating about in different directions; there was marked gastric irritability, flatulency and indigestion, febrile disturbance nil, obstinate constipation, and copious sweats would accompany the violent paroxysms of pain. Frequently the attacks would be of short duration, again they would come on instantaneously and the suffering would be intense for two days, and these sieges would be so exhausting to the system that it would require several days to regain his accustomed strength and health, which at best, was habitually deranged. I at this time secured the following interesting history of the case.

The patient said the first attack of this kind occured when he was but 11 years old, and it was during a convalescence from scarlet fever. The paroxysms of pain would occasionally be of short duration; usually, however, the suffering would be so great that he would be compelled to keep his bed for a day, or two, then there would be a remission of the paroxysms for a week, and occasionally for a month or two, but the slightest exposure to cold in any way would precipitate an attack. One of the longest sieges, and one which was not entirely unworthy the solicitude of the thoughtful, earnest, skilful physician, was caused by a day's fishing in the rain out at the government pier. His occupation was that of an engineer, and at times when his work was unusually laborious or fatiguing and he exposed himself while covered with perspiration, his old trouble would inevitably follow.

He had received treatment from several of our most successful physicians, and for the past twelve years, the family physician, who during these twelve years had called in a number of our best consulting physicians and surgeons. Microscopic examinations and urinalysis were made time and time again, medicines were given months at a time, and dozens of bottles of proprietary medicines taken without securing the benefit wished, or accomplishing the desired result. During the prolonged attacks, anodynes, hot packs, poultices, and hypodermic medication gave him the most relief, but not infrequently in spite of all medication and the combined skill and associated efforts of the attending physicians, the paroxysms would continue unabated from twenty-four to forty-eight hours. He had become so accustomed to the use of narcotics that it required the administration of almost phenomenal doses to narcotize or produce the constitutional or physiological effect of opium; his long and continued experience with the drug enabled him to say how large the dose and how frequently administered, and the manner it should be exhibited to secure perceptible and satisfactory results.

In all these years of suffering, he had not passed any calculi with his urine. I will modify this by saying, to the best of his knowledge, for he had been instructed by his physician what to look for, and the entire amount of his urine had been saved and examined day after day for weeks at a time and during his prolonged attacks but always with negative results.

After securing the above history, I gave morphia ½ grain hypodermically, pill opii, 1 grain each every two hours if necessary. At this time I made a very careful examination, following the method advised by the late Professor Gross:[1] The concretion, even if comparatively small, as when it does not exceed the volume of a pigeon's egg or an almond may sometimes be readily detected, especially in lean subjects, after thorough evacuation of the bowels, by firmly grasping the lumbar region, immediately below the last rib, with the fingers of one hand resting upon the anterior border of the erector muscle of the spine and making counter-pressure with the thumb, while the fingers of the other hand are passed up and down over the intermediate surface in front. In this way it is very difficult for any hard substance, irregularity of surface or distension from fluid to escape discovery. The patient during the examination, should lie on his back with the limbs well flexed to relax the abdominal muscles; chloroform being given if there is much pain or nervous agitation. The above plan of examining for the stone did not in this case reveal the slightest abnormality and there was but little pain experienced when quite firm pressure was applied over the kidney. I secured all the water he had passed during the previous twelve hours and subjected the same to an analysis, which I will here append. (Urine was of deep red color.) Specific gravity 1.028, of slight acid reaction, blood and albumen was found in small quantities, and a large amount of phosphates and pus a trace. A thorough and careful examination was made and an abundance of mucus corpuscles was found; some pus, but this was slight, however, there was a large quantity of small celled epithelium, (round cells to a large extent), these evidently came from the pelvis of the kidney; no tube casts could be discovered. I therefore hoped that the irritation had not extended into the secretory structure of the kidney proper, but was confined to the pelvis of this organ.

With the knowledge gained by the analysis and the microscope came the pertinent question, What shall I do for my patient? All of the best surgical authorities agree that renal calculi are generally composed of uric acid or oxalate of lime, most commonly the former; they also agree that when the concretion is an oxalate it is usually solitary.

Dr. Harlan N. Orton reported[2] a case of uric acid calculus which appeared to have been dissolved in the pelvis of the kidney by alkaline remedies. I had but little hope to accomplish disintegration of the calculus in this case, for he had taken alkaline remedies for precisely this purpose for months at a time.

Professor W. T. Belfield advises[3] the injection of large quantities of alkaline water. I quote from his admirable paper "Water under the Microscope."

[1] Gross' Surgery, vol. 2, pp. 709–10.
[2] Chicago Medical Journal and Examiner, Oct., 1884.
[3] Water under the Microscope.

In pyelitis, from whatever cause, the injection of such water is an absolute essential in treatment, for there is a tendency to the accumulation of catarrhal products in the pelvis of the kidney, sometimes even causing such obstruction to the escape of the urine as to induce hydronephrosis. Another tendency to be prevented is that toward the precipitation of urinary constitutents upon the inflamed mucous membrane as well as upon the clumps of pus retained in the pelvis. Both of these objects of treatment—the removal of the products of the inflammation and the prevention of the precipitation of salts in the pelvis—are attained by the administration of an abundance of pure water and in no other way. By securing these results we also secure the so-called "soothing" effect of the water, which is really soothing only in a negative sense; the positive benefit consists in the removal of the irritating products. In pyelitis caused by the presence of renal calculi—a frequent form—a pure alkaline water affords the only hope of a radical cure by medical means. Calculi have been disintegrated and even dissolved by the copious ingestion of simple rain water, and the same effects can be achieved in less time by the use of a water which, while not loaded with mineral constituents, contains nevertheless, a sufficient quantity of the proper ingredients to give it an alkaline reaction, for renal calculi are usually composed of uric acid and urates, whose solution is favored by alkalies.

Agnew advises[4] opiates hypodermically or by the bowel, either as enemas or as suppositories in combination with the extract of belladonna and when the paroxysms of pain are exceedingly severe, great relief may be obtained from inhalations of ether. In order that the concretion may be hurried through the ureter more rapidly than would be effected by the peristalsis of the muscular walls, it has been advised to administer largely diuretic remedies in order to excite a free secretion of urine which presses against the obstruction from behind. He says further, that it is quite proper to administer alkaline drinks as solutions of citrate or bicarbonate of potash, but their administration should only be to the extent of moderately stimulating the action of the kidneys, so that the *vis a tergo* should be exerted within the limit of safety; kneading has also been practised; an experiment, to say the least, of doubtful propriety. A fixed position of the body and limbs, by removing the tension of the ureter is favorable to the progress of the stone.

May 13, 5 P.M., twenty-four hours since commencement of attack, I was called to administer morphia hypodermically. I found the patient very weak and his temperature 100 F., pulse 120, respiration 20; his suffering was very great, and he would frequently exclaim: "Oh, father, I wish I could die! I wish my suffering would end; how many more long years must I suffer?"

I had now mapped out a line of treatment and was determined to follow it up thoroughly and faithfully; if I failed I would always have the pleasant satisfaction of knowing I did my best and that too in the light of our present knowledge. All previous attempts to give permanent relief had proven singularly unsuccessful, and show to some extent the utter insufficiency of all human effort, no matter how earnestly or arduously the attending physician applied himself to the inexplicable difficulties; in this case, at best, his efforts were only palliative. I directed patient to drink Waukesha water in as large quantities as he wished and as often as he could, this would quench the thirst, which was constant, acquainting him with the object in view and the diuretic influence of the water. I then wrote for the following:

℞. Tincture digitalis..... ℥ss.
Fluid extract hydrangea..... ʒij.
Elixir calisaya q. s. ad..... ℥iv.
One teaspoonful every five hours.

This was given for its direct effect upon the kidneys and would be soothing to the mucous membrane; advised a milk diet and one-half drachm of Carlsbad sprudel salt in a glass of water before each breakfast to correct constipation.

In order to facilitate the washing-out process to the greatest possible degree, it occurred to me that I should relax the system as much as possible; anodynes were pushed to the fullest extent; hypodermic injections of morphia and atropia given every two hours; large and hot poultices were applied and made to encircle the body about the loins and frequently changed. This treatment, together with the ingestion of large quantities of water, was continued the entire night; the patient directed to lie upon the right side as much as possible with the limbs flexed. At 7 o'clock the following morning, forty-eight hours from onset of attack, the father came to my office with message from patient, "Tell the doctor that I am free from all pain but so weak that I cannot pass my water." I advised the father to have his son make patient trials, and if he failed I would relieve him immediately.

8 A.M.—Temperature 100 F., respiration 18, pulse 90, free from all pain, had passed a large quantity of urine of a dark red color, and with it a calculus which is oval in shape, with numerous little nodules, or hard beadlike elevations which are composed of uric acid. The weight of the calculus was 14 grains. An analysis was made and the calculus found to be composed principally of the oxalate of lime with a small admixture of phosphates; this was but a trace.

My patient, while trying to express his gratitude for services rendered him, made this remark: "I felt a gurgling sensation in my left kidney and in the region of the greatest pain, and with this sensation all my pain ceased and (like Dr. Orton's patient said) he could distinctly feel the stone when it dropped into the bladder."

Patient continued with the Carlsbad sprudel salt before each breakfast, also with the digitalis, hydrangea and calisaya four times a day before the meals; a milk diet and as much of the Arcadian mineral water as he wished; his urine soon commenced to clear up and all kidney troubles ceased. He has had no recurrence since last attack and is now quite robust and strong, at the present time, seventeen months since last attack.

RECTAL SURGERY MADE SAFE FOR FOOLS.

BY EDMUND ANDREWS, M.D., LL.D.,

PROFESSOR OF CLINICAL SURGERY IN THE CHICAGO MEDICAL COLLEGE.

A few years ago I learned and published the secret method of treating piles employed by certain itinerants. The secret was sold from one quack to another at a high price, and consists generally in the hypodermic injection of various mixtures of carbolic acid. The hopes of many physicians that the method might prove a useful one, were greatly dampened by the discovery of about eighteen deaths out of some 3000 reported cases, and of very alarming symptoms in other instances; in short, it was the same fatal experience as that which previously put a stop to the injection of venous enlargements in other parts of the body.

Of late the Lake States are being treated to a new development; the little itinerant hypodermic syringe has budded and blossomed like Aaron's rod, and evolved little boxes of instruments and little books full of secret instructions, in short, little "systems" of rectal surgery, whereby, as one of the authors says, "*operations which would otherwise be difficult can be accomplished with but little skill.*" The first style of boxes sells at a price varying from a hundred to a hundred and fifty dollars, according to the size of the purchaser's purse and credulity. They generally contain a hypodermic syringe and a rectal speculum, with a probe and a few other simple instruments, having some peculiarities of construction but no special excellence. An equally good set of instruments for the purpose would cost about fourteen dollars at retail, in the ordinary instrument stores.

It is curious to notice the obvious effort to combine a set of instruments in such a way that an ignorant purchaser may accomplish something with them but shall not be able to do much harm. Generally there are no cutting instruments whatever, and the only sharp weapons are the hypodermic syringe and the tenaculum. The chief formula for injection for hæmorrhoids is the following:

℞ Acid carbol..... ℥ j
Ol. olivæ.....fl. ℥ v
Zinci chlorid..... gr. i ℳ

Armed with his little box and book the wayfaring doctor, though a fool, may read and practice, and perchance make money, if the crop of piles is good, although the science of the colleges never glanced upon his calvarium.

Such an easy way to make money soon bred imitations. New boxes and new little books are in the market. Some contain several more instruments than those above mentioned, and yet are sold at half the price, being offered at about fifty dollars. There is, however, the same careful attention to the fact that the purchaser is expected to be such a fool that he cannot be trusted with edge tools, though some of the later boxes contain the little blunt-pointed bistoury of Sims' uterine set, with an edge about half an inch long, for a purpose presently to be mentioned. One set which I examined contained the following instruments:

1. A small rectal speculum.
2. A hypodermic syringe.
3. A tenaculum.
4. A small Sims' uterine knife, blunt pointed, and having an edge five-eighths of an inch long.
5. A Sims' flexible uterine probe, for examining *fistulæ*.
6. A blunt hook to pull down the "pockets" presently to be described.
7. A similar blunt hook with two minute barbs to hold the pocket when it is so shallow as to slip from the smooth hook.
8. A scarifying probe, made so as to scratch the interior walls of a fistula to the depth of about a sixteenth of an inch. By a blundering combination of Greek and Latin in the same word, forbidden by the usages of educated men, it is called a "fistulatome."
9. A flat scoop for clearing out the rectal pockets and pouches.
10. A ligature carrier, to facilitate ligating piles.
11. A three ounce syringe.
12. A hard rubber tube for oiling the anus.

There are no scissors, probably because they could be dangerously used by ignorant purchasers.

The following were some of the printed directions in the box:

"RADICAL CURE OF FISTULA IN ANO.—First trace fistula with flexible probe. Wash out the track with a 5 per cent. solution of 'hydrogen peroxide.' Then inject a 95 per cent. sol. of carbolic acid, plus equal quan. of a 10 per cent. sol. of muriate of cocaine. Draw about 10 to 15 minims in the syringe. Push the flexible needle to the depth of fistula, then inject slowly as you withdraw the needle. Within two hours inject oleum eucalyptus and glycerine, equal parts, and the operation is finished. Keep patient quiet for forty-eight hours."

"HÆMORRHOIDS.—Hæmorrhoidal tumors should be injected with an eight grain sol. of muriate of cocaine, plus an equal volume of 'phenol sodique;' use of the injection from twenty minims to a drachm, according to size of tumor. It is seldom necessary to inject more than once or twice. This injection deposited in two and three drops, making the punctures one inch apart over the rectum, will seldom fail to cure prolapsus of the rectum. Should be repeated two or three times.

"During the treatment of hæmorrhoids or prolapsus, patient should take each night at bed-time a one-eighth grain pill of the solid extract leptandrin, and the parts should be kept anointed with 'ceratum taralinum,' once a day for a week after the operation. After operation on the rectum of a female, the uterus should be dilated, and after like operation on the male rectum, metallic sounds should be passed as large as the urethra will admit; and in all cases where there are *fissures of the anus*, the sphinctors should be forcibly dilated for ten seconds, while patient is under the influence of an anæsthetic.

"With our improved instruments designed expressly for treating the rectum, operations that would otherwise be difficult can be accomplished with but little skill. Our speculum is the only one that is self-retaining, thereby enabling the operator to use both hands, at the same time exposing every part of the

rectum, and not causing the patient great pain by over-distension of the sphinctors."

The "*Phenol Sodique*" is a French name for an article made and sold in Philadelphia. It is simply a solution of impure carbolic acid. The term "*Ceratum Taralinum*" is an ignorant man's effort to construct a Latin name without knowing the language. The article to which it is applied is a blackish, untidy looking *unguentum picis liquidæ*, or tar ointment, but probably not made according to the officinal directions. Druggists inform me that it is sold as a proprietary article under the name "taroid."

A recent addition to these "systems of rectal surgery" consists in exploring the anus for the little pockets in the mucous membrane which exist normally just above the external sphinctor, pulling them down with the blunt hook, and splitting them down with the Sims' knife. Another addition consists in cutting off the little projections, or caruncles, which are often found at the same part, under the preposterous claim that they are very injurious to the patient. The operators call these organs "pockets and fringes."

The possibilities of deception in this field are unlimited, since the patient can neither see the "pockets and fringes" for himself, nor dispute their alleged pestiferous influence. This practice originated in a paper read before a Society of irregulars, entitled "Rectal Pockets and Fringes." That the paper may be properly estimated I will recall to memory here the structure of the lower rectum, as described by authors, both in anatomy and surgery: Morgagni described, what any dissector can see, a reticulated columnar structure of the mucous membrane just above the external sphinctor. These ridges, or "columns of Morgagni," resemble the *columnæ carneæ* of the inner walls of the heart, but are very much smaller. Occasionally a probe will pass behind one of the columns, as under a bridge, but generally they are merely adherent pilasters, or ridges, running longitudinally but somewhat branched. They are described not only by Morgagni, but by "Curling on the Rectum," "Allen's Human Anatomy," "Kelsey on the Rectum," etc. Kelsey says, p. 10: "Between the lower ends of the *columnæ recti* (columns of Morgagni) little arches are stretched, forming pouches. They are more developed in old people, and may retain small pieces of fæces, and give rise to suppuration and abscess."

Curling says, p. 6, that between the lower ends of these *columnæ recti* "the mucous membrane is slightly dilated, variously in different subjects, but in many to such an extent as to form small sacs, or pouches; and in the spaces between them there is a series of short projecting columnar processes about three-eighths of an inch in length."

The latter are analogous to the *carunculæ myrtiformes* of the vagina. The writer of the paper seized on these "pockets and fringes," as he called the pouches and caruncles, and declared that "our current literature contains little or no mention of them." In spite of the fact that they are natural organs, and therefore must have a use, he asserts that "they are more prolific of mischief than you would believe," and that "nowhere, so far as" he is "aware, are they well described or properly noticed," hence he advocates their destruction. The author of this paper, boldly claiming old and well known anatomical facts as almost a new discovery of his own, excited a good deal of controversy among the members of the Society, some supporting his claims and practice, and some roundly denouncing them.

The truth is that these structures are natural, and should be let alone in ordinary cases, but, like other organs, they occasionally become diseased, and require surgical interference. The itinerants, however, have added the "pockets and fringes" to their stock in trade, and believe that whenever they are found the pockets must be split down, and the caruncles, or "fringes," cut off. For this purpose the blunt hooks and the Sims' bistoury have been added to the wonderful little box, which enables them to "accomplish operations with but little skill."

The plan of treating fistulæ by injections of peroxide of hydrogen, followed by other antiseptics, is in principle the same as the iodine method formerly in vogue, which fell into disuse because of its uncertainty. There are no statistics to show whether this modification will do any better, but there can be no harm in trying it. It will probably be found, like the iodine plan, to fail in a large proportion of cases, but yet may sometimes be useful. It is obviously adopted for the itinerants, because their average ignorance is such that it would never do to trust them with the the operation by incision. I shall be glad to receive letters from any physicians who have opportunity to know of the actual results.

No. 6 Sixteenth Street, Chicago.

RECURRENT HÆMORRHAGE INTO THE ANTERIOR CHAMBER.

Read before the Chicago Society of Ophthalmology and Otology, December 14, 1886.

BY BOERNE BETTMANN, M.D.,
OF CHICAGO, ILL.

Cases of concussion of the eyeball with subsequent hæmorrhage into the anterior chamber are not uncommon. Such occurrences are frequently noted in our journals, and are alluded to in text books as uninteresting matters of fact. The case I wish to bring to the Society's notice differs so much from the ordinary ones that its presentation need not be prefaced with an excuse.

On May 19, 1886, Mr. and Mrs. W. hurriedly entered my office with their little daughter Ettie, aged 4. They informed me that the child, whilst playing "Indians" with her comrades, was struck in the left eye by a projectile propelled from a toy gun in the hands of a boy. The projectile was a piece of a twig of a tree, its end was apparently smooth, to judge by the appearance of the contused lid. The stick could not be found. The propelling force was a broad band of rubber kept tense by a wooden trigger. The gun was within a few feet of the eye when the accident occurred, three-quarters of an hour before I saw the patient.

On examination I found the following condition: The upper right lid was œdematous and reddened. On lifting it the eye was found bathed in tears and the conjunctiva slightly injected. Cornea normal. The whole anterior chamber was filled with blood. In the lower part it formed a large clot, concealing the iris from view. The pupil was dilated and elongated in the vertical diameter. An ophthalmoscopic examination could not be made. The child was unable to count fingers close to the eye. I ordered cold compresses and instillation of 2 drops every four hours of a 1 per cent. solution of atropine. When I again saw the child, about three hours later, the pupil was dilated *ad maximum*, and the greater part of the hæmmorrhage was absorbed. Fingers were readily counted.

On the morning of May 20 but a small clot of blood remained in the lower part of the anterior chamber.

At the next visit, May 21, I learned from the mother that the patient had passed a very restless night, occasioned by spells of sudden intense pain. The first attack occurred in the evening. During a momentary absence of the parent, the child left its bed and ran to the window, which it opened. Hearing the mother return it hastily essayed to regain its bed, but stumbled and fell heavily to the floor. The fall was followed by severe pain in the injured eye. A second attack took place at midnight, and a third early in the morning.

I found the eye in a glaucomatous state. Tension + 1, very marked ciliary injection, anterior chamber full of blood. The eye was rebandaged, and cold applications applied over the roller. A 1 per cent. solution of eserine was prescribed, two drops to be instilled into the eye five times a day.

The child was kept quietly in bed. In the evening I found a great improvement. Tension reduced, but still higher than normal. Hæmorrhage mostly absorbed.

At midnight the child was again awakened by the excruciating pain in the left eye.

The morning showed a return of yesterday's condition; extensive hæmorrhage and increased tension. These sudden attacks of severe pain came on without any apparent restlessness on the part of the patient. Whilst in the midst of a sound sleep it would be suddenly awakened by the darting pains.

I hesitated to reinstil the eserine, thinking that the action of the drug favored a separation of the partly healed iris, which I supposed had been lacerated at the lower border, covered by the blood clot. The child had been kept quiet in bed. Both eyes were bandaged for a time; the right one constantly. Coffee and other stimulants were forbidden. In fact, everything had been done to favor a rapid union of the parts. I decided to try the effects of ergot, and ordered the fluid extract to be given in 12-drop doses every three hours, in order to reduce the action of the heart and permit a sufficiently firm organization of the blood clots in the lacerated blood vessels. The introduction of this remedy was soon followed by good effects. The blood disappeared entirely, the pupil remained for a long time elongated, but later on resumed its normal shape.

FRACTURE OF CRANIUM; HERNIA CEREBRI; RECOVERY.

BY WILLIAM HENRY, M.D.,
OF HARMON, ILL.

In June, 1886, my little daughter, aged 8 years, while trying to drive a horse running at large, was kicked on the side of the head, the skull being fractured over the posterior superior portion of the right parietal bone, crushing the bone and driving it in, producing compression of the brain.

I was absent from home at the time, and my friend Dr. Burns was called in; his opinion was that she would not live twelve hours. I was immediately telegraphed for, and on arriving at home in a few hours I found the child in a comatose condition, her pulse regular and about 110. I sent for Dr. Burns, and we soon went to work to remove the compressed bone, but after the removal of seven pieces of bone the comatose condition was not entirely relieved. She remained in a semi-comatose condition for five days.

We found the membranes ruptured in the anterior portion of the fracture, and portions of cerebrum oozing therefrom; in all about half an ounce was lost. The edges of the wound were united with stitches, the antiseptic used being a dilute solution of carbolic acid. In a short time the wound began to suppurate, and then became very much swollen. In the meantime I had returned to my place of business, leaving the patient in charge of Dr. Burns, who sent for me again when this last complication arose. I thought it would be best to open the wound in the lowest portion and let out the pus. On his doing so a considerable amount of pus escaped.

I again returned to my place of business, and in a short time Dr. Burns thought that the swollen condition was increasing, and cut the stitches. This caused the wound to gape open, and there soon appeared a hernia cerebri, about as large as a hen's-egg. Seeing this condition Dr. Burns called in Dr. Helm, of Rockford, and Drs. Donaldson and Herb; but they hesitated to advise active interference during my absence. On my return, in a few days, I found the hernia cerebri still increasing, and after a consultation with Drs. Burns and Donaldson I determined to ligate the tumor at its base. I accordingly tied it with silk ligature, drawing the ligature until the pulsation was almost diminished; and in a few days I again tied it, drawing the ligature until all pulsation ceased. It then began to heal under the ligature as the strangulated portion began to die and dry up; and in about fifteen days the tumor fell off, leaving the wound closed and nicely healed.

Harmon, Ill., Nov. 15, 1886.

MEDICAL PROGRESS.

PEPTONE.—DR. LABASTIDE, in the *Gazette des Hôpitaux*, publishes notes of cases showing the good effects of peptone. The first was that of a widow

over 80 years of age, of robust constitution and sanguine temperament; she had hemiplegia on the right side, and partial aphasia following a cerebral effusion which dated more than thirty years back; all the functions were normal. In the spring of 1884, she had another cerebral attack, but the symptoms disappeared under the influence of internal and external derivatives. In 1885 she had a third attack, which lasted longer than the preceding one; paralysis became more pronounced, aphasia more complete, and deglutition more painful, without any local change in the throat. The patient refused all nourishment. When obliged to take food, either solid or liquid, she immediately vomited it. Pure water, sweetened or aërated, was immediately rejected. At the end of six months the patient was extremely feeble. Dr. Labastide then decided to administer peptone. Injections of 20 grammes of "peptone Dufresne," mixed with 60 grammes of boiled milk, were given, both being occasionally substituted for milk. After twenty days of this regimen the patient had rallied from her state of prostration; her stomach retained water, and even milk, when taken in small doses at long intervals. Twenty grammes of peptone, mixed with a little tapioca, were then ordered three times a day. After fifty days of this treatment, the patient, though still paralyzed, had recovered her former condition, and had even begun to grow stout. At the end of March, however, she succumbed to a fresh cerebral attack. The second case was that of an infant 9 months old, of an extremely feeble constitution. At the cutting of the first tooth symptoms of inflammation of the intestines appeared, together with wasting. Aphthæ of the mouth prevented the child from taking the breast. Dr. Labastide then had recourse to injections of peptone, 10 grammes of which were given with 20 grammes of milk, a drop or two of laudanum being occasionally added. The little patient was nourished in this way for two months, and gradually gained strength. At the end of that time it could take peptone mixed with weak milk, taken from its mother, or tapioca. After five months' treatment all trace of cachexia had disappeared. The third case was that of a child 9 years old, of nervo-lymphatic temperament, and fairly good constitution. It had every symptom of anæmia, pallor, palpitations, headache, enlarged glands in the neck and elsewhere, and exostoses on both tibiæ. No treatment had been of any benefit. Peptone was then administered in doses of one, and, subsequently, two tablespoonfuls. In a few days the tumors on the legs began to disappear, the swelling of the glands diminished, the appetite returned, the little patient recovered his strength and color, and the limbs could be moved without effort. The child no longer suffers from headache or palpitations, and is now completely cured.—*British Medical Journal*, Jan. 1, 1887.

The Treatment of Telangiectasis.—Following the recommendation of an Italian physician, Dr. Böing has treated angiomata with applications of a four per cent. solution of mercurial bichloride in collodium, with remarkably favorable results. The solution is painted over the growth and slightly beyond its margins, in a number of coats, time being given for the evaporation of the ether as shown by the formation of a whitish follicle, before a new coat is applied; the applications are made once a day for four days. He found that the preliminary application of simple collodium to the surrounding sound skin will make the subsequent application of the corrosive solution almost painless, and regards this as a marked improvement on the Italian method. The application having been made, none or slight local inflammatory reaction sets in, a scab forms, this is thrown off in a week, and the remaining ulcer, treated with some simple dressing, heals in one or two weeks, leaving a firm, smooth, white cicatrix, level with the surface, with no tendency to contract and without a trace of the dilated vessels.

He reports five cases in which he made use of this treatment:

1. Boy, æt 7 months, angioma on internal margin of left scapula, 15 mm. by 11 mm., slightly raised; but two applications were necessary.

2. Boy, æt. 9 months, angioma on third dorsal vertebra, 24 mm. by 15 mm., raised 3 mm. above the surface; three applications were made; when the scab came off three-fourths of the growth was found destroyed, but during the process of repair it regained its former size. New applications were made, when the ulcer had healed, and now with complete success.

3. Girl, æt. 2 months, angioma size of 20 pfennig piece in centre of forehead, which had developed rapidly from pin-head to present size; two applications were required.

4. Girl, æt. 6 months, angioma on right labium majus size of 20 pfennig piece; after the first application erysipelatous inflammation of the lesser labium and of the integument of the right groin set in. After the inflammation had subsided, the surrounding skin was thoroughly painted with simple collodium and adhesive strips were laid over the inguinal region. Two applications were made; when the scab dropped off a small dilated vessel was discovered near one margin of the ulcer, and was cauterized with a red-hot knitting needle. The ulcer was dressed with bismuth, and was completely healed in three weeks. In this case there was considerable pain, which was greatly increased by the urine flowing over the sore. The author questions if extirpation with the knife would not be better practice in a similar case.

5. Girl, æt. 3 months, angioma on left parietal bone, size of a mark, of rapid growth; two applications were necessary.

The contraction of the scar being almost nil, Böing believes that this method should be employed in angiomata of the face, but questions if the results will be as brilliant in the large sized angiomata that occur in this region.

The solution is made by dissolving hydrarg. bichlor. 0.4 gms. in collodium 10.0 gms. (grs. vj to ℥ ijss). Sulphuric ether must be kept at hand to wash and preserve the brush.—*Memorabilien*, Hft. 2, 1886.

Muscular Percussion Reflex as a Method of Clinical Investigation.—When the chest wall is

subjected to a tolerably smart blow with the finger or percussion hammer, an elliptical elevation of the surface may frequently be observed for a few moments after the blow. This fact, which has been remarked by Mr. Lawson Tait, Dr. James Ross, of Manchester, and others, has acquired some importance from the somewhat analogous observations of Westphal, Erb, and others on the tendon, osteal, periosteal, and muscular percussion reactions. Quite recently, too, a Russian author, (Dr. V. V. Philipovich, of Odessa), has investigated the conditions under which the phenomenon is produced, showing that it may be made available like other reflexes for diagnostic and clinical purposes. In his observations he made use of a percussion hammer furnished with a spring and index, by means of which the force of each blow was registered. The pectoral regions of 100 presumably healthy young men were examined. The lowest force required to produce the phenomenon —which, by the way, Dr. Philipovich proposes to style "loco-tetanus," instead of "muscular contraction," the term used by Dr. Ross—was 400 grammes, and the highest 2000 grammes. On analyzing the observations, it was evident that the lower degrees of force were invariably sufficient in weakly and ill-formed subjects who had been either permanently or temporarily rejected by the recruiting authorities. Still lower figures were obtained on the examination of diseased persons, the lowest of all being afforded by phthisical patients. In all chest cases it was noticed that the "loco-tetanus" was more easily produced on the side where the disease was situated, or on that where it was the more extensive; thus in a case of dry pleurisy of the right side the figures obtained were—for the sound side, 550 grammes, and for the diseased side 150 grammes. The mean force required in the 100 healthy subjects was 750 grammes on the right side, and 850 grammes on the left; and as the limit of that which could usually be borne painlessly by healthy persons with the instrument used, (the head of which was a metal ball covered with gutta-percha), was about 700 grammes, it may be roughly assumed that if the contraction can be produced by a tap, the force of which is much below that which is sufficient to cause pain in a healthy subject, some pathological condition is probably present, or at least that the general state is below that of a vigorous man.—*Lancet*, Nov. 20, 1886.

DEATH AFTER WASHING OUT THE STOMACH.—At the meeting of the Cambridge Medical Society, on Nov. 5, MR. MARTIN brought forward the case of a patient who was admitted into Addenbrooke's Hospital, under Dr. Bradbury, for stricture of the pylorus. He was 48 years old, and seven years previously had been an in-patient, with symptoms of pyloric ulcer. His stomach was now much dilated, and he suffered from flatulence, vomiting, pain, and increasing weakness. He vomited large quantities of frothy fluid, containing sarcinæ. Ten days after admission, it was decided to wash out the stomach. Soon after passing the tube into the stomach the patient became very faint, so it was withdrawn. About two hours afterwards, he complained of stiffness in the jaws, with inability to open the mouth, and rigidity of the arms, which were strongly pronated and flexed, the thumbs being turned into the palms. He was conscious, and sweating profusely. The rigidity spread to all the muscles of the limbs and trunk, and the temperature rose to 103.4°. He became pulseless and livid, the temperature rising to 107.2° before death, which occurred six and a half hours after washing out the stomach. *Post mortem* examination showed a simple stricture of the pylorus with the scar of an old ulcer, and a much dilated stomach. There was no injury or abrasion of the mucous membrane. The other organs were healthy, and no lesion of the brain was discovered. Mr. Martin said the fatal symptoms very closely resembled tetanus, although no wound of any kind could be found to induce it. The symptoms were not characteristic of strychnine poisoning, and the patient had no opportunity of obtaining any.—*British Medical Journal*, Dec. 11, 1886.

TREATMENT OF WOUNDS OF THE BLADDER.—DR. JOHN HOMANS, Surgeon to the Massachusetts General Hospital, Boston, Mass., writes: "As bearing on the subject of the suprapubic operation for stone, which is being revived at this time, I may say that I have twice cut open the bladder during an ovariotomy. The first time was in my seventy-second case (one of dermoid tumor). The incision in the bladder was carefully sewed up with a continuous suture of silk, care being taken not to include the mucous membrane in the stitch. The bladder was closed tight, and a Sims catheter was kept in the urethra. The catheter was removed on the tenth day. The temperature was never above 99°, and there have never been any vesical symptoms at that time nor since. The second time was in my two hundred and tenth case—one of double papillomatous ovaries, the patient having been tapped eighteen times in five years for the removal of ascitic fluid. The wound of the bladder was more extensive than in the first case, and required twelve interrupted sutures of silk, in which the peritoneal and muscular coats alone were included. A catheter was kept in the bladder seven days. After that time the urine passed naturally. In neither of these cases was the bladder drained through the abdominal wound. If the catheter in the urethra will drain the bladder, it would seem unnecessary to have another exit in the roof of the bladder. It would be well, however, to leave a drainage tube in the integuments over the sewn-up bladder in case there should be any leakage." *Medical Record*, Jan. 15, 1887.

AN APPLICATION FOR PAINFUL DENTAL CARIES.—A contributor to the *Union Médicale* gives the following formula:

Dry alcohol extract of opium	1 part.
Camphor	1 part.
Peruvian balsam	1 parts.
Mastic	2 parts.
Chloroform	20 parts.

A pellet of cotton soaked in the solution to be introduced into the cavity.—*N. Y. Medical Journal*, Dec. 11, 1886.

SATURDAY, FEBRUARY 5, 1887.

RUPTURE OF THE URINARY BLADDER.

In the *Lancet*, of Dec. 11, 1886, Sir William MacCormac records the recovery of two cases of intra-peritoneal rupture of the bladder—the first positive record, we believe, of recovery from this accident, after operation. In these cases abdominal section was performed very soon after the patients were admitted to St. Thomas's Hospital, and the rent in the bladder exposed and carefully closed by numerous interrupted silk sutures; after which the peritoneal cavity was washed out with warm boracic acid solution, and the external wound closed. As the rarity and almost inevitable fatality of the operation are well known, it may be interesting to examine more closely the records of the two cases, and the remarks of the distinguished surgeon under whose care they recovered, as there is considerable diversity in the treatment recommended in such cases. Catheterism, simply, has been practised, or washing out the peritoneal cavity from the side of the perineum or urethra; median or lateral cystotomy has been done to give direct drainage through the perineum; in some cases aspiration of the abdominal cavity, abdominal section, sponging out the blood and urine, and leaving the rent undisturbed, have been done; and abdominal section, with suture of the rent, either completely or leaving the anterior part unclosed, or making an opening for drainage in the part of the bladder uncovered by peritoneum, has been done.

The first case recorded by Sir William MacCormac is that of a man, aged 33, who ran against a post, which struck him in the region of the umbilicus. He was admitted to the hospital fifteen and a half hours after the accident, having walked a distance of about a mile, unaided. There was complete inability to pass urine; no symptoms of shock; abdomen distended and tender all over, but especially in the epigastric and hypogastric regions, resonant anteriorly with dulness in both flanks, varying with the position of the patient. Ninety-five ounces of a slightly red colored fluid were drawn off, and the bladder was shown to be firmly contracted by its grasping the catheter, which did not move freely. The level of dulness in the flanks was now sensibly diminished, and taking the symptoms into account, intra-peritoneal rupture of the bladder was diagnosticated.

The operation was performed about twenty hours after the receipt of the injury. The bladder was found empty, and firmly contracted. "The rent was in the posterior aspect of the bladder, and extended from the superior fundus to the recto-vesical cul de-sac; it was median and vertical, and as nearly as may be four inches in length. The edges were rather irregular and thickened. So deeply did the rupture extend into the pelvis that great difficulty was afterwards experienced in the introduction of the deeper sutures. To facilitate this the parietal peritoneum was divided transversely on each side, and it was then found possible to draw the bladder much further out. The intestines were pushed back with sponges held by one assistant, while a second pulled the bladder forward. Sixteen sutures of fine silk were then introduced after Lembert's method, including the serous and muscular coats only, at intervals of about a quarter of an inch, beginning at the lower part, and the first and last sutures were introduced quite beyond the limits of the injury. The edges of the mucous membrane were thus thoroughly inverted and the serous surfaces brought into contact. Wherever the closure did not seem absolutely complete and perfect, catgut sutures were introduced to the number of six or eight between the silk ones, including the peritoneum only. The bladder was now twice moderately distended with a weak solution of boric acid injected through the catheter by a Higginson's syringe, and proved perfectly watertight. The peritoneal cavity was finally irrigated with two gallons of a 1 per cent. solution of boric acid dissolved in water previously boiled and cooled down to a temperature of 98° F. The fluid was introduced by means of a tube attached to an irrigating can raised 8 ft. from the floor. It overflowed into a macintosh and thence to a tube placed at the foot of the table, in the manner customary during ovariotomy. The irrigation was continued until the

escaping fluid became absolutely clear. There was no sponging of the peritoneum. A glass drainage-tube was introduced from the centre of the wound to the recto-vesical cul-de-sac. The edges of the peritoneum and external wound were then closed by deep silk sutures, and iodoform, iodoform gauze, and salicylic wool applied, with bandages of carbolic gauze. A soft black catheter was fastened in the urethra, the tip only projecting into the bladder. The operation lasted two hours, and was conducted under the carbolic spray throughout, save for a few minutes when the steam failed. The peritoneum and intestines looked quite healthy, presenting a polished appearance, apparently not injected. No blood-clots were observed." There was no sickness after the operation, and all pain and tenderness disappeared almost completely after it. Within the next five days the temperature did not reach 100° F. From 30 to 40 ounces of urine were passed daily, being drawn every four hours, but containing no blood. On the third day, the catheter was removed, after which he passed urine naturally. The drain was removed on the fourth day, a small amount of serous discharge being sucked out at each dressing. The sutures were removed on the eighth day, and within a fortnight the abdominal wound had cicatrised. In three weeks he was able to get up.

The second case was more obscure at first than the one just mentioned. He came to the hospital immediately after a fall, but no symptoms directing attention to the bladder were observed by a most careful house-surgeon. A catheter was not passed, as there was no desire to urinate, and urine had been passed an hour before. There were no symptoms referable to the bladder until about seven hours after the accident, when he desired to pass urine but was unable to do so. He was re-admitted to the hospital about twenty-four hours after the fall, the symptoms rapidly increasing in severity. Three ounces of dark-colored bloody urine and clots were drawn off; and the symptoms were such that intra-peritoneal rupture of the bladder was diagnosticated, and an immediate operation determined upon.

The operation was performed about twenty-seven hours after the accident. After reaching the peritoneal cavity, and introducing the finger, the rent in the bladder was at once detected. "The bladder was now drawn forwards, a transverse incision of the peritoneum of half an inch being made on each side. An irregular obliquely placed rent in the bladder was then clearly exposed, situated at the upper and posterior part, and slightly to the left of the middle line; it was much more extensive in the outer than in the inner wall, measuring two inches in length where the peritoneal covering and muscular coat were ruptured, and a quarter of an inch where the internal coat was torn. A blunt director passed into the wound came into contact with the catheter previously introduced. The rent in the bladder was closed by twelve fine silk sutures, rather less than a quarter of an inch apart; the ends were cut short. Each suture was passed by means of an ordinary fine curved needle introduced about a quarter of an inch distant from the margin. The first and last pairs of sutures were passed through the bladder wall completely beyond the limits of the rent, so as to prevent the possibility of leakage from its extremities. On drawing the sutures tight, the closure of the rent seemed so complete and secure that no additional ones through the peritoneal coat appeared necessary. The bladder was then fully distended by injecting nine ounces of a warm boracic acid solution through the catheter, and found to be perfectly watertight. The abdominal cavity was thoroughly washed out with about two gallons of a 1 per cent. solution of boracic acid warmed to a temperature of 98°. The irrigator consisted of a large glass vessel raised four feet above the patient's abdomen, with a long India rubber tube and glass nozzle attached. At first the fluid flowed out slightly tinged with blood; subsequently it became quite clear. There were no clots. Before the external wound was closed as much of the residual fluid as possible was expressed. No signs of inflammation could be detected in the peritoneum where it was exposed during the operation. The intestinal coats were free from injection; there was no adhesion or lymph visible. No vessels of importance were divided in the external wound, and all bleeding points were secured as they appeared, catgut ligatures being used. A suture was passed on each side, uniting the transversely divided edges of the peritoneum, and the abdominal wound and peritoneum were then united by eight stout silk sutures passed through the whole thickness of the abdominal wall. No drainage-tube was inserted in the peritoneal cavity, nor was a permanent catheter passed into the bladder, confidence being felt in the effective and complete manner in which the rent in the bladder was closed. A small, short drain was, however, inserted in the lower part of the external wound. Just before the dressings were applied, a fit of vomiting came on. There was severe abdominal strain and a certain quantity of boracic fluid was forced up between the sutures. The patient's pulse kept good, and the respiration was quiet and easy, except for a minute or two while the abdominal

cavity was being washed out. Iodoform was powdered over the abdomen and groins. Iodoform gauze and salicylic wool were applied to the wound and kept in position by carbolic gauze and flannel bandages. The patient was lifted into bed and a pillow placed beneath his knees. A half-grain morphia suppository was introduced into the rectum. Before removal from the table the bladder was ascertained to be empty and the catheter was withdrawn." This patient recovered even more rapidly than the first. The external wound was united throughout a week after the operation; on the twelfth day he was allowed to sit up; and a fortnight after the operation he was regarded as entirely well.

As with all operations on the abdominal cavity, the success of this one depends on matters of detail; and of these the matter of suturing is probably most important. "The accurate and complete suture of the bladder wound by sutures inserted through the whole thickness of the serous and muscular coats, carefully avoiding the mucous coats, is of the greatest importance. The serous surfaces should be inverted, brought into close contact, and the first and last stitches inserted quite beyond the extremities of the wound, so that leakage at either angle, the most common places for it to occur, may be rendered impossible." Znamensky, Maksimow and Vincent have shown that this is of the utmost importance. The double row of sutures recommended by Vincent—one sero-muscular, the other serous—cannot be said to be safe or necessary, as the serous sutures invariably give away. Znemansky, Petersen and Vincent think the interrupted silk suture the best method and material. The continuous suture is undesirable, and possibly dangerous. Carbolized (or disinfected) silk is probably the safest material, and they may be left without risk if the operation be properly performed —aseptically. A rectal tampon may probably render the deep stitches easier of introduction. A free abdominal incision is important, as will be readily seen, for proper inspection, for the introduction of sutures, for necessary manipulations, for the control of the intestines, and for the thorough cleansing of the abdominal cavity. "If the deeper structures be first divided near the pubes, the anterior surface of the bladder can be exposed and examined before opening the peritoneal cavity. If a rent be found there it may be unnecessary to proceed further; otherwise the serous cavity can be laid open and the upper and posterior surface of the bladder laid bare. No other manner of treatment seems likely to prove of real avail in rupture of the bladder. Lastly, great importance must be attached to the thorough washing out of the peritoneal cavity. The urine and bloody serum penetrate everywhere. Wegner's experiments prove that extravasated urine does not merely gravitate, but that peristaltic movements of the bowel speedily distribute the fluid over the entire peritoneal surface. A 1 per cent. boric acid solution dissolved in previously boiled water and cooled to a temperature of 98° F. seems well adapted for the purpose, or water simply boiled can be used."

There is but little room for a discussion of the question of diagnosis in cases of suspected rupture of the bladder. In the majority of cases the symptoms and history will usually enable the surgeon to diagnosticate the injury. But even with an uncertain diagnosis it is both safe and justifiable to make an exploratory laparotomy. "If this be done early enough, it will prove successful in uncomplicated cases, while the operation in itself scarcely aggravates the patient's condition, and is surely better than a hesitating, halting practice in expectation of improvement, which usually never takes place."

CHOLERA IN SOUTH AMERICA.

It appears from despatches furnished by the United States Minister at Buenos Ayres, and published in the weekly abstract of sanitary reports issued from the office of the Supervising Surgeon-General of the U. S. Marine Hospital Service, Washington, D. C., January 27, 1887, that about the first of November, 1886, the Italian ship "Perseo," plying between Genoa and Buenos Ayres, arrived at the latter place infected with cholera, several deaths from the disease having occurred during the voyage. Before the facts were made known, the ship had landed many passengers at the *Boca*, a low, filthy dock below the level of the river Platte, and then proceeded to Rosario, on the Pasaka river, 200 miles distant, where she discharged the remainder of her passengers and cargo. Cases of cholera occurred soon after the landing of the ship "Perseo," both at the Boca port and at Rosario, and continued to spread more or less at both places.

During November, the number of cases reported at the Cholera Hospital at Buenos Ayres was 200, of whom 93 died, 34 recovered and 73 remained under treatment, on December 3. Of the 200 patients, 130 were from the male and female lunatic asylums, 12 from a prison, leaving but 58 cases as having occurred in the general city population during the month. During the same month, in the smaller city of Rosario, having a population of about 50,000, more than 200 cases were reported, more than half of which died. One week later news from the United States Consul at

Buenos Ayres, December 10, says: "While a few cases of cholera are still reported in each day's bulletin, the disease appears to have pretty much run its course at this port." In regard to other places the same authority says: "On the 4th of December there were 13 deaths at Rosario and 14 new cases, and at Cordoba 2 deaths and 5 new cases." It is stated that a few cases have occurred at several small places outside of the cities named, but on the whole the disease is declining. At Buenos Ayres the health authorities appear to have adopted very efficient and energetic sanitary measures for preventing the spread of the disease, and thus far with encouraging success, and the alarm at first created has greatly subsided, but still the greatest vigilance is exercised to prevent the further spread of the disease in any direction.

LARGE CEREBRAL TUMOR.—DR. WM. S. ROBERTSON, late Professor of Practice of Medicine in the Medical Department of the Iowa University, died at his home in Muscatine, Iowa, on the 20th of January, 1887, aged 56 years. He had suffered several months from paralysis and symptoms of cerebral disease, ending in complete coma forty-eight hours before death. We are informed that a post-mortem examination "revealed a tumor in the right cerebrum, extending from above downward and slightly backward about three inches, and from before backward two inches," as the evident cause of the symptoms and the fatal result.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, January 6, 1887.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

W. H. H. GITHENS, M.D., SECRETARY.

The Secretary read

A REPORT OF 616 CASES OF LABOR IN PRIVATE PRACTICE BY DR. H. H. WHITCOMB,

of Norristown. Up to March 31, 1886, I had attended 616 cases of obstetrics. I have had no death of a mother and only two still born children; one of of these was destroyed by craniotomy. The forceps have been used in two cases only. I have had no case of twins. I have had one case of elbow presentation, one shoulder, one a hand and face, and three breech presentations; all the others were by the vertex. Placenta prævia was present in two cases at full term and in two miscarriages, one at seven and one at five months. A series of thirty-two cases of puerperal fever, but fortunately without a single death, followed me in the winter and spring of 1882. The first case occurred after I was in attendance on a case of scarlet fever, and was followed by three other cases; the next two or three obstetric patients escaped, when I was called to see a woman who was confined while convalescent from erysipelas. The fever developed in her, and then every case I attended that winter and spring suffered from it. Consultation confirmed the diagnosis in all cases. One instance was after a miscarriage at seven months following pneumonia. The patient had a tedious convalescence, but has since had a child weighing 13½ pounds. I tried to stop attendance on this class of patients, but could not get rid of them. The epidemic ceased as suddenly as it commenced, and I have not had a case since. The smallest child delivered at full term weighed three pounds and lived only three days. Three deaths of infants have occurred from trismus, and four deaths, in children a few days old, for which I was unable to assign a cause. They simply moaned until they died, while they appeared to be in good condition. I had one case of hour-glass contraction and four of severe post-partum hæmorrhage at term.

My success I ascribe to patient waiting and conservatism. I do as little meddling as possible, and do not use antiseptic injections. The credit is partly due to my old teacher, Prof. Penrose, who is a safe guide to follow. I owe much to his careful instruction. I see so many doctors who, in almost every case of obstetrics they get, if they arrive before the child is born, put on the forceps to "hasten delivery and shorten the woman's suffering." I am very positive that this frequent use of the forceps is abuse. I have had a number, possibly twelve, of ruptured perineums; they were immediately stitched with a perfect result in all cases. I have never had a vesico vaginal fistula, although one of our teachers would impress his classes with the idea that these cases occur in the hands of the country practitioner. I might say the only cases I have ever seen were those in the care of city doctors.

DR. H. A. KELLY remarked that Dr. Whitcomb's report was full of interest, and in criticising the observer must be careful not to impose the rules and statistics of an average Philadelphia practice upon the Norristown people. While it is true that ailing, delicate women live and require obstetrical services in Norristown, as elsewhere, yet it is a fact that in Philadelphia the up-town mill population, from all over the civilized world, and the down-town population of pampered society women and alley offscourings, present very different problems to the accoucheur.

With notable exceptions labor in the country is *easier*. Differences of the same kind in greater degree exist between our native and the foreign population. I was much struck with this fact this summer when I went to the Anatomical Institute in Leipsic, to Herr Dornfelder, to buy a normal female pelvis. I was going to Berlin to return in a month, and instructed him to find a pelvis as near a normal specimen in the museum as he could, in the large amount of material passing weekly through the Institute. On

my return he gave me a specimen I now have in my office, which was the nearest to the normal he was able to find; and he assured me that a normal pelvis was rare. This dried pelvis with artificial ligaments measures: Sp. I, 25½ ctm.; Cr. I, 29½ ctm.; Cr., 9 ctm.; Dr., 13 ctm. The argument as to different necessities in different localities holds with regard to the use of antiseptics.

Dr. Wm. Goodell read a paper entitled

A YEAR'S WORK IN OVARIOTOMY.

In it he stated that he had had during the past year fifty-nine laparotomies, but that, lest his paper should be too long, he should limit himself to the consideration of his ovariotomy cases. Of these he had had thirty-nine cases with three deaths.

Of these deaths one occurred on the table from the difficulties of the operation. It was a dreadful case of intra-ligamentous cyst with universal adhesions, from which it was shelled out without a pedicle. The ureter had to be dissected out for twelve inches, and the entire colon, womb, bladder and small intestines were attached to the cyst It was a very forlorn case from the start, and he operated merely from a sense of duty. He stated that in the removal of intra-ligamentous cysts the ureter is in great danger, and he believed that it had been repeatedly torn across without the knowledge of the surgeon. Dr. Goodell stated that before the death of this case, he had had in succession twenty-two successful cases, and afterwards a series of eight cases before the next death took place—viz., thirty-one cases with one death. The second death was due to obstruction of the bowels in a case of large fibroid of the womb and ovarian cyst weighing sixteen pounds. On account of the fibroid both ovaries were removed. He had had his share of cases of obstruction, but this was the first fatal one in his recollection. The remedies that he used were calomel and belladonna by the mouth, and turpentine by the rectum. The obstruction is due to the adhesion of a knuckle of intestine either to the stump of the pedicle, to the abdominal wound, or to some denuded surface. As soon as symptoms of obstruction presented themselves, he always aimed at once to open the bowels.

The third death occurred in a case of malignant cystic disease of both ovaries, in which the operation was incomplete. Malignancy had been suspected, but the operation was forced on him on account of the excessive pain from which the woman suffered. Yet he argued, from his own experience and that of Schroeder and Martin that, other things being equal, it was always wise to remove ovarian cysts even when malignant, for patients' lives would be greatly prolonged by the operation.

The right ovarian cyst had no pedicle, but ended in a brittle cancerous mass as large as his fist. This, with very great difficulty, was ligated *en masse*, and then bleeding vessels were secured separately. The left ovarian cyst was so fastened to the womb, pelvis and broad masses of cancerous excrescences that he did not attempt to remove it. He would have abandoned the case after he had discovered the nature of the complications, but he had gone too far to recede, for his hand had been inside of the right cyst to break up its septa, and blood was flowing profusely from it. The lady died twenty-six hours later from shock and hæmorrhage.

He stated that some ovariotomists do not report their incomplete operations or their exploratory incisions, but that he thought it fairer to do so. If his memory served him no trick, this was the only incomplete operation for ovarian cyst that he had ever had. None of his cases had been selected, and he had refused to operate in one case only, and that one on account of epithelial cancer of the cervix; so that he did not have any exploratory incisions to report. He had twenty-one cases of adhesions; a very large proportion of which he attributed to the tendency women in this country have of postponing the day of operation. He also had had twenty cases of double ovariotomy; but this large number was due to his rule of removing the second ovary in all malignant or suspicious cases, in all cases which have passed the climacteric, in all cases of incipient disease, and always when asked by the patient to do so. He further stated that he still adhered to Listerism, and that he used Keith's dressing of one part carbolic acid to seven of glycerine.

Dr. Parish cited a few instances of evil results following abdominal tapping for purposes of diagnosis or for relief from distension. In his first ovariotomy case, with the view of clinching the diagnosis, he aspirated and withdrew a few drachms of somewhat cloudy ovarian fluid. The patient presented some symptoms which in a few days became grave; pain in the tumor, rigors, rapid and feeble pulse and high temperature. I operated during the existence of these symptoms, and found suppuration of the interior of the cyst and extensive anterior adhesions; both conditions doubtless dependent upon the aspiration. The patient recovered.

A few years ago a well known medical gentleman of this city aspirated a tumor supposed to be a multilocular ovarian cyst. Though the fluid was stated to verify the diagnosis, the patient miscarried in one or two days of twins at about the fifth month, and the tumor proved to be simply a uterus enlarged by reason of a multiple pregnancy.

I have recently seen in the Philadelphia Hospital a shocking case of labor, in which active labor pains began one week previous to her admission to the hospital. No urine had been voided for several days. Pregnancy was denied by the patient and her friends, and was not recognized by two physicians. The woman was small and deformed, and in the abdomen were two fluctuating tumors, one due to a distended bladder, the other the uterus. Aspiration was resorted to in both tumors, a procedure that was not only unnecessary for diagnostic purposes in this case, but which would probably have been highly detrimental to the patient, had not the neglected and protracted labor already determined a rapidly fatal result. Though tapping for relief and especially for diagnosis is less frequently resorted to than was the case a few years ago, yet even now it is too frequently done.

In reference to the development of cancer or sar-

coma after the removal of seemingly benign ovarian tumors, I have seen recently an example in a patient operated on by Dr. Hickman and myself. A large cyst of one ovary and a small one of the other, both free from the appearance of malignancy, were removed, and the patient made a tardy recovery. In about a year sarcomatous growths developed in the neck and axilla, and a large one in the abdominal wall of the left lumbar region. The patient died a few weeks ago, and the autopsy was made by Dr. Morris Longstreth, and though the sarcomas referred to were present, there was not intra-pelvic disease. An interesting feature was the total disappearance of the ligature of iron-dyed silk with which the pedicles and several vessels were secured about eighteen months previously.

DR. H. A. KELLY stated that while simply tapping often was in no way injurious, it was also often productive of grave injury, and one of his own cases illustrated this point very well. The patient, having a cyst weighing 100 pounds, was tapped in the left iliac region by a notorious homœopathic surgeon. She had previously suffered from pressure symptoms. From now on she suffered from severe inflammatory pains around the puncture, and at the operation the extensive dense adhesions at this point constituted the chief difficulty. She is now well, more than a year since the operation.

It is a cause for mutual congratulations for American operators, that their results are becoming so good. The whole credit of this lies in the thorough use of antiseptic agents and the rendering the field of operation completely *aseptic*.

He believes, too, that our cases at home are more difficult than those now being operated on abroad. The tumors we operate upon are older, and with the increasing age of an ovarian tumor occur many changes detrimental to the patient, depression of vitality from pressure symptoms, diversion of so much albumen from the system at large, surcharge of the emunctories, as well as adhesions and unfavorable changes within the tumor itself. Keith's dressing, of a strong carbolized glycerine, has rendered excellent results in my hands in at least twenty cases.

DR. GOODELL, in answer to a question by Dr. Baer, said he operated during menstruation merely from pressure of time on the part of the patient, and little or no effect was produced on the discharge by the operation.

DR. JOS. PRICE, in commenting upon some points alluded to in Dr. Goodell's paper, fearing the contaminated atmosphere of a general hospital, cited the statistics of two hospitals: Special Department of Birmingham General Hospital and Birmingham Hospital for Women, covering a period from January, 1878, to September, 1885:

Special Dep't of General Hospital—Ovariotomy, 35 cases, 11 deaths; 31.4 per cent.

Birmingham Hospital for Women—Ovariotomy, 268 cases, 19 deaths; 7.1 per cent.

During the same period the total number of intra-abdominal operations in the

Special Dep't of General Hospital—85 cases, with 21 deaths; mortality, 24.7 per cent.

Birmingham Hospital for Women—632 cases, with 49 deaths; mortality, 7.7 per cent.

One point as to the value of the spray, quoting from Keith's report of cases treated in the Royal Infirmary, Edinburgh.

Carbolic acid spray cases:

Ovariotomy, 21 cases, 18 cured, 3 died.
Hysterectomy for fibroid, 2 cases, 2 cured.
Battey's operation, 1 case, 1 died.

Twenty-four cases with 4 deaths; 16.66 per cent.

Boro-glyceride spray cases:

Double ovariotomy with hysterectomy, 1 case, died.
Hysterectomy for fibroid, 1 case, recovered.

Result with boro-glyceride spray: Two cases, with one death.

No spray:

Ovariotomy, 47 cases, 46 cured, 1 died.
Hysterectomy for fibroid, 7 cases, 7 cured.
Battey's operation for fibroid, 1 case, 1 cured.
Interstitial pregnancy, 1 case, 1 cured.

Fifty-six cases with one death.

Mr. Keith says: "No cases of serous cysts of the broad ligament were operated on. These all were treated by tapping, and none of them have returned." One such case that Dr. Price saw died a few days later. Of Dr. Keith's cases, one-half had no adhesions.

DR. MONTGOMERY expressed pleasure at hearing Dr. Goodell's details and success, and considered his success gratifying, especially after tapping. A patient came to him one month after tapping. She had a high pulse, septicæmia, large adhesions to viscera, etc., putrid clots in the tumor, and died on the fifth day with a temperature of 105°. He does not approve of tapping broad ligament cysts. One patient with such a tumor was tapped seven times. He afterwards removed the tumor, and did not have a single vessel to tie. In this case the peritoneum had been pushed up by the tumor and was not opened until late in the operation.

DR. GOODELL made a few remarks on the subject of statistics. Dr. Keith's have improved, not because he has given up the spray, but because he has grown to his work. Dr. Goodell will give up the spray because it is an intolerable nuisance. As to the question of malignancy of ovarian tumors, it has been said that "all ovarian tumors are malignant and should be so treated." This is too sweeping; but the tumor should in all cases be removed as soon as possible, as soon as it is discovered.

DR. R. P. HARRIS desired DR. Parish to report the present condition of the patient from whom he had removed the ovarian tumor exhibited by him before the Society, at its meeting on March 4, 1886, the day after the operation. Dr. Parish requested Dr. Harris, who had seen her much more recently than he had, to report her condition. Dr. Harris stated that notwithstanding the fact that the tumor was largely solid; that it had grown rapidly; that the solid portion had an appearance of malignancy; and that there was a small morbid growth projecting upward from the fundus uteri, the lady was to all appearance a well woman. He saw her on December 26, when she claimed to have perfectly recovered her

health and strength after a very prolonged convalescence. Her appearance and activity certainly indicated that her statement was correct. The uterine nodule must have been a fibroid, as, had it been cancerous, it must have materially developed in nine months. The future of this case will be of much interest.

Dr. Chas. Meigs Wilson reported

THREE SUCCESSFUL TAIT OPERATIONS.

These cases are the first of a series performed without the use of carbolic acid solutions for instruments, and without the spray. Hydrant water boiled for six hours was used for the instruments and sponges in the first and second cases, and a solution of mercuric chloride, 1 to 8000, for like purposes in the third. The wounds in all three were dressed after the manner of Keith. The incisions were less than two inches in length. More than three months has elapsed since the operation in each case before it has been reported. It has seemed best to publish the cases in this manner, because the vast majority of all cases recover without accident from the operation, and hence mere statistics of the healing of the wound amount to little but evidence of individual skill. Statistics of the real relief afforded by the operation is what the profession needs in order to give the operation its just place in modern surgical procedures.

Case 1. Myo-Fibroma of the Uterus.—This case first came under observation in July, 1886. She gave her history as follows: Mrs. McM., æt. 32, multipara. For the last sixteen months has had a rapidly growing tumor of the abdomen, menses profuse, catamenial intervals ten to fifteen days; for the past four months has been rarely free from bloody vaginal discharge. She was emaciated and anæmic.

She was very nervous and alarmed about the constant bloody discharge. She had reflex pains, but no ovarian tenderness or pain. She was obstinately constipated, owing to the pressure of the tumor upon the rectum. She was found to have a large fibroid tumor of the fundus and anterior wall of the uterus. The enlarged uterus was incarcerated in the cavity of the pelvis and was very immobile. The sound entered the uterus 7¼ inches. Abdominal section was performed September 20, 1886, with assistance of Drs. E. Wilson, A. P. Noble, E. Longaker. The tubes were as thick as the finger, they had thin walls, and were distended with blood. The ovaries were over size, and the right one was cystic. The ligature slipped from the uterine end of the left tube, and before it could be secured there was free hæmorrhage. The operation lasted forty minutes. Convalescence was retarded by abscess of one of the suture tracts. The patient made an excellent recovery. Present condition: Has lost no blood since the second day after the operation; appetite good, and is able to resume her occupation of seamstress; frequently walks two miles to her work; all pain has disappeared; has gained twenty-two pounds since the operation. December 20, 1886, the sound entered the uterus 3¼ inches; the tumor was greatly reduced in size.

Case 2. Hystero Epilepsy.—Mrs. C., æt. 30, primipara. Had always enjoyed good health until after the birth of her child six years ago. She had been delivered with forceps, and the cervix and perineum had been badly torn. She was in bed nine weeks after her confinement. No clear history of her puerperal trouble could be obtained. She has had profuse catamenial discharges since. About six months after the birth of her child she first commenced to have attacks of loss of consciousness followed by epileptiform seizures at her menstrual periods. These gradually became so severe as to place her life in seeming jeopardy during their occurrence, and left her utterly prostrated. She had been in bed about twenty days out of every month for four years. Her epileptic seizures occurred only at her monthly periods. Everything that her medical attendant could think of had been done for her, and her family were about to place her in an insane asylum. The ovaries and tubes were removed October 3, 1886. The operation was an easy and simple one. The patient made a speedy recovery without any untoward symptoms. *Present condition:* She is now able to earn her living as a yarn picker, working full time; has had no discharge of blood, little or no pain, *and not one seizure since the day of operation.*

Case 3. Tubercular Pyo-Salpinx.—Miss E. R., æt. 19, nullipara. This patient was also operated upon on October 3, 1886. Since menstruation began, at 15 years of age, she has had constant dull, aching pain, deep seated in the pelvis. At her menstrual epochs "her agony has been unbearable." Menses have always been slight in quantity and regular as to time. She presented a badly nourished appearance. Physical examination showed marked evidence of general tuberculosis. In spite of this fact, and in view of her intense menstrual pain, oöphorectomy was deemed justifiable and was accordingly done. Both the tubes were as large as bologna sausages, and both ovaries were cystic. Tubes and ovaries were matted in a mass of adhesions which rendered the operation very tedious, it lasting one hour and ten minutes. Microscopic examination of sections of the tubes showed colonies of the bacillus tuberculosis. Both tubes were filled with a greenish pus which was very offensive. The recovery was complicated by an arthritis, the symptoms of which were so obscure as to render it difficult to say whether it was septic, rheumatic or hysterical. She eventually made a good recovery. *Present condition:* Her physician, Dr. Walter E. Bibby, of Kensington, Phila., reports: "She is entirely free from pain, able to walk about, and to attend to light household duties. Under the use of cod-liver oil and malt and alcohol her tubercular trouble seems to be making little or no progress." As her peritoneum showed evidence of tuberculosis, as an experiment, bichloride solution, 1 to 8000, was used to wash out the abdominal cavity. Cases 2 and 3 were operated upon before Drs. A. W. Biddle, W. E. Bibby, W. C. Goodell, E. Wilson, Longaker, and C. P. Noble. All were done at the Philadelphia Lying in Hospital. In each case the abdominal cavity was thoroughly flooded with boiled water before it was closed. The drainage-tube was not used. The carbolized Chinese silk ligatures

and silkworm-gut sutures were used. No anodyne was given after the operation, and no food was given for thirty-six hours after operation.

DR. H. A. KELLY was particularly interested in the tuberculous tubes, and regretted that an examination of the uterine discharges had not been made, as it would almost certainly have established the diagnosis. As to the right to operate upon a patient having a cavity in the lung, no general rule can be laid down; every such case stands by itself, and much must be left to the judgment of the operator.

DR. BAER would hesitate for some time to operate in a case of general tuberculosis with a pulmonary cavity. He did not think tuberculosis could cause pyosalpingitis.

DR. KELLY remarked that at least two cases have been observed here and many more abroad, and it has been recently formulated by Prof. Hegar among the tubal diseases which may require operation.

DR. PARISH thinks the general condition of the patient outside of the pulmonary disease would decide the question. Severe pain should be relieved unless the patient had a very short time to live.

HYDROSALPINX.

DR. H. A. KELLY exhibited the tubes of a patient who had suffered from metrorrhagia over thirteen years. She had been in five large hospitals in Philadelphia without relief, and had faithfully tried every plan of treatment, systemic and per vaginam. The diagnosis of enlarged tubes was made before operation, and on removal with their respective ovaries, the tubes were found, one as large as a bologna sausage and the other a small sausage, with a limpid fluid. She has lost no blood since the metrostaxis following the operation about six weeks ago.

DR. KELLY also exhibited fresh, large cystic ovaries and tubes of a large fibro-cystic tumor upon which he had operated in the morning. The ovaries were sessile, surrounded by congeries of great dilated vessels. The operation was one of extreme difficulty. (*Note five days after operation: "The patient's condition is perfect."*)

The patient whose history was read at the preceding meeting, who had ovaries and tubes removed for chronic subinvolution and endometritis, was presented to the meeting. She has lost all pain and feels perfectly well for the first time in years. The uterus is normal.

DR. PARISH reported a *Porro-Müller Operation.*

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, December 17, 1886.

THE PRESIDENT, CHAS. WARRINGTON EARLE, M.D., IN THE CHAIR.

DR. HENRY T. BYFORD exhibited the following specimens:

PROLIFERATING OVARIAN CYSTOMA.

This specimen, removed three weeks ago by Dr. William H. Byford, at the Woman's Hospital, is interesting in being a large ovarian cystoma, composed of an immense number of small cysts. Extremely formidable in appearance—resembling a malignant growth—it has pursued an exceedingly benign course. Adhesions were few and easily severed. The subsequent recovery was typical, one dose of morphine constituting the entire medication.

PAROVARIAN CYST AND APPENDAGES, COMPLICATED BY A UTERINE FIBROID.

This cyst, which was about the size of the head of a child 2 years old, developed between the layers of the boad ligament in a direction away from the uterus, lifting up the Fallopian tube, ovary and infundibulo pelvic ligament. The tube is straightened and hypertrophied, admitting the finger for an inch into the fimbriated extremity, and the infundibulo-pelvic ligament is separated from its ordinary pelvic wall attachment by a larger portion of the tumor, over and under which the peritoneum passes to form, with the ovarian ligament and uterine end of the Fallopian tube, the pedicle. Had there been no pedicle, or had it been desirable to leave the ovaries, the inner coating of the cyst could have been taken out of the serous investment in about two minutes, without violence or hæmorrhage. They separate now almost as easily as if they were wet pieces of linen lying in apposition. The ovary is slightly hypertrophied. On account of the presence of a uterine fibroid tumor, the size of an orange, the other healthy ovary and tube were removed. Three transparent cysts, about the size of beans, and feeling as hard as bone or wood are, as you see, hanging by long pedicles from the meso-salpinx. The ovarian artery runs over the tumor and under the tube, is elongated and four or five times its normal thickness. Here is also the left tube. It is congested, but neither it nor the artery is appreciably enlarged. The ovary is large but not pathological.

OVARIAN CYST IN THE BROAD LIGAMENT CONTAINING THE DEGENERATED OVARY.

This tumor, which was removed by enucleation and which was the size of a pregnant uterus in the sixth month, is interesting by comparison with the other, and also as illustrating the dangers of tapping. It evidently developed from the surface of the ovary between the layers of the broad ligament towards the uterus. The remainder of the ovary has developed into a multilocular cystoma the size and shape of a large orange, and projects into the large cyst. The firmness of the adhesions of this inner coat of the tumor to its peritoneal covering, as compared with the smaller cyst just shown, suggests that small tumors are more easly enucleated than large ones, and constitutes an argument in favor of earlier operations. The horn of the uterus with the Fallopian tube was hypertrophied and drawn up over the anterior surface of the tumor, so that when exposed during the operation it looked like a pregnant uterus with a large vein running over it, diagonally across the incision. Had the tumor been tapped in the ordinary place, trouble must have resulted, and the operation which, after the stripping of this hyper

trophied and congested uterine tissue from the tumor, was easily and rapidly completed, would have been complicated. The uterus in a few weeks was apparently normal in size, position and mobility. It is interesting to note that the tumor was mistaken for advanced pregnancy, about a year ago, by one of our most prominent general practitioners.

SUPPURATING OVARIAN ADENOMA, WITH UTERUS.—AUTOPSY.

This tumor, which was examined by Dr. F. S. Johnson, is an ovarian adenoma of the same histological nature as the first specimen shown, but presents a striking contrast by malignant course and small size, as the whole was scarcely larger than a child's head. An ovarian tumor was removed from the opposite side by Dr. William H. Byford several years ago. As this was not a malignant growth, although practically pursuing the course of one, an attempt was also made by him to remove this, or at least cure the discharging abscess that surrounded it, about five months before the patient's death, but it was, from the nature of the case, only partially successful. In attempting its removal after death, the exhibitor was almost equally unsuccessful, for it was surrounded and intermingled with pus cavities and intestinal loops, and had destroyed and occupied the place of all the pelvic tissues except the rectum, bladder and uterus with the right round ligament which you see hanging to it. The cul-de-sac was full of it, the posterior uterine surface inseparable from it, the right broad ligament supplanted by it, and the contents of the left broad ligament an agglomerated mass of inflammatory tissue. A blue walled abscess about the size of, and extending along the course of, the ascending colon, and secured an outlet just below the border of the ribs. Another abscess opening just below and to the right of the umbilicus gave exit to pus, fæces and semi-transparent, jelly-like ovarian fluid. The right ureter was dilated and hypertrophied. The pelvis of the kidney must also have been dilated, although that being left to be examined last,[1] was finally forgotten. The lower three feet of the ileum were compressed and atrophied to the size of a small lead pencil. Just above it ran a fibrous tube of the usual size of the ileum, straight from the cæcum to the lower opening in the skin. The uterus, which previous to the removal of the first tumor, had developed two healthy children, was of rather small size, in a normal position and healthy, excepting a moderate laceration of the cervix and a slight degree of injection of the mucous membrane about the os.

FIBRO-SARCOMA OF THE LEFT HORN OF THE UTERUS, LUNGS, PLEURA, PERICARDIUM, RECTUM, TRANSVERSE AND DESCENDING COLON AND ABDOMINAL PARIETES.

About a quart of serum was found in the right pleural cavity. Several round, fibro sarcomatous tumors, the size of nuts, and several indefinite spots of contracted fibrous tissue, were found in the lungs, suspending their expansibility except over small areas. The two exhibited were torn from the lungs; one from the center of the apex and the other from the pleura at the base. A fibro-sarcoma the size of a goose's egg, which is still attached to the left pleura, was also attached to the pericardium. The heart weighed 8¾ ounces, was drawn to the left by the contracted lung (which had but little fluid about it) and contained an ante-mortem clot. The liver was enlarged and mottled. The stomach lay entirely to the left side, in front of the compressing and atrophied spleen, with the pyloric orifice suspended vertically under the cardiac orifice, and not reaching as far to the right as to the median line. The transverse and descending meso-colon was stung with these fibro-sarcomatous masses, the size of hazel nuts, and the rectum covered with the same of a little larger size. A few were also found on the peritoneal surface of the abdominal parietes. The uterine tumor weighed twenty ounces, and, like all of the specimens, cannot be distinguished from fibroid or fibrous tumors by the eye, except over a limited area upon the anterior surface, where it has softened and degenerated into the round celled variety. The fact that the patient was twice tapped by physicians for ovarian cystoma makes it seem probable to me that this change has been produced by the introduction of the trocar, and that the little tumors on the abdominal parietes were due to the adhesions forming afterwards. The fluid obtained then was probably peritoneal which, to the amount of about eight pints, had again accumulated. It was dark-green in color. Abdominal enlargement was noticed several years ago. An operation had been advised two years ago. Dr. F. S. Johnson examined the specimens, with the result mentioned, and but for an attack of sickness would have reported upon them in person.

Dr. W. W. Jaggard exhibited the following specimens:

UNILOCULAR CYST OF RIGHT OVARY, THE REMAINING OVARIAN TISSUE SHOWING CORPUS LUTEUM OF MENSTRUATION.

He had recently removed the tumor, and the patient had made an excellent recovery. Menstruation ceased three days before the operation. The specimen was interesting, though not exceptional, in showing the persistence of functional activity in such an extensively diseased organ. The left ovary was normal, and was not removed.

A PLACENTA, SHOWING VELAMENTOUS INSERTION OF THE UMBILICAL CORD, AND REMAINS OF AN EXTENSIVE HÆMORRHAGE INTO THE PARENCHYMA OF THE ORGAN.

The term *insertio velamentosa* means a separation of the three vessels of the cord before they reach the placenta. The vessels pursue a straggling course between chorion and amnion, for a variable distance, and each one reaches the placental margin by itself.

According to B. Schultze (*Jenaische Z. f. med. u. Naturw.*, 1867, Heft. 2 and 3), the origin of velamentous insertion of the umbilical cord is as follows:

[1] The autopsy was performed in the midnight before the burial, and in a small town, in a cold room and without conveniences.

The allantois carries the fœtal vessels to the periphery of the egg, entirely irrespective of the future placental site. Indeed, it is comparatively seldom that the future placental site is immediately reached. The vessels penetrate all the chorionic villi indiscriminately. These vessels are subsequently obliterated in the chorionic villi not destined to form the placenta, and vascular connection only remains with that portion of the chorionic villi corresponding to the *decidua serotina*. With the further growth of the egg, under normal conditions—it makes no difference what point in the egg periphery the allantois originally touched—as the amniotic sheath forms around the rudimentary cord, the fœtus performs a movement of rotation, so that the vessels pursue a straight course to the placenta. Now this movement of rotation may be hindered, and the formation of a complete sheath prevented by anomalous adhesions. The hindrance is adhesions of the umbilical vesicle, the ductus, or the vessels to the amnion or chorion. In such cases, if the growth of the ductus does not keep equal pace with that of the amnion, a complete sheath cannot be formed, and the amnions forsake the vessels before they reach the placental edge. Velamentous insertion of the cord can occur at the pole of the egg opposite to the placenta, or at any intermediate point. The anomaly is observed most frequently in cases of multiple pregnancy.

Velamentous insertion of the umbilical cord seldom leads directly to interference with the development of the fœtus. In labor, however, the vessels may be compressed between the presenting part and the parturient passage, and the child may be asphyxiated, or, with the rupture of the bag of waters, a vessel may be torn and the child's life endangered by loss of blood. In general terms, the clinical picture bears a great resemblance to *placenta prævia*.

In the specimen presented, the cord is inserted into the chorion about 5 centimetres from the placental edge. The anomaly was not recognized until near the conclusion of the first stage of labor. A large vessel was torn at the same time with the spontaneous rupture of the bag of waters, and the life of the child was seriously jeopardized by the loss of blood.

The child, though probably mature in point of age, was small and feeble; weight 2,700 grams, length 47 centimetres. The failure in development could be ascribed to the large hæmatoma and numerous hæmorrhagic infarctions in the *placenta fœtalis*. The mother of the child was threatened with abortion, and suffered from uterine hæmorrhage when she was in the sixth month of pregnancy. The child, at the time of presentation of specimen, was living.

THE PRESIDENT exhibited the ileum removed from a child 22 months old, who died of typhoid fever, in which the characteristic lesions of the disease could be seen.

The child had continued fever for five weeks, the temperature reaching 105° F. part of the time, rose-colored spots in the third week, intestinal hæmorrhage, tympanites, and delirium.

The case is remarkable on account of the age of the patient, as many authorities deny the existence of genuine typhoid in children.

Stewart (1841) describes infantile remittent fever in which the bowels are sometimes relaxed, occasional delirium, followed by a low, quiet state. Evidently he did not recognize typhoid as occurring in children.

Condie (1853) says: "It is much more than probable that typhoid will be found to be a much more frequent disease among children than has heretofore been supposed."

Bedford (1856) does not speak of typhoid.

Hillier (1868) says: "Typhoid is not infrequent in children, Many cases of infantile and gastric fever belong to this class."

Meigs and Pepper (1870) say: "Typhoid fever has been observed during the first year of life, but is rare under the age of 2 years. It is comparatively infrequent between the ages of 3 and 8 years, and attains its maximum of frequency in childhood between the ages of 8 and 11 years."

Tanner (1871) believes that all those varieties of typhoid which have hitherto been described under the names of simple, continued and remittent fever, are but different degrees of one and the same disease, typhoid.

Eustace Smith (1884) says: "Enteric fever is common in children."

Steiner (1871) says of typhoid: "This is common among children. In the Prague Hospital, out of 80,245 patients, 1,180 had typhoid."

Vogel (1870) says: "Abdominal typhus is much more frequent than is commonly supposed."

He thought Lewis Smith did not mention typhoid in his first edition, but in his sixth (1886) he describes it fully, believing that it is not infrequent in children, and presents peculiarities not found in adults, hence his chapter of eleven pages.

From the above quotations it seems that foreign authors recognize it as moderately frequent, and writers in this country who, a quarter of a century ago, either did not speak of the disease as occurring among children or gave the subject very slight mention, are now describing it as more common, even among quite young children.

In all probability, as our malarial diseases become rare, typhoid fever increases in frequency.

DR. J. H. ETHERIDGE made the following remarks upon

A CASE OF ANTERIOR VAGINAL ENTEROCELE

with exhibition of patient.

I have a rare case that I would like to exhibit to the Society, one of anterior vaginal enterocele. I have had a few of my medical friends examine it, and they all concur in saying that they have never seen a case like it. The patient is 19 or 20 years of age and has one child, 11 months old. When she was about six months gone in pregnancy, she "jumped the rope" one day, and after that she felt something come down through the vagina. She went to full term and had a normal labor. Whenever she strains or lifts, the enterocele comes down, presses the vulva apart and comes out between the thighs. On examination I find quite a large opening in the roof of the vagina. The edges of the ring can be very easily outlined with the finger, and when the hernia is down the finger in the vagina is at once attracted

by a pendant mass, and by pressing it a little one can determine that it is filled with gas. The opening comes down to the left of the uterus, anterior to the broad ligament and posterior to the left of the bladder.

A Fowler pessary has been fitted which seems to answer the purpose of complete retention, and as long as the patient can avoid an operation my advice is not to have one. The uterus is in good position. She made a good recovery from her confinement and is nursing her child, and seems to be in a perfectly physiological condition. The question of operative procedure for a radical cure is a very serious one for this patient. Laparotomy is full of difficulty in attempting to close the hernial opening from within, is of a most unsatisfactory possibility in its outcome, and is followed by the very great risk to life which attends all laparotomies. Any operation through the vaginal tract will be attended by such a lack of certainty in results as to cause me to hesitate in essaying it. Until it is found impossible to retain the intestine in its proper place with a pessary, I have advised the patient to avoid submitting to any surgical procedure. The patient is present, and each gentleman desiring to do so can make the examination and verify what I have said.

Dr. Philip Adolphus: The case just presented for examination by Dr. Etheridge is a typical case of vaginal hernia, the intestine passing between the loosely attached connective tissue which unites the bladder and the anterior wall of the vagina, in its upper half. This mode of descent is much more infrequent than a hernia into the *cul-de-sac* of Douglas. In the case here presented the hernia is reducible in the upright position, contains intestine only, and has for its covering the peritoneum and vaginal wall. What can be done for the patient's relief? These hernia seldom becomes strangulated. During labor, however, besides being an obstacle to prompt delivery, they are liable to contusion and strangulation. No retentive apparatus is worthy of trial, for all distend the vagina and ultimately increase the evil. What surgical procedure should be attempted? The text-books to which I have access do not suggest anything. Is the hernia to be closed by way of abdominal section or *per vaginum*? I think the closure *per vaginum* is preferable, and I suggest the following procedure adapted from Stoltz's operation for cystocele: "The patient being placed in Simon's position with the perineum retracted, the hernia is to be reduced and kept in place by means of armed probangs. An incision to be made over the tumor, the tissues divided until the ring of the hernia is exposed. This ring is to be surrounded by a running ligature of very heavy catgut, and then closely approximated, tied, and the ends cut off short, or if thought preferable, interrupted catgut sutures may be introduced to effect the same purpose. This completes the first step of the operation. Then remove a piece of the vagina larger than the protruded tumor, over the region of the hernia. The wound may be closed by running a circular single ligature of carbolized silk in and out, about an eighth of an inch from the margin of the wound, all around it, the end of the ligature being brought out close to the place where it was first inserted. The two ends are then drawn tight and tied, leaving a puckered opening into which a little drainage tube may be inserted. During the introduction and the tightening of the ligature the intestine may be held back by armed probangs. It is easier to work in this region with the scissors than the knife. Great care should be practiced in operating in this neighborhood not to wound the uterus and the peritoneum, which can be avoided by elevating the mucous membrane as it is removed. Now a few words in regard to the abdominal section for reducible vaginal enterocele. After having opened the abdominal cavity and withdrawn the prolapsed portion of the intestine, will it be easier to close the hernial aperture than *per vaginum*? I think not. The peritoneum and cellular tissue beneath it (abundantly supplied with lymphatics and blood-vessels, the parametric tissue of Virchow and Spiegelberg) will have to be incised, the bladder and upper portion of the vagina separated, the redundant tissue of the anterior wall of the vagina drawn up and excised, then stitched and replaced; the peritoneum also closed below as well as externally in the abdominal parietes. Will this render the site of the hernial protrusion stronger? Will it be a safer and more efficient operation than the first? I think not.

Dr. H. T. Byford: Dr. Etheridge has shown us one of those rare and interesting cases of anterior vaginal enterocele. The protrusion is through the parametrium in front and to the right of the cervix, the entire uterus being pushed backward, and the bladder forward. The left ureter can be felt passing from the trigone in front of the tumor downward and to the left of it. The broad ligament is pushed backward, and the round ligament outward toward her left side. The parts to the left of the median line seem only slightly to participate in the general displacement. The remedy for this condition, of course, must be to get the displaced organs and tissues back into the place now occupied by the intestine. I think Dr. Etheridge was wise in rejecting abdominal section as a remedy, for no advantage could be derived from it that would compensate for the risk involved. An operation from the vagina that would be justifiably performed upon a girl of her age could not be expected to be permanently successful, as the parts could not be properly replaced, and vaginal support could only be given. The treatment by pessary, already adopted in this case, is better than either of these procedures, because it acts partly by replacing the organs, especially the uterus, and partly by providing a barrier to the descent of the enterocele. Its weakness is that it does not tend to strengthen the parts upon it, and that it weakens those under it. The most efficient and rational method of permanently replacing the parts, and thus curing the enterocele would be to perform Alexander's operation of shortening the round ligaments. This would draw the fundus forward over the bladder and thus replace the normal central barrier to the descent of the intestines. It would also draw the round ligament and upper portion of the broad ligament forward to form a lateral support

to them. By turning back the base of the broad ligament it would tend to draw back into position the ureter (which is in close relation with its posterior edge), and at the same time the connective tissue through which the ureter runs and which is displaced forward with it. I know of no other method in which the parts could be brought back so nearly to their former relations. A pessary could now be worn until the parts had contracted and regained tonicity. If then the anterior vaginal wall remained redundant a circular piece should be excised in front of the cervix and by a stitch passed around it drawn together, along with the parametric tissue immediately above it.

DR. ETHERIDGE: If Alexander's operation was satisfactorily performed, what would be the effect upon the bladder and upon subsequent pregnancy?

DR. BYFORD: After the operation the fundus is not, or should not be, held down upon the bladder as firmly as in some cases of anteflexion in which there are no bladder symptoms of any account. I have performed three operations. In one case the bladder symptoms were benefited, in the others there were none complained of, either before or afterward. As to pregnancy, already there is some experience to show that it does not interfere. The round ligaments are not elongated in pregnancy as much as would be supposed, since the uterus grows to a certain extent away from them. In many cases of anteflexion or anteversion the ligaments are shorter than after an Alexander operation, yet give rise to no serious trouble in pregnancy.

DR. ADOLPHUS: How could Alexander's operation be of benefit if it draws the fundus down and the cervix up, since the enterocele is between the bladder and the cervix?

DR. BYFORD: It draws the body of the uterus down under the intestines, displacing them upward. The cervix needs to be held upward and backward in order to secure a proper relation of parts.

(*To be concluded.*)

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York County Medical Association—Election of Officers—Dysentery at the Almshouse, Blackwell's Island—Indiscriminate Porotomy—Quinine as an Antipyretic in Pneumonia—Small-Pox—Proposed Reorganization of the Health Department—Deaths from Water Fuel Gas.

At the January meeting of the New York County Medical Association, the following officers were elected for the ensuing year: President, Dr. John Shrady; Vice-President, Dr. J. R. MacGregor; Recording Secretary, Dr. P. Brynberg Porter; Corresponding and Statistical Secretary, Dr. Glover C. Arnold; Treasurer, Dr. Charles Ellery Denison; Member of the Executive Committee, Dr. Edwin Sanders.

The report of the retiring Treasurer, Dr. E. S. F. Arnold, showed that seventy-eight new members had been added during the year. The introduction of moderate monthly entertainments after the scientific work of the evening he thought had been of material advantage, especially in promoting harmony and goodfellowship, and in making the members better acquainted with each other; and he expressed the opinion that, should these gatherings be a means of bringing the younger and older men into more friendly and intimate contact, and induce the latter, as occasion offered, to extend a helping hand to such of the former as might be benefited by it, the results of this fraternization would be all that could be desired.

Dr. H. M. Briggs read the history of an epidemic of dysentery at the Almshouse on Blackwell's Island, in which he stated that in the years 1884–5 there was some dysentery in this institution, though not of an epidemic character; but an examination made by an inspector of the Health Department showed the sanitary condition of the buildings to be good. Some closets which were undoubtedly the cause of the trouble were not, however, inspected, as they were separated from the main buildings and did not attract attention. The epidemic in question commenced early in June, 1886, and the cases increased in number and severity until the 15th of July, when Dr. Briggs came on duty. At this time from twelve to fifteen new cases of severe dysentery appeared each week in the female almshouse, and the weekly number of deaths from the disease amounted to five or six.

Believing, as he does, that dysentery, in the vast majority of cases, is an infectious disease, due to some definite, determinable cause, he immediately made a careful inspection of all the buildings in the institution, as well as of the food and water supplied to the inmates; examining closely into all the conditions which might possibly bear upon the development of the disease. Aside from the element of overcrowding, nothing could be found to which importance could be attached, as regards the causation of the epidemic, except the state of the water-closet above referred to, which was in general use by the inmates. This was separated from the main building by a roadway, and had a large cemented brick vault, with a sewer about one foot in diameter leading from it to the river below, which was found to be in an exceedingly bad condition. The vault was flushed by the water from the bath-house, which was in the same enclosure, and by the rain-water from the roof of the main building. At the time of the examination the vault contained two or three feet of semi-solid fæcal matter. During the early part of the summer the weather had been very dry; so that the supply of water from either source was very small. As far as could be learned, the closet had not been cleaned since the autumn of the preceding year, and it was ascertained that the outlet into the sewer mentioned was eighteen inches above the lowest portion of the bottom of the vault, which was round. Moreover, the sewer was found to be partly stopped up; and when it was remembered, said Dr. Briggs, that the closet was in constant use by nearly 800 persons, some idea might be formed of the conditions prevailing at the time.

At his request, the closet was immediately washed out and disinfected. At the same time orders were given for the careful disinfection of all beds used by patients who had suffered from dysentery, and who had been removed to the hospital, and a solution of bichloride of mercury was ordered to be placed in the vessels of all who were affected with diarrhœa in any form. The good effect of these measures was immediately apparent, for while there were thirteen deaths from dysentery in June, and seventeen in July, there were only four in August, and none at all in September until the 25th of the month. In fact, only one death occurred among those who were attacked with dysentery after the closet was cleaned, and in this case the immediate cause of death was cerebral hæmorrhage. From August 10 to September 25 no new cases appeared. During the interval between July 18 and September 25, the closet was cleaned a number of times. For about ten days preceding September 25, however, the closet was not cleaned, and at this time a number of new cases and several deaths occurred. Certainly, Dr. Briggs thought, more conclusive proof could scarcely be desired of the causative relation existing between the condition of the closet and the appearance of the disease.

But there were still other facts that pointed strongly in this direction. Among the inmates of certain wards who made use of a closet in the main building, which was provided with school-sinks and was in excellent condition, very few cases of dysentery occurred at any time, and it was ascertained that among this few, in every instance those affected had used the general closet referred to, at least at times; while not a single case appeared among those who used exclusively the closet in the main building. Again, no cases of dysentery occurred during a period of nearly seven weeks, from August 10 to September 25 (when the closet was kept clean), at a time when a larger number of cases would naturally be expected than in June or July. Thus, in September, 1884, more cases occurred than in any one of the summer months.

This epidemic of dysentery Dr. Briggs thought interesting from the almost conclusive evidence presented of the causal relation existing between the exposure to the emanations of decomposing human excreta and the appearance of the epidemic. There could be no doubt, in his mind, that epidemic dysentery was an infectious disease due to the action of some definite micro-organism. There was much evidence, he said, to show that dysentery, under certain conditions, is contagious; but, apparently, like typhoid fever, it was generally a miasmatic contagious disease propagated by the stools of dysenteric patients. The difficulty of isolating from the stools the specific micro-organism which causes any disease of the alimentary canal was very great, and in conclusion he expressed his regret that he was not able to make any satisfactory investigations on this point.

The President, Dr. Leach, said that he had often met with obstinate cases of follicular enteritis and dysentery in some of the most expensive houses in New York, and that in most instances it was ascertained that the cause of the trouble lay in some defect in the drainage. He had known of a number of dwellings about which there had seemed to be a fatality, since several persons who had previously been in good health successively died of this kind of disease after having become residents of them.

The Secretary, Dr. Porter, said that a few years since he had occasion, in connection with the State Board of Health, to investigate an epidemic of dysentery occurring in a village on Long Island, in which it was found, by expert analysis, that in every instance the well-water of the premises where the case occurred was contaminated; and it was ascertained, furthermore, that the position of the privy in reference to the well was such that defilement of the water by human excreta was possible. His report of the outbreak was published in the second annual report of the New York State Board of Health (1882).

The next order of business was a paper by Dr. Gouley, in which he made a vigorous protest against indiscriminate cutting of the meatus urinarius. Of late years, he thought, the import of such consequences of urethral stricture of the balanic region, such as dysuria, vesical irritation, and "reflex neuroses," had been greatly over-estimated; this had often led to very rash and unwarranted surgical interference. Meatus cutting, or, to give it a proper technical name, porotomy, had, he said, become the fashion, and every adult and adolescent who is not afflicted with congenital hypospadias must have his meatus cut; for he is told that the nozzle of his urine-hose must be of greater calibre than the hose itself. The doctrine that the meatus should be the largest part of the urethra, Dr. Gouley continued, was not only unsound, but most dangerous, and was leading to much evil. It was, therefore, high time to protest against the indiscriminate performance, and particularly against those incisions which resulted in deformity of the urethra.

The congenitally narrow meatus was very often met with, and yet comparatively few patients were ever inconvenienced by this defect. In many cases the meatus barely admitted a catheter of the diameter of 3 or 4 millimetres, and in this condition it was, of course, necessary to enlarge it to a moderate degree by incision when the passage of a catheter or a lithotrite was required. But to incise the whole balanic portion of the urethra, through and through, was, he thought, as unwarranted as it was unsurgical.

Strictures of the balanic region were not ordinarily amenable to treatment by dilatation, but required incision, which was the most prompt and efficient method which could be employed for their eradication. The incision, however, should be directed and proportioned in accordance with the size of the glans and the condition of the extremity of the urethra. When, for instance, the meatus was normally situated, a sufficiently free central cut along the floor of the urethra answered the purpose of simply enlarging the contracted urethral extremity within proper limits; but when there happened to be a slight balanic congenital hypospadias, this kind of incision only increased the deformity, and failed to relieve the stricture; which could be successfully treated only

by bilateral porotomy, performed in such a way as not to increase the hypospadias.

The probable object of these extremely free incisions of the urinary meatus was that instruments of extremely large calibre might be introduced through strictures of the deeper parts of the urethra. This, Dr. Gouley went on to say, was another of the many surgical heresies now prevalent. The ostensible reason for this over-stretching of the urethra was that the stricture or strictures might not recur; but the careful observation of many cases treated by the introduction of sounds of the diameter of 11, 12, and 13 millimetres into the average human urethra showed that, while the stricture in some instances did not recur, the urethra, as an organic channel, was entirely spoiled. It became, as compared with a normal urethra, what an old, worn-out, hardened rubber tube was to one which had just come out of the maker's hands. The urethra, when constantly distended, soon lost a very considerable number of its mucous follicles, and became dry, leathery, inelastic, patulous, and no longer capable of successfully propelling the urine, which slobbered out of a wide mouth instead of being forced in a well-formed stream through a narrow outlet. The genital functions were also said to be impaired by this over-distension of the urethral canal.

Dr. Gouley expressed the opinion that it is never justifiable to over-distend the whole urethra. Useful instruments, he said, had been devised to obviate this evil, which were so constructed as to over-distend the strictured part of the urethra only, and save injury to the normal part of the canal, but they were but little used. Dilating instruments of this kind, he thought, should be occasionally employed during the treatment of strictures in the deep urethra; but the main object of moderate dilating catheterism was to restore the urethra as nearly as possible to its normal suppleness.

Dr. Frank Graner presented a specimen of extra-uterine pregnancy, in which the seat of the development of the ovum was in the Fallopian tube, close to the uterine orifice. At the autopsy the fœtus, which was apparently of the age of seven or eight weeks, was found among some clots in the abdominal cavity. There are three points of special interest about the specimen, viz: the presence of a decidua vera in the uterus, the sympathetic enlargement of the walls of the uterus, and the thickening of the posterior part of the Fallopian tube at the point of rupture.

Dr. Briggs presented, for Prof. Janeway, a specimen of primary carcinoma of the cystic duct, with abundant carcinomatous deposits in the liver and in the stomach. Its special points of interest were, the primary growth in the cystic duct, which is a very rare location for such trouble, and the marked difference between the primary and the secondary growths; the former being so insignificant as almost to escape notice, while the latter was of the most extensive character.

At the last meeting of the Academy of Medicine the subject of discussion was the value of quinine as an antipyretic in pneumonia. The opening paper was by Dr. J. H. Ripley, who based his opinions upon a series of carefully recorded experiments made during several years at St. Francis' Hospital in this city. The conclusion at which he arrived was, that quinine is a feeble and uncertain antipyretic in pneumonia. Nor was this all. It had a bad effect on the appetite and digestion, and not infrequently excited nausea and vomiting. In addition, it was liable to produce marked cardiac weakness, profuse cold perspiration and profound nervous depression. Opisthotonis was observed in one instance, and in a number of cases it caused epistaxis. In these cases the urine was examined before and after the ingestion of large doses of quinine, and in one the urine, previously normal, was found to contain albumen, hyaline casts, and renal mucus, after the use of the drug. These bad effects, he thought, more than counterbalanced any good results that could be attributed. He had not seen in any instance that it shortened the natural course of the disease, and he expressed himself as skeptical in regard to the alleged action of the drug in promoting cell migration. In some cases the pneumonic consolidation had extended under its use. Finally, he said that if an antipyretic effect were desired, it could be secured much more efficiently by such agents as antipyrin and salicylate of sodium.

The various speakers who took part in the discussion agreed in the main with Dr. Ripley, with the exception of the President, Dr. Jacobi, who said that he thought that the inefficiency of quinine referred to was due in a great many instances to the condition of the stomach incident to the febrile state of the system, which prevented it from absorbing the drug; and that the same was true of the rectum. In order to secure the full effect of the remedy, therefore, it was necessary to administer it hypodermically. He had been very successful with this method, and the preparation which he was now in the habit of using, on account of its great solubility, was the carbamide.

More cases of small-pox were reported during the month of January 1887, than in the whole of the two years 1883 and 1884; but this does not indicate a very alarming state of affairs, as there were only twenty-six cases reported in the first of these years, and five in the second. In 1885 there were 105 cases, and in 1885, 109. The disease appears, however, to be on the increase, and in order to prevent its further spread as far as possible, six extra sanitary inspectors have been appointed.

There has been introduced into the Legislature a bill doing away with the present Board of Health, and providing for a reorganization of the department with a High Commissioner of Health, to be appointed and subject to removal by the Mayor. The bill has been very carefully drawn, and it is to be hoped that it will be carried through for one reason, if for no others, viz.: that it will dispose of the present head of the department, General Shaler, against whom the Mayor long since preferred charges, but whom the Governor has thus far refused to remove.

Considerable excitement has been occasioned in Troy by the death of a number of individuals from water fuel-gas, by the escape of the gas from leaking

pipes into cellars, and thus up through the house, on premises where it was not used at all. It is a perfectly inodorous gas, composed largely of the deadly carbonic oxide, and it is likely that its manufacture and sale will be prohibited by law until this can be conducted in an unobjectionable manner. Certainly the experience of Troy proves that it cannot be introduced in a city with safety even for those who do not use it. P. B. P.

ELECTROLYSIS IN UTERINE FIBROIDS.

Dear Sir:—I note on page 79, of THE JOURNAL of January 15, 1887, 2d column, lines 56–64, the following: "Dr. William T. Belfield said: Dr. Martin has conferred a favor upon us in bringing Apostoli's method before us. During the last twenty-five years various attempts have been made to reduce fibroids of the uterus by the galvanic current; yet none of them have been recognized as successful, because, doubtless, as Dr. Martin very properly says, the current has been used in an ignorant, inaccurate and bungling way."

I remark as follows: "During the last twenty-five years" I performed the first operation on Mrs. Robert Pierce, of Melrose, Mass., August 21, 1871, so it is about sixteen years since electrolysis of uterine fibroids has been performed.

"The current has been used in an ignorant, inaccurate and bungling way." In the February and succeeding numbers, 1887, of the *American Journal of Obstetrics*, will appear the full account of the first fifty cases of electrolysis for uterine fibroids, to which the gentlemen named are respectfully referred. These cases are brought up to date as far as possible. The following points are of interest: Apostoli used currents of 1-25 to 1-5 ampère, with up to 200 applications in his cases, and reports no absolute cures. The report about to be printed shows a current larger than Apostoli's, the battery measuring 27 to 30 ampères, and from one to nineteen operations. The general résumé is, seven non-arrests, four deaths, twenty-five arrests, three relieved, and *eleven cured*. Since these first fifty cases there have been quite a number of cures. Respectfully yours,

EPHRAIM CUTTER, M.D.

1730 Broadway, New York, January 18, 1887.

AN INCORRECT WOOD CUT IN GRAY'S ANATOMY.

Dear Sir:—I have before me the tenth edition of Gray's Anatomy opened at page 925, on which page is a plate representing a view from within the pelvis. This cut is given to illustrate the anatomy of hernia, and especially the relation of certain blood-vessels to the hernial openings. Let the reader now turn to this cut in his Gray, *no matter what edition*, although the page may not be the same as the one given. In looking at the cut it will be observed that the large artery and vein are designated: "Femoral Artery," "Femoral Vein." These names are printed on the vessels. The names are incorrect at this point on these vessels. The artery is the *external iliac*, the vein the *external iliac vein*. The names femoral artery and femoral vein are not given to these vessels until they pass beneath Poupart's ligament. This plate serves to confuse the student in his studies of hernia.

It will be noticed that the deep epigastric artery is represented as originating from the femoral, so-called, just above Poupart's ligament. The point of origin of said artery is correctly given, but it is from the external iliac and not the femoral. Correct the names of the large blood vessels mentioned and confusion will disappear. I am surprised to find this same wood cut reproduced in Stimson's Operative Surgery.

It would be well for the editors and publishers of Gray's Anatomy to have this plate corrected in their next edition. A. C. SIMONTON, M.D.

AMERICAN MEDICAL ASSOCIATION.

Dear Sir:—Lately in THE JOURNAL you made an appeal for papers to be prepared for the next meeting of the Association in Chicago, June next. In local societies the great difficulty lies in the selection of a subject. So often have papers been prepared based upon a single case that they have come to be looked upon as an advertisement of the writer. Would it not be well for the chairmen of Sections to select subjects in their various departments, and by correspondence learn who will write upon them? or publish a list of subjects in THE JOURNAL, with a request that those who would write upon them should inform the chairman, either personally or through THE JOURNAL. The members of the Association would, by this means, know what papers they could expect, and prepare themselves beforehand for their discussion. It seems to me in this way an interest would be excited that would attract attention, and both authors and disputants be benefited. It is very difficult, on the spur of the moment, to discuss any subject meritoriously and satisfactorily to either party. All special papers should be announced through THE JOURNAL at least one month in advance of the annual meeting, giving title, etc., with a brief intimation of what the writers propose to set forth in their papers. Yours truly,

WILLIAM BRODIE, M.D.

Detroit, Mich., January 27, 1887.

PSEUDO-MEMBRANOUS BRONCHITIS.

Dear Sir:—While reading, in THE JOURNAL, the report of a case of pseudo membranous bronchitis, by Dr. H. A. Johnson, and the discussion of the same, I called to mind a case in the Boston City Hospital. The case was acute and diagnosis not perfectly clear, but the autopsy showed a fibrinous false membrane lining the bronchi. I remember seeing perfect casts of the bronchi that he expectorated. If diphtheria could be excluded, it would leave acute pseudo membranous or fibrinous bronchitis as the diagnosis. Thinking the report of the case might prove of interest to one in writing upon the subject,

I would refer to the account of the case as published in the *Boston Medical and Surgical Journal*, of March 1, 1883. Yours respectfully,

HERBERT S. JOHNSON, M.D.

16 John St., Lowell, Mass., Jan'y 21, 1887.

INTERNATIONAL CONGRESS.

TRANS-ATLANTIC RATES.

For the information of our foreign brothers who propose to attend the meeting of the International Medical Congress, which takes place in Washington, D. C., on the 5th of September next, the following rates of travel across the Atlantic ocean have been submitted and recommended for their acceptance:

Red Star Line—$100, Antwerp–New York and return.

Inman Line—$100, Liverpool–New York and return.

Hamburg Line—$90, Hamburg–New York and return.

Royal Netherland—$80, Antwerp–New York and return.

The committee have proposed that each delegate shall have the privilege of bringing with him, at the same rate of expense, two lady members of his family, and believe that proposition will be accepted by those lines selected. Steps have also been taken to ascertain, at each of the four ports, Havre, Liverpool, Antwerp and Hamburg, the exact number of persons who will embark at these ports entitled to this reduction of rates. All further information on this subject will be promptly published in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

A. Y. P. GARNETT, M.D.,
Chairman of Committee of Arrangements.

MISCELLANEOUS.

WOMEN DOCTORS FOR INDIA.—The London *Graphic* says: Lady Dufferin appeals to the women of England to subscribe what they can to the funds of the National Association for supplying female medical aid to their dusky sisters in the East. It is a most laudable undertaking, very large numbers of women in India being without medical attendance during sickness. They would sooner die than allow a man to see them, and they have, therefore, to trust for their recovery to the old wives' remedies which are among the traditions of zenana life. Now, however, that education is beginning to invade the sacred precincts of the *purdah*, the inmates are no longer content to trust their lives to ignorant crones, who are more skilled in distilling poisons and witchcraft than in useful medical lore. The demand, therefore, for women doctors from England is a genuine one, and not one of those philanthropic "fads" which are too often palmed off on the British public. There is another feature, moreover, which should commend the appeal even more to our favor. Rumor says that the number of lady doctors in England is multiplying far more rapidly than are openings for practice. But in the East they have a splendid opportunity before them, in the multitudes of native ladies whose husbands can afford to pay substantial fees. They would be safe, too, from masculine competition, nor would they feel that they were intruding upon a province not belonging to them by right. Indeed, so promising is the enterprise that one can only wonder an exodus of lady doctors bound for the East did not take place long ago. There is one matter, however, in which they must be very careful, to respect native prejudices. It is said that some of them sedulously cultivate masculine manners and appearance, in order to gain the confidence of their patients. This will not do in India; the Asiatic husband is very suspicious, and would probably detect in the supposed female Hakim an enterprising Feringhee bent on making surreptitious love to his many wives behind the *purdah*.

A GOOD RESOLUTION.—At the recent annual meeting of the Ohio State Board of Health, Dr. Jones introduced a resolution requiring that every railroad company doing business in Ohio shall carry on its trains an emergency case, which shall contain bandages, cotton, and other things desirable in accidents, and that employes shall be instructed in their use by the surgeon of the road.

HYPNOTISM AND POLITICS.—While Charcot is electrifying Paris with the results of his hypnotic experiments at the Salpetrière Hospital, Virchow, in Berlin, for the nonce has withdrawn from "The Battle of Cells and Bacteria" and is fighting the battles of his party against the redoubtable Von Moltke.

DR. JOSEPH TABER JOHNSON was elected President of the Medical Society of the District of Columbia at its last annual meeting.

THE CODE.—The cheap reprint edition of the Code of Ethics of the American Medical Association is now ready. Physicians, or others, wanting single copies should send to the Editor of THE JOURNAL three cents in stamps. One hundred copies, $2.00

ST. LOUIS MEDICAL SOCIETY.—*The Weekly Medical Review* says: In the fifty years' history of this Society no administration was more successful than that of the president, Dr. E. H. Gregory. It also pays a high compliment to his successor for 1887, Dr. S. Pollak.

THE CHICAGO HOSPITAL FOR WOMEN AND CHILDREN.—Mrs. George M. Pullman gave an amateur theatrical entertainment at the Pullman residence on Tuesday evening, which netted $1000 for the hospital.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 22, 1887, TO JANUARY 28, 1887

Lieut. Edward R. Morris, Asst. Surgeon, granted leave of absence for one month, to take effect about March 10, 1887, with permission to apply for an extension of twenty days. S. O. 6, Div. Pacific, Jan. 19, 1887.

ORIGINAL ARTICLES.

CAN THE CÆSAREAN SECTION BE SAFELY SUBSTITUTED FOR CRANIOTOMY IN THE UNITED STATES AT THE PRESENT TIME?

Read before the Medical Society of the District of Columbia, January 12, 1887.

BY JOSEPH TABER JOHNSON, M.D.,

PRESIDENT OF THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Much interest has been excited of late in the improvements which have been made in the ancient and time-honored operation of the Cæsarean section. To Dr. Harris, of Philadelphia, are we mostly indebted for this revival of interest. He has repeatedly pointed out that this operation, which, in the past, has been regarded as almost universally fatal to the mother, can now be performed with great safety, and with the result of saving more lives, when resorted to early, than by any of its alternatives. This statement is made by Dr. Harris after collecting the histories of a comparatively large number of cases in this country and in Europe. These remarkable results have been achieved by a few men, mostly in Germany, who have had a large experience in abdominal surgery, and who brought to their assistance the many improvements which a number of operators had been gradually making, in different parts of the world, in the Cæsarean section for many years. These successful operations have aroused the enthusiasm of a few writers to such a degree that they have been led to declare, with great fervor, and an eloquent display of statistics, that craniotomy upon the living fœtus would hereafter be unjustifiable, and that the improved Cæsarean section must not only be the operation of election in the future, but of necessity also. Thus Dr. Meadows, of London, within the past three months, in a paper read before the British Gynecological Society, upon "The Total Abolition of Craniotomy," was so carried away with the wonderful and surprising figures of Dr. Harris, that he exclaimed, in a sudden burst of enthusiasm: "Where, I ask, is craniotomy now?" Dr. Meadows quite convinced himself, but, according to the record, none of his audience, that craniotomy should be forever abolished from the list of justifiable operations. It was generally agreed, in the discussion which followed, that the best thing ought to be done; that whenever the Cæsarean section offered the best chance it should, of course, be urged upon the family, but that there would always remain a certain small proportion of cases, mostly in primiparæ, where craniotomy would have to be performed.

When this subject was discussed in another society, in our city, two years ago, I took the ground strongly that past experience, as well as the teaching of nearly all the text-books in use by the colleges, declared that craniotomy, when indicated, should be considered the operation of election, and the Cæsarean section the operation of necessity.

In view of the growing success of "the improved Cæsarean section" abroad, and of my growing interest in abdominal surgery, I am inclined to change my views, exactly reversing the position stated above, making the Cæsarean section the operation of election, when possible. This, of course, leaves craniotomy as the operation of necessity; and when necessary, therefore, I would feel compelled to resort to it. I cannot agree with those writers who would entirely abolish it, and who denounce craniotomy as "child murder," as an "abominable crime," as that "murderous operation," as "killing the infant," as the "deliberate and cold-blooded murder of an unoffending child," etc. I think craniotomy, even upon the live child, *may become* a perfectly justifiable operation under certain exceptional circumstances.

Science advances, and as new facts come to our attention, and as the success of abdominal surgery strides on with such surprising and startling rapidity, we are entitled, without being considered inconsistent, to change our views, and to be convinced, by the onward march of events, that new practice, based upon late experience and improved statistics, may be better and safer than the old.

While I should be slow, as a teacher of obstetrics, to allow the writers in the ephemeral and frothy medical journals of the day to offset, with a few newly-acquired statistics, the crystallized teachings of the regularly authorized and recommended text-books, new as well as old, for the guidance of students and practitioners of medicine, I should hail with infinite satisfaction any practice which would give to the mother a better chance for life than craniotomy offers, and at the same time, while not diminishing her chances, afford us an opportunity of saving the child also. I do not think it is sound practice to be governed by the mere statistical intent to save the greatest number of lives without any reference to the value of those lives. The Cæsarean sectionists use an argument which sounds well, and which, for statis-

tical purposes, would undoubtedly carry a point, and perhaps an audience; inasmuch as by the performance of the Cæsarean section more lives could possibly be saved for the census to record among the inhabitants of our country than as if craniotomy were sometimes done. Of course, 50 per cent. of the "lives involved" are lost, as well as a very small per cent. of the mothers, but I thought, when I heard an argument some time ago upon this subject, that the speaker rather strained a point, when he added the 50 per cent. of the already dead or sacrificed fœtuses to the ascertained mortality to the mothers, of the craniotomy operation. I doubt if every one would stop to think about the unborn children, when the mortality of craniotomy would be stated, upon this basis of calculation, to be 50 per cent. higher than the deaths of the mothers would properly place it. Thus, of 100 craniotomies, if the mortality should be stated to be 60 per cent, the general reader might think that sixty of the mothers had perished as a result of the operation; when, according to this mode of making statistics, the statement would mean the death of fifty fœtuses and only ten mothers.

We cannot, as conscientious physicians, be bound in our practice by cast-iron rules, whether they are medical, ethical or theological. As long as the good Lord continues to make human beings to differ so widely from each other, just so long shall we be compelled to judge each case by its own peculiar symptoms, environment, vital force, extent of deformity or obstruction; and be governed to some degree by the wishes of the patient who engages our services.

This is a free country and we, of course, have the inalienable right to refuse to remain responsible where our advice is rejected. But the patient has the same right to refuse to have an operation done which gives her so little chance of recovery as even the improved Cæsarean section does in this country.

If we are in attendance upon a case of midwifery which lasts longer than twenty-four hours, where the powers of the patient are showing positive signs of failure, where the forceps have been tried a number of times and failed, where the head is too far down to resort to version, and where, in order to save the now rapidly sinking mother, a corps of consulting physicians submit to the agonized husband and wife the sad alternative of craniotomy or some modification of the Cæsarean section, and they refuse to permit a cutting operation to be done—what is the attending physician to do? Suppose he has bound himself by some cast-iron rule, or allowed somebody else to bind his hand and his conscience for him, never, under any circumstances, to destroy what little life is left in the long compressed and nearly lifeless unborn fœtus—is this woman (who has engaged this physician to see her safely through her labor) to be left in jeopardy while the fœtus is given the precious hours, to become unmistakably dead, which may decide adversely the fate of the mother also! Those who would refuse to do craniotomy upon the live child, but would be willing to do it if the child were surely dead, will sometimes, while obeying their cast-iron rule, let the mother slip through their fingers also. I should hold with Barnes upon this point, who says, on page 845 of his Obstetric Medicine and Surgery:[1] "On the continent especially, it is still urged by some to wait until the child is dead. If it be admitted—and the conditions of the case involve these postulates—1, that the child cannot come through alive; 2, that the operation is undertaken in order to save the mother, waiting till the child is dead is opposed alike to reason and to humanity. It seems a refinement of casuistry to distinguish between directly destroying the child, and leaving it exposed to circumstances which must inevitably destroy it, and it is risking the very object of our art, to wait for the lingering death of the child until the mother's life is also imperilled."

In speaking of the Cæsarean section, on page 855 same work, Barnes says: "If the operation could be done at a chosen moment, and so improved as greatly to increase the probality of saving the mother, then the already high probability of rescuing the child might turn the scale in favor of the Cæsarean section and against craniotomy. Unfortunately, art has not yet reached this point. The mortality to mothers from the Cæsarean section is still so great, whilst that from embryotomy, in fitting cases, is so small, that we are unable at present to raise the Cæsarean section to the rank of an elective operation."

In view, however, of the success of the improved Cæsarean section, I should be inclined to hold with those who would, if they could, raise the Cæsarean section to the rank of an elective operation; but we should hold ourselves free, in case this elective operation were not elected by those who had the right to vote, to perform craniotomy, upon the live child even, if we believed that by doing so we could save the mother. I should agree with Lusk, 1885 [Science and Art of Midwifery, p. 425] that "If in any case the decision is left to the physician, he should regard the welfare of the mother as of paramount importance. . . . The duty of the physician is, however, to his patient. He is not to constitute either judge or executioner."

As the work of Prof. Parvin has been published within the past month, it may be of interest to record his views as the latest authoritative statement from an American stand-point. Professor Parvin says, upon page 650 of his book:[2] "Some, indeed, have had so strong a repugnance to directly sacrificing the life of the child, that they have done it indirectly, waiting until it died before resorting to the operation; thereby in no sense evading the responsibility for its death, and, at the same time, this delay has added to the perils of the mother.

"The principle of morals upon which most obstetricians rest the right to sacrifice the child for the sake of the mother is a very old one, and has met with general acceptance. That principle, clearly enunciated by Cicero, for example, and sustained, in general, by moralists of all ages, is, that if two lives are in such peril that both cannot be saved, but one will be, by the sacrifice of the other, let that life which is of the least value to the State or to society perish. It is unnecessary to show that the adult woman, with her various domestic and social duties, has a life of

[1] Published in 1885 [only last year].
[2] Science and Art of Obstetrics.

greater value than that of the unborn child, and therefore, while the duty of the obstetrician is to save both when he can, if either is to be sacrificed, let it be that of the latter—in other words, if, in a given case, embryotomy is a less risk to the mother than Cæsarean section, the former should be selected. This is a rule of obstetric ethics which cannot be set aside."

There is an element of unfairness in comparing the statistics of craniotomy as given by Tyler Smith in his book, written as far back as 1858, and by Churchill about the same time, with the improved statistics of 1884–5–6 of the Cæsarean section, done under all the detail of the antiseptic methods, and in the light of all the wonderful improvements in abdominal surgery.

It is my belief that more *mothers* would be saved, and would be put to much less pain and in much less danger, by the "timely" performance of craniotomy, done under all the antiseptic precautions, than by the "timely" performance of the improved Cæsarean section, if we judge by recent reports of the mortality attending this operation in the United States. It is my belief, also, that more *lives* would be saved, if we include those of the unborn fœtuses, by the timely performance of the improved Cæsarean section than by craniotomy, and as the Cæsarean section is a much more conservative and clean surgical procedure than the "horrid and detestable operation of craniotomy," as it is now called by some, I should, with my knowledge of abdominal surgery, *greatly prefer to* do it. One of the chief points I am arguing against is, that it is cruel, unscientific, and impracticable to be bound by any inflexible rule in the management of these unfortunate patients. To "utterly abolish craniotomy," as recommended by Meadows and a few others, would leave us with our hands tied in some cases, and subject us to the mortification of being superseded by a physician who was governed more by the circumstances and necessities of this particular case, than by an unscientific prejudice. Our minds and hands should be free. Cases differ; people differ; obstructions differ; vital force, and the dispositions of patients, so differ that, as conservative physicians, we should act as the requirements of each case are presented to us. A timely and successful Cæsarean section, done before the patient had been exhausted by long-continued, various and unsuccessful efforts at delivery, cannot be fairly compared and quoted against an unsuccessful craniotomy, performed upon a woman who had been in labor several days, who had the forceps tried a dozen times by half as many doctors, who had completely exhausted themselves in their fruitless efforts to pull out the child, and finally, when they are worn out, in the middle of the night, perhaps, and by the aid of a tallow candle, with imperfect instruments, poor assistants and no antiseptics, they do a bungling craniotomy, through parts swollen, dry, and ready to lacerate or inflame.

It is no argument, in favor of always doing the Cæsarean section, because a woman succeeds in doing it upon herself with a carving knife, and closes the abdominal wound with sticking plaster. Neither is it just the thing to compare the marvelous results of Leopold and Sänger, in saving seventeen out of nineteen mothers, and all the children, by the improved Cæsarean section, when they bring to bear all their skill in abdominal surgery, have a corps of trained assistants and nurses scarcely less able than themselves, with craniotomy done under the circumstances just named, by inexperienced operators, and under the worst possible circumstances for success. Such comparisons are odious as well as incorrect. In the practice of medicine or surgery, it is very difficult to make correct comparisons, the cases are so dissimilar.

In Germany physicians can control the circumstances of their operations, and their patients, better than we do in this country. They have better and more opportunities to perform timely Cæsarean sections than we do in the United States. Having more cases of pelvic deformity than occur in America, they have made more thorough and correct studies in pelvimetry than we have, and make their diagnosis and perform their operations earlier than we do, and consequently, I believe, save more of their patients.

An early diagnosis, and the consent of the patient and her friends, to an early Cæsarean section, is more than half the battle. One reason, I believe, for the unwillingness of these unfortunate women, and those directly interested in them, to have this operation done early, is the belief of their physicians, as well as their own fear, that the result will be fatal; and they delay, and resort to other and unavailable means, until they have frittered away golden moments which cannot be regained.

Dr. Harris reports that there has been done, in this country, 144 Cæsarean sections, saving fifty-four or 37½ per cent. of the mothers; (and emphasis seems to be laid upon the point that sixty-four children were living when delivered. Perhaps a dozen or more of those children were dead in less than a week, and perhaps only twenty or ten lived to grow up.) According to the same authority, the first fifty Cæsarean sections done in the United States saved 54 per cent of the women. The last fifty Cæsarean sections done in the United States has saved but 24 per cent., a progress in the wrong direction of over 50 per cent. Dr. Harris adds to this sickening statement the information that, "operations performed in good season, when the condition of the woman was favorable, have saved 75 per cent. of the cases in this country, and 80 per cent. of the children."

These facts must have been culled from a few isolated cases, inasmuch as the last statement of operations done in the last decade, and seven months added to it, "ending August 1, 1886, there were thirty-seven Cæsarean sections—saving only eight women, or 21 23-37 per cent." Thus, with all the improvements in antiseptic abdominal surgery, in the last decade of the 19th century, in the United States, nearly 84 per cent. of the women operated on died. So that, in our country, instead of the statistics improving, they have been steadily growing worse and worse, as shown in the following late statistics and letter of Dr. Harris:

September 17, 1886.	
Cæsarean operations of the United States	144
Women saved, 37½ per cent.	54
Children living when delivered.	64
First 50 operations, saved 54 per cent.	27
Last 50 operations, saved 24 per cent.	12
Operations for decade ending Dec. 31, 1855	25
Women saved, 48 per cent.	12
Children living.	13
Operations for decade ending Dec. 31, 1865	24
Women saved, 45 5-6 per cent.	11
Children living.	10
Operations for decade ending Dec. 31, 1875	36
Women saved, 27 7-9 per cent.	10
Children living.	11
Operations for 10 7-12 years, ending Aug. 1, 1886	37
Women saved, 21 23-37 per cent.	8
Children living.	16
Late operations, nearly 84 per cent. of this division	31

Operations performed in good season, when the condition of the woman was favorable, have saved 75 per cent. of the cases in this country, and 80 per cent. of the children.

It will be seen by this record that the number of operations is gradually upon the increase, and that the results are steadily becoming worse year by year. If we take the last five years—August 1, 1881, to August 1, 1886—we have nineteen operations, ending fatally in seventeen cases, saving but 10 10 19 per cent. Of the children, fourteen were also lost; of which two were destroyed by craniotomy, and one had its skull fractured by the forceps. In this list is not included an operation upon a moribund woman, performed in the interest of the fœtus.

This is a frightful picture! In fact, it makes one sick at heart, in view of the fact that Europe, by the Sänger method, has saved 78 per cent., or 26 women out of 33; and 31 children.[3] There has been very bad management somewhere, and I am inclined to believe that much lies in the fact that American obstetricians have not paid sufficient attention to pelvimetry, and are wanting in the skill that has been acquired in the maternities of the old world, by which they first determine the possibilities of delivery *per vias naturales*, and finding the measure of obstruction, resort promptly to the knife without endangering the life of the woman by intermeddling and useless delay. ROBERT P. HARRIS.

Great stress has been laid by those who would always do the Cæsarian section, and never consider craniotomy justifiable if the child was not known to be dead, upon the recent successes in the Cæsarean section by the "Sänger method" in Germany. But Germany, unfortunately for this argument, is not the United States. To quote from recent authority in the October number of the *American Journal of Obstetrics*, page 1021, by Garrigues, who claims that the Sänger method should as properly be called by his name as by Sänger's, and further, that there is really nothing in this "method" after all, as the most successful operators get on better without using it—Garrigues says: "It is of particular interest to see that one operator, Prof. Leopold, of Dresden, has operated nine times, saving eight women and all the children. The two maternity hospitals, of Dresden and Leipzig together, have had sixteen operations with fifteen maternal recoveries, and the survival of all the children." This, I am glad to admit, is a most successful and glorious record, and one which American operators should strive to equal. But it is not fair or correct to state this phenomenal success as the present standing of the improved Cæsarean operation. You might as well quote the phenomenal success of Mr. Tait, in doing 146 ovariotomies without a death, as the present happy standing of ovariotomy throughout the world, and expect others to obtain the same results.

Garrigues evidently had this same thought in his mind when he wrote, less than a month ago, page 1021—"It is not to be expected that this record will be kept up to its present standard. So far, the excellent results are *due to the fact that* so large a proportion of the cases have been operated on by one man, and a still larger proportion by a few men, all intimately connected, all perfectly familiar with antiseptic precautions, and skilful gynecologists. It is to be expected that when the operation becomes so popular that it is performed by many, and less well prepared operators, the results will again decline proportionately."

Garrigues says, "further, on the other hand, I am not prepared, with several authors, to teach that the improved Cæsarean section should be substituted for craniotomy, and to stamp, as an abominable crime, the destruction of the living fœtus, if by such a sacrifice, there is reasonable hope of a safe delivery for the mother. We must remember that similar antiseptic precautions to those upon which success in the new operation seems *exclusively to turn*, have benefited the operation of craniotomy."

Garrigues then refers to three recent craniotomies done by himself, two upon the living fœtus. All the mothers made an excellent recovery, and at no time presented any serious symptoms—one of them did not even have the slightest fever. In view of the recent successes in the Poro operation, I should feel disposed, in cases where there was a demand for the Cæsarean section, and the parties interested consented to have it done, to go still farther, and remove the uterus, or at least the ovaries and tubes, and thus make it forever impossible for the woman to be environed by the same dangers again.

It has been demonstrated that the success of repeated Cæsarean sections on the same person is greater than first operations, but is nevertheless, a dangerous procedure. I am convinced that the failure of the Cæsarean section to succeed in our country is largely owing to the fact that the operation is performed after the patient has been worn out by prolonged and useless efforts to deliver her. If physicians and patients only believed this operation was the best one to perform and that it should be done early, and that it did not mean sure death, as so many seem to think, this obstacle would be removed and the door opened to a more successful future. Until we can do better than to lose 29 out of the last 37 Cæsarean sections, in the United States, we cannot bind ourselves never to do craniotomy, even upon the living child. According to Harris, of the last nineteen op-

[3] Medical News, Philadelphia, Sept. 18, 1886, p. 317.

arations, (C. S.), seventeen of the mothers died. These nineteen Cæsarean sections were all done within the past five years, and fourteen of the children were lost, a not very brilliant show for American operators. Garrigues saved more mothers than this by doing his three cases of craniotomy. It cannot be claimed that the results would have been improved by the practice of the Sänger method, inasmuch as there have been five Sänger Cæsarean sections done within as many years in the United States, and every one of the women died promptly.

There is something radically wrong, I fear, in our teaching as well as in our practice. If we could control the circumstances and environment of our patients as surgeons do in Germany, I believe we could succeed as well as they do; but physicians as well as people will require a good deal of educating, evidently, before such a happy state of things will be reached in America. While therefore, I should greatly prefer to do the Cæsarean section and should consider it, if called in time, the operation of election, I cannot see that we have reached a position in this country, which would give us the right to "totally abolish craniotomy," and substitute for it at present, an operation which I have shown is so seldom successful as even the "improved Cæsarean section."

I subjoin as an appendix to my paper (with the kind permission of the author, Dr. Wm. H. Parish, of Philadelphia, whose entire article will appear in the forthcoming volume of the Transactions of the American Gyecological Society) extracts from that portion of his paper relating to the Cæsarean section in the United States, and also remarks of Dr. Robert Barnes on Dr. Meadow's monograph referred to above, and which I adopt as a part of my paper.

APPENDIX.

Let us now turn to the mortality attending all Cæsarean operations in the United States. Of 144 operations only fifty-four or 37½ per cent. of the mothers have recovered. Ninety mothers died out of 144 operated on, a truly frightful mortality.

But many of these operations were performed before abdominal surgery had attained its present high degree of success. Has the Cæsarean operation profited by the conceded recent surgical advances? Let us see: Of the fifty operations first performed in the United States, twenty-seven of the mothers, or 54 per cent. recovered; and of the last fifty operations, only twelve of the mothers—*i. e.*, only 24 per cent. recovered. The mortality has steadily increased during recent years, until of thirty-seven women last operated upon, twenty-nine have died; and of the last nineteen operations, seventeen of the mothers have died—a horrible mortality! In these nineteen last cases, all occurring during the last five years, there were fourteen dead children. In the last nineteen Cæsarean sections, then, there were only two mothers saved, and only five children survived. Should not American surgeons and obstetricians hang their heads in shame at such a showing? Is it not time that we should look into the reasons for such shameful fatality following this operation in this country? The results in Europe show with certainty that such terrific mortality is not inseparable from the operation, when rightly done under proper conditions.

The two prime factors in producing such fatality are, doubtless, delay in performing the operation, and the attempts made at other methods of delivery before making the section. Look at the number of children dead, when the operation began! The death of the child could not have been due to the operation, but must have been produced prior to its performance. Of the 144 operations, eighty children were dead. What caused their death? Quite certainly, either manual or instrumental interference, or prolonged uterine contraction. The eighty dead children mean eighty cases either of prolonged labor, or of injudicious interference in some other way by the physician. Eighty dead children mean eighty cases in unfavorable condition for the operation. Notice that there were eighty dead children and ninety dead mothers. How nearly the numbers correspond!

The mortality in this country is attributable largely, then, to delay in operating, or to attempt at delivery with forceps, by version, or by craniotomy. Why this delay, and these injudicious resorts to other methods of delivery? First, The profession has been educated to believe that the operation is almost necessarily fatal; and statistics have been quoted to prove its terrible mortality. We have also taught, in text-books and in lecture halls, that the Cæsarean section is not an operation of election; it has been declared by authority to be the most dangerous operation in surgery. The practitioner has been demoralized into great dread of it; and he is prepared to undertake any other measure first. I have heard a once prominent teacher, now deceased, instruct his large classes, in cases of deformed pelvis, if in doubt: first to try the forceps, and if unsuccessful, to try craniotomy; and if this fails, then to try the Cæsarean operation. It would be equally, or more rational, in the management of an ovarian cyst: First, to try tapping; and if the cyst refilled, to try injecting with iodine; and if not then successful, to try drainage of the cyst; and if that failed to perform ovariotomy.

The delay is not, however, dependent solely upon the dread of the operation: It has frequently resulted from failure to recognize early the degree and character of the obstruction. In the United States large cities and large maternities are few, and medical schools are numerous, and the lectures are too limited in time, and students are taught but little of pelvic deformities and of obstruction in the soft parts. Pelvimetry is almost a closed book, and most young men, entering into private practice, have never seen even a normal labor, nor measured a pelvic canal. Is it surprising that, even later in life, they often cannot determine the degree of pelvic contraction, or of obstruction, when such exists? They cannot recognize the indication for the Cæsarean operation, hence, in part, the delay; or resort to forceps, version, or craniotomy.

The recent European success cannot be ascribed solely to the Sänger method of treating the uterine wound. Notice that in thirty-three operations by this method, in Europe, thirty-one children were saved. What does this indicate? It demonstrates that the operations have been performed early in labor; that forceps, version, and craniotomy had not been resorted to. It demonstrates that the obstetrician recognized promptly the degree of contraction, or character of obstruction; saw the indication and had sufficient confidence in the result to resort at once to Cæsarean section. The saving of 78 per cent. of the woman, under the Sänger method, does not mean that this result was attained merely because of that invaluable method; for in this country there have been five Sänger operations, and all have terminated fatally.

I submit that, in this country, we must recast our views and our teachings as to the dangers attending the Cæsarean operation, and as to the indications for its performance. Medical students must be instructed more fully in the recognition of degrees of pelvic obstruction, so that it will not be necessary for the physician to learn through delay, or through failure with forceps, version, or craniotomy, that a Cæsarean section is demanded.

In the performance of the Cæsarean operation, I will also submit a few essential rules:

1. At once carefully determine the degree of obstruction, and operate early in labor—*i. e.*, as soon as the os is sufficiently dilated to permit drainage of the lochia, and before the rupture of the membranes. Delay is fatal.

2. Operate with full antiseptic precautions; for, of all abdominal operations, no other demands so absolutely that asepsis should be secured; but the spray over the abdomen is unnecessary.

3. Control hæmorrhage by compression of the cervix, either manually or with rubber tubing, but preferably manually.

4. Introduce numerous deep and superficial sutures so as to approximate accurately the muscular walls and serous surfaces of the peritoneum; but do not carry the sutures into the endometrium. The removal of a section of the muscular wall is unnecessary.

5. Carefully protect the peritoneum from contact with fluids, and make a careful toilet of that membrane, if perchance it has been soiled.

6. Administer ergotine hypodermically at the beginning of the operation.

[Remarks of Dr. Barnes, in the discussion on the paper of Dr. Meadows, which he read before the British Gynæcological Society 13th October, 1886, in which he favored the total abolition of craniotomy:]

Dr. Barnes said he disclaimed the part of apologist of craniotomy. He earnestly hoped the time would come when this revolting operation might be abolished. He had worked hard towards this end. Some of the most trying hours he had ever spent had been caused by the conflict between the duty of saving a mother at the sacrifice of her child, and of seeking the safety of the child at the imminent risk of the mother's life.

The problem would be nearer solution could we bring the Cæsarean section in some form to such perfection that the mortality attending it would be reduced to the mortality attending craniotomy. And here he disputed the validity of the statistics cited by Dr. Meadows. Dr. Meadows put the mortality of the Cæsarean section according to Sänger's method at 20 per cent. Admitting this for the purpose of argument, and admitting further that the operation might be so improved as to attain an even smaller mortality, he would still most emphatically protest against the statement that the necessary mortality attending craniotomy approached 20 per cent., or even 5 per cent., excluding the cases of extreme pelvic contraction which forbade the hope of extracting the child after craniotomy, and which all acknowledged should be treated by the Cæsarean section. Craniotomy, done under fair conditions, such as are postulated for the Cæsarean section—that is, done at a chosen time with due skill—did not involve any maternal mortality. This being so, we were driven to fall back upon the long-recognized claim of the mother to be first considered. Now, assuming that twenty mothers out of one hundred, or even ten, or even five, were sacrificed to the Cæsarean section in order to save, say ninety children, might not those doomed mothers rightly plead their prior right to be saved? Her life is in our hands; the circumstances hardly admit of her forming a just judgment. We have to act for her, and are we not bound to do our utmost to save her?

On the other hand, the case for the child is undoubtedly strong. By Cæsarean section there is a strong probability of its survival; under craniotomy it is certainly destroyed. But this does not represent the whole case. This is what happens: A woman, with a minor degree of contracted pelvis, not admitting of the delivery at term of a live child, is delivered by craniotomy. She recovers, and time after time in subsequent pregnancies, labor being induced at seven or eight months, she bears a live child. Add these children saved to the mother, and it might happen that the aggregate lives, maternal and infant, saved by craniotomy would compare favorably with the aggregate saved by Cæsarean section.

Undoubtedly very much had been gained, and much more would be gained, in the direction of lessening resort to craniotomy. Still he feared he must feel that the abolition of craniotomy was as yet an aspiration, and not an accomplished fact.

THE TREATMENT OF CROUP WITH DIGESTIVE SPRAYS.

BY GEORGE MINGES, M.D.,

OF DUBUQUE, IOWA.

Pseudo-membranous laryngitis is always a grave affection, even under the most favorable circumstances, and any treatment which promises even slightly to diminish its mortality, is worthy the earnest attention of practical physicians. Four thousand

deaths are said to occur from it annually in England. If I offer here the tedious description of a series of cases treated by a method not new in principle, and attended by results not very brilliant, I hope that my communication may be received in a scientific spirit. I lay claim only to great perseverance in the treatment described, and I hope to prove that its details are readily carried out by parents, and kindly submitted to by the little patients.

I have treated sixteen cases with inhalations of solutions of one or the other of the digestive ferments, thrown in a spray by a steam-atomizer. The list includes sporadic, sthenic cases, as well as those of an asthenic nature, secondary to diphtheria of the fauces, and one secondary to measles. Two successful cases in which I at the time diagnosticated croup below the vocal cords, I have decided to ignore in estimating the results of treatment, having probably misinterpreted the phenomena, although Gerhardt states that all the symptoms may be absent in diphtheritic laryngitis, while they may be present in other diseases causing laryngeal stenosis. One fatal case I must also exclude, patient having been in the asphyxic stage when treatment was begun.

Let us now see how far the diagnosis can be substantiated in the remaining thirteen cases, by examining the following points:

1. The Presence of Membrane in the Fauces.—There is great diversity of opinion as to its significance. Most of the older authors, and most American and British authors to-day, recognize two distinct diseases, true membranous croup and laryngeal diphtheria; yet most of these even, and among others Wagner, admit the presence of an exudation in the fauces also in the former disease, although secondarily; while many unicists, among them Steiner, admit the existence of a localized laryngeal diphtheria. Niemeyer, a dualist, takes it for granted that the stenotic symptoms are caused by a coexisting laryngeal membrane when an exudation is visible in the pharynx. With Squire a single point of pharyngeal exudation decides for diphtheria of the larynx, while Monti, although he believes croupous laryngitis to be much rarer than diphtheritic, if I understand him correctly, thinks that croupous laryngitis may occur as a complication of faucial diphtheria.

In seven of my cases a distinct membrane was seen in the fauces. Now, we may think it tolerably certain that a pseudo membrane caused the obstruction in these seven cases at least; but the coexistence of catarrhal laryngitis with pseudo-membranous pharyngitis, first described by Trousseau, which J. L. Smith thinks must be rare, is said by Guersant to be quite frequent among the children of the upper-classes in Paris. I can see how the hyperæmic swelling surrounding a diphtheritic patch might extend to the epiglottis or vocal cords and produce symptoms of laryngeal stenosis, and I can also imaging the existence of a very small spot of exudation in the larynx without giving rise to much obstruction, so that any treatment would seem to abort the disease.

2. Dyspnœa.—Unless we have watched the development of croup secondary to some other disease, we generally find the dyspnœa alarming at our first visit, but from it alone we cannot always differentiate betwen true and false croup. Loud stridulous respiration and suffocative attacks are present in both forms. According to Steiner the dyspnœa is never so extreme in the latter, and the suffocative attacks occur earlier, although not so frequently as in the former disease. In all of my cases the dyspnœa was marked, but of course not so extreme in the favorable cases, where treatment was begun early. Jacobi lays particular stress upon its presence during expiration as well as inspiration in membranous croup. As my attention had not been directed to this point until lately, I failed to make any observations regarding it in my cases. The respirations were generally not much increased in frequency, and in proportion to the frequency of the pulse they were retarded. When they became very frequent, I took it for granted that the bronchi or lungs had become involved, and accordingly gave an unfavorable prognosis. The only measure which I know of the amount of stenosis is inspiratory recession of the epigastrium and attachment of the diaphragm. It was present to a greater or less extent in all of my cases, even in the two which I have excluded from the statistics as having probably been cases of false croup, although Meigs and Pepper say: "The persistence of a deep sulcus around the base of the chest and of recession of the lower end of the sternum and epigastrium during inspiration, for even a short time, is in the highest degree characteristic of the presence of false membrane in the larynx."

3. Aphonia.—According to Loomis and Steiner, the voice never becomes whispering or completely extinguished in spasmodic croup. According to Meigs and Pepper, it rarely does in false croup, while it always does in the membranous disease. The cough is also affected by the aphonia in true croup. Meigs and Pepper compare it to the sneezing of a young kitten, and say that they "have never heard this in catarrhal laryngitis, no matter how severe." The aphonic cough was present in all of my cases, even in the two which I have decided to exclude, but in these two the speech and cry were not at all hoarse. The so-called "croupy" or "brassy" cough which Sir Thomas Watson describes as characteristic of croup, I regard, with Trousseau, as a sign of the *absence* of membrane in the larynx. I have met it in numerous cases of spasmodic laryngitis, but only once in true croup, and there its sudden appearance at night at first led me into a mistaken diagnosis.

4. Totality of Symptoms.—Having seen that no one of the above-mentioned symptoms can be regarded as strictly pathognomonic of pseudo-membranous laryngitis, let us consider them jointly. Niemeyer says: "They can all be present temporarily in catarrhal swelling of the vocal cords." In that case, however, the symptoms are generally alarming from the start, the onset almost always being at night, and subside by morning, while pseudo-membranous laryngitis, as a rule, comes on insidiously, increasing for several days, and is not attended to until a dangerous stage has been reached. Hartshorne cautions us always to "pay prompt and careful attention to a day-time bark *with* fever." Ziemssen states that in

pseudo-croup recovery takes place by the ensuing morning. Gerhardt, in the absence of pharyngeal implication and glandular enlargement, would "rest the diagnosis for the first few times on the efficacy of remedies and the course of the disease, remembering that an exudation lasting more than thirty-six hours speaks decidedly for diphtheria, while in false croup complete well-being has occurred as early as the next morning." Meigs and Pepper recognize a severe form of spasmodic croup, with all the symptoms of the true disease, but they state that its duration is rarely longer than two or three days, that of true croup rarely less than six, often eight or ten days.

In my successful cases, after slight hoarseness of three or four days' duration, the alarming symptoms lasted at least four days, in one case over a week, with but slight remissions in the day-time, and nocturnal exacerbations of dyspnœa occurred for a week or more longer. Loomis says: "If recovery takes place, it is slow, weeks often elapsing before the voice returns, during all of which time the patient is liable to severe attacks of dyspnœa." Cormack seems to think that all the successful cases described in the classic works of Home and Cheyne, and many of the fatal ones, were cases of infantile laryngitis, the greater severity of symptoms in children as compared with those in adults being due to the narrowness of the glottis in the former. This theory is supported by the laryngoscopic investigations of Rauchfuss and Dehio, which showed that in acute laryngitis with œdematous infiltration below the vocal cords, especially where the cords are inflamed and swollen, there is laryngeal stenosis with the same dyspnœa, cough, and loss of voice that we have from membranous obstruction of the rima glottidis. Flint and Meigs and Pepper also think it necessary to see the membrane, either *in situ* or in the expectorated or vomited matters, in order to make an absolute diagnosis. I must confess that this requirement was not met in a single one of my cases, but I thought it possible that the membrane had undergone molecular disintegration under the digestive influence of the spray.

Should a supposed catarrhal croup turn out in reality to be a pseudo-membranous laryngitis, one consolation remains. We can smooth over our mistake by citing Loomis and Hartshorne as authority that the former disease can develop into the latter, suppressing the fact that most authors state that children subject to spasmodic croup rarely become affected with the membranous form.

Having shown that an absolute diagnosis could not be made in any of my cases, and leaving it to you to estimate the probabilities in each individual case, allow me to pass to the consideration of my method of using the peptonizing ferments. I claim no originality, but think I have used digestive sprays since a time when they were but little mentioned in current literature. About five years ago I read somewhere that Rossbach (?) was using a spray of papayotin solution to dissolve false membranes. I utilized the principle in the first case of croup, and that a bad one, coming under my treatment, but substituted pepsin for the expensive papayotin, and as patient recovered, I have used the method ever since, but of late in a modified form.

The mixture was prepared by adding grs. x Jensen's pepsin, dissolved in glycerine, to oj water, and acidifying with ℥ss lactic acid. This solution, thrown into a spray by a Codman and Shurtleff steam atomizer, was directed towards the child's mouth and nostrils continuously, day and night, until the worst danger seemed over, generally about a week, and after that during the nocturnal exacerbations for about a week more. Of course, it is not probable that much of the fluid reached the larynx, but it is an open question whether pepsin acts by its quantity, or only in a catalytic manner. Dr. Henry Dwight Chapin has shown by experiments with trypsin solutions, that the spray dissolves membranes relatively more quickly than immersion.[1] The person using the atomizer must be constantly on the alert to follow any movement of the patient's head and keep the spray playing on the mouth and nostrils; the child then becomes restless, opens its mouth to cry, takes a deep inspiration, and the cough proves that the fluid enters the larynx. Any one can satisfy himself of this by trying it on himself. Children, after a short time, do not mind the spray much, and in all except the most fulminant cases the relief has been marked and prompt. The child usually soon falls asleep, and at this time the spray can be used continuously without trouble. It is doubtful whether any of the fluid enters the respiratory passages during sleep, but the steam alone must do considerable good. If the dyspnœa again increases, the child awakes, and, if necessary, can be made to breathe through its mouth for awhile. Older children sometimes ask for the spray, and one (case 8) even for some time after full recovery, could be put to sleep only when the "little stove" was burning beside his crib.

If the membrane form again faster than it can be digested, the relief is only temporary; and after the stenosis has become extreme, there is not enough air-current through the trachea to carry the spray where it is needed, but after the performance of tracheotomy or intubation of the larynx per os, digestive sprays ought to be of immense benefit.

One drawback of the acid pepsin spray is that it causes considerable erythema, and sometimes swelling, of the face. This can be avoided to a certain extent by anointing the exposed surfaces with cosmoline and covering the eyes with a cloth. In my last four cases I have obviated this difficulty by substituting an alkaline pancreatic solution, prepared as follows: R. Ext. pancreatis (Fairchild Bros. and Foster's) ℥j; glycerine, q. s. ut. ft. sol.; nat. bicarb., ℥ij; sol. thymol (1 : 1000), ℥iv (to prevent decomposition of the ext. pancreas, which occurs very quickly); aquæ, q. s. ad. oij, filtered. These solutions I have used in large quantities, generally a quart during the day, and an equal quantity at night, and sometimes much more. Perhaps their strength could be increased with advantage.

Dr. Henry Dwight Chapin describes a hand-ball atomizer with tongue-depressor, combined in one instrument, by means of which a concentrated solu-

[1] Medical Record, vol. xxvii, p. 257, March 7, 1885.

tion of ext. pancreatis, gr. xv: ℥j, can be thrown more directly into the larynx for a minute or so every fifteen minutes.[2] In severe cases this might be occasionally used together with the constant spray from the steam atomizer. I have never had any trouble in getting parents to persevere with the treatment, but in one case, where, after the child had materially improved, even at night, the suction tube became stopped soon after my morning visit, by the scum always present in the pancreatic solution, and by evening the child was past all hope. I had explained to the parents how to cleanse the tube with a small feather from the large end, but, not being very intelligent, they failed in their attempts (case 15).

In New York they use a trypsin-spray, and according to Dr. B. M. Van Syckel, this ferment can be extemporized as follows: Add 5 grammes (℥j grs. xvij) ext. pancreatis to 500 cc. (℥j ℥vi) of a 1 per cent. solution of salicylic acid, and digest in a water bath at 37° C. for four hours; filter, and make slightly alkaline with bicarbonate of soda.[3]

Of course, other treatment must not be neglected. I have hitherto used a slice of salt pork externally, but think I shall hereafter try hot poultices. The body must be protected from the wet spray by being wrapped in shawls or oil-silk. Increased secretion diminishes congestion and aids in loosening the exudation. This I have striven to promote by pilocarpin mur. in doses of gr. $\frac{1}{48}$ to gr. $\frac{1}{24}$ q. h. or q. 2 h., day and night. To the pilocarpin mixture I add a few drops of dilute muriatic acid to aid solution, tr. ferri chlor., am. mur., and brandy to forestall the depressing effects of the pilocarpin. As I have once or twice seen considerable temporary collapse from the pilocarpin, I think I will omit it in asthenic cases occurring during epidemics of diphtheria. But it is necessary also to *prevent* the new exudation of pseudo-membrane. This I have aimed to do with small doses of calomel, gr. $\frac{1}{20}$ to gr. $\frac{1}{5}$ q. h. or q. 2 h. day and night, given between the doses of pilocarpin. If there is much fever, I give occasional doses of quinine. Nourishment is generally taken in sporadic cases, but must be insisted on in the asthenic, combined with stimulants. I do not believe in frequent large doses of mercury, although I generally begin treatment with a gr. v–gr. x dose of calomel, which I repeat once or twice during the following days. Mercury never salivates small children, but often produces sudden and profound asthenia without salivation, as the personal experience of several physicians testifies.[4] The treatment of this dread disease must be active from the very beginning, but should never be reckless. I would never dare to use the heroic doses of corrosive sublimate advocated by Jacobi, gr. ss. daily for many days in an infant of 1 year. J. Lewis Smith, a dualist, uses large doses of mercury in croup, but avoids them in asthenic diphtheritic cases. Opiates I would only give when the cough is distressing, and then only in small doses, as they have seemed to me to hasten the occurrence of the asphyxic stage. I prefer Dover's powder, as it keeps up a gentle diaphoresis, and stimulates the secretion of mucus.

Emetics I have hitherto studiously avoided, as I once saw a patient, whom I treated before I had begun to use pepsin inhalations, die of suffocation during the retching produced by an emetic. However, I shall hereafter try an occasional dose to expel mucus and membrane disintegrated by the spray and collected in the air passages, because Meigs and Pepper claim that of thirteen cases where they pushed emetics, ten recovered without, and one with, tracheotomy, while of eight others all but one died.

Where it is often impossible to make a definite diagnosis, we must of course be careful in estimating the results of treatment. On the point of prognosis there is even greater diversity of opinion than on that of diagnosis. Wood, of Philadelphia, gives the mortality of croup as low as 2 per cent. This is obviously a different disease from that described by Ware, who states that of twenty cases nineteen die. Then we must bear in mind that many authors recognize two distinct diseases, the one membranous croup pure and simple, the other laryngeal diphtheria, of which they find the latter much more fatal than the former. Monti has seen spontaneous recovery in not more than 2 per cent. of his cases of idiopathic croup, 2 per cent. more yielding to the lactic acid spray, while 50 per cent. recovered after tracheotomy; but in descending croup with enlarged glands and constitutional symptoms, he does not think that more than 25 per cent. can be saved by the operation. Even those writers who maintain the identity of croup and diphtheria, admit that sporadic cases recover more frequently than those occurring during an epidemic; but in their treatment they generally include tracheotomy. Thus, of a large number of cases treated by Steiner only three recovered without tracheotomy; with the operation his mortality was 60 or 70 per cent.

I have been able to obtain consent to perform tracheotomy but once, and then only after the child was moribund. Intubation by Dr. O'Dwyer's instruments would probably be more readily allowed,[5] and I can conceive it possible that in one or the other of my fulminant cases the operation might have gained time for the spray to act. Dr. F. E. Waxham, of Chicago, writes me that of fifteen cases treated by him by intubation, seven have recovered.

Meigs and Pepper have had sixteen deaths out of thirty-five cases, their favorable results apparently being due to the free use of emetics.

Secondary croup occurring in the first week of diphtheria seems to be much more fatal than that occurring in the second or third week. Dr. J. Lewis Smith thinks it is scarcely possible to cure more than one-eighth of the cases of the former, while of the latter one-third may be saved by the early and constant or almost constant use of trypsin inhalations.[6]

Now as to my own results. Before I began to use the treatment above described, I had three cases of croup, all fatal; but they were all very severe and

[6] Med. Record, vol. xxvii, p. 543.

apparently infectious, two occurring in families in each of which another child died of the same disease, either just before or soon after, and the third in a girl of 15, convalescing from typhoid fever, infected by a brother with diphtheria.

Of the thirteen cases which I will utilize in estimating results, six recovered. All of these ran a slow and protracted course, and hence gave the treatment some chance to succeed. Of the seven fatal cases, all but one (case 7) ran through the different stages very rapidly. Of seven cases where a distinct membrane was seen in the fauces, three recovered. Loomis says: "When the diagnosis is based upon the presence of the membranous exudation in the tonsils and epiglottis, recovery seldom occurs."

I have tried to compare my results with those of others reported in the Dubuque Health Office. Here again we must bear in mind the probability of frequent errors of diagnosis, especially by irregular practitioners, and of fatal secondary cases simply reported as having died of the primary disease. On the other hand, cases ending in recovery may have been not reported at all. I will select the report of the health physician for the year ending February 28, 1883, as the disease was then rather prevalent, and hence more liable to be fatal, and errors of diagnosis less likely to occur. During that year there were reported 37 cases of croup, with 21 deaths. Of these, 32 were treated by other physicians and by methods unknown to me, with 19 deaths, a mortality of 60 per cent; 5 were treated by me as above described, with 2 deaths, a mortality of 40 per cent. Of the cases which recovered, one occurred during convalescence from measles (case 5), when, according to Steiner, true croup is much more common than false, while the reverse holds true in the beginning of measles.

Both Steiner and Monti lay stress upon the rarity of recovery from croup occurring in the desquamative stage of measles, the latter never having seen one get well. In the second case (case 6) the extensive pharyngeal exudation, which had been seen by the mother, had disappeared when I was first called, but the submaxillary glands were much enlarged. The third case (case 8), may have been one of severe spasmodic croup, although the long duration of the prodromal stage (four days), the first occurrence of suffocative attacks at noon, the severity of the symptoms, and the slow recovery, speak rather for pseudo membranous obstruction. Of the fatal cases, the first (case 4), was fulminant, and time was lost by treating it at first for spasmodic croup; in the second (case 7), the treatment had a pretty fair trial, but failed to save the patient.

Following is a brief review of my cases:

Case 1.—Frank P. Treated him for sore throat, October 16, 1881, with cinchonidiæ sulph. and tr. fer. chlor. internally, and had throat swabbed with acid, carbol. and liq. ferri subsulph. in glycerine. Exudation in pharynx on 20th. Now added to other treatment pilocarpin mur. gr. $\frac{1}{48}$ q. 2 h.

October 22, add gr. iv quiniæ sulph. t. i. d. for fever. Considerable cough, for which gave morphine and ää hydrocy. dil.

October 24. Brush throat with pure tr. ferri mur. During following night laryngeal stenosis suddenly developed, while membrane in fauces had disappeared. Continuous pepsin-spray day and night.

October 25. Dr. J. M. Boothly saw patient in consultation in evening, and at his suggestion, am. mur. and cinchonid. were given q. 2 h., alternating with these calomel gr. $\frac{1}{5}$, tart. em. gr. $\frac{1}{15}$ pulv. Doveri gr. ss q. 2 h. Pilocarpin and spray continued. Stimulants and milk frequently repeated.

Condition remained critical for several days. Some improvement on 28th, and considerable by 30th, but now considerable cough. Spray continued some time longer, at last only at night. Aphonia remained for some time.

Case 2.—Mary U., æt. 4 years, taken with diphtheria on Dec. 2, 1881, while a brother was convalescing from sore throat with enlarged submaxillary glands. Cinchonid. sulph. gr. iv t. i. d., pilocarpin gr. $\frac{1}{24}$ q. h. Some improvement after a few days, when, after getting up, croupy symptoms began to appear and were well developed by the 8th. Alternated with pilocarpin increased to gr. $\frac{1}{20}$ q. h., calomel gr. $\frac{1}{6}$ and pulv. Dov. gr. ss q. 2 h. Pepsin-spray continuously.

December 16. Pilocarpin q. 2 h., and tr. ferri mur. gtts. ij added to each dose.

December 19. Patient slowly improving, but still considerable obstruction at night. Added tart. emetic gr. $\frac{1}{24}$ to each dose of calomel.

December 23. Convalescent, but weakness of heart for which gave quinia, iron, nux vomica and digitalis. Spray at night for some days longer. Last child in family came down with diphtheria.

Patient got out of bed on 30th or 31st. Aphonia remained complete for about two months.

Case 3.—Olivia H., æt. 1 year 9 months. Slight exudation had existed in fauces for four days when I first saw the child on January 6, 1882. Hoarseness had been increasing about thirty-six hours, and stenosis was so marked that an unfavorable prognosis was given. Pilocarpin mur. gr. $\frac{1}{32}$, am. mur. gr. $\frac{1}{4}$ q. h. Cinchonid. sulph. gr. j q. 4 h. Continuous inhalations of pepsin-spray.

January 7. Respiration frequent, fever higher, probably indicating lung implication. Mustard poultices to chest, covered by oil-silk. Tracheotomy refused and not urged on account of probability of lung trouble. Symptoms increased in severity until death occurred December 8, 6:30 P.M. Duration of whole disease six days, of laryngitis three days, of treatment forty-two hours.

Case 4.—Peter M., æt. 3 years. Called on night of April 9, 1882. Sickness began three days ago with cough. Croup symptoms came on suddenly this evening. Thinking it a case of spasmodic croup, I vomited the child with sulphate of copper, and prescribed tartar emetic and sulphate of morphia ää gr. $\frac{1}{64}$ q. h. Much worse next morning. Cinchonid. sulph. gr. iv q. 4 h., pilocarp. gr. $\frac{1}{24}$ q. h., and continuous pepsin-spray. Patient died at 3 P.M. Duration of disease five days. Pepsin inhalations only four or five hours.

Case 5.—Francis B., æt. 3½ years. About a week after an attack of measles she was taken with hoarse-

ness, which gradually increased for several days, until when I first saw her, on July 6, 1882, symptoms of stenosis and aphonia were well marked. Cinchonid. sulph. gr. ij q. 4 h., pilocarpin gr. $\frac{1}{24}$ with tr. ferri mur. q. h. Pepsin inhalations day and night.

July 8. Added to other treatment calomel gr. $\frac{1}{16}$ and pulv. Dov. gr. ss q. 2 h., after bowels had been moved with grs. v calomel.

July 9. Ammoniæ carb. gr. j every two hours.

July 10. Convalescent. Tr. ferri mur. gtts. ij q. 2 h. Last visit on July 11, but spray used at night for slight exacerbations for a week longer.

Case 6.—Albert M., æt. 3 years 10 months. Sore throat for several days with glandular enlargement. Mother said fauces had been covered with whitish exudation, but I could see none when called on October 24, 1882. Gradually increasing hoarseness for several days, now aphonia and symptoms of laryngeal stenosis. Pilocarpin gr $\frac{1}{24}$, am. mur. gr. $\frac{1}{8}$, tr. ferri mur. gtts. ijss, q. h. Continuous pepsin inhalations. Whenever atomizer became deranged for a short time, symptoms increased in severity. Dr. J. H. Wilson saw case after two or three days and agreed in diagnosis.

October 29. Ung. plumbi iod. to enlarged submaxillary glands.

October 31. Last visit. Continue inhalations at intervals, as necessary, for a few days longer.

Case 7.—Lisetta R., æt. 4 years 4 months. Gradually increasing hoarseness and stridor for several days, until stenosis was far advanced when I first saw her on evening of December 17, 1882. Complete aphonia. Continuous pepsin inhalations. Pilocarpin gr. $\frac{1}{48}$, tr. ferri mur. gtts. jss q. h. Cinchonid. sulph. gr. j q. 4 h. Tracheotomy refused. Patient became progressively worse, respirations hurried, high fever, and death occurred at noon of December 19, apparently from lung implication. Duration of sickness one week, of treatment forty-two hours.

Case 8.—Karl H., æt. 3 years. Treated patient January 20, 1883, for cough with slight hoarseness. Did not see him again until 31st. Hoarseness rather worse, but did not think of croup. Sent for at noon of February 1, and found symptoms of croup well developed with deep sinking in of epigastrium and base of thorax inspiration. Immediately began with continuous pepsin inhalations and relief marked. Internally gr. ij cinchonid, sulph. q. 4 h., and pilocarpin mur. gr. $\frac{1}{32}$ with tr. ferri mur., am. mur., and brandy q. h. day and night. Some improvement by February 5. Added to other treatment gr. $\frac{1}{24}$ calomel and gr. $\frac{1}{3}$ pulv. Dov. to prevent reformation of membrane. Whenever spray was discontinued for a short time, symptoms increased in severity.

February 6. Omitted pilocarpin. Ferri et quin. cit. t. i. d. Atomizer was used about two weeks, but during last few days only at night when dyspnœa still existed.

Case 9.—Mathias Sch., æt. 5 years, living seven miles in country. Called on evening of February 20, 1883, and found child in last stage of croup. Did not examine fauces. Child died two hours after treatment was commenced, and after an illness of five days.

Case 10.—Leonard L., æt. 5 years 11 months. Passed through severe attack of scarlatina anginosa with faucial exudation, in 1881, making a slow recovery. Had been sick about four days when I was called on October 15, 1883, but had gone to school until the day before. Found extensive diphtheritic exudation in fauces, and laryngeal stenosis far advanced. Pilocarpin gr. $\frac{1}{24}$, tr. ferri chlor. gtts. ijss, am. mur. gr. ss q. h. Swab throat every hour with carbolic acid and liq. ferri subsulph. Continuous pepsin inhalations begun after supper.

October 16, in morning much worse. Added calomel gr. $\frac{1}{20}$, and pulv. Dov. gr. $\frac{1}{3}$ q. h. Pilocarpin increased to gtt. $\frac{1}{20}$, q. h. Distressing cough almost constantly. Still worse in afternoon. Some relief followed an emetic dose of cup. sulph. Eased cough with small doses of opiates. At 8 P.M. membrane seemed looser, wherefore gave large doses of cup. sulph., but nervous sensibility so obtunded that they would not even produce nausea, and child died in a short time, twenty-four hours after beginning inhalations, and five days from beginning of sickness.

Case 11.—Josie B., æt. 14 months. Stenosis had been gradually increasing for nine days, until I was finally called November 6, 1883, at 4 P.M. Unfavorable prognosis. Continuous inhalations of pepsin-spray. Internally, pilocarpin gr. $\frac{1}{32}$ and tr. ferri mur. gtts. ij q. h. Also, calomel gr. $\frac{1}{12}$ q. h. Eight P.M. much worse.

November 7. Grew rapidly worse to noon. Tracheotomy mentioned but not allowed until 4 P.M., when child was in asphyxic stage. Dr. J. S. Lewis was immediately summoned to assist in operation; but we feared child would die before we could get ready. A few whiffs of chloroform were given. Trachea was reached in a few seconds without appreciable hæmorrhage, and promptly opened, but in enlarging the opening the churning motion of the larynx caused the innominate veni (?) to be punctured by the knife; at any rate, considerable hæmorrhage ensued. The smallest tracheotomy tube was too small for the small wind-pipe. Immediately introduced silver male catheter, but patient died the same moment, twenty-four hours after beginning of treatment, and ten days after initial hoarseness.

Case 12.—Annie T., æt. 7 months. Scrofulous. Symptoms of croup came on January 1, 1884, at 1 A.M., after slight prodroma of several days' duration, and were well developed when I saw patient. Began immediately with continuous pepsin inhalations. Internally gr. $\frac{1}{32}$ pilocarpin q. h.

January 2 gave also calomel gr. $\frac{1}{20}$ q. h. with pulv. Dov. $\frac{1}{16}$.

January 4, added to pilocarpin mixture gr. $\frac{1}{500}$ corrosive sublimate, tr. ferri mur. gtts. ij., am. mur. gr. $\frac{1}{8}$ pro dosi.

January 5, returned to calomel. Symptoms became considerably milder from beginning of inhalations, but increased in severity whenever apparatus got out of order, which happened several times, and whenever spray was resumed stenosis became much less alarming. Gradually improved to January 8, when tr. opii deod. gtt. $\frac{1}{4}$ q. 2 h. was given for severe cough.

January 9, last regular visit for the time being, but patient was kept under observation for some time longer, during which time there was more or less dyspnœa at night, wherefore spray had to be used at those times, and always with marked benefit. Child remained sick for a long time, passing successively through whooping-cough, pneumonia, and gastro-intestinal disorders, and in August of same year had an attack of undoubted diphtheria, with glandular enlargement.

The last fact would rather militate against the identity of croup and diphtheria, provided the child had true croup in January, as the long duration of the stenosis would seem to indicate, while the sudden onset at night rather speaks for spasmodic laryngitis. Almost two years later the same child was taken in the middle of the night with croupy symptoms more alarming to the parents than those of the previous attack, but on that occasion I promptly excluded true croup, and the recovery by morning under simple treatment proved the correctness of the diagnosis.

Case 13.—Annie W., æt. 3 years. Treated her three months ago for acute Bright's disease, of which the cause could not be discovered, and two weeks ago for bronchitis, which developed into lobular pneumonia. Had not seen her for several days, as she seemed convalescent. On the night of April 8, 1885, she was taken with croupy symptoms, which the mother relieved temporarily with a dose of hive syrup. Next morning, breathing accelerated, but not stridulous. Grew worse until I saw her at 7 P.M. Considerable fever, pulse 150, respiration 57, and of the character indicating stenosis of larynx and trachea, with recession of supra-clavicular and supra-sternal fossæ, as well as of border of ribs, during inspiration. Auscultation showed only prolonged expiratory sound, no râles of any kind. Pain in throat; no exudation visible. No hoarseness of voice in speaking, but cough aphonic. Diagnosticated ascending croup, beginning in the bronchi, which has not yet reached the vocal cords. Gave grs. v calomel. Pancreatic spray to be used all night. Pilocarpin mur. gr. $\frac{1}{2}\frac{1}{4}$ q. h. Breathing soon became easier, although still stenotic, and patient slept all night with the spray playing in her face.

April 9, stool at 5 A.M. At 8 A.M. respiration 54, pulse 150; no stridor, but some drawing in of diaphragmatic attachments during inspiration. Prolonged expiratory sound, some dry râles. Ate a soft egg for breakfast. Calomel grs. x, continue other treatment. Ate some dinner. Played all afternoon and had two liquid stools. Six P.M., respiration 45, dry râles, no longer recession of lower ribs. Used only steam with atomizer during following night.

April 10, patient playing, pulse 120, breathing accelerated but noiseless. Made a prompt convalescence.

The above case I will exclude on account of quick recovery.

Case 14.—Karl H., æt. 8 months, brought to office April 21, 1885, with very loud wheezing in- and expirations, little if any hoarseness when crying, but high-pitched, almost completely suppressed cough, no fever; all these symptoms of two weeks' duration. Playful during day and sleeps all night in spite of the dyspnœa. Auscultation of lungs negative, as stridor in trachea masks everything. Thinking it to be a catarrhal affection, I prescribed am. carb. and tr. sanguin. āā gr. $\frac{1}{3}$ q. 2 h., with hot poultices of linseed and mustard to chest. Wheezing soon improved some, but on 23d I was sent for in haste at 5 P.M. Wheezing much worse, with inspiratory recession of supra-clavicular and supra-sternal fossæ, xyphoid cartilage and free border of ribs. No fever. Respiration 48 to 56. In spite of this, child was excessively and wildly playful, laughing, crowing, kicking all the time, so that friends who came in thought it under the influence of liquor, although none had been thus far given. I now prescribed pilocarpin gr. $\frac{1}{4\,8}$ q. h., with brandy, no iron, and an initial dose of grs. v calomel. The atomizer was used constantly, but at present only water was used in the spray. Calomel operated several times, and child slept well during intervals of taking medicine. Vomited once.

October 24. Respiration seemed somewhat slower, but could not be counted, as child's excitement continued. Coughing spells more severe, child turning red in the face during the attacks. Found child asleep in the evening. Respiration 32, pulse 132. Increased pilocarpin to gr. $\frac{1}{3}\frac{1}{2}$ q. h. Spray used only during sleep, as child was too wild when awake.

October 25. Stridor increasing, and more like that of croup; cough more aphonic. Hands cold. As symptoms seemed to be increasing under water spray, and diagnosis of croup more certain, the pancreatic spray was substituted. Pilocarpin gr. $\frac{1}{3}\frac{1}{2}$ only every two hours, as salivation has been considerable. Atomizer became deranged for awhile and cough became still more suppressed. Child was restless and feverish. Ten P.M., collapse, cold, clammy perspiration, pale, no cyanosis, ceased breathing for a few moments, then vomited large quantities of glairy mucus; after this some improvement of stridor and cough; pulse 132, full, respiration 40, more moist. Thinking that the pilocarpin had caused the depression, it was diminished to gr. $\frac{1}{4\,8}$ q. 2 h., and the salivation then ceased, and calomel was now added, gr. $\frac{1}{2}\frac{1}{4}$ q. 2 h. From this time gradual improvement to 27th, when respiration during sleep, 28; no more recession of ribs. Pilocarpin stopped on 29th, but resumed again on November 2d, as respiration again became more stridulous.

November 3. Oil-silk jacket instead of poultices.

November 7. Slight recession of ribs. Chlorate potash gr. j, q. 2 h.

November 9. Stopped atomizer. Some wheezing when awake, but breathes noiselessly during sleep.

November 13. Breathes much louder, so that the stridor can be heard through two rooms, yet no dyspnœa whatever when asleep.

November 14. Wheezing only during expiration. Sounds very much like asthma, yet the stridor is distinctly in the larynx and trachea; no râles in chest.

November 15. Has been taking iod. pot. several days, which has produced iodism.

November 18. Expiration whistling. Boils have been forming on head, and muco-purulent and bloody casts are discharged from nose.

November 20. Breathing natural.

November 28. Aphthæ of tongue.

December 1. Otitis media, which has existed for several days, has ended in perforation of left drum-membrane.

December 10. Last traces of aphonia of cough now gone.

December 12. Double pneumonia, which underwent resolution in about a week, when a boil formed in left ear and broke.

January 8, 1886. Still considerable cough and discharge from left ear.

The above case I am now inclined to consider one of chronic catarrh, beginning in the larynx and trachea, ascending into the nares and middle ear, and descending into the bronchioles and air vesicles, and the improvement following the use of the digesting spray was probably only a coincidence.

Case 15.—Julia K., æt. 1 year, scrofulous child, has been sick a good deal, almost dying of enterocolitis last August, living in the basement of a damp house. On morning of November 18, 1885, during cold, wet, foggy weather, was suddenly taken with hoarseness, which became worse by evening, with some stridulous respiration. Still worse on following morning, but quite well again in the evening. Worse again on morning of the 10th, and in the evening of same day I first saw the child. Cry and cough devoid of all sound. Had a suffocative attack in my presence, and I thought I could hear a loose membrane flapping in the larynx. Dyspnœa not very severe in intervals between these attacks. Retraction of lower ribs and xyphoid cartilage very slight. White membrane on posterior wall of pharynx. Little, if any, glandular enlargement. Cannot nurse well. Prescribed pilocarpin mur. gr. $\frac{1}{48}$ q. h., with tr. ferri mur., and an initial dose of gr. v calomel. Spray of ext. pancreatis was kept up continually, and child slept well, breathing almost noiselessly until, at 5 A.M., the suction-tube of atomizer became stopped, and by 10, at my visit, the child was again in about the same condition in which I had left it the night before. In the meantime it had nursed without apparent difficulty. I cleansed the tube, but after I left it soon became clogged again, and at 5 P.M. dyspnœa was extreme, with deep recession of xyphoid cartilage, cyanosis, apathy, child lying with its head strongly extended, as in opisthotomos. Respiration 48, pulse very frequent and feeble. The medicine had been given in only one-third of the intended doses. The child's mouth was now held open with a spoon, and the spray used continually by myself for an hour, at the end of which time respiration seemed much moister. Tracheotomy not allowed. The parents kept up the spray until 8:30 P.M., when the child died quite easily, apparently of asthenia, twenty four hours after the beginning of treatment.

Case 16.—Fannie T., æt. 6 years, began to have sore throat on morning of December 5, 1885, a severe snow storm having occurred on previous evening. Better on 6th. Went to school on 7th. Very slight hoarseness on evening of the 8th. When I first saw patient on 9th, at 10 A.M., there was complete aphonia, breathing was beginning to be stridulous, and there was some inspiratory recession of free border of ribs. Pulse 120. Small spot of diphtheritic deposit on left tonsil. Ordered salt pork to be tied around throat, and gr. $\frac{1}{24}$ pilocarpin mur. to be given every hour, after an initial dose of grs. x calomel. The pancreatic spray was used so diligently that by 7 P.M. 2¼ quarts of the solution had been atomized. Respirations were then 28, pulse 132. Considerable perspiration, ptyalism, and some vomiting. Had eaten some potatoes and squash for supper. Almost incessant cough, for which gave gr. ⅙ pulv. opii. By 8:30 P.M. pultaceous deposit had spread over whole of left tonsil. Pulse 160, respiration 40. Discontinued pilocarpin. Calomel has operated several times. Thought I heard a creaking inspiratory râle, which to me indicated extension of the disease into the bronchi. Little cough; sleeps by snatches.

Dr. J. H. Lewis was called in consultation. Calomel gr. ¼ q. h. Brandy ℥ j, and quinia sulph. gr. ij q. 2 h. Inunctions of oleate of mercury over larynx q. 2 h. Room to be filled with steam by immersing red-hot flat-irons in vessels of water. Spray to be used for a minute every fifteen to thirty minutes, patient breathing through mouth. Tracheotomy not allowed. Was called at 1:10 A.M. and found patient asphyxiated, unconscious. Died quietly in a few minutes, fifteen hours after beginning of treatment, and five days after first symptom of sore throat.

Having given a sketch of the cases treated, and recognizing the imperfections of which I was guilty in their observation, I would like to urge physicians to give the digestive ferments a fair trial in conjunction with such other treatment as the individual cases may demand. If it would seem impossible for the extract of pancreas or trypsin to have any solvent action in the small quantities inhaled in this way, how much more inert must be the lime-water spray used in the same manner, and if the former be not more active than the latter, it has at least the virtue of being equally harmless. Should any one, stimulated by this report, devise a readier means of bringing the digestive fluid in contact with the false membrane, making the method applicable also to fulminant cases, and doing away with the reckless and dangerous doses of mercury now in vogue, the object of this paper will be accomplished.

Dubuque, Iowa, January, 1886.

LUPUS VULGARIS.

Read before the Chicago Society of Ophthalmology and Otology, on December 14, 1886.

BY LYMAN WARE, M.D.,

MEMBER ILLINOIS STATE MEDICAL SOCIETY AND CHICAGO MEDICAL SOCIETY; SURGEON TO THE ILLINOIS EYE AND EAR INFIRMARY; OCULIST AND AURIST TO THE ORPHAN ASYLUM.

History.—Lupus vulgaris is no new disease, but on account of its frequent occurrence and, until the past few years, its almost incurability, I beg to call the attention of the faculty to a few cases which have come under my observation. Before referring to the history of these cases or submitting to your examina-

tion two or three patients who have kindly consented to appear before you, I would, in a few words, recall to your minds some notable features of this disease:

There is no doubt that the disease was generally recognized at least 500 years since, and designated "lupus." That in many cases it may have been confounded with carcinoma, by ancient writers, is highly probable. Willan was the first to apply the term lupus exclusively to certain forms of ulceration about the face. Bateman made no actual distinction between the effects and course of carcinoma and lupus, except that he considered the latter cured by arsenic, the former not.

Symptomatology.—Lupus varies much in appearance, according to the age of the patient, constitution, state of health, kind of diet, and the part affected. At first it appears in the form of tubercles, either isolated or in groups, which may be deeply imbedded in the true skin, beneath it, or quite superficial, and always spreads by infecting the adjacent skin. It is never congenital, though it may appear early in life. Unchecked by treatment it increases more or less steadily for many years. At times the disease may appear checked for years, when it will again break out with renewed vigor. In old age the severity of the disease is often diminished. Lupoid tubercle may terminate either in involution, leaving the skin atrophied and glistening like a scar, or in disintegration and ulceration.

It may occur anywhere upon the body, although most frequently, by far, upon the face. The cases which have come under my observation have originated on the lower lid, extending gradually to the eye and nose. Lupus of the alæ nasi and the tip of the nose assumes the dissiminatic form. The tubercles are prominent, and coalescing, form large, irregular protuberances. Lupus on the lower lid produces, first, complete ectropion, in consequence of cicatricial contraction of the skin; then gradually extends to the palpebral conjunctiva, the ocular and deeper tissues of the eye, involving at last the entire orbit. As the disease involves the conjunctiva it imparts to it a dark, reddish-brown color, and is decidedly trachomatous in appearance; later it becomes smooth, glistening and atrophied.

Etiology.—Many theories have been advanced respecting the cause of lupus. Both ancient and modern writers refer it to scrofula or syphilis. Although the terms scrofula and scrofulous have been used for ages by physicians as well as by laymen throughout the entire world, it must be confessed we have no very clear idea as to what scrofula is, or to what exact condition scrofulosis should be applied. In my younger days I was taught that scrofula, being a literal translation of the Latin *scrofa*, swine, was a disease common to those who eat pork. I have since thought that such an explanation was unfounded, and that the term "scrofula" originated in the fact that the submaxillary furrow, which does not exist in well-fed swine, was obliterated by glandular enlargements. Some who hesitate to use the word scrofula, designate exactly the same condition by the term "struma," or "strumous diathesis."

Although we may not be able clearly to define the term "scrofula," or "struma," yet in a case of indolent swelling of the lymphatic glands, large lips, flabby, soft muscles, with a feeble constitution, and where the slightest irritation produced chronic inflammation, followed by suppuration, we would not hesitate to designate such a condition as scrofulous, or strumous. In most of the cases that have come under my observation such a condition was not present, nor was there any history of syphilis. Some writers, while not considering lupus a syphilitic disease, think that it shows a syphilitic taint, yet I was not able to discover a single symptom that pointed toward hereditary syphilis. The patients generally were in excellent health, appetite and digestion good. The more I compare the two conditions the less resemblance I find. Lupus is an exceedingly chronic, indolent disease, arising from small tubercles imbedded in the substance of the skin, does not become rapidly worse, may persist for years without producing constitutional disturbance, and is wholly unaffected by anti-syphilitic treatment. It is also essentially a disease of early life, seldom making its appearance before the third year and hardly ever after the twentieth or twenty-fifth. When it appears later, it will generally be found to be a recurrence and not a primary attack.

The treatment of lupus rather indicates that it may be allied to the malignant diseases, a connecting link, as it were, between the non-malignant and the malignant.

Volkmann has recently laid great stress upon the fact that every portion of the diseased tissue should be most thoroughly eradicated by the scoop, and the same thing has been taught and attempted for many years by means of the knife, the caustic, or the galvano-cautery. It has long been insisted upon that whatever method be adopted it must be thoroughly and unflinchingly carried out, and repeated, if necessary, from time to time, according to the exigencies of the case, or its tendency to relapse. Most authors have considered it necessary to treat the disease locally, some by constitutional remedies only.

In the cases reported I have tried each method separately, then unitedly, and have no hesitancy in saying that when the local treatment was combined with proper internal medication, the advance toward recovery was much more rapid and satisfactory than when only one method was followed. The internal treatment consisted principally of tonics, as quinia, iron, strychnia, phosphates, and particularly arsenic, either in the form of arsenious acid or Fowler's solution, and special attention to a plain, nutritious diet, and out-door life. The local treatment consisted in the complete destruction of the existing lupoid tubercles, in whatever state of development, by means, first, of the scoop, or Volkmann's curette; then by a thorough and prolonged application of pyrogallic acid in crystals.

In some cases, after removing the superficial layer, consisting of morbid products, scales, secretions, etc., a pledget of absorbent cotton was saturated in a four per cent. solution of cocaine and firmly held on the diseased tissue. In other cases, where the lupoid tubercles were deeply imbedded or where the disease

was at all extensive, general anæsthesia was first induced. The patients never complained so much of the acid application as of the curetting or scooping out of the lupoid mass. The pyrogallic acid uniting with the blood and lupoid tubercles, produces a thick, brownish, syrupy substance, and as long as this is produced the acid should be applied.

Jarisch, of Vienna, was the first to call the attention of the medical profession to the local use of pyrogallic acid, though it had long been used in the arts, particularly in photography. Dr. A. Vesey (*Dublin Journal Med. Science*, 1878), observing its remarkable astringent effects on the hands of those engaged in photography, was led to employ it in internal hæmorrhage, and especially in the hæmophysis of phthisis, in which he found it very efficient in grain doses frequently repeated (every hour or oftener.)

Jarisch first used it in the form of a ten per cent. ointment, with vaseline. Besnier, of Paris, makes use of a saturated solution of the acid in ether, applies it with a camel-hair pencil to the diseased portion, and at once covers this with a layer of traumaticine. These applications are repeated until the disease is thoroughly eradicated.

Schrummer, of Buda Pesth, after destroying the lupoid tubercles by means of the ten per cent. ointment already mentioned, prevents a return of tubercles in the cicatrix, which is of frequent occurrence, by the application of mercurial plaster.

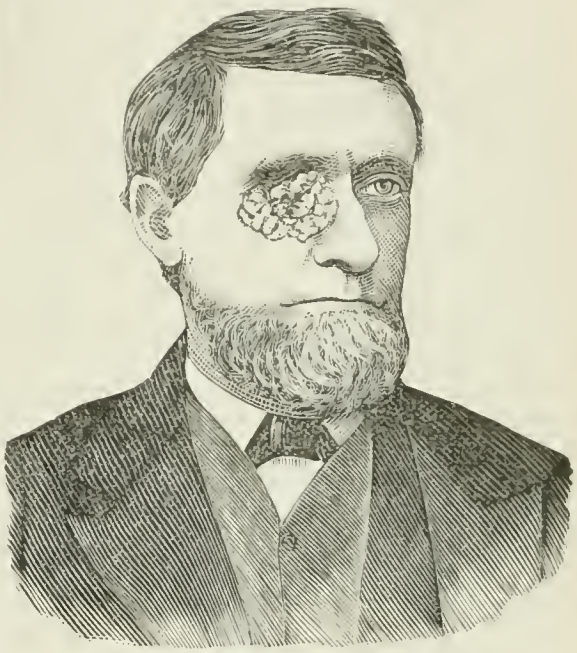
In some few cases in which pyrogallic acid has been used extensively and long-continued, poisoning has resulted; but when its use is restricted to the removal either of lupus or epithelioma, it is not at all likely to be complicated by any such unpleasant result. In cases of poisoning the kidneys are first affected, prostration and febrile disturbances appear, the urine becomes brownish or olive-green in consequence of hæmoglobinuria, the skin tinged with green, and a glairy mucus is vomited.

Dr. Charles W. Allen, of New York, has reported a number of cases of lupus treated by pyrogallic acid, and has expressed himself as most pleased with its effect. He made use of both the powder and ointment of varying strength, made with vaseline. He considers the acid of great value because it specially attacks the lupoid tubercles, induces destructive ulceration in and about them, leaving the healthy tissue unchanged.

In any preparation of pyrogallic acid care must be exercised not to combine it with an alkali, which would neutralize it; nor with a metal, which it would reduce.

Six cases have been treated, but in Case 1 iodoform in powder was used instead of pyrogallic acid.

Case 1.—Jas. M., æt 45 years. Was first attacked twenty years since while in the U. S. Army. The disease made its appearance at the inner canthus of R. eye. He attributed it to an injury received while riding under a tree and being hit by an overhanging limb. The disease gradually extended to the under lid, involved a portion of the upper, encroached upon the cheek, and finally the deeper tissues of the eye itself. The patient was given ether and the diseased mass thoroughly removed by means of the curette, and the wound dressed with powdered iodoform. Two weeks subsequently, a few lupoid tubercles again made their appearance at the inner canthus, but were easily removed by the curette without anæsthesia. The patient made a rapid recovery, and remained under observation about six months, and no relapse occurred. He assured me on leaving, that should there be a return of the disease he would surely let me know. He was placed from the first upon Fowler's solution of arsenic and advised to continue its use for at least six months.



The cuts shown give a good idea of the appearance of the case before and after treatment.

Case 2.—F. W., æt. 50., stone cutter; residence 441 Desplaines St., Chicago. Twenty years since a small tubercle about the size of a pea made its appearance upon the left ala nasi. It slowly increased until it attained the size of a large bean, ulcerating and extending at its edges. A few years later lupoid tubercles appeared at the inner canthus of the L. eye, and gradually extended to the lower lid.

Mr. W. had submitted to a great variety of treatment, which had only partially kept the disease in check. When he came under observation the protuberance on the ala nasi was, at least, the size of a large lima bean, dark-red and ulcerated at the edges. The ulceration at the inner canthus occupied an irregular space, about the size of a ten cent piece. Although there was at least an inch of perfectly healthy skin and tissue intervening between the two, the patient was confident that there was some connection between them. When the ulcer of the nose was red and painful that of the eye was also worse. As the patient had considerable fortitude the lupoid tubercles of both nose and eye were thoroughly curetted without the aid of ether, and the pyrogallic acid applied until the brownish syrupy substance ceased to form.

The history of this case differed somewhat from the others, in this respect, that for years there had been more or less pain. In fact, of late, the pain had been so great that it was impossible for him to work at his trade or sleep, sometimes for several nights in succession. The operation relieved him completely of the pain and he was able to sleep, and returned at once to his work. Several operations have been necessary, but he has been able to sleep regularly and work constantly, and at the present time he appears to be completely cured.

Case 3.—Minnie —, æt. 16. The lupoid ulceration first began when she was 12 years of age, unaccompanied by any pain. When she first came under treatment, the entire upper and lower lids and about one-third of the adjacent cheek were involved. Ether was administered, the entire ulcerated surface was curetted and the acid applied.

This case being at the Illinois Charitable Eye and Ear Infirmary, and my term of service about expiring, came under the charge of my colleague, Dr. Gardner, who continued the same course of treatment. After remaining a month or two in the institution, and no indication of the disease reappearing she was allowed to return to her home. Six months have now elapsed and there has been no return of the disease, but as there is slight ectropion of the lower lid, in consequence of the deep ulceration, a plastic operation will be necessary to restore it to its normal condition.

In all cases of lupus about the eye, I have considered it prudent to protect the cornea from the action of the acid, by means of a thick layer of absorbent cotton.

I have now used the pyrogallic acid in five cases, and in three or four very extensively and freely, yet in no case have I seen any symptoms which would indicate poisoning.

MEDICAL PROGRESS.

SEROUS CYSTS OF THE ORBIT.—At the meeting of the Académie de Médecine on December 14, M. PANAS read a communication on "The Pathogenesis of so-called Serous Cysts of the Orbit." The greatest obscurity has hitherto attached to the nature and pathological signification of these cysts. After a careful consideration of the subject M. Panas draws the following conclusions:

1. These cysts, without exception, are of congenital origin, even when their presence is not manifested until an advanced age.

2. They present seats of election, corresponding with the bronchial clefts of the embryo.

3. Their contents (epithelium, hairs, teeth, solid or liquid fat) may vary without the dermoid origin being doubtful, and this is due to the histological constitution of their walls.

M. Panas gives the record of an interesting case, with a full histological account of the cyst.—*Bulletin de l'Académie de Médecine*, No. 50, 1886.

DOUBLE PNEUMONIA TREATED WITH PILOCARPINE.—A man æt. 18, who had been greatly broken down with dysentery complicated with nephritis, suddenly acquired a double pneumonia. Antipyretics, expectorants, etc., resulted simply in a fresh lighting up of the dysentery. As in this way the organs of secretion as well as those that regenerate the blood became unfit for their work, uræmia and asphyxia combined threatened to set in, and to combat at least one of these dangers, recourse was had daily to hypodermatic injections to 0.1 gm. of pilocarpine. Thanks to the profuse perspirations and the salivation, purification of the blood was in this wise obtained until the lungs were again able to do their work. Improvement became more pronounced after every injection, and patient recovered in a very short time. With like good effect this drug was used in the case of an old lady sick with broncho-pneumonia, with intense dyspnœa.—*Memorabilien*, Hft. 4, 1886.

TREATMENT OF WHOOPING-COUGH.—The following method of disinfection of sleeping and dwelling apartments and clothes is recommended by M. MOHN in the treatment of whooping cough. It is said to cure the cases immediately. The children are washed and clothed in clean articles of dress and removed to another part of the town. The bedroom and sitting-room or nursery are then hermetically sealed; all the bedding, playthings, and other articles that cannot be washed are exposed freely in the room, in which sulphur is burnt in the proportion of 25 grammes to the cubic metre of space. The room remains thus charged with sulphurous acid for five hours, and is then freely ventilated. The children return the same day, and may sleep and play in the disinfected rooms.—*Lancet*, Dec. 18, 1886.

STERILITY FROM TEA-DRINKING.—DR. DAVIS (*Therap. Gaz.*) states that tea-drinking acts in the direction of producing sterility in females.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

PROGRESS OF MEDICINE AND VOLUNTARY MEDICAL ORGANIZATION UNDER A FREE GOVERNMENT.

The brief message of President Cleveland recently calling the attention of Congress to the propriety of making preparations for properly celebrating the completion of the first century of our country's progress under our present written Constitution establishing a true representative form of government, both State and National, suggested the question, What progress has medicine and medical organizations made under such form of government during the same period?

The written Constitution of the United States by which the previously existing thirteen loosely confederated States became one Nation, was passed by a Congress or Convention of delegates chosen for that purpose by the several States, and was officially promulgated on the 28th day of September, 1787. Consequently the 28th of September, 1887, will mark the completion of the first century of National progress under a well-defined constitutional form of government, adopted by the unrestricted choice of the people, and administered in all its departments by representatives chosen either directly or indirectly by the same people. Measures will undoubtedly be instituted for appropriately celebrating so important an anniversary day in our country's history; and if so it must provide for a careful and impartial review of our progress, not only in population, commerce, wealth, and political freedom, but equally so in education in its broadest sense, popular, scientific, and professional. It is perhaps the first time in the history of the human race, that an experiment on so grand a scale, unbroken for a century, has been allowed for determining how far a people holding not only all political power in their own hands, but equally the shaping and maintenance of all educational institutions, from the grammar school to the University with its departments of science, art, law, medicine and theology. In no department would such a review be more intensely interesting and profitable than that of medicine. Commencing the century in 1787 with but one organized medical college in actual operation in the entire country, and that one patronized by much less than one hundred students and granting less than a dozen diplomas annually; with State Medical Societies existing only in New Jersey and Massachusetts, and not a single medical periodical issued from the printing press of the country, and ending in 1887 with more than 100 organized medical colleges, educating more than 10,000 students and granting 3,000 or 4,000 medical diplomas annually; with active State Medical Societies in every State and inhabited Territory, all represented in one National Association, constituting a Republic of Medicine; while one hundred medical periodicals, weekly, monthly, quarterly and annual, are regularly issuing from the printing presses in all parts of the country, what a field for philosophical study is afforded by such a professional development, in comparison with all other elements of progress, all resting on the voluntary support of a free people.

It has been suggested that the attention of all the County and State Societies should be directed to a careful collection of all items of educational, scientific, sanitary and practical interest in their respective counties and States, and have it in readiness for such demonstration of the real progress of medicine during a century almost untrammeled by legislation, and equally unsupported by Government appropriations. The fact that the Ninth International Medical Congress is to be held in Washington, during the same month that marks the centennial of our constitutional government, gives much additional interest to the medical review we have suggested.

THE VEGETABLE ASTRINGENTS.

A valuable contribution to our knowledge of the vegetable astringents is a report to the Scientific Grant's Committee of the British Medical Association, by DR. RALPH STOCKMAN, of Edinburgh, on "The Action and Therapeutic Value of Vegetable Astringents." Dr. Stockman's investigation was undertaken with the purpose of determining the action of the vegetable astringents, after absorption into the blood, and of ascertaining to what extent

the current ideas as regards their therapeutic value are supported by experimental research. Dr. Stockman's paper may be found in the *British Medical Journal* of December 4, 1886. Briefly, the term "astringents," including "styptics," may be defined as "substances," which, either when locally applied, or after absorption into the blood, cause contraction of tissues, diminished secretion, and arrest hæmorrhage;" and those which act in this manner after absorption into the blood are known as "remote astringents." All the vegetable astringents which now have a reputation as remedial agents owe their value to tannic acid, but the chemical composition of this acid is not identical in all of them, the variety of tannic acid present being designated by such terms as "kinotannic," "catechutannic," etc. But all have the common property of precipitating albumen and gelatin from watery solutions, of producing an "astringent taste in the mouth, and of giving green or blue color reactions with persalts of iron.' The different varieties, however, have different powers of precipitating albumen. Gallic acid, which may be more properly classed as a remote astringent, does not precipitate albumen or gelatin, and does not tan; and its astringent taste is but barely perceptible Pyrogallic acid, while it precipitates albumen, differs markedly in other respects from tannin. In making his investigations Dr. Stockman selected, as representative members of the vegetable astringents, gallotannic, catechutannic, rhatany-tannic, gallic and pyrogallic acids, using the pure material, or as nearly pure as it could be obtained, first giving attention to the form and amount in which these bodies are absorbed, in which they circulate in the blood, and are excreted, and then to their action on the blood-vessels and circulation.

The experiments on absorption and excretion were made with gallotannic (ordinary tannic) and gallic acids. When tannic acid, says the writer, is taken into the stomach, it unites with the alkalies and the albumen present, and both these, and in the intestines, becomes converted, wholly or partially, according to the dose and time allowed, into gallic acid—as was shown by Schroff in 1853. "Absorption into the blood may take place as tannate and gallate of alkalies, or possibly as tannate of albumen dissolved in the alkaline intestinal secretion." Cavarra, Mitscherlich and Hennig, who investigated this subject over thirty years ago, found only a trace of these substances in the blood; and it is probable that their failure may have been due to crude processes of analysis. Dr. Stockman made ten experiments on rabbits to ascertain the form and amount in which tannic, or its derivatives, circulate in the blood. Tannic acid, in doses varying from one to ten grammes, dissolved in water, was given by the mouth, and the rabbits killed by bleeding at various periods after the administration of the drug; but not until it was ascertained by examination of the expressed urine that the addition of ferric chloride gave a copious blue precipitate. In no case did the blood or serum show the faintest blue coloration when ferric chloride solution was mixed with it on a white porcelain slab. The ordinary method of examining serous fluids was followed in the analysis of the blood. "The freshly defibrinated blood was precipitated with alcohol, filtered, and the residue washed with hot alcohol-ether and water." The filtrate and washings contained only the merest trace of a substance striking a greenish color with persalts of iron. Various other methods were tried, and with no better success; and it therefore seems evident that tannic and gallic acids are absorbed slowly and in small amounts from the intestines, and are so rapidly excreted from the blood that only a very small quantity is present in the circulation at any one time; and the experiments also show that tannic and gallic acids are excreted chiefly by the bowels, to a small extent by the kidneys, and by no other channel. Careful examinations of the various organs and secretions showed that only the urine, genito-urinary apparatus and the alimentary canal gave any reactions at all.

The only remaining method left by which to determine the forms in which tannic acid is absorbed, was by examination of the urine. Dr. Stockman confirms Lewin's observation that the amount of tannic acid excreted in the urine of rabbits is always considerable. Gallic acid is also invariably found, both being in combination with alkalies. The details of his method of analysis may be interesting. "The urine was distilled to a scrapy consistence either *in vacuo*, at a temperature of 110° to 120° F., or in a carbonic acid atmosphere. The residue was shaken up with alcohol, the whole filtered, the filtrate evaporated to dryness, and extracted with acetic ether. The acetic ether was then drawn off at a gentle temperature, and the residue (which must be quite free from water) washed several times with hot benzole. The washing with benzole was for the purpose of removing any pyrogallic acid which might be present, tannic and gallic acids being quite insoluble in it. The gallic acid was then removed by washing with anhydrous pure ether, in which tannic acid is insoluble. The residue left is dark-brown in color, syrupy in consistence, and contains the tannin

mixed with various impurities. When dissolved in water, if tannin be present, it precipitates albumen and gelatin (the alkali-tannate being decomposed by the acetic ether), the precipitate being soluble in lactic acid and alkaline carbonates. It also gives a copious blue-black precipitate with ferric salts, not clearing up on boiling." This method has the advantage that it is carried out at a low temperature, and oxidation is thus in a great measure prevented. From experiments on dogs it was found that when pure uncombined tannic acid was given there was generally found in the urine only gallic acid, with sometimes a varying, but always small, quantity of tannic acid. Whatever pyrogallic acid may be present cannot be detected by ordinary test for it. But if tannate of soda be given a large quantity of tannic acid will be found in the urine, along with a smaller quantity of gallic acid, pyrogallic being also absent in this case. Dr. Stockman's explanation of this is as follows: When uncombined tannin reaches the stomach (the contents of which are acid), it combines with the albuminous matters present to form tannate of albumen, only a minimal quantity combining with alkalies to form alkali-tannate. In the alkaline intestine, only such of it as has escaped combination with albumen is free to form alkali-tannates. The tannate of albumen thus formed is absorbed from the intestine with difficulty or not at all, and hence, remains there a comparatively long time, thus affording ample opportunities for the conversion of the tannic into gallic acid, in which latter form it is absorbed; the greater part being, however, excreted by the bowel. When, on the contrary, tannate of soda reaches the stomach, the chemical affinities of the tannic acid are already satisfied, and it is rapidly absorbed into the blood, thereby affording much less time for its sojourn in the intestine, and its conversion into gallic acid. Hence the large amount of tannic acid and the relatively smaller amount of gallic acid in the urine. The observations on man were conducted in a similar manner, and gave exactly similar results. Tannic acid may be given to man in considerable quantities and for a long time, without obtaining any bluish coloration on the addition of ferric salts to the urine. The fact that pyrogallic acid was not obtained in any case seems to show that it is not formed in the body.

Experiments with gallic acid showed that it has a dilating action on the blood-vessels; and that it has the power of dilating them again after they have been made to contract by the circulation of a weak alkaline solution through the frog. As alkalies contract vessels and gallic acid dilates them, we would naturally suppose that neutral gallate of soda would have no effect on their calibre; and a large number of experiments showed this to be the case. The circulation of salt solution containing gallic acid through mammalian blood-vessels also causes them to dilate. But when gallic acid is added to blood it becomes neutralized, and if the blood be circulated through an organ, either slight dilatation or no effect at all is produced on the calibre of the vessels. In the experiments the dilatation was in all cases so slight that it might be attributed either to accident, or, more probably, to the addition of the gallic acid diminishing the alkalinity of the blood. Though it has been generally assumed that tannic acid contracts blood-vessels, the experiments made by Dr. Stockman show that dilute solutions act exactly like dilute acids, and cause vascular dilatation. Solutions of catechutannic and rhatany-tannic acids, made with saline of the strength of 1:7500 to 1:1500, caused distinct dilatation. With such solutions it is sometimes possible to recover vessels which have been contracted by the circulation through them of alkaline solutions. From the fact that gallotannic acid is insoluble in sodium chloride solution it is difficult to investigate its action; for when it is added to the saline it is immediately precipitated, and in the circulation solid particles come in contact with the vessel-walls, thus causing contraction at once by coagulating the albumen. Still, in spite of the difficulties attending the experiments with it, it is proper to draw the conclusion that its action is similar to that of other varieties of tannin; and experiments on the excised sheep's kidney show that when the chemical affinities of tannin are satisfied it has no action on the vessels. Dr. Stockman's experiments with hypodermatic injections of tannic acid showed that it does not produce the effect stated by Fikentscher—that hypodermatic injections cause contraction of the arteries from stimulation of the vaso-motor centre in the medulla.

What, then, is to be said of the therapeutic value of vegetable astringents? In regard to gallic acid; it has no other action than that of a weak inorganic acid, either locally or when absorbed, and cannot be said to have any special action as an astringent. It does not lessen the calibre of vessels, either by peripheral or central action; and the fact that it does not precipitate albumen when used locally shows that it has no influence on catarrhal inflammation. It does diminish the alkalinity of the blood, and thus increases its tendency to coagulate; but stronger acids act in the same way, and more powerfully. "As regards tannic acid, the matter is somewhat more

complicated. Locally applied, its action for good depends on its power of precipitating albumen, the layer of tannate of albumen which is formed acting as a protective to the underlying mucous membrane. To this action is due its value in catarrhal inflammations of the alimentary canal, and in discharging surfaces generally. Its usefulness is limited to such cases, and as a remote astringent it is valueless. In weak solution, and uncombined, its action on contractile tissues, such as the vascular walls, is simply that of a dilute acid, while it is only when stronger solutions are used (much stronger than can ever exist in the blood, even if it were not in combination there) that its power of precipitating albumen comes into play. When its chemical affinities have been satisfied it is no longer capable of precipitating albumen, and therefore exercises little or no influence on the parts with which it comes in contact." The very small quantity in which it can exist in the blood at any one time also precludes its having any marked remote action; and as it is excreted by the bowels and kidneys, it can scarcely exert any effect on other mucous membranes, as the bronchial. Finally, while it is conceivable that it may have some influence in albuminuria, this is to be regarded as very doubtful; and the reported cases in which it has been used and careful measurements and analyses made confirm this doubt.

W. C. WILE, M.D., Editor of the *New England Medical Monthly*, has been appointed to a Professorship in the Medico-Chirurgical College of Philadelphia, and makes his future address 1006 Walnut Street, in that city, from which he will continue to edit his journal, as heretofore. Dr. Wile is one of the most active and talented members of the New England profession, and the Medico-Chirurgical College, though the youngest of the regular medical schools of Philadelphia, is nevertheless organized on a full graded system of instruction, and manned by a Faculty as worthy of the confidence and patronage of the profession as are her older competitors.

THE INTERNATIONAL MEDICAL CONGRESS OF 1887 AND TRANSATLANTIC STEAMSHIP FARES.—On the last page of THE JOURNAL of February 5 we gave a card from the Chairman of the Committee of Arrangements, Dr. A. Y. P. Garnett, giving information concerning liberal arrangements with several of the steamship lines, and the following appropriate acknowledgment should have been appended to the card: "The Committee wish to express their thanks to Mr. Edward Droop, of Washington, for his active interest and efficient aid in consummating this arrangement."

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, January 12, 1887.

THE PRESIDENT, JOS. TABER JOHNSON, M.D., IN THE CHAIR.

H. M. CUTTS, M.D., Secretary.

DR. D. S. LAMB presented

A PORTION OF THE ILEUM, WITH PERFORATION, FROM A CASE OF TYPHOID FEVER.

This specimen consists of a portion of ileum removed about 1½ feet from ileo-colic valve. It contains several Peyer's patches, all of which show slight thickening. The lowermost one is thickened, ulcerated and perforated. The ulcer is irregular in outline, edges slightly undermined; the base shows muscular fibres. The perforation is one-eighth inch in diameter; peritoneal surface of specimen plastered with pseudo-membrane. The case is one of typhoid, or perhaps more properly *enteric*, fever. The patient was a white man, age 29; had been perfectly healthy until this sickness. After several days malaise, typhoid fever was diagnosticated. He died ten days afterwards. The disease appeared in all to last two weeks. Temperature, taken twice daily, ranged from 102° to 104°. Symptoms of perforation occurred the day before death. The attending physician, for whom I made the necropsy, was unable to arrive at the cause of the disease. The post-mortem examination showed the body well nourished, lungs and heart normal. There was dirty, malodorous liquid in abdomen; some flatulent distension of stomach and intestines; intestinal peritoneum reddened, and in right iliac region plastered with dirty looking lymph. In lower two feet of ileum some Peyer's patches were nearly normal, others thickened and irregularly ulcerated; and one of them ulcerated and perforated, as described. Small ulcers in cæcum and vermiform appendix; liver normal; gall bladder ulcerated and contained over eighty gall-stones with facettes; spleen large and soft; kidneys normal.

According to Murchison, quoted by Fagge, peritonitis occurs in three per cent. of all cases of typhoid fever, and in nearly twenty per cent. of all deaths from the fever. The cause of the peritonitis is usually, as in this case, a perforation of the ulcerated Peyer's patch and escape of the intestinal contents into the peritoneal cavity. The perforation is most often excited probably by a sudden movement of the patient, as vomiting, straining, rising up; or by flatulent distension of the bowel, enemas, etc. The indication is, of course, to prevent so grave an occurrence by insuring the utmost quietude to the patient. And since perforation occurs sometimes in cases called mild, the patient perhaps walking about, the necessity of absolute rest is the more emphatic. In this particular case the date of perforation is placed at the end of the second week, which is several days earlier than that usually assigned. When,

however, it is considered how difficult it is to ascertain the precise date of beginning of the disease, the actual date of perforation becomes doubtful. The fact that many Peyer's patches in the lower ileum were but little thickened, while scattered among these were others ulcerated and one perforated, seems to confirm the theory that usually all the patches are not involved at one time, but with some hours or days of interval between. The fever, depression and danger are doubtless greater when all the patches are involved at the same time. But few cases recover after perforation in typhoid fever. It is quite likely that laparotomy has been tried in some cases, but I have not looked this up, and from what we know of the disease I should not expect healing to take place. I regret that the attending physician has not found it convenient to furnish a history of the case.

Dr. S. C. Busey remarked that as Dr. Lamb had brought up the question of laparotomy in perforation of typhoid fever, he would like to hear the subject discussed. Neither Dr. Lamb nor himself could recall an operation with this in view. As he understood Dr. Lamb, he said that the physician attending the case could not make out the cause of the fever. There is no question but that there is a specific cause for typhoid fever. Usually we get it in drinking water, food, etc. While it is easy to diagnosticate typhoid, it is not always so easy to tell when perforation has taken place. The peritonitis, which is sometimes present in typhoid, cannot always be ascribed to perforation. He has seen cases complicated with peritonitis get well, but he was sure that there was no perforation, because such cases usually die. Cases of recovery after perforation have been reported, but the diagnosis was only presumptive.

In his opinion, if the diagnosis is certain, laparotomy is justifiable, as the only hope of saving life. Of course, the diseased Peyer's patches and extravasation of fæces would complicate matters a great deal. He thought it difficult to make a diagnosis of perforation. He said that he used to think that all cases of peritonitis were from perforation, but now he believes that if they get well there has been no perforation.

Dr. J. Ford Thompson said that he had had no experience in laparotomies for perforation in typhoid. He thinks that while the operation may be justifiable, it would, probably, be unfavorable, not only on account of the local condition of the bowel, but on account of the general condition of the patient as well. He does not think that union of the gut would take place readily even if it were healthy. A better procedure would be to make an artificial anus, with the intention of operating again when the patient had somewhat recovered. He thinks the diagnosis of perforation easily made. The wound cannot be closed as a bullet wound, for if it was it would probably tear open in a few days and we would be worse than when we started. He thinks that the artificial anus will eventually be the legitimate operation.

Dr. H. D. Fry said that the specimen illustrated one reason why repair of perforation would be difficult. There was so much diseased tissue about the perforation, which it would be necessary to take away, that, as Dr. Cook has just suggested to him, cicatricial stricture would be likely to follow.

Dr. Lamb explained to Dr. Busey that the physician could not find the cause of this particular case of typhoid, not that the specific germ of the disease was not known.

Dr. R. Reyburn thinks that laparotomy for typhoid perforation has been done, but he cannot now recall where he has seen the report. He thinks the diagnosis of perforation easy, and that laparotomy would be justifiable.

Dr. Jos. Taber Johnson read a paper entitled

CAN THE CÆSAREAN SECTION SAFELY SUPPLANT CRANIOTOMY IN THE UNITED STATES AT THE PRESENT DAY?

(See page 169.)

Dr. A. F. A. King congratulated Dr. Johnson upon the masterly manner in which he handled the points of his argument, and upon the mode of presenting his figures. Two years ago, he said, he read a paper giving some conditions in which craniotomy would be absolutely necessary, and now, if after hearing them once, he had understood them correctly, he endorses Dr. Johnson's views and declares his belief that craniotomy will always prove a valuable operation.

Dr. J. Ford Thompson said that he had been following Dr. Johnson's paper very closely, and as near as he could make out the doctor recommended craniotomy in this country and Cæsarean section in Germany, where there are better operators. Dr. Johnson even expresses his personal preference for Cæsarean section, but advises us to do craniotomy. This cannot be the scientific way of looking at the question. One or the other is right, and the duty of the scientific surgeon is to find out the truth as to which is the better operation. There must be something better than the ghastly operation of craniotomy. There can be no doubt, however, but that in the hands of the ignorant more mothers will be saved by it than by Cæsarean section; but the ignorance of the operator is not the question to be considered. Other things being equal, which operation will save more lives, is what we must endeavor to find out.

If he had a good case and was called upon to decide on the operation, he would choose the Cæsarean section. He would not select the Sänger operation in all cases. Sänger's operation has a wonderful list of successes following it, but on the other hand he has seen C. Braun save three mothers and three children by the Porro. It is not so much the operation, as the time at which it is done. It is like the operation for strangulated hernia. The operator is hardly responsible for a fatal issue when the patient is brought to him after a prolonged taxis. If done in time the result would almost certainly have been successful. Thus, no one system can be implicitly followed out, and he would advise the Porro where the pelvis is so small that a future pregnancy would be likely to be fatal, and a Sänger where there was a possibility of a subsequent premature delivery.

Craniotomy may also be useful. If he found the patient very far gone and the fœtus dead, he would

advise craniotomy. In any case, if the mother alone is to be regarded, craniotomy is the safer operation; but if the child be alive, and we are to consider how most lives are to be saved, Cæsarean section is the operation.

Upon Dr. King's calling the speaker's attention to the fact that craniotomy is more fatal to the mother than Cæsarean section, when the pelvic diameters are below 1½ inches, Dr. Thompson said he supposed that that exception was understood.

DR. R. F. A. KING said he had long been in doubt as to whether the argument advanced by Dr. Barnes, viz.: that of considering the number of human lives that might arise from future pregnancies if the woman were saved, was a legitimate one. Should we admit this argument, on the one side, by saying that if the woman survive she might bear other children by induced premature delivery; so, on the other hand, it might be said that if she did *not* survive, her husband would then be at liberty to find a better breeder in another wife. Moreover, if the question of increasing population is to be admitted, we should also have to consider the future capacity of the child, or children, in this respect. But he thinks it is not a matter so much of *populational increase* as it is one mostly, or entirely, applying to the *individual* life of the lying-in woman and the *individual* child to be delivered. We deal with the existing emergency only, or at least chiefly: future children, yet unbegotten, must be left for the future.

DR. H. D. FRY said that he thought some explanation of Dr. Garrigues's position in regard to the Sänger operation was due to that gentleman. It did not seem to him that Dr. Garrigues, as implied in Dr. Johnson's paper, meant to claim for himself the origin of the so-called Sänger modfication. He raised the question whether an operation should be named after the one who proposes it or after the one who first performs it. Dr. Garrigues thought it might with equal justice be called after his name because, in a published list of the number of Sänger's operations performed, he occupied third place and Sänger eighth. His operation therefore antedated Sänger's. The method, moreover, differs as now practised from the original one suggested by Sänger. It has been found unnecessary to remove the wedge-shaped piece of uterine tissue. He said, further, he was not familiar with the histories of the five cases operated upon in this country after the Sänger modification, all of which, as Dr. Johnson states, terminated fatally. In the case operated upon by Garrigues, the patient had phthisis and was in the worst possible condition to stand any grave surgical operation. At the autopsy the peritoneal wound was found united and the uterine cavity entirely separated from that of the peritoneal. In this instance it is unfair to attribute the result of the operation to a failure of the Sänger modification.

Dr. King very properly makes a point of the degree of pelvic contraction existing in a given case when considering the advisability or not of craniotomy. The statistics of the operation in this country show a mortality of 40 per cent. in the higher degrees of contraction. Consequently our surgeons make as bad a showing, compared with Continental operators, in craniotomy as they do in Cæsarean section. In Europe craniotomy gives a mortality of only 8 per cent. or 5 per cent, and some operators have had a series of cases without a single death. There are three principal causes, Dr. Fry thinks, why our success in this line is not so good as that of our foreign brothers viz.: They follow antiseptic precautions more rigidly; they have had greater experience with the improved modifications of Cæsarean section; and they possess a better knowledge of pelvimetry—and, Dr. King added, more cases of pelvic deformity. Two of these disadvantages, the doctor continued, the surgeons of this country should overcome; the third is more difficult to remove, because the facilities for obtaining equal knowledge in pelvimetry do not exist in our country.

The importance of being able to ascertain the degree and nature of the pelvic deformity is indicated thus:

Suppose, in a case of dystocia, the antero-posterior diameter of the brim is ascertained to be three inches. With this amount of contraction of the conjugata and with no knowledge of the transverse and oblique diameters, efforts may be made to deliver by version, symphysiotomy or craniotomy. If the case, however, should be one of justeminor or equally faulty pelvis and a decrease of one inch in all the diameters, the early performance of Cæsarean section would offer the best chances for the mother, and efforts at delivery in other ways would jeopardize the result.

The great value of enforcing antiseptic precautions is shown by the fact that before the introduction of this method, Cæsarean section was uniformly fatal when performed by skilful operators connected with maternity hospitals. Now, they obtain brilliant results by the use of antiseptics. The German operators take the most minute precautions to avoid infection. Let the surgeons of this country advance in this respect. They can do that and they can operate skilfully, and adopt all the improved modifications of performing Cæsarean section.

DR. S. C. BUSEY said that he would like to congratulate Drs. King and Johnson on the reformation of their opinions. Two years ago, when he had advocated entirely abolishing craniotomy, these gentlemen had opposed his ideas.

(DR. KING explained that he had not altered his views. He had opposed the complete doing away with craniotomy, which Dr. Busey had advocated, and had himself shown conditions in which it would be absolutely necessary.) Dr. Busey replied, that at all events he had made some progress, as he had just indorsed Dr. Johnson's paper.

DR. BUSEY, continuing, said that he congratulated himself not a little that the views expressed by him two years ago were coming to be held by the profession at large. If he recalls Dr. Johnson's paper rightly, the chief reason why craniotomy should still be practised is that it is an easier operation than Cæsarean section—that there are still so many men illtaught that it cannot be entirely done away with. This cannot be, as Dr. Johnson says, the scientific standpoint from which to look at the question.

The doctor quotes from a table of Sänger operations prepared by Dr. Harris (*Med. News*, September 18, 1886), in which 38 cases are reported. Of the 76 lives involved 59 had been saved. He compared these with 38 cases of craniotomy, where at the outset it is only possible to save the 38 mothers, and called attention to Dr. King's remark that in the high grades of contracted pelves craniotomy was more fatal to the mother than Cæsarean section, thus making the outlook of saving even the 38 mothers a bad one.

Dr. King remarked that he did not think that a good basis of comparison.

Dr. Busey replied that the two operations were always to be compared. Each was the alternative of the other, and no woman was to be delivered by craniotomy or Cæsarean section who could be delivered by forceps, version or symphysiotomy.

Dr. Johnson thought that 38 cases of Sänger's operation was rather more than had been done, and put in evidence an autograph letter from Dr. Harris giving the synopsis of only 26 cases collected by the writer, and he further reminded Dr. Busey that his paper dealt only with the Cæsarean section in the United States.

Dr. Busey replied that the discussion of such a question should not be limited by any boundaries. Even if we confine ourselves to the United States, Dr. Johnson has wrongly undertaken to lay down a law by previous unlucky experiences, and to assert that the results will continue bad, in the face of the fact that surgery has made the most astonishing advances in the past few years, and is capable of advancing still further. By limiting the discussion to one locality he is discouraging the surgeons of that locality from making advances, and just so long as craniotomy is taught, it will be practised, because there will be men too ignorant to do Cæsarean section. The more craniotomies there are done, the more there will be done. He agreed with Dr. Meadows that it will have to be discussed from a moral as well as from a scientific standpoint, for just so long as teachers teach to kill at will the killing will be done.

Dr. King remarked that the killing could hardly be said to be done at will.

Dr. Busey replied that it was most assuredly done at will. The operator fully considered the mother before proceeding, and then voluntarily and at will killed the child.

Dr. Acker asked Dr. Busey how he would get around the objections of the friends and relatives to the Cæsarean section?

Dr. Busey replied that their objections did not relieve the doctor of his responsibilities—that because they will not permit the right thing to be done, it does not make it right to do a wrong act.

Michigan State Medical Society.—The executive committee have changed the date of the annual meeting of the Society to May 12 and 13, so as not to conflict with the meeting of the American Medical Association.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, December 17, 1886.

The President, Chas. Warrington Earle, M.D., in the Chair.

(*Continued from page 164.*)

ÆTIOLOGY, PATHOLOGY AND CLASSIFICATION OF SALPINGITIS.

The Secretary, Dr. Edward Warren Sawyer, read the following communication from Dr. Sänger, of Leipsic, in reply to a letter by Mr. Lawson Tait, read before the Society, May 28, 1886.

Dr. Sänger's letter was translated by Dr. Ivo Bernauer, of the Cook County Hospital, and revised by Dr. Christain Fenger.

Leipsic, Oct. 10, 1886, Lindenstrasse 16.

To Daniel T. Nelson, M.D., President of the Chicago Gynæcological Society.

Dear Sir: I have been personally attacked by Mr. Lawson Tait in a letter addressed to you; as I desire that my reply go by the same way, I take the liberty of requesting you to bring my letter to the notice of your Society and to have it assigned a place in the Transactions of the same. Nobody will dispute that up to the present time Mr. Lawson Tait, of all laparotomists, has had the best results, at all events in regard to ovariotomy and salpingo-oöphorectomy. His practical results have, however, raised his conceit to so high a degree that in pathological questions also he assumes a certain infallibility, which vents itself in numerous sallies and attacks upon others. The consequence of this is that just at present, Mr. Lawson Tait is being subjected to various energetic criticisms as by Bigelow, Schröder and others.

Now Mr. Lawson Tait has also shot one of his shafts at me. I feel very thankful toward Dr. Christain Fenger for having received it on my account. However I do not wish to allow the matter to rest there.

At the sesssions of the Gynæcological Society of Chicago, held in February and March, the treatment of pelvic abscess by laparotomy was discussed in a highly instructive manner. Dr. Fenger in his excellent and exhaustive remarks, said that "my statements regarding ætiology were the most complete" inasmuch as there must necessarily be as many forms of pelvic abscess as there are forms of disease of the Fallopian tubes. The latter were enumerated by Dr. Fenger, according to the classification given by me in a paper read at the *Versammlung Deutscher Naturforscher* in Magdeburg. (See report, Archiv. f. Gynæk. Bd. XXV, pp. 126–33.) In this classification six different forms are recognized, and it is this distinction which Lawson Tait is pleased to style "absurd." Although Dr. Fenger reiterated his statement "that he regarded my classification as correct and complete and in accordance with the laws governing inflammatory processes in all organs of the body," yet I do not think that this defense of my position is sufficient. Considering the great influ-

ence Lawson Tait exercises upon the profession, I deem it my duty to refute him in every particular. I shall attempt to do so in a scientific manner, and I may thus hope that my reply will prove of general use and interest.

The pathological anatomy and the course of salpingitis can be understood only when we bear in mind the theories of infection. The whole sexual tract, from the ring of the hymen to the *ostium tubæ abdominale*, is open to the entrance of the external air and the germs suspended in it. Carriers of infection coming from the abdominal cavity and its contained organs may also enter at the *ostium tubæ abdominale*. Even microbes originally lodged in the external parts, in the vagina around the cervix, may, by way of the lymphatics, reach the peritoneal cavity, and thence gain entrance into the tubes.

The normal vaginal and uterine secretions at the age of puberty and the menstrual blood contain numerous non-pathogenous micro organisms. Still greater numbers are found in the catarrhal secretions of the uterus in cases of endometritis as was demonstrated by Küstner. As to the normal tubal secretion and the tubal secretion in cases of *salpingitis catarrhalis*, consequent upon *endometritis catarrhalis*, no investigations have as yet been made to show whether or not they likewise, contain non-pathogenous microbes. However, as the secretion of an endometritis contains microbes we may assume that if the inflammation is continued into the tubes, its secretion will here likewise contain the same. It has been clearly proven that pathogenous micro-organisms pass from the external parts to the tubes, and the peritoneal cavity, a fact which is doubted by no one, perhaps, except by Lawson Tait. These organisms have, in part, been acurately studied, and it is well known that different kinds produce distinct forms of salpingitis, and secondarily pelveo-peritonitis. The fact was already established by Guréin and Guerrier, that in making vaginal and intra-uterine injections air, and thus, also micro-organisms, might pass into the tubes (Physo-Salpinx). S. Hennig, in his book "*Krankheiten der Eileiter*," p. 52, surmises that, in cases of putrid endometritis and physometra, gases may escape from the tubes into the peritoneal cavity.

Our present knowledge of the above mentioned pathogenous micro-organisms will enable us to divide them into three groups:

GROUP 1.—FORMS OF SALPINGITIS PRODUCED BY KNOWN SPECIFIC MICROBES.

1. *Salpingitis gonorrhoica*, produced by the gonococcus of Neisser.

2. *Salpingitis tuberculosa*, produced by the *bacillus tuberculosis* of Koch.

3. *Salpingitis actinomycotica*, produced by the *actinomyces bovis* of Bollinger.

1. *Salpingitis gonorrhoica* in the only specific infectious form of salpingitis which is recognized as such by Lawson Tait, although he stops short of admitting that the gonococcus is the exciting agent. Without doubt the gonorrhœal is the form most frequently met with. This fact was clinically established as early as 1872, by Nöggerath, long before Neisser had discovered his gonococci or Lawson Tait performed his first operations for "suppuration of the uterine appendages." In Germany, I myself was one of the first gynæcologists who at our meetings showed the frequency of gonorrhœal salpingitis, emphasized its causal connection with pelveo-peritonitis, and removed by operation the gravely implicated uterine adnexa. (Magdeburg, 1884, and Munich, 1886.) Gonorrhœal salpingitis is never followed by a destructive "suppuration" of the uterine appendages; it remains invariably a disease of the surfaces of the mucous and serous membranes. The pus formed by the specifically diseased mucous membrane gradually distends the tube; in one class of cases in which there is a great accumulation of free pus the tube is transformed into a large sac with thin walls, in another in which the wall of the tube, especially its muscular tissue, is hypertrophied to a greater extent, the tube becomes much thickened and rigid. In most cases, both conditions are found, the uterine portion of the tube is thickened, the abdominal end dilated. The serous surfaces of the tubes, the albuginea of the ovaries, the serosa of the peritoneum are attacked or become pus secreting surfaces only in cases in which gonorrhœal pus has escaped from the tubes, and thus infected the above named structures. We may then have peri-salpingitis, peri-oöphoritis, peri-metritis, s. *pelveo-peritonitis purulenta gonorrhoica*. I do not believe that gonorrhœal pus ever penetrates the walls of the tubes and thus produces these diseases. But a specific gonorrhœal inflammation of the mucous membrane of the tube, with secretion of pus into the cavity of the latter, is accompanied by a non-specific inflammation of the entire tubal wall. This may also excite peri salpingitis, peri-oöphoritis and so forth; the organs involved may become adherent to each other and displaced, but we never meet with a purulent exudate of the same nature as that found in the cavity of the tube itself. This also explains why, in some instances, gonorrhœal disease of the uterine appendages is accompanied by severe and violent symptoms, frequently resembling those of a peritonitis following perforation, whereas in other instances it develops insiduously, scarcely manifesting any symptoms at all. In the former cases, gonorrhœal pus escapes through the *ostium abdominale* into the peritoneal cavity; in the latter the inflammation of the external surfaces of the adnexa is non-specific in character.

According to what I have just stated, I must necessarily regard the terms. "suppuration of the uterine appendices and peri-uterine s. pelvic abscess." as inaccurate, and from a general pathological point of view, as productive of confusion; we invariably find free pus in the tubes and peritoneal cavity or an inflammation of the adnexa, but never destructive suppuration of the tissues of the pelvic organs. In cases in which abscesses are discovered in the walls of the tubes, in the tissues of the *ligamenta lata* and in the ovaries, these abscesses are, as I shall later on show, due to septic infection, but not to gonorrhœa.

The latter disease produces suppuration only on surfaces.

I purposely enlarged somewhat on gonorrhœal salpingitis and its consequences, as this form presents a typical example of infectious salpingitis in general.

There is one more point to which I wish to call attention. Gonococci have not always been discovered in pus coming from the tubes, in cases in which clinically there existed no doubt as to the gonorrhœal nature of the infection. The conditions under which the gonococci are destroyed, or prevented from further development, have not yet been ascertained; further investigation will also have to show whether, in cases in which gonococci are absent, there are not present other microbes belonging to one of the groups mentioned further on.

2. *Salpingitis tuberculosa.*—Alfred Hegar's lately published work, "*Enstehung, Diagnose und Chirurgische Behandlung der Genitaltuberculose des Weibes,*" relieves me of the necessity of entering more fully into the consideration of this form of salpingitis. Lawson Tait denies the existence of this form, or rather, he admits it, but only "for the third and contracting stage of pyosalpinx." This admission simply discloses his ignorance of the true nature of tuberculous infection. The pus in a case of purulent salpingitis, whether it be gonorrhœal or otherwise, may of course undergo caseation. This was called tuberculization before Koch's discovery of the *bacillus tuberculosis;* now it is termed coagulation-necrosis, according to Cohnheim-Weigert. It is this, which Lawson Tait confounds with the genuine infection by the bacillus of tuberculosis.

A pyosalpinx may remain in this third stage indefinitely; a tuberculous salpingitis will never result therefrom unless there be added a tuberculous infection.

3. *Salpingitis actinomycotica.*—This form is called by Lawson Tait "an equally ridiculous subdivision based on mere theory, not on fact." It seems to me before making such an unintelligible assertion it would have been his duty to enquire whether there really is no case on record to support me in including this form in my enumeration. In my paper, above mentioned, I named the author who had furnished this case; I will now accurately give my authority: Adolph Zemann, "*Uber die Aktinomycose des Bauchfells und der Baucheingeweide beim Menschen, Medicin. Jarhbücher der K. K. Gesellsch, Arzte in Wein,*" 1883, S. 477, Fall 4. The tubes in this case were dilated and filled with pus and clumps of the actinomyces, their walls were thickened and exhibited numerous granulations produced by the fungus. The fungus had migrated either from the vagina or from the intestines which were found extensively adherent to the tubes. What Lawson Tait does not know, has no existence for him. "Germanica sunt, non leguntur."

GROUP II.—FORMS OF SALPINGITIS DUE TO SPECIFIC MICROBES IDENTICAL WITH THOSE PRODUCING TRAUMATIC INFECTION.

Salpingitis septica (*pyæmica, ichorosa, purulenta, diphtheritica*).—The term *salpingitis septica,* is rather general and inaccurate; as when speaking of a pyosalpinx we simply mean that the tube contains pus, when employing the term *salpingitis septica* we merely indicate that the disease is due to infection by a septic virus. It is at the present time, a matter of extreme difficulty to diagnose the nature of the pus, and the nature of the infection presented to us in an individual case. Now, we certainly know that the microbes producing the different kinds of traumatic infection known clinically as septicæmia, pyæmia, diphtheria, phlegmon, erysipelas, may one and all invade the general tract; we may, hence, infer the existence of an equal number of varieties of salpingitis, *i. e. salpingitis septica, pyæmica, diphtheritica, phlegmonosa, erysipelatosa.* In order to complete our scheme we should add *salpingitis putrida,* corresponding to putrid infection, whereby the difficulties are still further increased.

Notwithstanding the progress made in bacteriology, we have not yet succeeded in isolating and classifying the microbes which cause the clinically different forms of traumatic infection; consequently it is impossible to do this with regard to the different forms of *salpingitis septica.* However, the work done by Doléris, E. Fränkel, Lomer, A. H. Barbour, Nöggerath, Cushing, in the domain of puerperal infection has given us some positive results.

These are two points which are to be considered fundamental:

(1). The microbes of puerperal septicæmia are identical with those producing traumatic infection in general. During the puerperium after abortion, as well as after parturition at term, the genital track is far more susceptible to infection, or the conditions are far more favorable to the spreading of infection, than at other times.

(2). As has been demonstrated by Ogston, Hueter and Rosenbach, all suppuration is due to the action of microbes; several varieties of these, like the *streptococcus pyogenes* and *staphylococcus pyogenes,* have been closely studied, but it is known that they are not the only varieties which produce pus. As doubtless all of these carriers of infection may play a rôle in the production of salpingitis, we can readily see how complicated the question of infectious diseases of the tubes has become, and how unscientific and untenable is the meaningless name of pyosalpinx. Yet there is a certain comfort in hoping that the matter may be somewhat simplified. Some of the forms of traumatic infection, for instance, sepsis, and diphtheria, pyæmia and phlegmon, are probably produced by identical micro organisms, and the course of the disease may be modified by the nature of the tissue first attacked, and by the manner in which the infection spreads, whether by the blood or lymph channels.

All of these infections, as is well known, have a double effect—a local one in the genital tract, and a constitutional one, which is brought about through the medium of the circulation, and which is seen not only in the system at large, but also in the localization of the infection in organs distant from the point of entrance of the micro-organisms. When systemic effects are produced by the virus of putrid infection,

the disease is called sapræmia; when by the virus of septic infection, septic toxæmia or ptomaine poisoning; when by that of purulent infection, pyæmia.

We thus meet with an essential difference between the diseases of the genital tract, produced by the microbes of Group I, and those of the traumatic infection. The above mentioned severe and acute constitutional symptoms are but slightly indicated, or may even be absent in the diseases of the first group, *i. e.* gonorrhœa, tuberculosis, actinomycosis, whose course is chronic; whereas in diseases of the second group, the rapidity of their development, and the malignity of their course may almost entirely obscure the local disturbance in the genital tract.

As is readily seen, the septic diseases of the tubes are not independent diseases; aside from the local disturbances co existing in the uterus, vagina and external genitals, the whole circulatory system is usually affected. In this respect, as Lawson Tait rightly remarks, septic disease of the tubes is not a specific ailment; this, however, is of no importance in an enumeration of the varieties of salpingitis. An endometritis or a *colpitis gonorrhoica* may coexist with a *salpingitis gonorrhoica*, and in the same way *salpingitis septica* may be accompanied by other diseases of the sexual organs, which are due to the same cause. There is, of course, no such thing as an affection of the tubes merely.

Salpingitis septica, co existing with severe puerperal septicæmia or "lymphatic peritonitis," has never as yet, it is true, given the surgeon an opportunity to remove the principal focus of the disease by extirpation of the tubes. It is possible, however, that under certain circumstances such a procedure might be indicated. B. S. Schultze, "*s. Verhandl. d. gynækolog. Section d. Versammlung deutscher Naturforscher*," in Berlin, 1886, has lately succeeded in amputating a puerperal uterus, in a case in which it was impossible otherwise to remove the placenta, which had become the source of septic infection. Lately two cases came to my knowledge in which the tubes burst from over-distension with pus, whose nature, whether gonorrhœal or septic, was not ascertained. In both cases a general peritonitis resulted, which proved fatal, in one on the fourth, in the other on the twenty-first day after confinement. It is clear that in both these cases the salpingitis had existed before delivery. I shall afterwards relate a case of my own in which this certainty was the condition. Cases of this kind will be diagnosed more frequently and more readily as soon as our attention has been called to them, and we may then expect to hear of their treatment by operation. Cases of salpingitis, consequent upon traumatic infection in non-puerperal women, are, of course, of much more frequent occurrence. The carriers of infection may, for instance, be directly introduced into the tubes by means of an infected sound. The introduction of a septic instrument into the uterine cavity may be followed by a septic salpingitis. In cases in which we observe an exudative pelveo-peritonitis after the introduction of an infecting sound, after an intra-uterine injection or a *eurettement* of the *mucosa uteri*, the infection almost always spreads to the pelvic peritoneum by way of the tubes and exceptionally only through the muscular walls of the uterus. The severe systemic disturbances, the diseases of the uterus and pelvic peritoneum, may gradually subside, whereas the tubal affection remains. A pyosalpinx has formed, the tubes are filled with pus, which can have been produced only by the action of one of the specific microbes of traumatic infection: perhaps by the *staphylococcus pyogenes*.

Two cases of my own may serve as illustrations. In one of them a physician had performed *abraiso mucosæ uteri* without antiseptic precautions, infection took place and a *pelveo-peritonitis exudativa* followed, after the subsidence of which I could easily feel each tube thickened to the size of a thumb. At the operation both tubes were discovered to have thinned walls and to contain thick pus resembling that found in an abscess. The ovaries were small and enveloped in masses of very dense, connective tissue. I removed the tubes, but left the ovaries. The woman made a good recovery. The adnexa had been in a healthy condition before the mucous membrane of the uterus had been scraped. I have already published the other case (*"Verhandlungen der Gesellch. f. Geburtsh," zu Leipzig*, 17 April, 1882; *"Centralb. f. Gynæk."* 1882, p. 558); multipara of twenty-nine years; three spontaneous deliveries, at fourth *placenta prævia*, and forceps applied before complete dilatation of the os. Puerperal fever. Recovery, but permanent pains in the right epigastrium. A short time after, renewed pregnancy, in the third month of which a prominent gynæcologist ascertained disease of the right uterine appendages; at full term rapid and spontaneous delivery. On the third and subsequent days of the puerperium, chills, high intermitting fever, icterus, in short the symptoms of acute pyæmia. Death on the thirtieth day. The autopsy revealed *salpingitis purulenta dextra*, and several abscesses in the right ovary and right broad ligament. The remainder of the genital organs, the adnexa on the left side normal. I explain the course which the disease took in this case in the following way: At the fourth parturition, septic infection and localization of the disease in the uterus and the appendages on the right side; subsidence of the grave constitutional disturbances and persistence of a pyosalpinx, probably due to *streptoccocus pyogenes*, latency of pyosalpinx during subsequent pregnancy. After delivery increased absorption of pus, abscesses in the ovary and broad ligament, acute pyæmia and death. In a case of this kind a septic-infectious disease, originally extending over large portions of the sexual tract, is finally concentrated in the tubes. Why should not such a case, in which the tubes chiefly appear affected, present a "specific ailment" as well as does a case of *pyosalpinx gonorrhoica*, in which *ceteris paribus* we have the same limitation of the disease to the tube as a principal focus for further infection.

What I desire to prove by these somewhat extensive remarks is, briefly, as follows:

1. Numerous cases of *salpingitis purulenta* ("pyosalpinx") are due to traumatic infection, are septic forms of salpingitis.

2. There are as many forms of septic salpingitis as there are forms of traumatic infection, and of microbes producing the same.

There is, however, an additional reason why Lawson Tait denies septic salpingitis to be a specific ailment. As we see from his startling remarks in the *Medical News*, April 24, 1886, he does not believe in sepsis at all, does not believe in infection, denies the principles on which the practice of modern surgery and obstetrics is based. He has been taught nothing by the researches of Semmelweis and Lister, Pasteur and Koch. And why? Because his own success in combating septic infection is to him proof of the non existence of septic infection. We are accustomed to Lawson Tait's reckless statements. Without taking the trouble to refute them scientifically, I but wish to call to mind his assertion that menstruation does not depend upon the ovaries, but upon the tubes; that the mortality of the Cæsarean operation is still 99⅔ per cent. His denial of traumatic infection is a statement of the same kind. I should like to hear Lawson Tait's answer to the following questions:

1. What disease, before the introduction of Listerism, killed trousands of patients who had received wounds or who had been operated upon? What, according to his views, was the cause of death in his own cases, when he lost patients after operations, if not, as everybody else believes, septic infection?

2. What is puerperal fever?

Lawson Tait disputes the correctness of our teachings regarding infection, but he has failed to give us any other explanation of its phenomena.

(*To be concluded.*)

DOMESTIC CORRESPONDENCE

"ELECTROLYSIS IN UTERINE FIBROIDS."

Dear Sir:—In Dr. Cutter's letter of last week, "Electrolysis in Uterine Fibroids," I am indirectly criticised for remarks that I wish to modify somewhat as far as they concern me. Dr. Belfield's remarks on my article, "Electrolysis in Gynecology, with a Description of Dr. Apostoli's Method," were quoted by Dr. Cutter, and these remarks made me appear to say, "During the last twenty-five years various attempts have been made to reduce fibroids of the uterus by the galvanic current; yet none of them have been recognized as successful; because, doubtless, as Dr. Martin very properly says, the current has been used in an ignorant, inaccurate and bungling way." I do not wish to be understood as saying, "yet none of them have been recognized as being successful," because I have reported successful cases within the last two years of my own, and have also quoted successful cases of other operators. Neither do I wish to be quoted as saying, "the current has been used in an ignorant, inaccurate and bungling way," because it is not what I said, although I do not impute to the author of the remark any intention to misquote. What I *did* say, however, was this: "Unfortunately, the term electrolysis, as applied to the treatment of diseases, has been by many, for some unaccountable reason, greatly misunderstood." This statement, while it does not differ widely from the remark quoted, is somewhat modified and not nearly as sweeping.

Dr. Cutter, I am sure, will agree with me, after having had sixteen years' experience with this method of treatment, that there is a great deal of ignorance abroad in regard to the principles it involves. He must also admit that improvements in the methods of electrolytic treatmen· have been rapid, and that with the new improvements in electrodes and means of measurement of the current, its usage is rapidly resolving itself into a science.

Within the last three years I have been able, by adopting improved electrodes, to increase the maximum strength of current used through a fibroid tumor without causing pain enough to require an anæsthetic, from 25 milliampères to 10 ampères—and this with *one surface electrode*. All who are acquainted with the history of electrolysis in the treatment of fibroid tumors will concede to Dr. Cutter his claim of priority in that field. Respectfully yours,

FRANKLIN H. MARTIN, M.D.

163 State St., Chicago, Feb. 8, 1887.

CASE OF GANGRENE OF THE MOUTH.

Dear Sir:—I desire to report the following case: Stella S., æt. 4 years, was attacked with gangrena orum on December 22, 1886. A gangrenous condition presented itself over all the visible part of the mouth, including the lips. There was fever, restlessness, loss of appetite. The face had a livid, sunken appearance. The discharge from the mouth was fetid and had the ante-mortem odor. The mouth finally presented a brownish-black and dry appearance, with black ulcers on the lips. The mouth and lips often bled. I put the child first on tinc. of chloride of iron and chlorate of potassium, and washed the mouth with a saturated solution of chlorate of potassium. No improvement took place until Christmas day, after I had changed the chlorate of potassium wash for a wash of bromo-chloralum, ℥ij to the pint of water, and to-day, December 31, the mouth is moist and clearing, the fetor is subsiding and the appetite is improving. In fact, the child is convalescing.

About the time I commenced the solution of bromo-chloralum I had a powder of subnitrate of bismuth blown through a quill into the mouth of the child. I think the bromo-chloralum is worthy of trial in these cases of gangrene of the mouth. J. M. BATTEN.

309 Fifth Ave., Pittsburg, Pa., Dec. 31, 1886.

SECRET REMEDIES.

Dear Sir:—In THE JOURNAL of January 15 is a communication from Dr. Amos Sawyer on "Rumex Acetosa" as the probable secret remedy used by traveling cancer doctors for taking out tumors. His falling on the article used *by chance* reminded me of a secret with which I was entrusted some two years since. I had operated on an old gentleman for cat-

aract, and one day, when visiting him, he told me if he received sight from the operation he would give me two valuable recipes: one a sure cure for cancer, the other a never-failing cure for all kinds of sore eyes. To sum up the results of the operation, I got the recipes. Here is the one for cancer: Gather the leaves of the common sheep sorrel, bruise them by pounding, and press out the juice; put the juice in a thin layer in a wide and flat-bottomed new tin pan and set in the sun; when evaporated to the consistency of honey, scrape up with a knife and spread on a piece of cloth large enough to cover the cancer, and bind it on. For two or three hours the pain will be intense, but will then subside. In twelve to twenty-four hours, according to the size and depth of the cancer, it should be taken off, and the cancer will be found loose to its *roots* and will readily come out. He claimed to have seen it used successfully a number of times, and never knew it to fail. Of course, *diagnosis* was a small matter with him; the *cure* was all he wanted.

On speaking of this one day to one of our old and respected physicians, he told me he saw this same remedy tried twenty-five or thirty years ago. A patient of his had cancer, and friends urged a trial of sheep sorrel. He consented and it was applied. The cancer failed to come away and the patient finally died from it. According to the above formula, would not oxalate of tin be the product? Might it not be well to experiment a little along this line? I write this, also, to show Dr. Sawyer how widespread *secret remedies* sometimes are. Very truly,

T. E. MURRELL, M.D.

111 E. Fifth St., Little Rock, Ark.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

Section of Medical Jurisprudence.

The following valuable and instructive papers will be read at the coming meeting:

James G. Kiernan, M.D., Chicago (two papers): "State Supervision of the Insane;" "Medico-Legal Relations of Epilepsy."

Joseph F. Edwards, A.M., M.D., Editor *The Annals of Hygiene*, Philadelphia, Pa.: "The Suppression of the Illegal Practice of Medicine."

Judge Amos G. Hull, Counselor-at-Law of New York Bar: "Medical Jurisprudence in its Relations to undue influences as affecting Wills and Contracts."

These papers the authors *positively* promise to be *present* and *read*. Besides these, almost positive assurance of papers has been received from Prof. H. O. Marcy, Boston, Mass.; Dr. W. C. Wile, Philadelphia, Pa.; Dr. F. E. Daniels, Editor *Texas Medical Journal*, Austin, Tex.; Dr. E. C. Spitzka, New York; and Dr. Herman J. Boldt, New York.

As titles of papers are received they shall be forwarded for publication in THE JOURNAL.

I. N. QUIMBY, M.D., Chairman.

582 Jersey Ave., Jersey City, N. J.

MISCELLANEOUS.

DR. J. ADAMS ALLEN, President of Rush Medical College, Chicago, was on Wednesday made the recipient of a handsome present from the students of the College. The doctor had entered the class-room for the purpose of delivering his usual lecture when L. E. Tifft, one of the students, interrupted the routine proceedings, and on behalf of his fellow-students presented "Uncle Allen," as the doctor is familiarly called, with a "tripod," consisting of a fat, chubby hand, made of solid gold. The thumb and little finger of the hand were bent so as to touch, the remaining digits being extended. The hand was set on a small block of alabaster, and this, in turn, on a base of black onyx. On the onyx was a solid gold plate bearing this inscription:

UNCLE ALLEN'S TRIPOD.
Remember these three
When we practice the art:
The condition of blood,
The nerves, and the heart.

The quotation is a verse of a college song based on some of Dr. Allen's sayings, and the position of the hand is a favorite one with him when addressing the students. The doctor was greatly surprised on receiving the present, but managed to thank the boys in a way to make them feel happy. He sails Saturday next for Europe, to be gone until September, and this presentation was a token of the good wishes of the students.

THE Governor of New York, in his annual message, has called attention to the practice of adulterating drugs, and denounced it in appropriate terms. Governors of the other States might follow his example with advantage to the profession and the people.

DR. WM. PERRY, the oldest person in Exeter, N. H., and the oldest graduate of Harvard College, died on January 11, aged 98 years. He was the sole survivor of the passengers on Fulton's first steamboat trip down the Hudson River, seventy-nine years ago.

A PHYSICIAN'S PROTECTIVE ASSOCIATION is being organized in Indianapolis.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 29, 1887, TO FEBRUARY 4, 1887

Capt. Junius L. Powell, Asst. Surgeon, granted leave of absence for two months, to take effect when his services can be spared by his department commander. S. O. 24, A. G. O., Jan. 29, 1887.

First Lieut. Paul Clendenin, Asst. Surgeon, ordered for duty as Post Surgeon at Camp Pena Colorado, Texas. S. O. 14, Dept. Texas, Jan. 26, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SIX WEEKS ENDED JANUARY 29, 1887.

Wyman, Walter, Surgeon, granted leave of absence for three days. Jan. 14, 1887.

Wheeler, W. A., P. A. Surgeon, to proceed to Erie, Pa., as Inspector. Jan. 12, 1887.

ORIGINAL ARTICLES.

THE AFTER-TREATMENT OF CATARACT EXTRACTION AND IRIDECTOMY ACCORDING TO DR. MICHELL'S METHODS.

BY T. E. MURRELL, M.D.,
OF LITTLE ROCK, ARK.

Dr. Charles Michell's method of dressing an eye after extraction of the lens and after iridectomy, together with the non-exclusion of light from the eye at any time subsequent to the operation, was brought before the general profession of the country for the first time in St. Louis last May, in the Section of Ophthalmology of the American Medical Association. As might be expected, it created no little surprise. Opinion was divided as to the propriety of such seemingly extreme measures. Dr. Chisolm said, for one, he would test it. How many others have made a test of it I know not, but it is somewhat surprising that so little literature on the subject has thus far appeared. Evidently few have ventured to put the matter to the test else, I think, more would have been written in commendation of so valuable an acquisition to ophthalmic surgery. In the *American Journal of Ophthalmology*, June number, Dr. Chisolm reports sixteen cases in which he used Dr. Michell's after-treatment with most flattering results. Again, in a more lengthy report in the *N. Y. Medical Record*, of July 31, he further comments on the after-management of extractions, and adds other cases from which he draws conclusions more firmly confirming his faith in the safety and advantages of the innovation. Dr. Michell very modestly gives an account of how he came to adopt this dressing, and to allow the patient abundant light after extractions, in the third number of the *Archives of Ophthalmology* for 1886. He has been too modest in bringing this matter before the world; besides, I regard it so valuable as to have made it his duty long since to have done so. As for myself, I am willing to subscribe to Dr. Chisolm's strongest commendations, having used no other after-treatment in extractions and iridectomies since last May, when Dr. Michell very kindly gave me in person all the details of the treatment. Nothing can be more simple, and nothing more sensible.

As would be expected, claims of priority are now coming in. One writer asserts that for fifteen years or more Dr. Levis, of Philadelphia, has discarded bandages. He is not alone in this. Some of the English and Continental surgeons have been in the habit of dressing the eye after extraction with strips of adhesive plaster, but they were very careful to keep the patient in a *dark room*. See "Wells on the Eye," third edition, p. 268; "Haynes Walton on the Eye," third edition, pp. 788–89, and other works that might be cited; some preferring the compress bandage, some the adhesive strips. As I understand, Dr. Levis' dressing consists of a piece of black court-plaster completely covering both lids, leaving only a small opening at the inner canthus to allow the escape of tears. I don't know whether he uses a dark room or not, but he could not more effectually exclude the light than by the above dressing. In the August issue of *Progress*, Dr. Dudley S. Reynolds, of Louisville, Ky., puts in a claim in the following words: "The use of the bandage after extraction of cataract has long since been abandoned by the writer. Instead of this useless and sometimes dangerous form of dressing, a little dry absorbent cotton, secured by strips of adhesive plaster drawn from the cheek to the forehead, answers a better purpose." He makes no mention of a dark room, but had he not regarded the light, he would not have omitted putting in his claim here also, since it is one of the strong points in Dr. Michell's methods. Dr. Reynolds' dressing defeats two important features in the after-treatment under consideration, viz.: the filling in of the orbital space with cotton heats the eye, excludes the light, and precludes the daily inspection of the lids without disturbing the dressing; and second, the play of the facial muscles would certainly disturb the equilibrium of the dressing through traction on the adhesive strips. These, the two strongest claims yet put forward, speak for themselves, while whatever honor may come of this valuable measure certainly belongs to Dr. Charles E. Michell.

In my former experience after extraction I had much trouble with slow convalescence, and long-continued photophobia oftentimes; and, in addition, quite a large percentage of iritis of a mild grade, which usually made its appearance after the fifth day. None of these have troubled me with the new after-treatment, and I now feel quite sure that the majority of iritic inflammations were the result of exposure of the eye to a bright light at the time of the first examination. It was always painful and caused a flow of tears. Well do I remember how I used to go through the eye wards in Baltimore and in New York with the surgeon to dress the eyes op-

erated for cataract, with candle in hand, to see how to change the dressing. And when I began practice I followed in my preceptor's tracks, and carefully excluded every ray of light. I came to notice, however, in the course of time, that the more effectually the light was excluded the more intense and the more persistent the photophobia; hence I came gradually to be less careful of utter darkness, until I had come to using a well lighted room for the patient, and only using the cotton and bandage dressing over the eyes. I always directed, if the light was too bright, to put a piece of black goods over the bandage, but I found they seldom called for this. On hearing, therefore, of Dr. Michell's after-treatment, I felt prepared to try it at once. To show what I founded my faith on, I give, by way of illustrating the effects of this simple treatment, a few cases from my record book:

Case 1.—Miss W., æt. 23. Old irido cyelitis, with exclusion of the pupils and opacity of the lens in each eye. V= perception of light. Extracted the right lens, leaving a thick calcareous capsule. Dark room and bandage. Ten days later removed the bandage permanently and put on a shade for the eyes. There was some iritis at this time, which soon subsided, but the most intense photophobia continued for fully a month, and it was after two months or more that she could tolerate full daylight without discomfort. Some months later I extracted the left lens in its capsule, which was also treated with bandage and dark room, and was followed by a like train of iritis and long continued photophobia. These operations were performed last winter and spring. In September of this year I extracted the calcareous capsule from the right eye. It was a dense hull of lime salts so thick that it crushed like egg shell. A large corneal section was made and the mass seized with forceps and withdrawn. Both eyes were dressed with a narrow strip of isinglass plaster just long enough to catch well on the two lids and hold them together. The room in which she stayed had two large east windows without blinds, curtains or shades. and I directed that none be put up. The walls being white, the light in the room was very bright. The morning sun shone in her face and she found it more comfortable to put a screen between her face and the window until the sunshine had gotten off of her bed. No other discomfort was complained of. On the fifth day the left eye was turned loose, and on the seventh day the right. She was at once given the liberties of the house, and on calling to see her the next day I found her walking in the yard barehead, with a bright sun overhead, utterly indifferent to the light. There was no iritis or photophobia at any time.

Case 2.—Mrs. R., æt. 81. Hyper-mature cataract in the right eye, dislocated downwards fully one-third its diameter; fluid vitreous.

July 22, made an upward iridectomy. Lids closed with narrow strips of isinglass plaster and full day light allowed in the room. Six days later liberated both eyes and let her go where she pleased. A mild conjunctivitis ensued, but there was no photophobia whatever. The result of the iridectomy was not satisfactory as regards vision on account of a filmy opacity above the periphery of the lens; so on September 29 I removed the lens and its capsule. The after-treatment was the same as before. No pain at any time. On the eighth day removed the plaster and gave her the liberties of the house. There was union by first intention, a clear black pupil, and not the slightest trace of iritic engorgement. The effect of full daylight was not at all disagreeable from the first exposure of the eye. Ophthalmoscopic examination revealed a fluid vitreous with floating opacities from former choroiditis, and of course there was but moderate vision.

Case 3.—Mr. S., æt. 76. Cataract in both eyes. August 2 I extracted the right lens and dressed both eyes in the usual way, allowing the light in the room just as they had been accustomed to having it. On the fifth day I removed the strip of plaster from the left eye, and on the seventh day from the right. Perfect healing, no iritis, no photophobia or lachrymation, no discomfort of any kind. He was out in the bright sun in less than two weeks, and remarked that daylight seemed brighter to him than it ever did in his life, much like being near an electric light; but it was not at all disagreeable, and caused no irritation of the eye. He soon went to work at his trade—type-setting.

Case 4.—Mr. Y., æt. 60. Is nearly blind in his left eye from old choroiditis, and has immature cataract in his right eye, with which he can still count fingers readily at four feet. I determined to operate. On September 12 I extracted the right lens, taking pains to remove as nearly as possible all the cortical substance. Closed the eyes with a strip of isinglass plaster on each, and directed that the window blinds be left open and the curtains kept up. Before leaving the room I noticed that the lids of the right eye had not been drawn closely together, sufficient space intervening for me to see the cornea. I did not interfere, however, as Dr. Michell had told me he frequently left a small space between the lids on purpose to allow the easy escape of the tears. When I called the next day the patient exultingly told me how he lay in bed and counted the bars in the window frame, and his fingers at arm's length, and saw across the street with the eye that had been operated on. As all was going well, I did not disturb his recreations.

On the sixth day I turned his eyes loose, and on the eighth day he walked to my office, underwent a thorough ophthalmoscopic examination and test for glasses, and took the train for home, one hundred miles distant. I received a letter from him a few days since, saying his eye had never given him a particle of trouble. I never saw so little restraint after operating for cataract as in this case, nor did I ever see smoother healing.

Case 5.—G. W, Negro, æt. 70. Cataract in both eyes, mature in left. November 6 operated at the Medical College before the class, removing the right lens. Operation smooth. A narrow strip of plaster to close each eye. After the operation he walked down stairs and sat by a stove nearly an hour, waiting for some way to get home. Finally a wagon called and he got in and rode to his home, more than

a mile distant, over very rough streets. I directed that the light should not be excluded from the eyes, but his prudent wife carefully sealed all cracks and hung quilts over all windows. On calling the following day I found a pitch dark room, and in addition found the old darkey lost in a wilderness of blankets and comforts wrapped about his head. I at once stripped all the windows and uncovered his head, and enjoined him and his wife not to repeat it. On the fifth day from the operation I found the old man with both eyes wide open, enjoying himself in looking about the room. Finding the corneal wound nicely healed, I did not put on the strips again, but let him go free. About two weeks later I saw him driving a wagon on the streets. Not long since he called at my office and received a formula for glasses, with the effect of which he was delighted.

It is not worth while to report other cases, including iridectomies, as those already given are sufficient to demonstrate the effect of not placing the patient in the dark after an extraction or iridectomy. The foregoing cases have not been selected from the most favorable. In the second case there was fluid vitreous and a very hazardous eye to operate on, and which I undertook with considerable misgivings. Those who have attempted removing a dislocated lens with a fluid vitreous can appreciate my feelings. And in case 3 there was an incurable stricture of the nasal duct, chronic abscess of the lachrymal sac, and a lachrymal fistula. I should have greatly dreaded bandaging this eye, covered with cotton, and yet with free escape to the secretions and careful daily inspection of the lids and soaking away the secretions from the inner canthus with absorbent cotton, it healed without an untoward result.

I have not yet ventured to treat iridectomy as an office operation, as does Dr. Michell, but my experience with case 5 goes far toward proving its safety. I leave to others to draw their own conclusions from experience, as I have done, and in conclusion will say, I shall use no other method of after treatment of extractions and iridectomies until something better offers, which, in the nature of things, I cannot now conceive of.

111 E. Fifth St., Little Rock, Ark., Dec. 20, 1886.

INTUBATION OF THE LARYNX, HISTORY OF FOUR CASES.

BY L. H. DUNNING, M.D.,
SOUTH BEND, IND.

The unusual interest manifested by physicians in the treatment of pseudo-membranous croup by the O'Dwyer method, induces me to report the following cases:

Case 1.—Nov. 18, 1886, I was asked by Dr. Kettring to see a child of Mr. Galata, of this city. I responded at once and found a well-marked case of pseudo-membranous croup that had been in progress six days. It had commenced lightly and gradually grown severe until now it threatened to prove speedily fatal. I advised intubation of the larynx or tracheotomy, giving preference to the former procedure. The family consenting, Dr. Kettring was called and concurred in my diagnosis, and agreed to the plan of treatment. We proceeded at once to introduce the tube, using the size for a child 2 to 3 years of age, our patient being 2 years and 4 months old. A marked improvement in respiration occurred in two or three minutes after the thread was removed. Stimulants were ordered, and drachm doses of a saturated solution of potass. chlor. every three hours. At 4 P.M., five hours after intubation, the patient was resting and breathing easily. Continued the same treatment.

19th. Patient rested well last night, but did not sleep much. She is now breathing easily. Temp. 100, pulse 115 and resp. 24 per minute. The child objects to medicine and nourishment, so everything has to be forced, and family are not willing to give either. The same orders were given as yesterday.

20th, 8 A.M. Patient rested but little during the night, but breathed easily. This morning is quiet. There is considerable cough and profuse expectoration, in which occasionally appear shreds of pseudo-membrane. The patches of membrane have nearly all disappeared from the fauces. The bowels moved several times during the night. Temp. 99.5, pulse 105 and resp. 20 per minute. Has taken but little nourishment. Same treatment. 5 P.M. Same condition as in the morning, except that there are sonorous and sibilant râles to be heard all over chest.

21st, 8 A.M. Bronchitis somewhat more pronounced. The breathing is easy and regular, and the pseudo-membrane has all disappeared from the fauces. The expectoration is profuse. The patient is very weak, and this is due largely to its refusal to take nourishment. Believing the danger from croup had nearly or quite disappeared, the tube was removed, Dr. Hitchcock assisting. It was quickly removed upon first effort, and came away clear of obstruction. After its removal there were but slight indications of croup. From this time on the case was uneventful, passing on to complete recovery in a few days.

Case 2.—Essie B., aged 2 years and 4 months. She had been ill of bronchitis several days. Upon November 26 she became very hoarse, and there was a slight croupy cough.

Nov. 28, 7 A M. During the night the child had had several slight paroxysms of dyspnœa that yielded readily to emesis.

Dec. 1. Despite the most energetic measures, there has developed a most alarming case of membranous croup. There is continuous labored breathing and severe and prolonged attacks of dyspnœa. Dr. Kilmer had seen the case with me a number of times. He was called again, and after consultation we decided to intube the larynx, as in this procedure or tracheotomy we saw the only hope of recovery. At 1 P.M. the tube was introduced, and considerable difficulty was experienced in securely placing it in position. The difficulty was in pushing it down into place. There was considerable resistance, and when left in place was inclined to rise out of the larynx. After the second effort it was left well in position.

In removing the thread it broke off, but as we could see nothing of it on depressing the tongue, we thought best to wait a time to see if it produced any reflex irritation. At the end of one half-hour the tube had given no relief and the child had one severe attack of dyspnœa, so it was removed, and in a few minutes replaced with the assistance of Dr. Hitchcock, Dr. Kilmer being detained elsewhere. This time the child experienced perfect relief, and soon fell into a quiet sleep.

6 P.M. Was called in haste and found the patient apparently in a state of collapse, having cold hands and feet and a pinched, sunken appearance about the face. The respirations were hurried, but not difficult. Ordered whiskey and comp. spts. lavender by mouth, stimulant and nutritive enema. The nurse was directed to rub the child with hot whiskey frequently. 8 P.M. Patient has rallied and is now breathing easily, though sonorous and sibilant râles are distinct over whole chest.

Dec. 2. Child rested well during the night, but had a few slight attacks of dyspnœa.

Dec. 3. Respiration hurried and somewhat difficult. Patient has had two attacks of dyspnœa during the last hour. Large quantities of mucus and shreds of pseudo membrane are being coughed up. Loud sonorous and sibilant râles heard over upper part of chest. 12 M. Dyspnœa more frequent. Breathing more labored and râles more distinct. Over the upper part of the chest rough grating sounds are heard instead of respiratory murmurs. 5 P.M. The condition above described is more marked. Had consultation with Drs. Kilmer and Hitchcock. It was concluded that there was an extension downwards of the diseased condition, that the larger bronchial tubes were becoming gradually occluded by intumescence of the mucous membrane and by deposition of pseudo membrane. Prognosis exceedingly unfavorable. Even now the respiration is so much less than it was before the tube was inserted that the parents refused to allow it to be removed. From this time the patient grew gradually worse until 9:30, when it expired.

Case 3.—Merritt F., aged 3½ years, resides in the country. I was called to see him December 9, 1886. Found a well developed case of diphtheria, with pseudo-membrane covering both tonsils, soft palate and uvula. Patient complained of being tired; was sitting up part of the time, and the remainder of the time lying upon the lounge. The temperature was 100.6, the pulse 120, and resp. 22 per minute. Prescribed tr. chlor. ferri and chlor. potass. locally, and internally small doses of calomel, and sponge baths of tepid water, to be followed by inunctions of quinia and lard, were also ordered.

Dec. 11. The throat is clear of pseudo-membrane and patient otherwise improved.

13th. The father of the child reported at my office that his son was resting well, but that he complained of the same tired feeling, and that his throat was noticed that morning to be covered with the same white patches.

14th. Was sent for early in the morning to see the little boy. Reached his bedside at 11:30 A.M., and learned he had had the croup during the night. Examination showed loss of voice, stridulous expiration, and extreme recession of the chest walls. Fauces were covered by pseudo-membrane. He had two severe attacks of dyspnœa while I was examining him. I advised intubing the larynx. The parents consenting, a messenger was sent to town for instruments. At 2:30 P.M. they were brought, and Dr. Hitchcock accompanied the messenger. The doctor examined the patient and gave it as his opinion that we had a case of diphtheritic croup to deal with, and that it would prove fatal in a few hours unless relieved by intubation. We proceeded at once to introduce the tube, and succeeded without difficulty. Immediate relief was given, the child falling into a quiet sleep within five or ten minutes after he was lain down. We directed the mother to give enemata of beef-tea and whiskey, or milk and whiskey, every four hours, and ordered quiniæ and potass. chloras by mouth, with limited quantities of liquids. Cracked ice in limited quantities was allowed. 9:30 P.M. Child still breathing easily. The pulse was quite rapid, 140 per minute, temp. 101.5 and resp. 34. The hands and feet were inclined to be cold. Ordered whiskey in 10-drop doses every hour, that the child be bathed frequently with hot whiskey and water, and take tr. digitalis and tr. nux vomica in appropriate doses.

15th, 7 A.M. Child in better condition than last night. Hands and feet are warm. Respiration 30, temp. 100 and pulse 130. Considerable mucus and shreds of pseudo membrane are being coughed up. The alæ nasi expand and contract during respiration, and there is slight rising and falling of the trachea. Continued whiskey and enemata, discontinued digitalis and nux vomica, and ordered sol. pot. chloras in teaspoonful doses every two hours, and left gr. ij doses of Dover's powders to be given as needed to relieve restlessness. The child swallows readily, but coughs violently after each act, so we give as little as possible by the mouth.

16th, 3:30 A.M. During a violent paroxysm of coughing the child expelled the tube, with a considerable quantity of mucus and flakes of pseudo-membrane. I saw the patient at 6:30 A.M. The father stated that during the first two hours after the tube was expelled the child breathed without much effort, but that during the last hour he had encountered more difficulty, and that the difficulty was increasing. Now there is marked dyspnœa and occasional severe paroxysms. The tube was reinserted with the assistance of the attendants, and gave complete relief. Same treatment continued, with addition of quinia, grs. ij every two hours.

17th, 7 A.M. Patient showing signs of exhaustion. Continued same treatment and ordered more nourishment by mouth. Child swallows better when he drinks from the cup.

18th, 7 A.M. Patient better. Temp. 99, pulse 130, resp. 28, breathing easy. Concluded to remove the tube and attempted to do so with the assistance of the attendants, but made a complete failure. I made four attempts, each time seizing the tube, and each time the forceps slipping off. I ascribed my failure in part to the inefficiency of the assistants, as

the one holding the gag would allow it to slip out of the mouth. On this account my left index finger was fearfully bitten by the patient. Our patient being much exhausted by our efforts, he was put to bed and allowed to rest. Same treatment continued.

19th, 6 A.M. This morning, with the assistance of Dr. Hitchcock, the tube was easily and quickly removed. Our efforts produced but little exhaustion, and patient continued to breathe without effort after the removal of the tube. Ordered citrate of iron and quinine, also fld. ext. hyoscyamus to relieve restlessness. Owing to difficulty in swallowing, enemata were directed to be continued.

20th, 12 M. Patient breathes easily. Swallowing produces coughing: his strength is returning. From this time on the case pursues a favorable course, though the patient was not able to speak aloud for two weeks.

Case 4.—January 3, 1887, was called by Dr. Kilmer to see a case of membranous croup. The patient was a child 2 years and 3 months old. The croup was of six days' standing and had gradually developed. Now there is marked dyspnœa, considerable pallor, and rising and falling of trachea, all indicating the approaching fatal termination. We concluded to try intubation. It was accomplished easily and relieved the dyspnœa. Prescribed stimulants and inunction of quinine and lard, and directed the parents to give nourishment freely and allow the child a liberal quantity of cracked ice.

4th, 7 A.M. Patient seen by Dr. Kilmer, who kindly reported to me as follows: "The child breathes easily, though rapidly. There is slight expansion and contraction of the ala nasi during respiration. Temp. 99, pulse 140, and resp. 40 per minute. She swallows well without much cough. I feel hopeful of recovery, but there is a condition of exhaustion that is somewhat unfavorable." At 2 P.M. the doctor reported to me the patient died at 10:30 A.M., and that from the description given him by its father it probably died of exhaustion.

There are a few points I have observed in the five cases (one previously reported) of intubation of the larynx I consider worthy of note. One is the marked relief this means gave to the most distressing symptom, viz.: the labored breathing. So great has been this relief in all the cases that, if called upon so to do, I should use the tube in a child of mine if I could not hope for any greater benefit.

Another notable feature in the clinical history of all the cases except the first—and it may have been present in that case, as it was not under my observation—was the condition of exhaustion that appeared a few hours after the introduction of the tube. In both of the successful cases this condition very nearly proved fatal, and in the fourth case it is believed to have resulted in death. There are doubtless several factors operative in the production of this exhaustion; the disease itself is one tending toward exhaustion, after the introduction of the tube there is no further need of the powerful voluntary effort so long required to obtain sufficient air to sustain life, the patient rests easily, and, like the freezing man, is willing to sleep his life away. The partial withdrawal of nourishment on account of the difficulty the patient has in swallowing also has its influence in bringing about exhaustion.

Moderate doses of alcoholic stimulants, quinine, nutritious food, and gentle means calculated to arouse the flagging energies of the patient, were the means found most beneficial in this unfavorable condition. It is my firm belief, after having observed these few cases, that the recovery of the patient after intubation of the larynx will many times depend largely upon the skill exercised in the after-treatment.

Much has been written and said about the difficulties encountered in removing the tube. The writer has never experienced any such difficulty, except as mentioned in the history of case 3; indeed, he has invariably, except in this instance, found it much easier to remove the tube than to introduce it. He has never given an anæsthetic in either case, and never had any previous practice upon the cadaver. He does not believe either is essential to skilful and successful accomplishment of this surgical procedure. Any surgeon possessing a knowledge of the anatomy of the parts and a good degree of surgical skill, will be able to easily and quickly introduce the tube, and to remove it when the proper time arrives.

By a little experimenting at my office with the tube and forceps for its removal, I came to the conclusion that the difficulty in removing the tube in case 3 was due largely to the fact that the position of the tube was such that the long diameter of the opening in the upper extremity ran obliquely across the larynx instead of antero-posteriorly, as intended. Upon trial it will be found that as we ordinarily introduce the forceps into this opening the blades expand, if the tube is in normal position, in the direction of the long diameter, but if the tube is rotated, even slightly, it is not so; the blades of the forceps will not open in the direction of the long diameter of the opening in the tube, but obliquely across it. Now, if the blades of the forceps are opened and traction is made, one of two things will occur: either the tube will rotate so that the axis of the long diameter of the opening in the tube and the expanded blades of the forceps will correspond, or the blades of the forceps will slip out of the opening. The latter occurred to the writer four successive times in case 3. Having discovered the difficulty, the tube was the following day quickly removed by the following procedure, viz.: the forceps were introduced in the usual manner, and the closed blades inserted well into the opening in the tube, the handle of the forceps was carried slowly and gently from side to side. While thus describing an arc of a circle with the handle of the forceps, the blades were opened two or three times to determine, if possible, the direction of the long diameter of the opening. Very soon it became evident that when the handle was considerably to the right of the median line, the blades of the forceps, when expanded, seized the tube in the line of the long diameter of the opening, and then, with slight effort, the forceps and tube were withdrawn together.

One reading the description of this procedure will doubtless think it required so much time to execute

it that the child was in great danger of suffocating. It was not so, as only a few seconds were required to effect the end in view, the removal of the tube. Whether the tube was placed when inserted in the position he found it, or was properly placed and subsequently rotated, the writer is unable to say. It seemed to be a matter of little importance so far as the recovery of the patient was concerned, but was in the matter of its removal of considerable consequence. Should he in the future experience much difficulty in the removal of the tube, he will conclude it is in a mal-position and resort to the same procedure that was successful in the case related.

THE TREATMENT OF INSOMNIA BY FOOD, BATHS AND EXERCISE.

BY WM. G. EGGLESTON, M.A., M.D.,
ONE OF THE PHYSICIANS TO THE DISPENSARY OF THE CHICAGO POLICLINIC.

The first case of insomnia with which I had to deal, my own case, taught me the utter uselessness of depending solely upon hypnotics for the relief of this condition; and subsequent cases treated successfully by food, baths and exercise have shown that hypnotics are not only not to be depended upon, but that in many cases they are not required at all, and do more harm than good. I do not wish, however, to be understood as advocating the disuse of hypnotics in all cases of insomnia; my remarks must be taken to apply only, so far as my experience goes, to febrile insomnia, or the insomnia of convalescence from acute diseases, to the condition of sleeplessness arising from long hours of mental activity or excitement, and to insomnia from exhaustion. The two last may often be classed together.

In febrile insomnia there is a greater or less degree of cerebral excitement, which, when active, calls for an exhibition of bromides and chloral. In a still more active stage morphia may be indicated, especially if pain, such as headache or backache, be so pronounced as to demand attention; but as a rule, drugs which interfere with elimination should not be given. On this account paraldehyde is of very great value in some of these cases. In the eruptive fevers, when the cutaneous irritability is so great as to induce insomnia, sleep may be often produced by the use of warm or tepid baths. In many of these cases of febrile insomnia, I have noticed that the patient would often fall asleep soon after the administration of food, and more particularly if a bath was administered just before the food was given.

Wakefulness in these cases, and in many others, may be considered as the symptom of an irritable weakness of the brain or nerve centres. We know that in the latter stages of a protracted illness the condition of insomnia often depends upon the malnutrition of the patient, and that the indication is to furnish material which will delay or stop the processes of malassimilation or disassimilation. The failing power of the heart, due probably to the same irritable weakness of the nerve centres which causes the wakefulness, demands, as we all know, such diffusible nutriment as the system can assimilate with the least expenditure of force; and hence, we give milk and meat juices, sometimes alcohol, but rarely opiates. There is a tendency, I believe, to rely very much upon hypnotics in these cases, as in all cases of sleeplessness; and I believe this to be wrong. To say nothing of other objections to their frequent use, they disorder the stomach, and in the weakened condition of the patient his system soon falls into the habit of demanding these aids to artificial sleep. There is usually but little positive appetite, and bromides and opiates take away whatever there is.

But it is not alone in the cases of febrile insomnia that the nervous system is in a condition of irritable weakness. It is frequently seen, and I believe it to be the cause of a very large proportion, if not all of those cases of insomnia from intense mental activity or excitement, and of insomnia from exhaustion. Among hard working college students, newspaper men, accountants, and men whose lives are given up to literary pursuits, insomnia from exhaustion or excitement is not an uncommon affection; and it is common also in women who have been exhausted by protracted nursing of a sick child or friend, or who have been subjected to some unusual excitement. In dealing with this condition it is not sufficient to say that a complete change of habits must be made. In the majority of cases the patient cannot change his or her habits, and take a long vacation or a protracted voyage; and in the majority of cases this is not necessary.

I have noticed that most students, and women, who are troubled with insomnia are dyspeptic; and, in fact, I rather believe that a greater or less degree of dyspepsia or apepsia, and gastric irritability, will be found in all persons who are much troubled with insomnia. It must be very evident that a course of bromides or other hypnotics will not ameliorate the condition of the gastric or intestinal mucous membrane. It is quite clear also, that bromides will not permanently lessen the degree of nervous irritability which depends on the want of proper food. I have found it not only possible, but comparatively easy to treat cases of this kind without a single dose of any hypnotic, and without a change of or vacation from work. In some cases one or two doses of bromide of sodium or potassium, or paraldehyde has been necessary.

In cases of students and women who complain of insomnia, I have usually found that they take but little exercise, that they are constipated, have but little appetite, and suffer with gastric oppression after the main meal of the day, whether it be about midday or in the evening. They usually drink tea or coffee, sometimes immoderately. If the case has gone on for some time, there is an evident condition of anæmia. The first thing I do is to unload the bowels, and keep them open with cascara sagrada, though to begin with I usually order blue mass. The medicine ordered, as a tonic, is usually either nitro muriatic acid (equal quantities of nitric and hydrochloric acids and water), or tincture of the chloride of iron ℥ij, Fowler's solution ℥ij, and strychnine gr. j. Two to six drops after each meal (or

more), or else Fowler's solution alone. In the majority of my cases with students, I have used small doses of these drugs, and sometimes no medicine except the purgative. They are then instructed to eat before going to bed, having put aside every form of work at least half an hour before bed time. A formal menu cannot be made out for these cases; they should simply be instructed to eat, and if they are hungry they should eat whatever they want. A glass of milk and a biscuit or a piece of toast is sometimes all that can be taken at first; or a mashed potato buttered. In a short time the night appetite will grow, and the appetite will then need no particular directions. If possible the night meal should be taken in another room than the sleeping apartment, and for men in the city, it will be found advantageous to go out to a restaurant. The idea of going out for something to eat, and having to wait a short time for it will exite the appetite.

Before eating, however, a bath should be taken. I much prefer cold or cool baths, which should be given with a sponge or stiff brush, and the body thoroughly rubbed off with a coarse towel afterwards. The bath need not be more than five minutes in duration. The objection to the warm bath is that the patient is liable to take cold after it, and it is not so refreshing as a cool or cold bath. After the bathing and rubbing, or after eating, a moderate amount of exercise should be taken. For this a few minutes with Indian clubs or dumb bells is sufficient. Further than this, the patient should go to bed at the same hour every night, and arise at the same hour every morning.

I have seen a considerable number of cases of insomnia among night men on morning newspapers. These men usually take the evening meal about 6 o'clock, and then often work until 2 A.M. Within the past two years and a half, I have had more than twenty cases of this class, and I have not given a dose of medicine, other than a purgative, to a single one. These patients cannot conveniently stop to take a bath, and then go out to eat. They are instructed to go from the newspaper office to a restaurant, and eat what they want. Here we usually find that the appetite is good. After eating, anything from half a dozen oysters to a good steak, or as much, in fact, as one would eat for a hearty breakfast, they go home, bathe the face, head, neck and chest, take five minutes' exercise and go to bed. In each one of my cases of this class, the patient has reported that the treatment was a success from the first.

Since the age of 18 I have been more or less troubled by insomnia, and nothing has ever given such decided relief as a course of hearty meals just before going to bed. When the temporary insomnia has been relieved by this, I continue the sponge-baths and exercise before going to bed; but sleeplessness often returns after a sustained degree of mental labor and excitement, and is almost immediately relieved by a generally hearty meal before going to bed. At 19 years of age, while a student of medicine, I was dosed for this condition with every then known hypnotic, without any perceptible effect. Accidentally, I found that after eating late at night I slept well; and I now make it a rule never to go to bed hungry, and always to eat at night when I am in the midst of an unusual amount of work, or engaged in work of an unusually exciting character.

I have had to deal with only two cases of insomnia in old people. In both these cases they had been advised to take a "night cap" before going to bed. At first the remedy was efficacious, but in a short time it was found that the quantity of alcohol in the "night-cap" had to be increased, or it had no effect, and finally an excessive quantity of alcohol was demanded. I rapidly diminished the quantity of alcohol as the amount eaten was increased, until, with with the aid of a full supper and no alcohol whatever, the sleep was plentiful and much more refreshing than before. I do not know of anything which will more readily impair a digestive apparatus than alcohol on an empty stomach. Further than this, one runs the risk of inducing the alcohol habit by prescribing it in this way; and it must be acknowledged that the drowsiness induced by alcoholic drinks will not pass into a natural and calm sleep; and an artificial sleep is only demanded when a patient is positively ill. A cup of hot beef tea (made from some good extract of beef) taken just at bed time, will often be sufficient to cause a good natural sleep.

There is a popular superstition that grown people should not eat immediately before going to sleep; that it will give them indigestion or "night-mare," or both. I cannot see why adults are so very different in this respect from babies. We know that young children awaken at night and must have something to eat before they will sleep quietly; and some children actually fall asleep with a nursing bottle leaking into the mouth. It may be true that digestion is carried on slowly during sleep, and that the digestive function is less active; but here one need not be in a hurry for the completion of the operation. The average person should be in bed seven or eight hours, which is time enough for the digestion of almost anything edible. In our American city life I think that digestion carried on during sleep probably has the better chance for thoroughness.

65 Randolph St., September 2, 1886.

CASES OF POISONING FROM THE EATING OF DRIED BEEF.

BY R. HARVEY REED, M.D.,
OF MANSFIELD, OHIO.

On July 31 I was called to the family of Mr. James E., living at 92 East Market St., and found all the members of the family then at home, sick with a peculiar line of symptoms, of a similar character. I at once suspected a toxic agent of some kind, and on inquiry found my suspicions well grounded. The family consisted of Mr. E., aged 67, Miss E., aged 21, James E., aged 16, and Mrs. E. (age unknown); the last being away from home at that time was not taken ill. Upon further inquiry I found they had all been in their usual health the day before (July 30), on the afternoon of which day they had bought some chipped beef, and all had eaten freely of it for supper.

Miss E., a rather delicate young lady, was taken violently ill about 8:30 o'clock on the same evening, first vomiting the contents of the stomach, after which the emesis still continued throughout the night, the patient throwing up a greenish, frothy mucoid substance, which came up in great quantities. She had marked thirst, with constriction of the fauces and great prostration. Shortly after the vomiting commenced the bowels began discharging, and would move every time she vomited; the discharges consisting of a brownish liquid substance. This was associated with more or less griping.

A homœopath had been consulted in the evening, but considered it a case of cholera morbus and treated it accordingly. The patient not improving as desired, sent for me the next morning, at which time I elicited the above history, and found the patient with a fiery red tongue, a bitter taste in the mouth, vertigo, twitching of the muscles, cold extremities, no fever, and with a pulse of 120, and very much prostrated. With others of the same family suffering in a similar manner, and the associated history, I was led to the legitimate conclusion that it was the result of eating poisonous beef.

James E., Jr., had eaten of the beef on the evening of July 30, but being a very strong, healthy young lad, was not taken sick until after breakfast the next morning, at which time he ate still more freely of the same dried beef. In about an hour and a half he was taken with severe vomiting, which continued for several hours, but was not followed with any considerable diarrhœal discharge, although the bowels were moved quite freely. He complained of a bitter taste in the mouth, with a deathly sickness and weakness, and vomited a peculiar mucoid substance, after discharging the food contained in the stomach; his pulse was 88, and not associated with fever.

James E., Sr., ate but little of the beef for supper, but said he had had a bad taste in his mouth all night. He was not taken sick until after breakfast, at which time he ate of the beef more freely, and in about an hour and a half was taken violently sick; first with purging, which was soon followed by violent vomiting, first of the contents of the stomach, and then of a greenish frothy mucoid substance which was very tenacious, and would string out from his mouth to the floor like white of egg; the tongue was fiery red and covered with slime. He said he had a peculiar sickening sweetish taste in the mouth, and was very dizzy. He had aphonia, twitching of the muscles, some trouble with the vision, but not marked, at times complete loss of consciousness, and at one time was for several seconds in a spasm. He had great difficulty in urinating, the urine being scanty and high colored; pulse 80 and weak, no fever; extremities cold, and the surface of the body covered with a cold sweat, with general exhaustion and depression Specimens of the urine were secured from all the patients suspected of beef poisoning, and carefully examined, chemically and microscopically, showing the following results:

Miss E.: Color, light straw; reaction neutral; sp. gr. 1022. A trace of sugar was found, but no albumin. Earthy phosphates not materially increased.

James E., Jr.: Color, very light brown; reaction acid; sp. gr. 1020. No albumin and no sugar, and but few earthy phosphates or deposits of any kind.

James E., Sr.: Color, a dirty yellow; reaction acid; sp. gr. 1028. No albumin and no sugar, but large quantities of earthy phosphates, and the chlorides.

The general outline of treatment consisted in the use of opium and bismuth, together with lime-water and milk, with stimulants and diuretics, followed with tonics and pepsin; while locally were applied heat and stimulating lotions, together with brisk rubbing.

The young man soon recovered, and in a few days felt as well as ever. The young lady was several days in making a recovery, and did not get over the effects for almost a fortnight. Mr. E., Sr., did not entirely recover from the effects of the poison for more than two weeks. They were all troubled more or less with indigestion and constipation for some time after they had recovered from the primary effects of the poisonous ptomaines.

Specimens of the meat were procured, and through the kindness of Dr. J. U. Barnhill, of Columbus, O., sent to Prof. David O'Brine, of the Ohio State University, for a chemical analysis, who subsequently reported finding the ptomaines. His full report is herewith given:

"No. 341. Chemical Laboratory of the Ohio State University. Quantitative analysis of —— beef from Dr. Reed, Mansfield, Ohio. Determination of —— ptomaines or cadaveric alkaloids. Method of analysis—described by Selmi.

"Found ptomaines and confirmed by tests=H_2SO_4—I_2O_5Cu $(C_2H_3O_2)_2$ H_3PO_4.

"The substance was nicely shown under the microscope. The method of analysis is described in 'Blyth on Poisons,' pp. 461–468."

Dr. Barnhill also sent some of the meat to Dr. Leech, of Columbus, for microscopical examination, besides making a careful microscopical examination of the meat himself, which revealed in both instances degeneration of the muscular fibres, with myriads of micrococci.

On August 5, 1886, I was called to visit Mrs. John M. and son Claude, the former aged 42 and the latter 17. They had bought and eaten a lot of dried beef, and in the course of an hour or more were taken violently sick.

Mrs. M. was taken with vomiting and purging; the matters vomited were, after the contents of the stomach were discharged, of a viscid, ropy character. She complained of a nauseous, sweetish taste in the mouth, twitching of the muscles, was badly nauseated, had cold extremities, with vertigo; the tongue was very red, with pulse 120, but no fever.

Claude M. was taken ill very shortly after eating the dried beef, with vomiting and purging, and vomited large quantities of a ropy mucoid substance; had a bad taste in his mouth, cold extremities, tongue red, pulse 100, but no fever.

The treatment in these cases was the same as in the others, with the exception of using small doses of calomel instead of bismuth, on the principal of it being an antiseptic.

I considered both of these cases the result of eating poisonous dried beef; although not quite so severe as the cases of the Ewing family. The young man soon recovered and in a day or so was all right; but Mrs. M. was several days regaining her health, and in fact is still (at the writing of this report) troubled more or less with gastro intestinal irritation.

I regret very much my inability to procure specimens of this meat.

Remarks.—That the ptomaines or cadaveric alkaloids were the cause of the illness in the above cases is without a question in the case of the Ewing family, and scarcely without a doubt in the last two cases. That there is a poisonous alkaloid which is liable to form in meat, under certain circumstances, has been established without a doubt; but the question of chief importance to the public in general is, when, and under what circumstances, these poisonous ptomaines may and do form, and how to prevent their formation.

When it is remembered that these poisonous alkaloids were first discovered by Selmi in exhumed corpses, the key to the mystery is at our command; chemistry has unlocked the door that led to their once mysterious approach, and has shown their presence to be synchronous with the decomposition of meat of any kind. This being the fact, all tainted meat, from whatever source, should be strenuously avoided; the "shop soured" meat that has spent days on the counter, or in the ice chest, should be shunned, even when cooked and canned, or when made into bologna sausage, or pudding meat, or salted or dried; for it must be remembered that no amount of cooking or curing will remove these poisonous ptomaines from meat in which they have once formed. They are not like the trichina spiralis, or the cysticercus, which can easily be destroyed by thorough cooking.

The commercial process of canning meat in our large cities or packing houses, is another source of these ptomaines; the rapid and slip-shod methods resorted to by the most of these houses, by which meat is turned out upon the market in a few days as cured (but which, in reality, has not been cured sufficiently to prevent its decomposition, and as a result the formation of these poisonous alkaloids), should not only be shunned, but these "near cut" and imperfect methods of curing condemned; and no process of curing and packing meat should be permitted that does not insure the most perfect preserving of the same; and no meat should be put through any preservative process of any kind that is not perfectly healthy, "sweet meat" to begin with, that is not absolutely free from any taint or decomposition.

The detestable habit of working up beeves that have been killed by railway accidents, and have not been bled or dressed for days after being killed, and the wholesale slaughter of "bony old cows" and "unborn calves" and placing them on the market for food, is a disgrace to any country.

MEASUREMENTS FROM SKULLS OF THE SEVENTH CENTURY.

BY C. F. DIGHT, M.D.,

PROFESSOR OF ANATOMY AND PHYSIOLOGY IN THE AMERICAN MEDICAL COLLEGE IN BEIRUT, SYRIA.

During a recent visit to Jerusalem, Palestine, I had an opportunity to examine and take the measurements of a large and rare collection of human skulls, which are stored away in the old monastery of Mar Saba, a distance of three hours' horseback ride down the Kedron Valley, midway between Jerusalem and the Dead Sea. The results of this examination are such as are believed to be of interest, and for this reason I am led to publish them.

These skulls are said to be those of the early Christian monks, who in the fifth and sixth centuries lived in great numbers along this Kedron Valley, as far down as the Dead Sea, and also in and about Jerusalem, who in 614 were massacred by the Persians, when they invaded Syria and Palestine under their leader Chosroes. They are, therefore, Caucasian skulls, and probably those of the ancient Greeks and Romans, which were gathered up and stored here to the number (they say) of 10,000. Such being the size and antiquity of this collection, it can hardly fail of being a valuable one. The great traveler and writer, H. B. Tristram, once on looking at it said: "It is certainly a collection the Anthropological Society might envy, and out of which they might select as many types as it suited their fancy to create."

The measurements which I will give are the only ones, so far as I have been able to ascertain, that have ever been taken of any of these skulls. Omitting as far as possible anatomical terms, the five measurements which I took are as follows:

1. The *horizontal circumference;* learned by measuring with a tape the distance from the middle of the lower part of the forehead around the largest part of the occiput to the starting-point.

2. The *naso-occipital length*, or the distance from just above the root of the nose, back over the top of the head to the external occipital protuberance.

3. *The height*, or the vertical distance from the opening of the ear to the level of the centre of the top of the head.

4. The *width*, or the greatest distance through the head from side to side above the level of the cheek bones.

5. The *cranial capacity*, learned by closing the little openings at the base of the skull, then filling its interior with mustard seeds, which are then poured out and measured in a graduated vessel.

Of the ninety-one skulls which I measured, the largest one gave a horizontal circumference of 22.45 inches (570 millimetres), which is ¾ of an inch above the average for all races. This same skull gave a cranial capacity of 113.6 cubic inches, which is 28.6 cubic inches greater than the average for all races, and 18.1 greater than the average for the Caucasian race (whose cranial capacity exceeds all other races), and but 4.4 cubic inches less than the capacity of Cuvier's skull—the largest on record. Its width was also the greatest, being 6.38 inches (162 mm.).

Its naso occipital length, 13.39 inches (340 mm.), was reached by but one other, and its height was 4.72 inches (120 mm.).

The smallest of the ninety-one skulls gave the smallest horizontal circumference 18.91 inches (480 mm), and a cranial capacity of 76.6 cubic inches, which is 18.9 cu. in. less than the average Caucasian capacity. Its height was the lowest, being 3.97 inches (101 mm.), its width 5.27 inches (134 mm.), and its naso-occipital length 11.42 inches (290 mm.). All the portions of this brain had been very small.

The one giving the greatest height, 5.2 inches (132 mm.), gave a horizontal circumference of 20.68 inches (525 mm.), width 5.63 inches (143 mm.), and naso-occipital length of 11.85 inches (301 mm.).

The one giving the least width, 4.72 inches (120 mm.), gave a horizontal circumference of 20.48 inches (520 mm.), a naso-occipital length of 12.21 inches (310 mm.), and height of 4.45 inches (113 mm.), being narrow and low, but long from before backwards.

The one giving the shortest naso-occipital length, 8.94 inches (227 mm.), gave a horizontal circumference of 19.7 inches (500 mm.), height 4.37 inches (111 mm.), and width of 4.92 inches (125 mm.).

The average measurements of the ninety-one skulls are found to be as follows:

Average horizontal circum.....	19.98 in.	(507.2 mm.).
" height	4.51 in.	(114.5 mm.).
" width.....	5.57 in.	(141.4 mm.).
" naso-occipital length.....	11.84 in.	(300.6 mm.).

The average cranial capacity of the nineteen whose capacities were measured was 91.8 cubic inches.

Comparing the average measurements of these skulls with the *present* average measurements of skulls of the same race (the Caucasian), and if the above measurements are taken as the average of the race at that time (and persons of their rank at that time should have skulls above rather than below the average), it follows:

1. That ours, the Caucasian skull, has, during the past thirteen or fourteen centuries, increased in horizontal circumference 1.72 inches, and to a less extent in height, and not at all in width, and has gained in cranial capacity 3.7 cubic inches.

2. From the fact that our skulls have not gained in width, it follows that this gain in capacity of 3.7 cu. in. is due to increase in their height and length, which, bearing in mind the plan of development of the brain, implies an increase in size of the upper and the anterior parts of the brain—the exact parts which, on *a priori* grounds, we should expect to increase by education and civilization, since these parts of the brain specially preside over the moral and intellectual functions.

3. The lower portions of the brain, being the parts which specially preside over the selfish propensities, or the so-called inferior functions, and which give breadth to the head, being called into activity less as education and civilization advance, have failed to grow as rapidly as other and more exercised portions of the brain; hence the non-increase in width of our skulls.

It need scarcely be said that these were adult skulls, and probably all males, and that among this large collection numerous abnormalities and peculiarities exist—such as absorption and perforation of both tables of the skull from growth and pressure of the Pacchionian bodies; non union of the two halves of the frontal bone in the usual way, leaving a persistent frontal suture; marked difference in size of the two halves of the skull, the left half usually being the larger; and Wormian bones in different localities. A few presented spots which appear sometime to have been burned, and the knife shows these places to be charred. Many of them yet contain a considerable number of teeth, which were sound at death, but are now brittle because of their great age. Others present fractures at different places, and those which are broken open show internal depressions at points corresponding to external elevations, and *vice versâ*, showing that the inside of the skull corresponds in shape to the outside, and that, consequently, the shape of the brain may, as a rule, be determined by the shape of the head, as certainly as the shape of a tree may be known by the shape of the bark which covers it.

POISONOUS ARSENICAL WALL-PAPERS.

Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Suffolk District Medical Society, January 12, 1887.

BY JAMES R. CHADWICK, M.D.,
OF BOSTON, MASS.

In the presence of so many chemical experts and learned general practitioners, it would be presumptuous in me to treat this subject systematically or exhaustively. Moreover, my purpose in opening this discussion is to present, by fresh instances, to the public and profession, the dangers to which every citizen of this commonwealth is exposed by the manufacture and sale of papers for our walls, so charged with arsenic as to produce characteristic symptoms of the poisoning by that mineral in the persons occupying the rooms thus papered. The Legislature of this State, last winter failed to pass a bill prohibiting the use of arsenic in the coloring of wall-papers, so that the only means by which we can save ourselves from this poison, is to disseminate so full an appreciation of our danger throughout the community as to cause every individual to protect himself and his family. This end can only be attained by the publication, by every one who has suffered, of the exact circumstances attending his experience, together with the names of the dealers retailing the papers and the chemists who have analyzed them. This I shall aim to do without animosity to any individual, but with the single purpose of making every one feel more keenly than they now appear to do, the responsibility for the lives and health of our wives, our children, and our families.

In September, 1885, Messrs. J. F. Bumstead & Co. put upon my nursery and one sleeping-room new papers, which they assured me had been analyzed and pronounced free from arsenic. In the nursery slept a boy of 4 years and a nurse, in the chamber slept a girl of 13, in a third room, not then

re-papered, slept two other children. All the children passed several hours of every day in the nursery. During the winter of 1885–86, the boy and nurse remained in good health, the girl of 14, however, suffered much, for the first time in her life, from dyspepsia, colicky pains and headaches; the younger of the two girls had many attacks of palpitation of the heart, lost color and strength; the other girl kept in good health. The symptoms in the two affected girls yielded somewhat, but never fully, to treatment. During the summer of 1886 they regained their health and strength at Mt. Desert; within a month of their return to their homes many of the old symptoms reappeared. About the first of December, the attacks of colicky pains became more severe and frequent in the two affected girls, and were attended by vomiting and diarrhœa.

My attention was then aroused, and I set about to discover a common cause for all these similar symptoms. Having suffered severely in past years from the poisoning of my family by arsenic, I naturally thought of that possibility, and sent samples of the papers most recently put upon the walls (nursery and small chamber) to Professor E. S. Wood for analysis, and received the following reply:

"BOSTON, December 10, 1886.

"The enclosed paper (from the nursery) is very arsenical, I should advise its removal. The other was all right, non-arsenical.

EDWARD S. WOOD."

I was naturally in a state of great indignation that, despite my care, I should have put upon the wall of my nursery a paper which contained a dangerous amount of arsenic. I wrote at once to J. F. Bumstead & Co., asking the name of the chemist who had made the analysis for them. The reply was as follows:

"BOSTON, December 13, 1886.

"DR. JAMES R. CHADWICK:

Dear Sir:—The paper about which you enquire was analyzed by Professor S. P. Sharples, and by him pronounced 'free from arsenic.' Yours truly,

J. F. BUMSTEAD & CO., *per* HENRY."

It happened that a week previous to this correspondence my wife had taken a friend to the store of J. F. Bumstead & Co., where he had purchased several hundred dollars' worth of papers for a newly-erected house in California. On the same evening I questioned my wife closely as to whether she had been careful to select only papers that were free from arsenic. She said she had insisted upon that point with Mr. Bumstead himself, and had been told that only those papers would be shown her which had been analyzed and pronounced to be free from arsenic. I asked if she had inquired who their chemist was, to which she replied that Mr. Bumstead had told her that their chemist was a Professor Hills. As I knew that this could only be Professor Wm. B. Hills, of the Harvard Medical School, I felt assured that the papers were safe. A week later, however, on discovering that my own paper was arsenical, and feeling responsible for my friend in California, I went to the store of Bumstead & Co., and demanded to see the reports of Professor Hills upon the seventeen papers selected by my friend. I was told to call the next day when they would be shown me. I did so, and then found that all the papers had been, (owing to a misunderstanding) sent to Professor Hills for analysis since my visit the previous day. One of them had been pronounced by him to contain "considerable arsenic," and another a "small amount," both being regarded as more or less dangerous to health. The others were all practically free from arsenic. On asking upon whose certificates the two first mentioned papers had been supplied as "free from arsenic," I was shown the certificates of Prof. S. P. Sharples.

In order to confirm the presence of arsenic in dangerous amount in the three papers about which the reports were conflicting, I have since had each of them analyzed independently by Professor E. S. Wood, Professor W. B. Hills, and Dr. Chas. Harrington, all of the Harvard Medical School, with the result of perfect concurrence as to finding arsenic in dangerous amount.

But little comment is needed on this recital of facts. It is, however, but just to Mr. Bumstead to say that I fully exonerate him from any intent to mislead my wife with regard to the analyst of the papers supplied to my friend. His statement that Professor Hills is now his analyst is true, yet I think I am right in pointing out to him that his reply was so framed as to be misleading, because the papers he was offering for sale had many of them, as is manifest, been analyzed in previous years by other chemists.

I may say, in conclusion, that it makes no difference whether the symptoms manifested by two of my children be adjudged by those present as due to arsenic or not; if I demand papers free from arsenic I ought to be able to obtain them. My own belief is that the symptoms are attributable to that cause, and that the exemption of the nurse and two other children, though in two instances more constantly exposed to the influence, was attributable to the fact that they were less susceptible to the poisonous effects of arsenic. I pass around samples of the papers with the arsenical mirrors obtained by the Berzelius-Marsh test.

I should add that the two affected children have had no symptoms since the paper in my nursery was removed a month ago.

MEDICAL PROGRESS.

HYDRIODATE OF HYOSCINE is recommended by DR. J. MITCHELL BRUCE as being the most convenient salt of the alkaloid for use as a cerebral sedative (*Practitioner*, pp. 321–333). He finds that it is best administered by subcutaneous injection in doses of $\frac{1}{200}$ of a grain. Although it is usually only necessary to give one dose in the evening to secure a quiet night, in cases of high delirium it has been repeated within four or six hours with advantage and safety. If given by the mouth, larger doses are required, as much as $\frac{1}{120}$ to $\frac{1}{30}$, or even $\frac{1}{50}$ of a grain given at bedtime, having proved satisfactory in the hands of Dr. Wetherill, Jr. In America, $\frac{1}{100}$ of a grain has been fixed upon as the average working dose. Mr.

Freeman and Mr Hardy, of Charing Hospital, have, however, come to the conclusion that $\frac{1}{200}$ of a grain of the hydriodate produces most of the benefit that may be expected, without any risk of unpleasant effects. Dr. Bruce confirms the results obtained by previous investigators as to the little value of hyoscine as an anti-hidrotic. On the contrary it frequently produces a distinct increase of perspiration. It does not produce unpleasant dryness of the skin and the throat like atropine. The province of the application of hyoscine is defined by Dr. Bruce to be in combatting urgent symptoms in cases of delirium and to procure quiet and sleep. It must not be expected to cure any disease, although it is true that cases have occurred in which symptoms once controlled by hyoscine have not returned. Sometimes hyoscine gives rise to unpleasant symptoms in connection with the circulation and respiration. Within half an hour after the administration of a full dose ($\frac{1}{100}$ to $\frac{1}{75}$ hypodermically) it may cause failure of respiration in the form of shallow breathing, or even Cheyne-Stokes' rhythm. It has been found, however, by Dr. G. W. Mann, that chloral can neutralize the effects produced by hyoscine. A lady who had taken $\frac{1}{30}$ of a grain of hydrochlorate of hyoscine by mistake, was seized with convulsions, loss of speech, illusions and hallucinations. Chloral in 10 grain doses was given every quarter of an hour until the convulsions had disappeared which took place in less than an hour from the commencement of the treatment. It was then continued in the same dose every hour, but after 90 grains in all had been given, there was no further necessity for its use.—*Provincial Medical Journal*, Jan. 1, 1887.

RARE CASE OF EPILEPSY.—At the meeting of the Medical Society of London, on November 15, 1886, DR. HUGHLINGS JACKSON related the case of a boy, 7 years of age, in whom Epileptic Fts were artificially induced by an unexpected touch on the head. When 3 days old the boy had a convulsion. At the age of 2½ years he had an "ordinary" epileptic fit. Of these latter fits he had four attacks of the same kind, or rather *degree*. Ever since the first so called ordinary epileptic fit some imperfect use of the left arm and leg was noticed, and has ever since remained. About the age of 2½ years the boy began to fall down, but these falls were really fits. He never "fell" unless the head or face were touched, but the fit would not occur if he knew he was going to be touched. Stoppage of respiration was very evident in the fit. The eyes were turned to one side, generally the right. Sometimes as many as fifty falls occurred in one day, and never a day passed without some. Touching any part of the head or face was effective. Several appeared also during sleep when he accidently touched his face or head. These sudden inopportune falls had caused enlargement of the left frontal eminence, and also that of the right side. The left arm was slightly less in circumference, and its movements were clumsy; there was something like athetosis in the left hand when the right hand was engaged in drawing or writing. He limped with the left leg, which was also less in circumference than the right. There was no alteration in the knee-jerks, and no ankle clonus. Perhaps the left side of the head was more sensitive, but no one place could be made out to be more sensitive than another. At times the boy said his left arm felt "heavy." The fits were not opisthotonic, as happened in feigned fits. Dr. Jackson described three forms of epilepsy —(1) epilepsy proper; (2) epileptiform seizures; (3) due to nervous discharges in the pons Varolii or medulla oblongata. In the case above there was a local lesion somewhere, as the hemiplegia showed. The epileptogenous zone was less defined than occurred in Brown-Séquard's guinea-pigs. Nervous discharge in some part of the pons was the probable cause of the falls or fits.—*Lancet*, Nov. 20, 1886.

PELLETIERINE IN INFANTILE DISORDERS.—M. F. MÉPLAIN, bearing in mind the difficulty of giving children vermifuge medicine in sufficient doses, and the fact that Dr. Bétancés had administered 6 centigrammes of pelletierine, which had expelled a tænia, resolved to try this remedy on an infant 32 months old, which was suffering from convulsions. M. Béranger Féraud and other writers recommend that pelletierine should not be given to children, on account of the symptoms of congestion of the brain, which it occasionally causes in adults. Be that as it may, M. F. Méplain administered to his little patient a large teaspoonful of solution of Tanret's pelletierine, which represents about 6 centigrammes of the alkaloid; twenty minutes later, 20 grammes of manna, dissolved in a cup of milk, were given. The expulsion was tardy, owing to the insufficiency of the purgatives used, but was, nevertheless, complete. M. F. Méplain, who remained several hours with the patient, observed no alarming symptom. From the observations of MM. Bétancés and F. Méplain, it appears, therefore, that whilst a small dose of pelletierine is sufficient to expel the tænia, the use of the drug is, in the case of children, unattended with the risks which might have been expected from its physiological action, and from the effects observed in adults.—*British Medical Journal*, Jan. 1, 1887.

DENTAL ANÆSTHESIA.—M. GEORGES VIAN claims to have solved the problem of local anæsthesia in dentistry. After numerous trials of solutions of different strengths, he has found that the soft parts about the maxillæ may be rendered completely insensible by the use of cocaine, associated with a 2 per cent. solution of carbolic acid. Five minutes before operating M. Vian dissolves 5 centigrammes (1 grain) of hydrochlorate of cocaine in 50 centigrammes (10 drops) of the solution, and injects it into the gums, half-way between the neck and the extremity of the root of the tooth. Half of the solution is injected on the palatine and the remainder on the labial side, pressure being made by the finger, when the needle is withdrawn, to prevent the exit of the fluid. Anæsthesia is perfect in three minutes. The quantity of cocaine advised by M. Vian seems somewhat large, but it is said to have been so used in eighty seven cases without causing any unpleasant symptoms.—*Medical Record*, Jan. 15, 1887.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

The Editor of this Journal would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

Subscription Price, Including Postage.

SATURDAY, FEBRUARY 19, 1887.

THE MARINE HOSPITAL SERVICE.

There is much of general medical interest in the recently received "Report of the Supervising Surgeon-General of the Marine Hospital Service of the United States for the Fiscal Year 1886." There are many medical men and health officers who do not seem to have yet seen the necessity or good of this Service—and this, we think, may be attributed to a want of information as to the duties required of and performed by the Service.

During the last fiscal year the number of patients relieved by the Service was 43,822; number treated in hospitals 12,624; number treated in dispensaries 31,198; and days' relief in hospital furnished 316,205. Previous to October, 1885, the Service was supported by a tax upon the beneficiaries, and it was held that only those who contributed to the fund could receive relief from it; but after the enactment of the law providing for the support of the Service from the tonnage tax, it was claimed that fishermen, whose vessels paid tonnage tax, became contributors to the fund; and it was decided by the Solicitor of the Treasury that seamen employed on vessels licensed for the fisheries are entitled to the benefit of the Service. By a calculation based on the receipts from all sources (including special appropriations) it will be found that the average cost of each patient relieved during the year, supposing that all the funds were expended, was a trifle over $12. Even at the present low rate of tonnage tax, the tax alone is sufficient to support the necessary *general* expenses of the Service with the exception of the amount necessary for fuel, light and water. Of course special appropriations are required from time to time for extraordinary alterations and repairs for the older hospitals. In the long-run the expenses would probably be reduced if the recommendation of General Hamilton regarding a laboratory and warehouse were carried out; for it would undoubtedly be cheaper to manufacture many of the drugs now in use than to buy them; and with ample store-room articles which cannot now be kept in stock could be purchased at better rates, and be subject to more thorough inspection. Certainly, all non-perishable articles needed for use in the hospitals should be kept in stock.

Of the hospitals, the one at Baltimore will probably be occupied this winter; the one at Boston is in bad repair, especially with regard to the heating apparatus; and the one at Chicago is probably in a worse condition. The hospital at Detroit is too small, and that this is a very important station was shown during the small-pox epidemic in Montreal little more than a year ago. The hospitals at Key West and New Orleans, each a very important station, are sadly in need of repairs. The Government does not own a hospital at New York, but the necessity for one is without question. An appropriation of $250,000 has been asked for to enable the Secretary of the Treasury to purchase a site and erect a suitable hospital, (and we have gained the impression in some way that the site has been purchased). The hospital at Wilmington, N. C., is also too small, and during the last year it was so crowded that the attendants had to be lodged in the cupola. It is recommended that quarters for the medical officers be constructed outside of the building. The other hospitals are generally, with the exception of minor repairs needed, in good condition.

Although there were no epidemic diseases imported into the United States during the last fiscal year, the country was threatened from various sources, especially from cholera in Europe and small-pox in Canada. Against the introduction of these diseases the Service did some very efficient work, as will be seen from the "Report." General Hamilton says, and it is a matter which has long been discussed, and needs still further ventilation, that a more stringent law should be made regarding hospital and other accommodations of the steerage on merchant passenger ships. The berth decks are badly ventilated, and in many cases there is an absence of light. These ships also need better medical attendance, and laws should be made which will give the medical officers some voice in matters relating to their position and duties. At present the medical officers are not subjected to examinations as

to qualifications, and in some cases they have to perform the duties of *purser* in addition to those of the medical attendant. "That portion of the quarantine act requiring the publication of weekly abstracts of sanitary reports, etc., has not been carried into effect of late years, the force of this office being inadequate for the performance of the duty. The detail of an additional officer to act as registrar of vital statistics would fulfil the requirements, at a minimum expense. These reports are very much sought after by State and local boards of health, and were the publications resumed it would be of great service to them." Since this was written these abstracts have appeared with an irregular regularity.

Hitherto the annual reports have mentioned the necessity for providing for old, decrepit, and worn-out seamen, and those suffering from incurable affections. This would prevent the over-crowding of the hospitals to some extent, and concentrate these seamen in one place, where they could be better cared for. It is recommended that a "National Snug Harbor" be established in the District of Columbia, which would also serve as the headquarters of the Service, and of the purveying division, laboratory, etc. The approximate cost of this establishment would be $155.000.

THE INDUCTION BALANCE AND TELEPHONIC PROBE.

At a recent meeting of the New York Academy of Medicine DR. JOHN H. GIRDNER gave an interesting demonstration of the detection and locating of metallic masses imbedded in the human body, by means of the *induction balance* and the *telephonic probe*. As is well known, this apparatus is the invention of Professor Alexander Graham Bell, of Washington, and the method was suggested in the summer of 1881, in connection with the case of the late President Garfield. It will be remembered that an attempt was then made to locate the ball in the President's body by means of the induction balance; but on account of the crudity of the apparatus, the lack of experience in its use, and, more than all, to the disturbing influence of a large steel mattrass on which the patient lay—the existence of which was unknown at the time of the attempt—the result was anything but satisfactory.

In working the apparatus a bichromate of potassium battery of six cells is employed; and an interrupted current with about six hundred interruptions to the minute has been found to be most satisfactory. For the induction balance two circles of electric influence are required: one, the primary, directly connected with the battery; and the other, the secondary or induced, with a telephonic receiver. In each there are two coils of No. 25 wire, one of which is twice the size of the other; the larger coils being designated as "exploring coils," and the smaller as "adjusting coils." The former, which are simply laid one upon the other, are secured to a large disc of wood, provided with a handle, which is called the "explorer," and which is to be moved over the surface of the body in the locality where the metallic mass is supposed to be lodged, while the "receiver" of the instrument is held to the ear of the operator.

When no metallic body is in the vicinity of the "explorer" no sound whatever is heard through the "receiver;" but when the "explorer" is brought near any metallic mass the presence of the latter is indicated by the sound heard in the "receiver." This sound increased in intensity as the "explorer" approaches nearer and nearer the mass, and the greatest intensity of sound is, of course, reached when the centre of the "explorer" is at the nearest possible point to the metallic mass. Fortunately for the successful application of the apparatus, experiment has shown that living tissue is the best conductor of the sound.

In the telephonic probe a telephonic receiver is brought into connection with an ordinary piece of steel upon the external surface of the body, and also with a long needle which is to be inserted into the flesh at the point indicated by the explorer of the induction balance, as that at which the sound in the telephonic receiver of the latter is most distinct. As soon as the point of the needle comes in contact with the metallic mass a sharp "click" is heard in the receiver; and the special value of the telephonic probe lies in the fact that this "click" is never heard when the needle comes in contact with bone or other non-metallic substance. At the meeting at which the instrument was described and exhibited, its practical working was shown by the detection of the location of a mass of lead in a piece of beef. It was also shown to some extent by the detection of the location of a ball in the chest of a gentleman who was wounded in the late war; but the gentleman respectfully, though firmly, refused to allow the telephonic probe to be used. The induction balance showed that the bullet was about the junction of the clavicle with the sternum. It seems, however, that the practical working of the instrument might be easily demonstrated beyond doubt by experiments upon anæsthetized dogs by shooting them and then locating and extracting the bullet.

THE LIGHTING AND HEATING OF RAILWAY CARS.

The recent disaster on the Vermont Central Railway, and others which have but lately occurred on other roads, seem sufficient ground for again calling attention to the dangerous methods of heating and lighting of railway passenger cars, especially since of the 300 lives already lost in railway accidents in this country this year about one-half have been caused by fires originating from the stoves and kerosene lamps with which the cars are heated and lighted. In a few States the State Boards of Health have undertaken systematic sanitary inspection of passenger cars, and it would be well if the Boards would set this matter before the legislatures in the strongest possible light; since it is clearly within the province of a State Board of Health to take cognizance of such matters—certainly as much as the disinfection of closets, water supply, means for rescuing passengers from wrecks, etc. In Dakota a bill has been presented to the legislature, and we are informed that it will most probably pass, which declares that a fire in a railway car is a "culpable negligence," and renders the road liable to the survivors of the person burned in the sum of $10,000 damages; and in the Illinois Legislature two bills have been introduced—the one requiring railway companies to use some other method than stoves for heating cars, and the other providing that a chemical fire-extinguisher shall be kept at each end of the car, or, in lieu of them, three hand fire-extinguishers.

It has been shown on the Connecticut River Valley Railway and on the elevated roads in New York City, that cars may be efficiently and satisfactorily heated by steam, without fire of any kind in the cars, and without danger to the passengers by breakage or disconnection. On the elevated roads in New York each car contains pipes in which is a quantity of soda solution, which is heated by steam from the engine; this solution being used because it stores more heat than any other available solution.

In the matter of lighting cars, it is now practicable to use the incandescent electric light, which is in partial use on the Pennsylvania Railway and on some of the cars of the Boston and Albany Road. Even gas, which has been used for several years on some of the roads, is much more safe than kerosene lamps. There may be said to be no danger whatever from the incandescent light, for any accident which breaks the glass bulbs at once extinguishes the light.

It is also within the province of the supervisors of public health to recommend that wooden bridges shall be superseded by iron bridges with a guard-rail (such as is in use on the New York elevated railways)—a high rail on the outside of the track-rail on each side, which prevents cars leaving the track even if derailed.

A CLASSICAL PATIENT.

The following message (?) was left on the slate of a Boston physician:

οἱ ἀναγκαῖοι ἐμὲ χρήζουσιν οἶσθε εἶναι.

The physician, in writing to the *Boston Medical and Surgical Journal*, claims that his inability to translate the line "shows the necessity of requiring Greek" (in the colleges). To us it only shows that the patient should have been taught to express his wants in English.

Doubtless one or two dozen translations of the line (no two alike) have been sent in by lovers of the classics residing even under the shadows of Harvard and the Bunker Hill monument. It is, then, perhaps too late for us to venture a translation, and it would be presumption extraordinary for those who do not see the necessity of requiring Greek, and who are somewhat out towards the periphery of the universe, to do more than offer a diagnosis of the patient's malady. If the patient cannot write English it is scarcely probable that his tongue has no mastery of the words immortalized by Dr. Noah Webster, not to mention other lexicographers. We may therefore imagine the dismay and confusion of face of our enquiring *confrère* when the patient returns, finds him in his office, and begins to describe his symptoms in the native tongue of Aristotle, which has been more recently brought prominently before the public by Prof. Anthony and Mr. Charles Francis Adams. There is, of course, a possibility that the person who left the inscription on the slate was a Boston blacksmith who called to collect a bill. It is equally possible that what was written was not Greek at all, but a prescription written by a prominent consultant while thinking of something else. But, on the assumption that the perpetrator of the outrage was a patient, we venture the diagnosis of *Anglo-agraphic aphasia*, and would recommend a writing master and a school dictionary.

CHOLERA IN SOUTH AMERICA.—From the latest weekly abstract of sanitary reports, issued from the office of the Supervising Surgeon-General of the U. S. Marine Hospital Service, Feb. 3, 1887, it appears that the cholera epidemic is steadily spreading to new places in the Argentine Republic, regardless of both quarantines and military cordons.

PROPOSED AMENDMENTS TO THE LAW REGULATING THE PRACTICE OF MEDICINE IN ILLINOIS.

A few weeks since we called attention to the very imperfect returns of births and deaths in this State, as shown in the last general report of the Illinois State Board of Health, caused by the neglect of physicians in reporting cases as required by the law. Some amendments to the law designed to aid in securing more complete returns in future have been presented in the State Legislature, now in session, and we trust they will receive early and favorable consideration.

If the State will furnish the members of the profession in every town convenient blank certificates, both for births and deaths, and annually publish the results in a form accessible for convenient study or reference, most certainly the physicians should be willing to fill the blanks and promptly mail them to the proper town or county officer. Correct vital statistics relating to the population of any town, county or State, constitute necessary factors in the study of etiology and the results of various measures for sanitary improvements. As every physician has a personal interest in whatever will advance any department of the science and art of medicine, he ought to coöperate cheerfully and promptly in securing full and reliable statistics of births and deaths, so long as the published results return *free* in the form of reports from the Health Board of the State. tabulated and associated with much additional valuable matter, all arranged convenient for use.

ANOTHER DEATH FROM CHLOROFORM.—According to the daily press, during the surgical clinic of Professor Wm. H. Pancoast in the Medico-Chirurgical Hospital, Philadelphia, February 9, 1887, a patient, male, aged 30 years, presented himself on account of false anchylosis of the proximal joints of the thumb and index finger resulting from previous injury. On attempting to forcibly restore motion the patient complained so much, that the professor ordered him a few inhalations of chloroform, and while he was still sensible enough to voluntarily hold up his hand, the professor took it, quickly flexed the joints freely, and removed the napkin in which had been placed at the beginning only "half a teaspoonful of chloroform," but respiration had ceased. The statement gives the whole time during which the chloroform had been administered as "only four minutes;" and that from a napkin admitting free intermixture of air. The most active and persevering efforts failed to resuscitate him. The post-mortem examination revealed much disease of the kidneys, and fatty degeneration of the liver and muscular structure of the heart.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, January 17, 1887.

THE PRESIDENT, EDMUND J. DOERING, M.D., IN THE CHAIR.

DR. LYMAN WARE read a paper entitled

A CLINICAL STUDY OF GLAUCOMA.

The author briefly referred to the history, pathology and etiology of glaucoma, and expressed his belief in the curative power of von Graefe's operation of iridectomy. Unmistakable symptoms of glaucoma are supraorbital and ciliary neuralgia, increased ocular tension, periodic diminution of vision, the appearance of a halo around artificial lights, a sluggish and widely dilated pupil and a shallow anterior chamber. Although increased tension may be associated with other diseases of the eye, its presence should always lead to a critical examination. Several cases were detailed: Mrs. M., aged 50, while riding in an open street-car, contracted a severe cold, which was followed by neuralgia over both eyes. The pain was so intense that at times she was delirious. Her weight was reduced from 110 to 80 pounds. She became entirely blind. On account of the eye being small and deeply set and the anterior chamber very shallow, sclerotomy was advised and performed. This gave immediate relief, but the pain returned again in a few days. When Dr. Ware saw the case the anterior chamber was almost obliterated, the glaucomatous lens pressed the iris forward until it came in contact with the cornea. With a von Graefe cataract knife a free sclero corneal incision was made and a portion of the iris excised, and the lens removed from both eyes. The pain greatly subsided, but the sight was irrecoverably lost. Another case was a man æt. 52 years, who complained of having had pain in and over the left eye for five or six months, and had seen the halo about street lights. On examination tension was found increased, vision diminished one-half. Some months later iridectomy was performed, and a solution of eserine (4 grs. to the oz.) instilled every four hours into the other eye. Pain was at once relieved and all symptoms of glaucoma rapidly disappeared. Mrs. M., aged 45, had frequent attacks of neuralgia and noticed defective vision in the left eye six months before coming under observation. Tension was found much increased; she had seen halo about artificial lights for eight or ten months. Distant objects could be clearly perceived by right eye. Iridectomy was performed on the left eye with a view of abating the

pain and preserving the vision of the right eye. The relief from pain was great, vision of right eye fully restored and left eye much improved.

Dr. E. E. Holmes reported

A CASE OF FOREIGN BODY IN THE ANTERIOR CHAMBER.

This case was of special interest to me on account of the difficult diagnosis and the difficulty attending the removal of the foreign body. The doubt regarding the diagnosis arose from the fact that there was a small central perforation of the cornea. Below this, and not connected with it, was a fine greyish line extending downward and inward (R. eye), apparently in the substance of the cornea, fairly into the angle of the iris and cornea. This resembled the channels left after the removal of fine slivers of grain stalk which are sometimes thrown into the cornea obliquely from threshing-machines. The patient explained the accident as follows: He was setting a machine punch so the punch would accurately fit the die. The power was applied, when the punch did not accurately correspond to the die. At the same instant something entered the patient's eye. He came to my house twenty-four hours after the accident with the eye slightly red, but not painful. I prescribed atropine and sent him to the hospital. The next morning the pupil was round and fully dilated. The media were all clear. I felt great anxiety in regard to the case, but inasmuch as during five days there were no symptoms of inflammation along the supposed track in the cornea, I finally became convinced that there was a fine splinter in the anterior chamber, in close contact with the cornea.

I made quite a long incision through the lower border of the cornea, the knife touching and moving the piece of steel. I endeavored by means of a fine forceps to seize the lower part of the steel and disengage the point from the tissues at the angle of the iris and cornea by carrying the steel farther towards the pupil. This was found to be impracticable, since the lower end of the piece was firmly held by the tissues. I used all the violence I considered warrantable. As the anterior chamber was without aqueous humor, there was some difficulty in further procedure without violence to the lens or iris. I consequently extended the wound in the cornea upward so the upper end would correspond with the upper end of the steel. This end was easily seized and with considerable force withdrawn. The splinter was three-sixteenths of an inch in length. Eserine at first, then atropine with antiseptic dressings were applied with great care. There was no reaction, the patient recovering perfect sight, except as far as there was dimness from the central cicatrix in the cornea. Vision was good five weeks after the patient had returned home. I must confess the almost V-shaped incision in the lower border of the cornea did not please me.

Dr. Holmes also reported

A CASE OF INTRA-OCULAR TUMOR.

This tumor, filling the sclerotic, is a sarcoma of the choroid. The patient, a man 62 years of age, had been under the observation of several specialists during the past year, but could not give me a definite expression of their opinion. When he came to me, a few days ago, the cornea was perforated and presented a staphylomatous projection of the growth. For a year there has been pain and for the last six months very great pain. The tissues of the orbit around the globe were greatly swollen, but not indurated. In enucleating the eye I expected to find the sclerotic destroyed posteriorly and the orbital tissues invaded. The enucleation, however, was performed as easily as in ordinary cases. The optic nerve is seen to be enlarged several millimetres behind the sclerotic. The swelling in the orbit was caused by nodules of fat filled with numerous blood-vessels. Dr. Ochsner pronounces the tumor to be a small round-celled sarcoma with very little pigment. The nodules of fat are free from sarcoma cells. This class of tumors, if removed early, are not very liable to return in the orbit. They may, however, reappear, especially in the liver or other internal organs. They must, consequently, be regarded as quite malignant.

Dr. Boerne Bettman read a paper on the

CONNECTION BETWEEN OCULAR AND NASAL DISEASES.

The author thought that numerous pathological conditions of the eyes and lids are attributable to abnormal changes in the nose, and that in these cases treatment of the ocular organs alone will fail to alleviate the trouble. After referring to Hack's monograph on the subject, Dr. Bettman detailed several cases in substantiation of his theory: A boy of 10 applied for treatment of epiphora of both eyes. The eyes were constantly weeping. An examination of the nose revealed an extensive swelling of the anterior portion of both turbinated bones. When these parts were touched with the probe profuse lachrymation was induced, and a light thrown into the eye by means of the ophthalmoscope produced violent sneezing. A deep incision was made in the swelling with a knife electrode, and a flat burner was also employed. The slough was completely thrown off in fourteen days and the boy cured in one month, the eyes receiving no treatment. Polypi of the nose have been found to produce secondary affections of the eye: Hermann S. was prevented from following his trade of a cabinetmaker on account of the excessive flow of tears; he also complained of pain in the eyes. Polypi were removed from the middle turbinated bone with the Jarvis snare and a cure effected. E. B., aged 16, was extremely sensitive to light and the eyes were both bathed in tears. Each time the eyes were exposed to a glare of light she sneezed violently. There was Hack's swelling in both nostrils. Two pledgets of cotton were soaked in a 5 per cent. solution of cocaine and allowed to remain five minutes at a time. There was an immediate effect, and in three-quarters of an hour she was able to bear the light. The patient refused cauterization and employs cocaine to avert photophobia. The majority of cases coming under Dr. Bettman's observation have been treated by applications of the galvano-cautery to the nasal membrane. The applications restricted to the anterior end of the turbinated bone frequently fail to give relief. It has been found that a sensitive area

exists at the posterior end of the inferior turbinated bone and also at the anterior part of the nasal cavity, in the angle forming the boundary of the vestibule. In conclusion, the author thought oculists should always subject the nose to a thorough examination when seeking the source of ocular complaints.

DR. H. M. STARKEY read a paper entitled

SOME MODIFICATIONS IN THE TREATMENT OF STRICTURE OF THE NASAL DUCT.

The author said that about 1883 the Western Suppository Co. made a lachrymal bougie of medicated gelatine of such elasticity that it could easily be passed into the nasal duct. It was less painful than a metal probe, and its slow solubility kept the mucous membrane at the point of stricture distended so that it could be acted upon by the medicine from thirty to sixty minutes. He thought results showed the use of electrolysis in these cases to be often unsatisfactory. The object to be attained is to restore the diseased parts to as nearly a normal condition as possible, and the most satisfactory treatment is by using injections more and probing less frequently. The author determined to try the effect of probing the punctum without slitting the canaliculus, followed by astringent injections over the inflamed surface. This treatment proved entirely satisfactory, and in about five weeks a patient went to his home in another State with apparently perfect recovery, and no destruction of tissue.

The following case was given as illustrating the author's method of treatment: Mrs. L. suffered from lachrymation of each eye for two years. There was severe lachrymal conjunctivitis of the right eye, the punctum being contracted one-half. On dilating the right punctum a No. 2 probe could be passed without difficulty, but the whole interior of the nasal duct had the peculiar velvety feeling that is caused by thick villous mucous membrane. The same condition, in less degree, was found on the left side. Treatment was commenced by applying a weak astringent and washing out the lachrymal canals thoroughly each day with boric acid lotion, followed by a weak astringent. Once a week a probe was passed through the dilated punctum down to the naris, using a larger probe each time until No. 7 was reached. The result was satisfactory, and in six weeks the patient returned home apparently well.

DR. W. FRANKLIN COLEMAN read a paper on

SYMPATHETIC OPHTHALMIA.

Disease in the sympathetic eye generally occurs when there has been a wound or operation in the dangerous zone of the diseased eye. Becker, in 1875, collected twenty two cases of sympathetic ophthalmia from cataract operations, foreign bodies lodging in the eye, and degeneration of a lost eye, or other causes. Dr. Coleman read in detail the clinical history of the disease, and enumerated the causes, histories and results of the treatment of a large number of cases. In regard to treatment he advised as per the following:

CONDITION DISEASED EYE.	CONDITION SYMPATHETIC EYE.	TREATMENT.
Blindness.	Normal	Enucleation in unintelligent and children.
Blindness.	Sympathetic irritation.	Enucleate.
Blindness.	Sympathetic inflammation	Enucleation not often advisable.
More or less vision	Normal.	Do not enucleate generally.
More or less vision	Sympathetic irritation.	Better enucleate.
More or less vision	Sympathetic inflammation	Do not enucleate.
Acute ophthalmitis	Normal.	Never enucleate.
Acute ophthalmitis	Sympathetic irritation.	Puncture and foment diseased eye, then enucleate.
Acute ophthalmitis	Sympathetic ophthalmitis.	Treat ophthalmitis, and then enucleate.

DR. F. C. HOTZ said: I think the theory of the author in regard to the closing of Schlemm's canal and the approximation of the iris to the cornea interfering with filtration cannot account for glaucoma. Pathological anatomy has so far failed to find the cause, and we have to rely on clinical studies to build up a theory which will account not for the late stage, the fully developed glaucoma, where the sight of the eye has been permanently destroyed by the disease, and which the pathologist gets from the oculist after enucleation, but for the first stage, the premonitory symptoms before it becomes an acute attack; a stage which the pathologist has not yet investigated with his microscope. At that stage who can say certainly what glaucoma is? It is probable that various causes lead to the same result. I believe that the agglutination of the iris to the cornea, the compression of Schlemm's canal or any other part of the eye, are consequences, and not primary causes of glaucoma. I was somewhat surprised that, in a paper addressed to general practioners, the author attached so little importance to the clinical symptoms in glaucoma, of a general character, such as gastric and febrile disturbances in connection with hemicranic headache. These symptoms often cause the practitioner to fail to discover glaucoma. I can recall a number of such instances. Last October a lady came under my care who had been under the treatment of a physician for four or five weeks for malarial fever and dyspepsia, which was the beginning of an undoubtedly characteristic and typical attack of glaucoma. But the attending physician's attention was attracted by the coated tongue, the nausea, vomiting, severe headache and excited pulse, and he treated the patient for these daily attacks of headache, which he diagnosticated malaria, and used antiperiodic remedies, utterly disregarding the condition of the eye, although the sight was at first nearly extinguished, and only returned to a certain extent after the attack lost somewhat its severity. Another case: A poor woman lost one eye from glaucoma ten years before; the eye was blind and hard, showing the characteristic state of an eye in which glaucoma had run its course. She was attacked by a severe pain in the head extending over the left side, could not sleep for several weeks, was nauseated, vomited, and showed symptoms of some general disturbance. The physician

treated her for the stomach trouble and headache, and although she told him time and again that her sight was getting poor, and suggested that an oculist had better examine her eye, he paid no attention to this, and the result was that two months after this attack the sight was entirely gone and could not be restored. In still another case both eyes were neglected until the patient could perceive only a little flicker of light, before it was considered necessary by the attending physicians to pay any attention to the eyes. Dyspepsia, gastric fever, malaria, and sick headache were the diagnoses, and the treatment was in accordance. I think it is well to bring out these points, and to call the attention of every physician to the fact that such attacks sometimes mean something more serious than a disturbance of the stomach, and that when the patient, during such attacks, speaks of the eyes as being troublesome, or the sight as becoming dim, it is worth while to pay attention to it, and to remember that acute glaucoma is often ushered in with these general constitutional symptoms.

Dr. Lyman Ware said: I have only a word to say about the disturbance of the equilibrium of secretion and excretion. It has been fully demonstrated that it is only by restoring the equilibrium that sight is saved. I quite agree with Dr. Hotz regarding febrile symptoms, but it is my experience that they are *secondary* rather than *primary*.

Dr. Henry Gradle said: The cases which Dr. Bettman presented are of great interest from the fact that they have only lately been recognized. Dr. Gruening, of New York, was the first to point out that there existed affections apparently of the eye, but which in reality originated from the nose. I have watched for these cases ever since Gruening's paper first appeared, and would say that the cases in which the nasal trouble is *entirely* the cause of eye disease are not very frequent. But I have seen instances where affections of the eye were certainly complicated by nasal trouble, and the nasal trouble prolonged the eye disease. I recollect a number of cases of eye disease either kept up or originated by nasal trouble. The first of these is a pseudo-erysipelas of the lids, which is not an infectious disease, but merely a secondary affection of the blood-vessels, only resembling erysipelas clinically. It is entirely due to irritation and engorgement of the blood-vessels in the front part of the inferior turbinated bone. A second type of nasal affection giving rise to eye trouble is true periodical hay fever, and a non-periodical irritability of the nose, resembling hay fever. I have published four cases, and have since seen another, of periodic conjunctivitis characterized by the formation of granules and follicles, which trouble always receded in winter, to reappear again in the spring or summer. In two of these cases a diagnosis of hay fever has since been made. I have seen a case which had been treated for trachoma by a number of specialists, where the history of the nose showed that the affection was of nasal origin. The same trouble may exist in a non periodic form, and present all the symptoms of hay fever, the trouble not being limited to any season, but occurring in any part of the year, lasting a few days or weeks. But these cases are not common. In one of these cases I was able to effect a complete cure by cauterization of the nose. A third type of nasal affection giving rise to ocular symptoms is true catarrh of the upper and front part of the mucous membrane of the nose, where the membrane is distinctly reddened and where there are generally slight and by no means prominent symptoms of catarrh. In these cases I have very frequently found troublesome epiphora without any stricture of the duct; in some cases the test was made by using delicate probes. Such cases, I can testify from my own experience, are entirely curable by simple treatment of the nose. I have found a not sharply defined case of astheropia, due not entirely to the nose, but complicated with refractive trouble, where nasal treatment was necessary to complete a cure. Once or twice I have seen polypi play the same rôle, and a number of times I have found the starting-point of the irritation not in the front of the nose, but in the posterior part, in the form of the common adenoid vegetations.

This is a subject which has not been fully dealt with in literature, but I have several cases where the extirpation of the large post nasal tonsil has given decided relief to the eye. Then I have found that in a few cases ulcers or chronic inflammation of the cornea were kept up by nasal trouble, which was probably started in the first place by a copious flow of tears from the eye. I have observed that local treatment by means of calomel, atropia, and the customary applications to the eye, proved inefficient, while the addition of nasal treatment hastened the cure of some of these tedious cases. The nose was probably normal to start with, but the continued flow of tears produced either small erosions or some little catarrhal troubles of the mucous membrane at the front of the nose, subsequently increased to chronic catarrh, leading to congestive obstruction of the tear passages, or exerting an unfavorable nervous influence upon the eye trouble. Finally, as a rare instance, I will mention one case which is now cured. The patient was sent to me for polypi, which, however, proved to be the minor trouble in the nose, the real trouble being an immense vascular tumor occupying the entire floor of the right side of the nose, covering the inferior turbinated bone and reaching about to the middle turbinated bone. The patient had been reduced in strength, and the slightest exertion on his part produced hæmorrhage, therefore the most careful operative procedure was necessary. I finally succeeded in removing the entire tumor by the galvano-cautery in twenty sittings. As the tumor began to shrink the hæmorrhage was less, but he lost thirty or forty ounces of blood in six weeks. During the latter part of the treatment his right eye began to bulge, and he complained of double sight. It has remained healthy, but there was an unmistakable development of vascular tissue in the orbit and behind the eye, which receded by the time the tumor had been extirpated from the nose.

Dr. Boerne Bettman said: I was very glad to hear Dr. Gradle corroborate my statements. I am well aware that these cases are comparatively rare; although I have recorded in my case book about

twenty, seen during the last two years. I am acquainted with the article published by Gruening. My attention was first called to the subject by the work of Hack, and since reading that I have made it a point never to allow an eye patient to leave my office until his nose has received a very thorough examination. I have seen a number of cases such as mentioned by Dr. Gradle, but I thought it better to describe to-night only the typical ones. The connection between ocular and nasal troubles is a point all oculists should bear in mind, and when they find no local cause for epiphora they should examine the nose.

DR. A. P. GILMORE said: I would like to add one word in regard to glaucoma, and that is, the importance of tension does not seem to me to have been sufficiently dwelt upon. Any careful general practitioner can ascertain whether the tension is increased or not, simply by comparison with the tension of his own eye. All pain referred to the eyeball, with or without the accompanying neurotic symptoms mentioned in the paper, does not mean glaucoma. Unless there is increased tension you cannot diagnosticate glaucoma. The author does not mention Badal's operation in the treatment of glaucoma. It is certainly entitled to a place among the operative measures. I will only speak of one point in Dr. Starkey's paper, viz.: epiphora. I do not believe, with many, that epiphora is due primarily to a stricture which prevents the escape through the nose of the natural amount of fluid secreted, but is due rather to reflex irritation causing an hypersecretion of tears. In health the eye is moistened with a moderate secretion. When the lachrymal gland is removed the eye continues to be moist and the cornea retains its lustre. Tears are not essential to the lubrication of the eyeball; their function is to protect the eye against foreign bodies. A bit of dust under the lids will cause profuse lachrymation and the tears will flow over the face, not because of an obstruction to the natural amount of fluid secreted through the natural passage, but because of a hypersecretion due to reflex irritation. For treatment I never use a probe larger than Bowman's No. 6, usually No. 4. I seldom find it necessary to make Bowman's operation in epiphora. I think its use is unnecessarily frequent. I use astringent and antiseptic solutions with a syringe small enough to be easily introduced into the puncture when slightly dilated. I am very careful to treat any nasal complications; it is impossible to treat diseases of the eye successfully without recognizing and treating reflex irritations of the nose.

DR. STARKEY said: My paper was necessarily cut down very much. As first written I had given some space and attention to cases similar to those mentioned by Dr. Bettman. I had also spoken of the probability that in many cases of epiphora, where there had been inflammation of the tissues lining the lachrymal canals with partial closure, a continual irritation of the canal in some way, perhaps reflexly, so stimulates the lachrymal gland that the tears are poured forth more abundantly. There are well-known cases where the lachrymal canals have been completely closed by injury or operation, and yet lachrymation is not annoying, although the gland has not been extirpated; tending to show, as mentioned by Dr. Gilmore, that the normal secretion of tears is ordinarily very limited. It seems to me that in many instances lachrymation is due to irritation propagated reflexly, and therefore in treating such cases I thought of trying to restore the mucous membrane of the lachrymal canals to the normal condition, as well as to look for and treat points of irritation elsewhere.

DR. J. E. COLBURN said: In cases of injury where there is danger of sympathetic irritation, a foreign body being lodged in the anterior chamber, iris, ciliary body, or the choroid, where the chances are that in order to give all the advantages of treatment the patient must necessarily be idle for a considerable length of time, and where the sight in the injured eye has been irretrievably lost, I think it advisable to make the operation of evisceration or abscission as early as possible. The patient, if a laboring man, is then relieved from a long enforced idleness and anxiety, and the danger that lack of care frequently causes in this class of cases. Where the appearance is first to be considered, and the patient can be constantly under observation, the operation can be postponed, but with the strict injunction the patient is to be under constant surveillance. In a large majority of cases where there is great damage done and the foreign body is out of sight, it is safe and advisable to make the operation, trusting to that to save the other eye. In a case that came under my observation recently a piece of steel entered the anterior chamber near the centre of the cornea, passed through the iris and lodged in the sclera. No operation was performed, and the fellow eye became sympathetically affected, and on account of its sympathetic disturbance had to be removed. The steel produced some local irritation, and the eye was caught and rolled strongly toward the nasal canthus, and the piece of steel was found projecting into the orbit from the sclera and was removed. The track of the steel through the sclera was surrounded by a large mass of fatty degeneration, which was also removed. Vision remained about one-half.

DR. W. FRANKLIN COLEMAN said: I agree with Dr. Colburn as to the desirability of timely enucleation in the case of a laboring man to save his time, but should ophthalmitis set in I should not, under any circumstances, enucleate the eye. I believe it is rare for German operators to risk removing an eye in a case of ophthalmitis, but in England they scarcely hesitate to remove an eye under any circumstances. I have never regretted recommending a patient to have an eye enucleated, but I have sometimes regretted that I did not urge the patient to have the eye out in order to avoid the fearful risk of sympathetic inflammation. I am astounded at the position of so eminent an authority as Noyes who says, "I hesitate to enucleate the eye on account of appearances, and do not do so unless symptoms of irritation or inflammation appear which I cannot relieve with medical treatment." In nineteen out of twenty cases the lost eye is not worth saving, but is a blem-

ish, and an artificial eye would be more ornamental. And if a man wishes to get work he will deceive the very elect as to which is the real and which the artificial eye. I cannot see any advantage in not advising enucleation where the eye has been injured to such an extent as to menace the fellow eye.

Dr. Gilmore asked Dr. Holmes why he did not try a magnet?

Dr. Holmes replied that he had been in so much doubt what to do that he thought best to first try incision and forceps. He did not believe the best magnet could have liberated the end of the steel, buried in the tissues of Fontana's space. It is remarkable that so long a piece of metal could have been thrown through the cornea, making so minute an opening, and lodged in the anterior chamber, as described, without injury to the iris or lens.

Dr. Coleman said: To my mind the magnet in the eye is a delusion and a snare. For instance, if you introduce a magnet within the eye not knowing where the foreign body is before placing the point of your magnet, you have to search the whole cavity of the eyeball and reduce it to a jelly before you can extract the body. Granted no great harm is done if you do not extract it with the magnet, for you can afterwards enucleate the eye. But so far as I have tried it, and have seen others experiment with the magnet, it does not give satisfaction.

Dr. Holmes replied: That is very true in many cases where the steel cannot be seen with the ophthalmoscope, but I think where a view of the foreign body can be obtained early, the magnet may be employed with brilliant results. There are now so many cases reported with excellent results after extraction with the magnet, that I cannot think it a delusion and a snare by any means.

Dr. Colburn said: I recently saw an interesting case in which the foreign body was lodged about half way between the ciliary body and the entrance to the optic nerve. The operator cut through the sclera about where he thought it was lodged, passed the magnet in and brought out the foreign body apparently without wounding the retina at the point of attachment. The patient made a good recovery.

SUFFOLK DISTRICT MEDICAL SOCIETY.

Section for Clinical Medicine, Pathology and Hygiene.

Stated Meeting, January 13, 1887.

Albert N. Blodgett, M.D., Secretary.

The meeting was called to order at 8 o'clock by Dr. F. I. Knight, Chairman. On motion, the reading of the records of the last meeting was omitted. The Chairman announced the subject for the present meeting to be a debate upon the danger to the public from

ARSENICAL WALL-PAPERS,

and called upon J. R. Chadwick to open the discussion.

Dr. Chadwick, in response, presented an interesting and vivid account of the occurrence of arsenical poisoning in his own family[1] on several distinct occasions, and spoke of the uncertainty which exists in relation to the presence of arsenic in wall papers, even when the dealer presents the certificate of a chemist as evidence that the papers are free from this dangerous substance. At the close of his remarks, Dr. Chadwick offered the following resolution:

Resolved, That it is the opinion of this meeting that the clinical evidence already adduced in this and other countries, establishes beyond doubt the fact that arsenical wall-papers will, in many instances, produce symptoms of poisoning by arsenic in persons occupying the rooms whose walls are covered by such papers.

The resolution was seconded, and was then declared open for discussion.

The Chairman introduced Mr. J. F. Bumstead, the well-known paper dealer, who was invited to address the meeting. Mr. Bumstead responded by saying that he did not desire to occupy the time of the members to any great extent. In all large establishments there are many persons employed, and the facts in regard to the purchase of paper by Dr. Chadwick are, that Mr. Bumstead did not personally exhibit the papers, but a salesman in the service of the firm was the person who made the transaction. The statement was made to the purchasers that no papers would be shown except such as had been pronounced by chemists of repute to be free from arsenic.

It is desirable that the position of the paper dealers should be placed before the profession in a more correct light than is at present the case. The efforts and desires of the dealers are directed toward the elimination of dangerous articles from the colors and other processes of manufacture of wall-papers, and the substitution therefor of equally useful, but harmless methods of treatment, by which the health and lives of the people may not be endangered. Personally, the paper dealers do not place credence in very many of the alarming reports which are, from time to time, circulated in relation to the occurrence of dangerous interference with health from the action of the colors used in wall papers. It is both a mistake and an injustice to suppose that the dealers do not take pains to have their wares examined in relation to their safety. Messrs. Bumstead & Co. have had four different chemists in their service during the last twelve years. The intention was to exclude dangerous papers from the business. About two or three years ago, an agreement was made between the wall paper manufacturers and the dealers, that the manufacturers should take back all arsenical papers. For some time the manufacturers would not accept any orders from the trade, on account of the great frequency of rejected papers, but lately they again consented to receive all papers returned to them which contain more than a trifling amount, called a trace, of arsenic. A portion of the present disturbance in regard to arsenical papers arises from the fact, that many of the papers now examined are such as were manufactured some years ago, and some of the papers have been for years on

[1] See page 206.

the walls of inhabited rooms, where they have produced no appreciable symptoms of poisoning until the present excitement was inaugurated. Certain papers are even now purchased from a stock which has long been in the store, and which may contain an amount of arsenic never at present used in the manufacture of wall-papers. The occurrence of arsenic in these accidental ways should not be looked upon as fairly representing the paper manufacture at the present time.

DR. C. E. STEDMAN said that he had little to offer to the remarks of those who had preceded him. Some years ago he purchased wall-paper from a firm now gone out of trade, and it was put on the walls of his house. For two or three years the occupant of that room was continually ill, the symptoms being a persistent diarrhœa, with colicy pains, etc.; and finally a severe form of eczema supervened, for which various forms of treatment were ineffectually tried, and at length the patient was placed under the care of Dr. Wigglesworth, of this Society. At a later period, Dr. Stedman for a time occupied the room in question as a sleeping room for himself, and soon became ill, suffering from an obscure form of ocular disease, for which he consulted Dr. Wadsworth, of this Society. After some time, Dr. Wadsworth suggested the possibility of arsenical poisoning, and that the wall-paper might be the source of the trouble, when the paper was subjected to chemical analysis, and was found to contain a large amount of arsenic. The paper was at once removed from the walls, and a paper substituted which contained no arsenic, since which time there has been no recurrence of the symptoms of poisoning, or in fact, any other signs of impairment of health in any member of the family.

PROFESSOR D. G. LYON, of Cambridge, was called upon by the Chairman, and rising, said that on the 19th of January last he caused the publication of a long account of the troubles which had occurred in his house and family, for which, in his mind, their existed no cause, except the arsenical paper on the walls of his house. His family consisted of three members, Mrs. Lyon, himself, and another instructor in the University. They were all affected by a variety of distressing symptoms, one of which was persistent insomnia. It was almost impossible for any member of the family to sleep at all. In addition to this, a common symptom was pain in the head, palpitation, general debility, etc., which proved refractory to all methods of treatment for its relief. Physicians were called, but were not able to alleviate the distressing conditions, which now began to cause serious alarm. Professor Sänger was consulted, and he examined the furnace, sewers, etc., but being unable to locate the trouble in either of these parts of the household apparatus, he at length suggested the possibility of the wall-paper being the agent which had operated so disastrously upon the family. This was immediately submitted to chemical analysis, and yielded a large amount of arsenic.[2]

[2] I had recently read the admirable paper of Professor Wood on the subject of "Poisoning from Wall-Papers," and observed that the symptoms which he there recorded, were almost identical with those experienced by the members of my family, from circumstances similar to those surrounding the cases mentioned in the article by Professor Wood.

Four rooms were covered with paper containing extremely large quantities of arsenic, as determined by chemical analysis. The papers were at once removed, and the walls recovered with papers which were free from arsenic, and the immediate result was the entire and rapid disappearance of all the symptoms of disease which had so long existed, and which had thus far been quite unaffected by any form of remedial treatment.

Chemical examination of the wall-papers of different dealers, a year ago, showed that more than 50 per cent. of the papers in the stock of the Boston dealers contained a much larger amount of arsenic than the bill at that time presented before the Legislature asked for. The manufacturers claim that a law which should limit the amount of arsenic contained in wall-papers would seriously affect their trade, and that certain forms of papers cannot be produced without the aid of arsenic, or at least, without the use of substances in which arsenic may exist. Within a stone's throw of my house in Cambridge are families which have suffered more than my family did. In all parts of this Commonwealth, cases of poisoning from the use of arsenical papers are known, and the appeal of all these people is only for a law by which they may be protected from a danger which they have no means of recognizing for themselves. Those people who bought wall-papers in Massachusetts, and especially in Boston, a year ago, assumed a serious risk to the health of their families, from the almost universal presence of arsenic in the wall-papers of that time. I could report more than forty families thus affected from this cause.

PROFESSOR E. B. YOUNG said that he has never appeared before the legislature, nor has he ever published anything in the papers in relation to the dangers from arsenic. He has been a long, but silent sufferer from the effects of poisoning by arsenic in wall-papers in his house. In his case the symptoms were a palpebral inflammation of both eyes with continual lassitude, weakness, etc. His daughter, formerly strong and robust, became weak, languid and feeble. Professor Young himself was not well. The occurrence of such an amount of sickness in his family without adequate cause made him anxious. He employed men to overhaul the sewers of the house, but the drainage was found in good condition. At this time Professor Lyon suggested the possibility of arsenic as the cause of their distresses, and the papers of the house were at once subjected to analysis. In a light-blue paper arsenic was found to the extent of 4.97 grains to the square yard. In some English cretonne used for upholstery, there was discovered 4.00 grains of arsenic to the square yard. This had been in service for some time, and had begun to wear, and with the destruction of the texture of the fabric, the arsenic had become more readily disseminated. The paper of another room contained ¼ grain to the square yard. Professor Young's daughter was much troubled by an affection of the throat, for which she was placed under the care of Dr. Knight, the Chairman of this meeting, and, as she did not improve, she was sent to Dublin, where she began to get better. After a time the urine was

examined, and was found to contain arsenic. After the restoration of the house, the daughter's health was again restored, and a letter from her physician who has had the urine again examined, contains the the report, "no trace of arsenic in the urine at present." In the dining-room of the house arsenic was discovered in the paper. The result of all this has been to cause a large outlay in money, as well as a great amount of anxiety through a long time; and we feel that we have the right to demand legal protection from this known and recognized source of danger to our families. Nobody claims that arsenic causes *all* the illness in families, but it undoubtedly causes *some* of it. Nobody thinks arsenic does any good in the papers, and is certainly better out of the way, than to be thus a constant source of possible danger. Another case was that of the daughter of a clergyman of Jamaica Plain, who was ill from an obscure cause, but in whose house the papers were found to contain arsenic. She was quite well soon after the old papers were replaced with non-arsenical ones. Another case was that of an entire family in Cambridge, the name of which would attract attention as belonging to the higher walks of literature, in which there was unmistakable poisoning. Another instance occurred in Milton, where there is a house, one room of which possessed the peculiarity that every person who occupied this particular apartment was certain to become ill. Each member of the family had in turn occupied this chamber, and each in turn had been similarly affected. The paper from the walls of this dreaded apartment was analyzed and contained a very dangerous quantity of arsenic. An Episcopal clergyman and his wife were both poisoned by arsenical paper not long since. The husband was confined to the bed in the room, and grew worse, while the wife, who was not so ill, but could pass a good portion of the time out of the room, was not so seriously affected. Another well-marked case occurred in Waltham. Perhaps the most amusing fact, however, is that Professor Sänger was himself poisoned last summer at the seashore. He was assigned a room which was papered with highly arsenical paper, and was soon made ill by it. Professor Young then passed specimens of the papers removed from his house, to the members of the Society, remarking that there is absolutely no way in which arsenical papers can be detected excepting by chemical analysis, and that therefore the most careful selection is no protection against this danger.

Prof. Wm. B. Hills, of Harvard University, was then announced, and spoke as follows: It has fallen to me to examine as many papers, probably, as to any one in this city, during the past few years, and I now examine for two of the most prominent paper houses in the State. From my experience I am convinced that the present alarm concerning arsenical poisoning from this source is unnecessarily great. The results of analysis during the past few years show this fact conclusively, as the following figures will prove. During the period from 1879 to 1883 the percentage of arsenical papers was from fifty-four to sixty-five per cent. of all papers examined. In 1884 the percentage had fallen to forty-seven per cent. arsenical.

In the first series of figures, those from 1879 to 1883, from thirty-one to thirty-five per cent. of the arsenical papers were strongly or dangerously arsenical. In the second series of figures, the proportion of strongly arsenical papers had fallen to twenty-two per cent. In 1886 there was a large decrease in the arsenical papers, only thirty-three per cent. of all papers examined containing any traces of arsenic. Only thirteen per cent. of these papers contained anything more than a trace of arsenic. These figures are the more startling on account of the extreme delicacy of the Marsh-Berzelius test, which was employed in 1886 only; and it appears that the matter is slowly settling itself by the common efforts of the manufacturers and the trade toward satisfying the demand of the public that papers shall be made without the use of dangerous substances. It has been stated in this meeting that all papers are at present still strongly arsenical. This statement is not in accordance with my experience. Most of the papers taken from the walls of rooms are such as were manufactured some years ago, and may naturally be different in chemical composition from the papers made to day. The fact is that papers now manufactured do not contain a dangerous amount of arsenic. I do not think that it is desirable to appeal to the legislature until we know definitely the present state of the case, and until we know the limit which it is safe to establish in relation to the accidental presence of small amounts of arsenic in the papers. A law to prevent the sale of "Rough on Rats" would save more lives than a law to prohibit the sale of wall-papers containing a trace of arsenic.

Dr. H. J. Barnes asked what reason exists for the use of arsenic at all in the manufacture of wall-papers?

Professor Hills replied that there is no reason for its use. It is not used intentionally, but exists as an adulteration in some of the pigments employed in the preparation of the paper. It is an impurity in certain of the mineral pigments which have been employed in the manufacture of former papers. Manufacturers are now trying to keep the arsenic out of their colors.

Dr. Edward Wigglesworth said that he had but little to add to what had been said in relation to the dangers from arsenical papers. He had suffered in his own family of four persons, from this cause. The symptoms were not alike in all, but were clearly traceable to the papers on the walls. Among the peculiar symptoms in this instance were certain not mentioned by those who had preceded him, and one of these was a tremendous desire to urinate, with a burning at the neck of the bladder, which ceased as soon as the urine was passed. There was no kidney trouble, and no affection of the bladder or meatus, nor any other condition to account for the distress which was present. A little boy occupied a newly-papered room, and was soon affected with a palpebral irritation of considerable severity. The paper was analyzed and found to be arsenical. A little girl of three years was poisoned. Dr. Wigglesworth stated that both he and his wife are still ill from the effects of poisoning, and the papers were found to

contain from fifteen to twenty times the amount of arsenic which has been considered the limit of safety. When the symptoms of poisoning first became evident the cause was not recognized, and a journey to the South was made with the result that all symptoms of disease entirely disappeared. On returning, however, the original disturbances again appeared in their former intensity. The paper was removed and replaced by non arsenical paper, and the family is now on the way to recovery.

DR. STEDMAN mentioned a case of eczema which had been treated by Dr. Wigglesworth. The child had been under the best of care before, and nothing in the shape of attention could have been rendered that had not been most conscientiously carried out. When the child was placed under the care of Dr. Wigglesworth, he at once decided that there must be some unsuspected cause for the disease. He went to the house of the patient, who was a dispensary case, and examined the plumbing with great care, and also inspected the premises in other directions. He at length decided to have the wall-paper examined, and it was found to contain arsenic in large amount. The child was removed to another room and soon became better, but was not well. Upon removing to another house, however, there was complete recovery from all symptoms of disease. The daughter of a medical friend was seriously ill, with symptoms which would not yield to treatment. The paper on the walls was examined and was found to be loaded with arsenic. In the house of a relative is one room which seems to be a source of disease to all who inhabit the apartment. It has proved nearly fatal to two persons, and many more have been ill from occupying it. The cause was not suspected until the paper was examined and was found to contain a very large amount of arsenic.

MR. C. TENNANT LEE, an analytical chemist, was present by invitation, and spoke as follows: The discussion of the subject of arsenical poisoning from wall papers, which has been carried on here, is of a very interesting character, and the cases are numerous and interesting, but the matter seems to rest on a very insufficient basis, and must certainly be considered as not proven. The cases so often classed by physicians as arsenical poisoning are most generally deduced from defective or careless observation, and are in reality not due to arsenic at all. I have been surprised to see how often I have been consulted in relation to the sanitary conditions of dwellings, in which some dreadful condition was supposed to exist, and have found a defective drain, a leaky closet or some other hygienic fault, the remedial treatment of which has removed all symptoms of the threatened danger. It is often the case that a foul tank in connection with the furnace will cause serious, and sometimes truly alarming symptoms, but these causes are seldom heard of by the physician or public. The excitement at present in relation to arsenic, is due, in great part, to the fact that the attention of the public is at present directed to this subject, and every one is thinking of it. When the scare about arsenic has abated, the number of cases supposed to be the result of poisoning from this source will become less, and substantially the same immunity from the trouble will be restored, as existed before the people were so much aroused by this imaginary danger. Physicians make the mistake of frequently ascribing to arsenic those conditions which are due to quite another set of causes. The cases of arsenical poisoning thus far reported, all end in recovery, and the entire history of the present craze is but two or three years old. It is far too early to be certain that these are cures, or that arsenic will produce such a varied series of clinical conditions. An example of the careless way in which physicians often account for strange symptoms by wrong theories, was illustrated by a case in which a girl was sick in a room papered with an arsenical green paper. This was removed, but the girl died. Some sensitive persons are poisoned by simply passing by a bed of poison ivy. In a certain family a new carpet was bought, and from motives of economy, the family decided to sew the carpet themselves. Those engaged in this work soon fell ill, but on relaxing their occupation rapidly recovered. On resuming the carpet-sewing, the old symptoms quickly returned. The carpet was now examined by the physician and was found to be "full of arsenic." The carpet was then analyzed by a chemist, and not a trace of arsenic could be found in it.

Rose-aniline is made by reduction of the substance by means of arsenic. The scarlet shirts and stockings which cause so much irritation of the skin, do not, however, contain arsenic. They are colored by nitro-benzole colors, which are not arsenical. The workers in the manufacture of Paris green are said by their employers, not to be injuriously affected by the nature of the substance on which they are employed. The skin of the employees is sometimes made raw, but they are not poisoned by the arsenic. There is one other point in which physicians are greatly in error. The opinion is generally disseminated throughout the profession that the arsenic is liberated as arseniuretted hydrogen. This is a great mistake, as arsenic cannot be liberated in any natural way in this form, and therefore cannot be a source of injury to the public in this form.

PROFESSOR HILL, of Cambridge, said that within the last few months he had seen but few cases of poisoning from arsenic, but formerly he had seen a great many of these cases with Dr. Sänger. The idea of establishing a *limit* to the degree to which arsenic may exist in wall-papers seems faulty, from the fact that there is no reason for the use of arsenic at all in the manufacture of wall papers. There are occasionally substances used in the papers which may possibly contain a trace, but this is too insignificant to deserve notice. In most cases in which the paper is examined, the amount of arsenic is almost nothing, or the amount is quite large. There is no medium grade. It is almost nothing, or the quantity is very great. Colors can now be easily obtained which are free from arsenic as an impurity, and those colors should be employed in all papers.

DR. R. STURGIS stated that a case of poisoning was known to him, in which the paper had been upon the walls of the room since the year 1873.

Dr. Henry Carmichael said that, there is no protection without analysis. No eye can discern where the arsenic is deposited, and no other means will adequately detect its presence. There is need of a clearer understanding upon another point. When we say that a paper is free from arsenic, what do we mean? If we mean that the paper does not present the indication of minute traces of arsenic, then it has not been my fortune to have discovered any papers free from arsenic. All papers will present the traces of small amounts of this substance, under any circumstances. Some of the ores used among the mineral pigments which are employed in the manufacture of wall-papers often contain arsenic as an impurity. Such is the ore of iron, which is extensively combined in the colors of wall papers. In this combination the arsenic is absolutely inert, and is quite harmless. In fact, this combination is almost identical with the preparation which is used in medicine, as the antidote to arsenic in cases of acute poisoning. Another source of error is found in the fact, that we are often inclined to lay the harm to the wall paper when there are other substances from which the poisonous symptoms might occur with fully as much probability as from the paper on the walls, such as the colored fabrics of dress, or the decorations or upholstery.

Dr. F. W. Draper spoke of his researches upon the dangers of arsenic to those employed in its use, or exposed to its influence. He said that he did not consult the employers of the men, or the contractors who did the work, but that he went directly to the men themselves. From them he learned that those men whose duty required them to be in the presence of the arsenic, and to handle it, were often sick, and not infrequently were obliged to suspend their labors. It is difficult to understand the statement made by one of the speakers, that constant employment in contact with so powerful and injurious a substance as arsenic should be without harmful influence.

Dr. G. E. Francis, of Worcester, offered a word of caution in relation to the accuracy of the opinion that all the disturbances so frequently ascribed to arsenic are in reality due to this cause. Before any further appeal is made to the Legislature we should be prepared to meet our opponents in every direction. Let us suppose that a paper which has been in service for twenty years has at length caused the appearances of arsenical poisoning. The analysis of the paper proves that it contains 2 grains of arsenic to the square yard. Now the question which must be answered is this: How much arsenic has been lost by the paper during the many years of service, if it still contains so large an amount at present? If the paper, after so long a time, still contains a large amount of the poison, then certainly it could not have lost much during that time; for the arsenic can be in only one place at a time. We should seek to ascertain how rapidly arsenic is dissipated by exposure to the air, and find out the rate at which it leaves the paper. We shall then certainly not be so liable to erroneous opinions and statements.

Dr. B. F. Davenport stated that the papers of almost any manufacturers may contain arsenic, even if the color is absolutely free from any appreciable amount of the poison. There are two principal questions: First, how much arsenic is really present in honest and well-selected papers? The second question is: What is the minimum quantity of arsenic which may induce the symptoms of poisoning? One undoubted form in which arsenic may be liberated is in the form of arsenuretted-hydrogen, from the presence of arsenious acid in contact with moulding substances, which evolve the hydrogen gas. In a case in which suicide was committed by the aid of "Rough on Rats," there was an evident odor of arsenuretted hydrogen on opening the stomach. The limit to which arsenic may be contained in wall-papers has received the attention of chemists all over the world, and only recently Professor Pettenkofer has suggested that the safety of the public would not be imperilled if the amount of arsenic did not exceed $\frac{5}{10}\frac{5}{0}$ of a grain in each square yard.

Dr. E. W. Cushing asked Professor Wood if there is any method by which a country physician may make an approximate analysis, or ascertain if there is any considerable amount of arsenic in a suspected paper?

Professor Wood said that the organic matter may be easily destroyed by the addition of a small amount of sulphuric acid with water, and the liquid could then be filtered and submitted to any of the common tests. If it is desirable to obtain the mirror of arsenic in a tube, it will be necessary to employ a cubic decimeter of the suspected paper; if it is thought necessary to produce the mirror upon a plate, a larger amount of the paper will be necessary, and the amount of arsenic required to form a mirror in this way will roughly be about $\frac{1}{10}$ of a milligrame.

The Secretary then read the resolutions offered by Dr. Chadwick, after which the question of adoption of the same was put. The resolution was unanimously adopted.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, December 17, 1886.

The President, Chas. Warrington Earle, M.D., in the Chair.

(*Continued from page 195.*)

ÆTIOLOGY, PATHOLOGY AND CLASSIFICATION OF SALPINGITIS.

GROUP III.—FORMS OF INFECTIOUS SALPINGITIS PRODUCED BY SPECIFIC, BUT AS YET UNKNOWN, MICROBES.

1. *Salpingitis Syphilitica.*—This form has been described by Bouchard and Lépine (*Gazette Med. de Paris;* 1866, No. 41). Both tubes were swelled to the thickness of fingers, and contained three gummata of the size of hazel-nuts. The description given by these authors of the tubal disease agrees fully with the changes brought about by syphilis in other organs. Of more recent authors, Gill Wylie expresses his opinion that tubal syphilis does occur ("Diseases of

the Fallopian Tubes," etc., January 24 and February 7, *The Medical Record*, 1885). He says that "syphilis may cause salpingitis, just as it does otitis or ozæna." He also calls attention to the fact that "endometritis in syphilitic subjects has a most obstinate character." Compared with the actual observations of Bouchard and Lépine, the clinical remarks of Gill Wylie are, of course, of theoretical value only.

Like Lawson Tait, I, myself, have never yet had occasion to observe an undoubted case of tubal syphilis. We should bear in mind, however, that our attention has been but little called to the anatomy and clinical forms of this disease. We are not justified in denying this form altogether, as we are not in a position to dispute the reliable authors who have testified to its existence. Others may have seen what we ourselves have never had occasion to witness. I desired to give a most complete enumeration of the forms of infectious salpingitis hitherto described; I could as little have omitted *salpingitis syphilitica* as I could have done *salpingitis actinomycotica*, of which also, up to date, but one authentic case has been observed.

2. Occasionally we find in young girls, who have never had intercourse with a man, tubes filled with pus and pelveo-peritonitis. This has been accounted for in various ways. It has been said that in these cases a serous catarrh is intensified and changed to a purulent inflammation; that the suppuration is due to catching cold at the menstrual period, or to a trauma. These cases have also been adduced as evidence to show "that tubal suppuration is not always of gonorrhœal origin." Yet also in these cases there is always an infection, and usually a gonorrhœal infection. I, myself, have seen a comparatively large number of girls of all ages, from infancy to puberty, who were infected with gonorrhœa. We know how easily the infecting germs are carried from one person to another; for instance, parents and children may use the same sponge or bath-tub; the germs may adhere to fingers, linen, etc. The girls infected may further spread the disease in school, and so on.

Aside from the gonorrhœal, the tuberculous infection is to be mentioned as a cause of pyosalpinx in young girls. Just at present I am treating a girl of 17, who is suffering from a disease of both appendages, complicated with pelveo-peritonitis. The tubes can be distinctly felt, and are thickened and nodular. She has a hectic appearance, like that of a consumptive; her lungs, however, are normal. The father of the girl was, not long ago, operated on for tubercular orchitis. I hope that the operation will confirm my diagnosis of *salpingitis tuberculosa*.

Undoubtedly the microbes of traumatic infection may also, after accidental lesions of the external genitals, get into the tubes of young girls; they may also enter from the peritoneal cavity. I know of a case, a girl of 16, in which an inflammatory disease of the right uterine appendages developed, consequent upon a retro-typhlitis.

My reason for again considering these forms of infectious salpingitis belonging to Groups I and II, in regard to their occurrence in children, is this: there are evidently other infections of the female genital tract which have been observed in children, but which have not as yet been recognized as special forms; consequently they are to be placed in Group III, in opposition to the forms of the two preceding groups. E. Fränkel, of Hamburg, ("*Bericht über eine bei Kindern beobachteten Endemie infectiöser Kolpitis, Virch. Arch.*," February, 1885), and Johann C'seri, Budapest ("*Zur Ætiologie der infectiœsen Vulvo-vaginitis bei Kindern*," *Wiener Med. Wochenschrift*, 1885), describe an infectious disease of the vagina and vulva, the former believing it to be due to a special coccus, the latter to a coccus identical with Neisser's gonococcus.

Hennig (*Krankheiten der Eiliter*, p. 67), in a girl of ten, and Eppinger (*Prager Zeitschrift für Heilkunde*, 1882, p. 36) in an adult, witnessed a dysenteric inflammation extend to the mucous membrane of the genital tract; the disease in its new location assumed the appearance of a diphtheritic inflammation.

Suppuration is sometimes observed in the vaginæ of children suffering from helminthic disease. In these cases the suppuration is not caused by the irritation of the parasite, especially the oxyuris, but by certain microbes carried into the vagina by the parasites. The nature of these microbes has not as yet been sufficiently investigated to allow of their classification.

It has long been known that certain infectious diseases, like typhoid fever, scarlatina, variola, cholera, may invade the genital tract. The local affections are probably caused by the same specific microbes which produce the typical constitutional disease. This, however, still remains to be proven.

At the close of this enumeration, I wish to repeat that in every case where the vagina or uterus is the seat of one of the diseases named, such disease may extend into the Fallopian tubes. I am well aware that I am standing on an unsafe scientific basis regarding my third group of forms of infectious salpingitis. For this very reason I deemed it advisable to group them together, thus keeping them apart from the better known forms; besides, I desired to point out the object which should be kept in view in investigating this subject and in endeavoring to elucidate it still further. It is, finally, self evident, that there are also mixed forms of salpingitis. Different varieties of micro-organisms may enter the tubes, either simultaneously or successively. The forms most frequently found combined are the microbes of the gonorrhœal and tuberculous, and of the gonorrhœal and traumatic infection, and those of the different varieties of the latter.

Every physician whose scientific standpoint is the same as mine will admit that matters regarding salpingitis are immensely more complicated than Lawson Tait imagines, and that it is not sufficient to make an abdominal section, to remove the uterine appendages, and to satisfy oneself with the diagnosis of pyosalpinx in case the tubes are found filled with pus; but that it is our duty, employing all the means furnished by modern science, to endeavor to make an accurate diagnosis of the form of disease affecting the uterine appendages before the operation, and afterwards to add to our clinical observation careful

pathological and bacteriological examination of the specimen. This certainly is a higher standpoint than that occupied by Lawson Tait, to whom the removal of the uterine appendages is the chief thing, and who, neither before nor after the operation, concerns himself with the nature of the disease treated. He admits, himself, that in every fifth case he made an error in diagnosis. In a man like Lawson Tait, so great in his own estimation, it seems rather small to attempt to conceal his ignorance by resorting to insulting and scurrilous remarks in regard to German scientists. I advise Mr. Lawson Tait to learn German and to read the works of German gynecologists: he may then perhaps come to the conclusion that there is much which he might profitably study.

Here in Germany, Lawson Tait is held in high esteem, as he deserves to be, on account of his brilliant practical results. We have long since, however, ceased to regard as serious his theoretical utterances, which pretend to be scientific. The tone which he adopts in his polemic writings does not prevail with us in Germany, and it is certainly looked upon as undignified by every gentlemanly Englishman. I am, sir, etc., DR. M. SAENGER,

Privatdocent at the University of Leipsic, President of the Obstetrical Society of Leipsic.

DR. EDWARD B. WESTON, on presentation of a thesis entitled

METRITIS,

read by the SECRETARY, was elected Fellow of the Society.

DOMESTIC CORRESPONDENCE

ONE OF THE "ITINERANT SYSTEMS" OF RECTAL SURGERY.

Dear Sir:—In a recent number of THE JOURNAL I described the amusing instrumental outfit of the itinerant practitioners upon piles, fistulæ, and fissures. The following is a condensed statement of the oldest of these secret "systems" so far as it relates to rectal ulcers. The information is from a trustworthy source, but I am not at liberty to use the name at present:

Once or twice a month, as the itinerant comes around on his circuit, he inserts his little speculum, cleans out the ulcer, and applies to it a solution of nitrate of silver, 40 grains to the ounce. Between the applications, the patient uses a morning and evening treatment himself. Each morning he is to evacuate the bowels, then inject the rectum with lukewarm water, and finally insert into it a little ointment consisting of 3 grains of carbolic acid and 8 grains of sulphur to the ounce of vaseline or lard.

For evening treatment he uses "Brinkerhoff's Ulcer Remedy," having the following composition:

R.	Extract of hamamelis (distilled)	fl. ℥v.
	Solution of persulphate of iron	" ℥j.
	Cryst. carbolic acid	grs. ij.
	Glycerine	fl. ℥ij. ℥x.

Add half a teaspoonful of this to the same quantity of starch, and about an ounce and a half of water. Inject into the rectum every evening.

This energetic use of nitrate of silver will of itself often cure a fissure, as has long been well known to us. I find, however, that if the ulcer is situated upon the sensitive verge of the anus, as it usually is, the application is atrociously painful, causing suffering equal to that of an incision. I am now experimenting upon the plan of daily unfolding the fissure, washing it out with mild antiseptics, and then packing it with dry iodol. I am not prepared yet to state final conclusions, but there is reason to think that many fissures may be cured in this way without incision, and with little or no pain.

EDMUND ANDREWS, M.D.

No. 6 Sixteenth St., Chicago, February 10, 1887.

COCAINE IN URETHRAL CARUNCLE.

Dear Sir:—In the *British Medical Journal* of January 1, 1887, is a query regarding the use of cocaine in urethral caruncle, as to strength of solution, pain during and after operation, and whether the caruncle is removed by excision or cautery.

In August, 1886, I was called to see Miss W., æt. 16, who had been lying helpless for one month with a urethral caruncle. She was lying on her back with the legs crossed, and unable to move on account of the pain. I applied a 5 per cent. solution of cocaine on absorbent cotton, and having no scissors with me, I trimmed a small twig flat, pushed it up under the caruncle to steady it, and removed the growth with one sweep of my pen-knife. The cocaine acted within five minutes, rendering the caruncle painless, and before I left the house the patient was out of bed and walking about the house. There was no pain during or after the operation, and the hæmorrhage was inconsiderable. Very truly yours,

J. D. EGGLESTON, M.D.

Worsham, Va., February 1, 1887.

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS. Section IV—Obstetrics.

The attention of gentlemen who desire to contribute papers to the Section of Obstetrics, is respectfully invited to the following extracts from the Rules of the Preliminary Organization:

"Brief abstracts of Papers to be read in the Sections shall be forwarded to the Secretaries of the proper Section on or before *April 30, 1887*. These abstracts shall be treated as confidential communications, and shall not be published before the meeting of the Congress. Papers relating to topics not included in the list of subjects proposed by the officers of the Sections, may be accepted after April 30, 1887, and any member wishing to introduce a topic not on the regular lists of subjects for discussion, shall give notice of the same to the Secretary-General, at least twenty-one days before the opening of the Congress. The titular officers of each Section shall decide as to the acceptance of such proposed communications, and the time for their presentation.

No communication shall be received which has already been published or read before a Society.

"The official languages of the Congress shall be English, French and German. Each paper or address shall be printed in the '*Transactions*' in the language in which it was presented. Preliminary abstracts of papers and addresses shall also be printed in the language in which each is to be delivered. All discussions shall be printed in English.

"All communications and questions relating to the special business of any Section, must be addressed to the President or one of the Secretaries of that Section. As many details of the Congress and numerous appointments of officers are yet to be completed, other circulars will be issued from time to time, as circumstances may demand."

The meetings of the Section of Obstetrics will be held in Washington, D. C., on the afternoons of September 5, 6, 7, 8, 9 and 10, 1887.

PROF. DE LASKIE MILLER, M.D., *President.*
2011 Prairie Ave., Chicago.

} *Home Secretaries.*

MISCELLANEOUS.

NEW FOREIGN JOURNALS.—*Revista de Medicina e Chirurgia* is the title of a new monthly journal published in Oporto, 56 Rua de Libertade, the first number of which appeared in January.

Therapeutische Monatshefte is the title of a new monthly journal published in Berlin, and edited by Professor Oscar Liebreich, A. Laugaard, and S. Rabow. The first number appeared in January.

Annales de l'Institut Pasteur.—M. G. Masson, 120, Boulevard St-Germain, announces the journal of this name, soon to appear, to be published monthly, under the editorship of M. Duclaux, with the assistance of MM. Graucher, Chamberland, Nocard, Roux, and Straus.

A PRIZE ESSAY ON HAY FEVER.—At its last meeting, September, 1886, at Bethlehem, N. H., the U. S. Hay Fever Association decided to offer a prize for the best essay from a competent source, preferably a physician, on some question relating to *Æstivis*, or Hay Fever. The amount is necessarily small; but as the accepted essay will be published in the Association's report, when the extent of its circulation, and the character of those whom it will reach, shall be considered, it is thought that the successful treatise will give to its author a reputation worth the effort.

In order to carry out the above the following is announced officially:

1. Subject of the essay, Hay Fever. (a) Its pathology. (b) The predisposing, and the aggravating causes. (c) Advice to the sufferer.

2. The essay not to exceed *four thousand words*, and to be as practical and non-technical as possible.

3. The manuscripts to be received at the office of Samuel Lockwood, Freehold, New Jersey, not later than April 30, 1887.

4. Each manuscript to have a motto under the title, and to be accompanied with a sealed letter containing said motto, also the name and address of the author. These letters not to be opened until after the award is decided.

5. The prize to be $25. The accepted essay to be published immediately in the Association's annual report, one hundred copies to be given the author.

6. The Committee of Award: Samuel Lockwood, Chairman of Committee on Scientific Facts; Frank B. Fay, President U. S. H. F. A.; Charles C. Dawson, Secretary U. S. H. F. A.

CENTRALBLATT FÜR BACTERIOLOGIE UND PARASITOLOGIE.— Dr. Uhlworm, Terrasse 7, Cassel, Germany, the editor of this journal, requests that American authors will send reprints or papers containing their articles on the subjects to which his journal is devoted, directed to his address, as given above.

AN ELECTRIC PRIZE.—A prize of 50,000 francs is offered by the French Minister of Education for a discovery rendering electricity economically applicable in the shape of heat, light, chemical action, mechanical power, transmission of messages, or treatment of disease. M. Bertrand, of the Académie des Sciences, is chairman of the committee of award.

THE HAIRS OF OUR HEADS.—It is said that a German of an inquiring turn of mind and much patience has taken four heads of hair, of equal weight, and counted the individual hairs. A red head was found to contain 90,000, a black 108,000, a brown 109,000, and a blonde 140,000 hairs.

BACTERIOLOGY AND ITS CLINICAL THERAPEUTICS is the title of the general address which will be delivered by Professor Mariani Semmola before the Ninth International Medical Congress.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 5, 1887, TO FEBRUARY 11, 1887

Major Blencowe E. Fryer, Surgeon, ordered to Ft. Lowell, Ariz. Ter. S. O. 29, A. G. O., Feb. 4, 1887.

Capt. L. Y. Loring, Asst. Surgeon, leave of absence still further extended three months on surgeon's certificate of disability. S. O. 29, A. G. O., Feb. 4, 1887.

Capt. Louis Bruhenrin, Asst. Surgeon, granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be spared by his department commander. S. O. 28, A. G. O., Feb. 3, 1887.

First Lieut. C. C. Barrows, Asst. Surgeon, ordered for temporary duty as Post Surgeon at Ft. Barrancas, Fla., to take effect upon the expiration of his present leave of absence. S. O. 24, Div. Atlantic, Feb. 3, 1887.

First Lieut. Jno. L. Phillips, Asst. Surgeon, leave of absence further extended one month. S. O. 29, A. G. O., Feb. 4. 1887.

First Lieut. Leonard Wood, Asst. Surgeon, ordered to proceed to these hdq'rs and report to the Dept. commander for temporary duty. S. O. 12, Dept. Ariz., Jan. 31, 1887.

ORIGINAL ARTICLES.

ABDOMINAL SECTION FOR TRAUMATISM, WITH REPORTS OF FIVE CASES.

Read before the Philadelphia County Medical Society, on January 26, 1887,

BY THOMAS S. K. MORTON, M.D.,

OF PHILADELPHIA.

The term "abdominal section for traumatism" is meant to include those cases where the operator deliberately opens the belly, or greatly enlarges an existant wound for the purpose of discovering intraperitoneal wounds, and, if they are present, repairing them as far as possible, together with more or less final cleansing of the peritoneal cavity. Such cases as those in which wounds of prolapsed viscera are simply repaired, and the parts returned to the abdominal cavity, are not included. My excuse for this paper is, that I have been so fortunate as to be associated as an assistant to more than one-half of all the cases that have occurred in Philadelphia. In four of the cases I have been the assistant, and in three the care taker also. These four cases have been treated in the Pennsylvania Hospital. I had at first expected to read merely the history of these cases, and make a few remarks, but the matter grew so interesting that I determined to make a study of the subject, and I believe that I have canvassed the literature of the world. I must express great obligations to the gentlemen who now permit me to report their cases for the first time, and to Dr. Billings, of Washington, who had translated for me the reports of two Russian cases. I have used the libraries of the College of Physicians and Pennsylvania Hospital, and have found the *Index Medicus* of great service. I have prepared a large table, which contains a mine of information. It represents an abstract of every case which I have been able to find in the literature of the subject.

I shall, in the first place, read a few statistics derived from the table. The total number of cases is 57. Of these, 36 died and 21 recovered: mortality, 63 per cent.

These 57 cases were done by 42 operators, viz.: 23 United States operators did 35 operations, with 11 recoveries and 24 deaths: mortality, 67 per cent. Nine English operators did 10 cases, of which 3 recovered and 7 died: mortality, 70 per cent. Two Australian operators did two operations, with 2 deaths. Two French operators did 2 operations, with 2 deaths. Two Russian operators did 2 operations, with 2 recoveries. One German and 1 Swiss each did an operation, with success. One Italian operator did 2 operations, with 2 recoveries. Seven operations have been done in Philadelphia by 5 operators, with 2 recoveries and five deaths. Five of these have been performed at the Pennsylvania Hospital by 3 operators, with 2 recoveries and 3 deaths.

Of the 57 tabulated cases, 38 per cent. were for pistol- or rifle-shot wounds; 35 per cent. for stabs; 17 per cent. for ruptured bladder, and 10 per cent. for ruptured intestine.

Operations were done according to years as follows: 1862, 1; 1876, 1; 1879, 1; 1882, 1; 1883, 7; 1884, 5; 1885, 13; 1886, 29.

In every case which died after operation, lesions certain to cause death, if uninterfered with, were found. One case of penetrating wound was opened, in which no visceral injury was found; it recovered.

The first case of abdominal section for traumatism was that of Walters, of Pittsburgh, for ruptured bladder, in 1862. The first successful case was the same. The first case after Walters' was that of Heath, in 1876. The first recovery after Walters' case was that of Dr. W. O. Roberts, done for stab wound, August 28, 1882.

The sex was reported in 56 cases: males 52; of this number 33 died, and 19 recovered. There were 4 females, of which number 2 died and 2 recovered. Four were negroes, all males; 1 recovered and 3 died.

The age was reported in 46 cases, the oldest being 58 years, and the youngest 7 years. The ages ranged as follows: One each 7 and 8 years old, both died; 11 between 10 and 20 years, 4 recovered and 7 died; 15 between 20 and 30 years, 5 recovered and 10 died; 9 between 30 and 40 years, 5 recovered and 4 died; 1 each 53 and 58 years, both died; 2 57 years, 1 recovered and 1 died.

The indications for abdominal section for traumatism are in many cases very clear; in others, with only our present knowledge, exceedingly obscure. Taking up the consideration first of wounds, it seems to me that, with what we already know, the operation is clearly indicated in every case where penetration of the abdominal cavity is proven, and with fair surroundings it becomes one's duty to open the abdomen and search for wounds, for there are no omnipresent symptoms which invariably indicate intraperitoneal wounds, even when extensive. With reference to the cases suitable for operation, I would

say that, besides gun-shot wounds, stabs, etc., which have already been operated upon, I conceive that in the future many other traumatic conditions will be subject to interference by section, such as rupture of the stomach, gall bladder, spleen, or kidney, ruptured blood-vessels, various hæmatoceles, etc. Dennis, of New York, had a case in which he opened a penetrating stab wound of the abdomen. He found, besides the injuries, an intussusception evidently caused by the violent peristalsis excited by the point of the knife touching the intestine, and I therefore conceive the possibility of intussusception without wounds. In this paper, no consideration is paid to the effects of traumatism upon diseased organs, such as ulcerated stomach or bowels, or upon the pregnant uterus or its diseased appendages, or perforating typhoid ulcers.

I shall consider the subject of diagnosis as a whole, with the exception of that of ruptured bladder, which I shall take up later. The diagnosis of penetrating wounds of the abdomen is occasionally very easy—occasionally exceedingly difficult. Where there is a pistol shot wound of the anterior wall of the abdomen and a probe can be inserted, or where there is extravasation of fæces, the diagnosis is easy enough. Emphysema is given as one of the best symptoms of perforation of the intestine. I regard it as a poor one. One of the cases occurring in the Pennsylvania Hospital presented marked emphysema of the abdominal walls without injury to the lung or intestine. Injury of the lung may give rise to emphysema, which may be mistaken for that due to a wound of the intestine. Diminution of the liver, dulness due to the escape of flatus into the abdominal cavity is another symptom, but this is fallacious. Shock is usually marked, but in some cases the patient is not at all shocked. Instances are on record where patients have walked long distances, and yet, on opening the abdomen, wounds of the intestines have been found. One man did not even know that he was shot until he had walked some distance to his home—yet he had numerous intestinal perforations. Of course, vomiting of blood and the passage of bloody stools are good signs, but they are not always reliable. The symptomatology of penetrating wounds of the abdomen is very obscure, and we should like to have some light thrown upon it. Of course, a wound through the back is more difficult to diagnose than one from the front, and frequently the diagnosis can only be made by incision. Even where the ball is found lying under the skin, you cannot be sure, for it may have passed around the abdomen. The most interesting class of cases is that in which there has been a blow or injury upon the abdomen and we suspect rupture of the intestine, the spleen, liver, or blood-vessels. These are most difficult cases to diagnosticate, and I predict that in the future we shall open many abdomens in order to determine whether or not these conditions are present.

In regard to the surroundings under which one should operate. In a metropolitan hospital surrounded by every convenience, I think that the majority of cases should be operated upon. In cases where injury to the gut is known to have occurred, and in many cases where it is suspected, it is our duty to operate. In the country and in unskilled hands only those cases which are the most desperate should be operated upon, unless they can be removed to some centre.

If the patient appears to be coming out of shock, he should be allowed to do so as far as possible. Shock from hæmorrhage is, of course, the worst. Where there is extravasation, the shock will be kept up, and under such circumstances etherization and removal of the cause would be the best way to overcome it. The preparation of the patient should be by judicious treatment and thorough cleansing. I shall not now go into the subject of antisepsis or asepsis, although I hold positive views of their great value. Everything should, however, be surgically clean.

Where there is a wound of the anterior wall of the abdomen, first prove perforation by cutting down to the peritoneum. That should be a sufficient warrant for section. In wounds of the back some judgment must be exercised. The incision should, I think, in almost every case be median. In the majority of the cases recorded in the table, and, I think, in nearly all the successful cases, the incision was median. In several instances where section has been done for a special purpose, such as removing an injured spleen, the incision has been made to one side of the median line. In one case of stab wound which I saw, the original wound was enlarged and gave rise to great difficulty in the subsequent steps of the operation. One wound was overlooked in that case, which error, I think, was largely due to the position of the incision. The length of the abdominal wound is to be governed by the circumstances of the case. It may extend from below the ensiform cartilage to the pubes. There is no harm in a long wound if it be properly treated. After opening the peritoneum, note carefully the abdominal contents. If we find fæces, we are encouraged to prolong the search until the wound is found. If there is blood, we should look for the vessel injured. The search for wounds should be thorough and systematic. In most of the cases where wounds have been overlooked, it has resulted from not making a systematic examination. We should begin at the entrance of the œsophagus into the stomach, if it is possible to reach that high, go over the stomach and all the intestines, examine the mesentery, the rectum, and bladder, and look at the spleen. Unless this is done, wounds will sometimes be overlooked, and even with apparently the utmost precaution they will sometimes escape detection. Only those who have seen such cases can imagine the difficulty experienced in finding some wounds, especially when the upper part of the transverse colon and the surrounding omentum are involved. If the intestines are much distended, it may be necessary to puncture them. It is important to remember that extravasation has followed such a puncture, and they should always be closed with a Lembert suture. If the vermiform appendix or an epiploic appendage is injured, it should be excised. In wounds of the intestine, it makes a difference whether the injury is

the result of a gunshot or of a stab. Gunshot wounds are more apt to slough than knife wounds, and where many wounds of the former are located close together, it has been found advisable to excise a portion of the gut including the numerous wounds. Probably a foot of the bowel may be excised without much disadvantage. Six or eight feet have been excised, but in this case the operation was followed by emaciation and death. In such a case it would probably be better to make several excisions. Perforations when found should be turned into the bowel by the suture of Lembert. Wounds of the large intestine and stomach are to be treated in the same way.

Where the ball has perforated the mesentery, the wound edges should be excised. This is the opinion of those who have done most operations. The opening is then brought together with stitches on both sides, or passing all the way through. If the omentum be badly injured, no harm will come from its excision. It may be ligated in various places and the whole cut off without injury. In a hernia case, I cut off what I supposed to be almost the whole omentum, and the man got perfectly well. Where the spleen is wounded, the only method seems to be to excise the organ. This has only been done, so far as I know, twice. Very little is known about the treatment of injuries of the spleen. Wounds of the liver have been met with a number of times and all the cases have died. Whether or not it would be practicable in these cases to stitch the liver to the abdominal wall, etc., I cannot say. Tait has done it in chronic disorders a number of times and has had favorable results. We should be encouraged to experiment in this direction. About wounds of the pancreas little is known—I doubt if they could well be reached. If the kidney is extensively wounded, its excision or complete drainage is indicated. If the ureter is divided, the only remedy is excision of the corresponding kidney. If the projectile has gone through the diaphragm, the same operation as in the case of the mesentery would be indicated, namely excision of the edges and sutures. Of course, all bleeding vessels are to be tied. If this is impossible, the main trunk, even if this be the aorta, must be tied. Wounds of the uterus and appendages have not been dealt with, but would probably require excision.

Then there is another class of wounds entering the abdomen—that is, wounds through the vagina and rectum; for instance, a stab wound through the vagina. If we knew that it penetrated, abdominal section would be indicated. In all these cases contusions or brush burns of the omentum and intestine frequently are found. In time, nearly all of these will slough and give rise to pus. In several cases death has been attributed to this cause. All severe contusions involving the mesentery or omentum should be excised. When they involve the intestine, the peritoneum should be united over them with Lembert sutures. The suture materials which I have seen used have been silk and catgut. I think the latter is preferable if fine and chromicized.

I have one table which gives the average time after injury when the operation was performed. This is one of the most important things that we can consider. The sooner the operation is performed, the better are the chances of the patient. The cases in which the time is reported number forty-five. The average time after the injury for which operation was done, was eighteen and a half hours. Deducting four cases where more than two days had elapsed, the average falls to twelve and a half hours, while a deduction of all the cases where the time was over twenty four hours, brings the figures to nine and a half hours. The average time after the injury when the operation was begun in the successful cases was seven and three quarters hours; the average in the fatal cases was twenty-three and one-quarter hours. These are significant facts. In the five cases operated on at the Pennsylvania Hospital, the average time was six hours. Deducting one case in which from unavoidable circumstances twenty hours elapsed, the average comes down to three hours.

In all cases the question of drainage will arise. It is difficult to decide, in any given case, whether drainage should be employed or not. If there have been extravasation and numerous wounds, drainage seems to be indicated. Glass and rubber tubes have been used with apparently equal success and failure. I think that tubes of glass or other hard material are to be preferred. Where there has been extravasation of the contents of the stomach or intestine, this is usually followed by great oozing of serum.

The final steps of the operation are irrigation and cleansing. In irrigation I believe most thoroughly. It should be very large in quantity and can hardly be too much so. If the patient is shocked, there is no better treatment than pouring hot water through the abdominal cavity. It probably acts directly upon the solar plexus. I have seen this frequently used with marked benefit. The patient will be in far better condition after the use of a gallon or more of water at a temperature of 100° to 110°, than before its application. It has occurred to me that in profound shock from other causes, it might be well to puncture the abdomen with some form of double canula and thus irrigate the abdominal cavity with large quantities of hot water. What shall be put in the solution used for irrigation? Several agents have been so used: Water, distilled water, boracic acid solution, mild solution of bichloride of mercury, and solution of carbolic acid. Carbolic acid should be expunged from the list. Bichloride of mercury, when employed, should be in very dilute solution—1 to 5000 or 10,000. Boracic acid was used in two successful cases in 3 per cent. solution in unlimited quantities. In four cases at the Pennsylvania Hospital the bichloride solution in the strength of 1 to 5000 and 1 to 10,000 was used and apparently without any bad effect. It was used in both of the successful cases there. Distilled water is very good and especially in cases where extravasation has not occurred. Where there has been extravasation, purulent peritonitis set up, or it is not certain that all foreign matters have been removed, I think that an antiseptic is indicated. Where we have a solution like that of boracic acid, possessing fair strength with little danger of poisoning, it should be used.

The parietal wound is closed and dressed in the usual manner.

One question in the after-treatment would arise in cases where a drainage-tube had not been left, and would be with reference to reopening the wound and drainage where a large amount of serum was present. Each individual case must be decided for itself. The onset of violent peritonitis would be an indication for reopening the belly, irrigating and draining it.

I wish now to take up a few of the classes of these cases in succession. Those which have been discussed before will not be reconsidered. Rupture of the bladder will be discussed separately. First, with reference to gunshot wounds. The total number of cases recorded is 22. Of these, 5 recovered and 17 died, a mortality of 77 per cent. Of these 22, 18 were done in the United States; 4 recovered and 14 died, a mortality of 77 per cent. The foreign cases were 4 in number, with 1 recovery and 3 deaths, a mortality of 75 per cent. The first recorded case of gunshot wound treated by abdominal section is that of Dr. Kinloch, of North Carolina, in 1881. The first recovery was the case of Kocher, of Switzerland, in 1883. The first recovery was a case operated on by Dr. Wm. T. Bull, of New York, in 1884. These 22 cases were done by 15 operators—11 American and 4 foreign. In Philadelphia there have been two cases of abdominal section for gunshot wound. One was done at the Pennsylvania Hospital two days since by Dr. Thomas G. Morton. In one case of gunshot wound a wound of the intestine was overlooked, with a fatal result. McKellar, of London, reports a case of two wounds of the lower portion of the sigmoid flexure in which it was impossible to introduce stitches. All that he could do was to throw a ligature around the wounds. The patient died, and fæcal extravasation was found at the autopsy. It struck me that in this case rectal distention by a colpeurynter might have been of some assistance, lifting the bowel up so that stitches could be inserted, for I understand that the openings were on the anterior wall. Such cases are, however, exceedingly difficult to remedy.

I will read the notes of a case of gunshot wound of the abdomen:

Case 1.—B. B., a negro, aged 36, of splendid frame and constitution, was admitted here late in the afternoon of January 23. Three-quarters of an hour before admission, he had been shot by a ball fired not more than a couple of feet from him; its calibre was 32. When admitted, he was not shocked; but slight nausea and severe general abdominal pain, were present. Pulse and respiration slightly accelerated; temperature 98°. A bullet wound was found an inch an a half above and half an inch to right of the umbilicus. No tympany, emphysema, decrease of liver dulness, or other marked symptoms, were present until just before anæsthesia was begun. He then vomited more or less altered blood copiously. Abdominal section had been decided upon by Dr. T. G. Morton over the telephone, and full preparations having been made meanwhile, the operation was commenced almost immediately upon his arrival—an hour and a half after the accident.

The man's condition at that time was very good. The belly wall having been made surgically clean, and penetration proved, an incision was made by Dr. Morton from two inches below the ensiform cartilage to the pubes. Instantly upon opening the peritoneum a large quantity of fluid and clotted blood, together with much flatus and partially digested food and fæces, gushed forth. The peritoneum, where not injured, looked in good condition. The cavity was first cleaned as well a possible by rapid sponging, and then searched for wounds. Three perforating wounds of the stomach first came into view. They were situated in a straight line, transverse, just above the omental attachment, and rather to the left of the centre of the organ. Two were anterior; the third posterior, and came out through the omental sttachment. One other perforation of the stomach was found. This was in the lower edge of the right hand portion, about three inches from the pylorus. All of these holes were bleeding pretty freely, and vomiting gastric contents. The posterior perforation was found only after several careful searches. Next, a linear rent of the transverse colon, just before it curves downward, was found. The tear was an inch and a half or two inches long, and through the omental attachment. All of these wounds were trimmed and sutured with Lembert sutures, of fine chromicized catgut, about an eighth of an inch apart.

The omemtum was terribly torn in a number of places, and filled with very large extravasations of blood, which had become clotted. The clots were removed as thoroughly as possible, and one long rent corresponding to the colon wound was stitched by a continuous suture. A number of ecchymoses of the small intestine and mesentery were found; one of these ecchymoses of the intestine looked as if it would be likely to slough. This was turned in by uniting the serous surfaces of the bowel above it with the Lembert suture. The entire cavity was thoroughly searched, including the liver, gall-bladder, and spleen. The bullet could not be traced after leaving the stomach. The spinal and dorsal regions had been carefully examined for evidence of it there before the operation was begun.

Every portion of the abdominal cavity was then sponged and thoroughly irrigated with $HgCl_2$ solution, 1 to 10,000, and the parietal wound closed without leaving in a drain, and dressed in the usual manner of the hospital. Time from patient's being taken from bed until put back again, two hours. Time from beginning incision to putting on dressing, an hour and a half.

After the operation the patient was somewhat shocked, but in an hour had reacted well, and was perfectly rational. He remained in this condition for four hours, complaining only of slight pain in abdomen. Five hours after operation he presented all the signs of hæmorrhage, and rapidly sank, breathing much interfered with, and no radial pulse. He died in another hour—six hours from the completion of the operation.

Post mortem.—Abdominal cavity contained about a pint of faintly blood-tinged serum; intestines con-

gested; no additional or overlooked wounds found; the repaired ones in good condition and water-tight. Ball, after leaving stomach, penetrated diaphragm, and, without injuring the lung, struck the lower border of the seventh rib three inches anterior to its angle, chipping it and cutting the intercostal artery, which had bled a pint and a half into the pleural sac. The ball was found an inch and a half further along anteriorly in the same interspace.

The only point that I would add is in reference to finding the ball. As a rule, it is not found. In this case we traced it as far back as the diaphragm, and thought that it might have gone through the edge of the spleen, but examination showed no wound of the spleen. The difficulty experienced in finding wounds of the upper portion of the stomach, where the omentum is cut and ecchymosed, is almost beyond description. It is a wonder that some of the wounds were not overlooked.

I will now refer to stab wounds. In all the recorded cases, with the exception of one, the wound was produced by a knife. In that one instance, it was caused by a sharp splinter of wood. As we should expect, these cases present the most favorable showing. The total number of cases reported is 19. Of these, 12 recovered and 7 died; a mortality of 36 per cent. These operations were done by 14 operators, 10 American and 4 foreign. The 10 American operators did 15 operations, with 8 recoveries and 7 deaths. The foreign operators did 4 operations, and all recovered. The first case on record is that of Kwiectuski, of Russia, April 15, 1883. The first American one is that of Dr. W. O. Roberts, operated on August 28, 1885. The first recovery was the case of Kwiectuski. The first American recovery was the case of Dr. Roberts. The credit of the first recovery properly belongs to Dr. Roberts, of the United States, for the Russian operator had a large wound already made, which he enlarged to a certain extent, and sought for the intestinal wounds. Dr. Roberts had but a small opening made by a penknife.

I shall now read the histories of two cases:

Case 2.—G. W. J., æt. 40, a powerfully built man, was admitted to the Pennsylvania Hospital September 9, 1886, at 10:30 P.M. He had been stabbed by a long and narrow butcher's knife a few minutes previously, and had lost considerable blood. Had frightful pain in right side of abdomen; scarcely any shock. Upon examination a wound three-quarters of an inch long was found about two inches above the centre of Poupart's ligament on the right side; through it were prolapsed several inches of small intestine. Dr. John B. Roberts saw him in about three quarters of an hour, and determined upon abdominal section. The operation was begun at once by making a five-inch median incision, strict antiseptic precautions being adhered to. The peritoneal cavity contained a large amount of dark fluid and clotted blood, while the intestines were almost wholly collapsed and empty. The prolapsed bowel was first reduced and then brought out through the operation wound and carefully examined, cleansed, and returned. The entire intestinal canal was thus examined, as were also the other viscera and mesentery.

This research revealed six wounds of the intestine and mesentery, namely: four wounds opening small intestine, one cut opening the colon just above the cæcum and running into the mesocolon, one transfixion of the mesentery.. The wounds of the colon and mesentery were bleeding actively—the former permitted escape of bowel contents. The lesions of the small intestine were occluded by prolapsed mucous membrane. All open wounds were about one-half inch in extent, and were closed with Lembert's sutures of silk. After repairing these injuries the abdominal cavity was most thoroughly irrigated with hot 1:10,000 $HgCl_2$ solution, and then sponged dry. A glass drain-tube was put in as far as the rectovesical pouch, and the parietal wound closed with chromicized catgut. He reacted well, and was perfectly comfortable next day after the drain had been removed, for it caused great pain in the lower pelvic region. Previous to its removal, about six ounces of faintly blood-tinged serum came through it. No pain afterward. Its exit was stitched.

No food was given for three days, but bromide of potash, chloral, and brandy were administered in large doses, as delirium tremens was anticipated. Nutriment was begun on the fourth day, and gradually increased. Delirium then present, and on the increase. On the fifth day he seemed in a fair way to die from the great exhaustion incident to the mania. With Dr. Roberts' consent I determined to give strychnia to physiological effect—regarding that drug as indicated in the profound nerve exhaustion of delirium tremens. One-thirtieth of a grain twice daily by hypodermic was started, and the quantity rapidly ran up until twitching, etc., became manifest. This did not occur until he had been taking one-tenth of a grain every hour, and a half for half a day. The same dosage was kept up for thirty-six hours and then reduced to one-tenth of a grain every fourth hour for another day, as that amount kept up the full effect, since he was becoming more and more sensitive to its influence.

He was thus kept, by smaller and smaller doses, in the full physiological effect of the drug for nine days; at the end of which time ten minims of tr. nux vom. could not be comfortably borne, and the drug was suspended entirely.

The effect upon him of this medicament was very marked indeed, and both Dr. Roberts and myself firmly believed that it saved his life. I have since tried this treatment upon similar cases with exceedingly good result.

Beyond the above his convalescence was uneventful. The belly healed by primary union. He was walking about his room on the fifteenth day, and in the yard on the seventeenth.

Discharged on the nineteenth day.

Case 3.—J. D., an Italian fruit vender, aged 30, was brought to the hospital at 1 A.M., December 25, 1886. He had received a stab during a broil some squares distant from the institution, and had walked all the way. Almost immediately upon receipt of the injury he had vomited the contents of his stomach; not much pain was present, and that little was just around the wound, which was situated two inches

to right, and three quarters of an inch above umbilicus. *Decided emphysema was present* for a space of three inches all around the wound. Temperature, pulse, and respiration normal. He was given a dose of morphia by hypodermic, and slept quietly until morning. There was no odor about the wound, no signs of fluid in peritoneal cavity, no diminution of liver dulness. At that time, 1 A.M., the wound, one-half an inch long, was cleansed, stitched, and sealed with benzine and collodion.

At 7 A.M. pulse, temperature and respiration still normal, but much pain was complained of, which seemed centred about the region of the wound, and was stated to be increasing and spreading every moment. Vomited green material then.

It was decided to do an abdominal section, and at 10 A.M. the operation was commenced by Dr. T. G. Morton.

The original wound was first proved to penetrate —the intra-abdominal opening was not more than one-quarter of an inch long. Median incision was done from two inches above umbilicus to within one inch of pubes, and the abdominal contents searched. A small amount of fluid and clotted blood (℥ss) was found immediately below the stab wound. This blood was mainly entangled in the omental tissues. A rent of one layer of the omentum, about two inches long, was found in this region, also a divided and bleeding omental vessel just outside the tear. The artery was ligated, and the tear sewn with catgut. The peritoneal opening of the stab wound was then closed by a single stitch of the same material. No other lesions could be found, as the cavity was carefully cleansed with sponges, and plentiful irrigation with warm 1 : 10,000 $GgCl_2$ solution, and the external wounds closed with closely placed interrupted fourteen-day catgut sutures. An antiseptic dressing and flannel bandages were applied, and morphia to mild narcotization administered. No drain was used. Strict antisepsis prevailed throughout. Time of operation, one and a half hours.

December 29. The only annoying symptom from which he has suffered has been bilious vomiting from time to time, and which still keeps up in spite of various medicaments and champagnes, of which latter has been taking f℥j every second hour; also has been taking f℥j of peptonized milk every two or three hours since 12:27 A.M. Dressed, because of disordered dressing yesterday, and wounds found united throughout.

Bowels opened last night, and again this morning, by enema. Urine had to be drawn twice following operation. He had no special pain.

January 11, 1887. Up to-day and walking about. All sutures are away. No dressing on wound since January 8.

January 21. Discharged cured; walked home; twenty eight days in hospital.

I will now consider ruptured bladder. The total number of cases reported is 10, with 4 recoveries and 6 deaths, a mortality of 60 per cent. There were 9 operators—3 American and 6 foreign. The American operators performed 3 operations, with 1 recovery and 2 deaths. The foreign operators performed 7 operations, with 3 recoveries and 4 deaths. The first recorded case of abdominal section for ruptured bladder is that of Walters, of Pittsburg, in 1862. This case was also the first recovery. In Walters' case he diagnosed rupture of the bladder, with infiltration of the peritoneum with blood and urine. He opened the abdomen, cleansed it out, and put in a drainage-tube, but did not sew the bladder wound. The second case was that of Alfred Willits, of London, operated on June 12, 1876. This case died. The second American case was that of Dr. Bull, operated on October 27, 1884. This case also died. Two recoveries have recently been reported by MacCormac. Philadelphia has had one case which was operated on by Dr. Joseph M. Fox, August 16, 1886, with fatal issue. I will read the report of this case.

Case 4.—E. M., a man aged 38, at 1 A.M. on August 16, 1886, walked out of a second story window. Two and a half hours afterward he was admitted to the Pennsylvania Hospital. He had been drinking much the previous evening, and the bladder was distended at time of accident. Upon examination, the resident surgeon, Dr. Alexander McAllister, found that the neck of one femur was fractured, and that he had marked symptoms of ruptured bladder, namely, great pain over bladder and lower abdominal region; intense desire, but no power, to micturate; bloody urine by catheter. He was much shocked, but had recovered by 9 A.M., when he was in good condition. Dr. Fox at that time saw him, confirmed the diagnosis, and determined to operate, but through the intervention of circumstances beyond his control was prevented from so doing until evening, when the operation was performed.

Strict antisepsis prevailed. A four-inch median incision was made over the bladder. Ten ounces of blood and urine were found in the peritoneal cavity. Intestines congested, and in places looked almost gangrenous. A 2½-inch triangular opening was found in the anterior portion of the fundus. The viscus was held up by two long sutures passed through the sides of the rent, and the wound was then sewed with closely placed Lembert sutures of catgut; fifteen were introduced. It did not leak when distended with 1 : 1000 $HgCl_2$ solution. The abdominal cavity was then thoroughly washed with 1 : 5000 solution, the parietal wound closed, leaving in a bone drain-tube down to the bladder; but, of course, not entering that organ. A rubber catheter was left in the urethra. He died in forty-two hours.

Post-mortem examination showed localized peritonitis about wounds. Wound of bladder water-tight. Blood clots in pelvic basin.

Now a few details with reference to ruptured bladder: The symptoms of ruptured bladder are more definite than those of most other cases. The condition of the bladder at the time when the injury is received is of some importance, but cannot always be ascertained. Shock is usually present, as in other cases. Pain in the hypogastrium, fruitless efforts at micturition, vomiting, hiccough, distension of the abdomen with fluid, the withdrawal of blood or bloody urine by the catheter, are all good indications. If

there is no urine in the bladder, or none comes in, it is a fair sign. The catheter can sometimes be introduced to a great length, and occasionally the rent in the bladder wall may by this means be detected. The withdrawal of an enormous quantity of fluid is another indication. If warm water is injected, it may be felt by the patient in the loins and other locations. With the catheter in the bladder, the liquid sometimes ebbs up and down with the movements of respiration. Recently Dr. Weir, of New York, has suggested a test for ruptured bladder, which consists in injecting a certain amount of fluid and percussing over the region of the bladder. If a definite outline of percussion dulness is noted, it is a fair inference that the bladder is not ruptured.

It is important to determine whether the rupture is extra- or intraperitoneal. Stephen Smith has shown, in a collection of 65 cases, that the peritoneum is injured in 80 per cent. of the cases. Max Bartles found, in an examination of 166 cases, that the rent was intraperitoneal in 98, and extraperitoneal in 54. In 84 cases of intraperitoneal rupture the rent was situated in the fundus in 40 cases; in front, near the fundus, in 9; posteriorly in 33; and at the side in 2 cases. In 50 cases of extraperitoneal rupture, the rent was at the neck in 19, anterior in 23, posterior in 2, and at the side in 6. In 15 of these cases there was fracture of the pelvis. In these cases, as a rule, the urine found in the peritoneum is healthy, and not decomposing. An interesting paper has been published by a Russian, giving the toxic effects of urine which has escaped into the peritoneal cavity.

The method of operating is an interesting one. Having determined upon interference by section whether the diagnosis has been made positive or not, a median incision should be made and enlarged to suit the convenience of the operator. The incision may at first be made down to the bladder, as for a suprapubic lithotomy. If there is a wound in front, you may feel if it enters the peritoneal cavity; but even this is fallacious. Having found the wound in the bladder, the first thing is to clean the peritoneal cavity. Next, it is necessary to get the bladder into a position to suture it. This has been, until recently, found one of the most difficult steps of the operation. To obviate this, distension of the rectum with a colpeurynter has been practised. More recently, as in the case of Fox, sutures have been introduced on either side, and may be combined with the use of the colpeurynter. MacCormac, who found considerable difficulty in bringing up the bladder, made a lateral incision on each side through the peritoneum. This liberated the bladder immensely. These peritoneal wounds he stitched together in the usual way, but it appears to me that this might be improved upon by introducing the stitches as Dr. Emmet does when sewing up his relaxation incisions of the vagina or elsewhere—that is, by uniting the wound by stitches passed in its longitudinal diameter. It has been found that the cases in which the sutures penetrate all the coats of the bladder invariably terminate fatally. This must be borne in mind, and the sutures passed only through the serous and muscular coats. The bladder wound is to be brought together with Lembert sutures of silk or catgut.

The after-treatment brings up the question of drainage, which has been discussed. A catheter should be left in the bladder. Another important thing is to prove that the stitches effectually control the opening in the bladder. This is done by injecting some solution—better, a weak antiseptic solution—into the bladder. If there is any leakage, additional sutures should be introduced; or the first row of stitches, by a second set, turned in.

The last division of the paper relates to rupture of the intestine. The total number of cases reported is five, of which number none recovered. One operation was performed in America and four abroad—two in Australia, one in France, and one in England. The first recorded case is that of F. H. Girdlestone, of Australia, February 14, 1883. The only American case recorded is that of Dr. E. A. Wagner, on August 2, 1886. One case fell, and pressed a truss down upon a descended hernia; one was thrown from a horse; two were kicked in the abdomen; and one was crushed by a horse. In five cases the small intestine was ruptured, and in one the colon was the part involved. I have the notes of one case of ruptured intestine which occurred in my father's wards in the Pennsylvania Hospital. I wish, in conclusion, to relate it, though it was not an operative case.

Case 5.—B. R., aged 57, was brought to the Pennsylvania Hospital, a distance of ten miles, on a bitter cold night, sitting in an upright position. Upon his arrival he was in a state of collapse from exposure, cold, pain and weakness. He stated that he had long been subject to a hernia (indirect inguinal) of the right side; that he habitually wore a truss that did not keep it reduced properly; and that while it was down, about thirty hours before admission, he had been violently kicked in that groin. He experienced some pain and nausea at the time, and both steadily increased up to the time of his admission. His bowels had not moved.

Upon admission his condition was as above; no vomiting or belly pain. A large swelling was present along the proper position of an indirect inguinal hernia. In this lump he had severe pain. All endeavors were directed to bringing him out of his shocked condition.

December 3, 1886. Late last night he had reacted sufficiently to receive an anæsthetic, which was administered, and a thorough examination of the affected region made. No hernia was present; simply a mass of inflammatory exudation. Considerable emesis and some recurrence of shock followed. This morning his condition seemed fair. He stated that he had none or very little pain; took liquid nourishment; and had his bowels freely moved by enema; *no abdominal symptoms whatever.*

In the afternoon he vomited several times, material with a suspicion of fæcal odor about it, and during the night it became very markedly so. It now became evident that he was suffering from one of three conditions, namely, either a ruptured gut, a reduced though still strangulated hernia, or an intussusception.

4th. The first thing this morning preparations were made for opening the scrotum, and, if necessary,

the abdomen; but the anæsthetic so depressed him, and his condition within the last few hours had become so bad, that the operation had to be abandoned. He died in the course of a couple of hours.

Post-mortem.—Upon incising the scrotum a quantity of fæcal material was found; no hernia was present, but the internal ring was patulous. The peritoneum was found in a state of general peritoneal inflammation, and a great quantity of fæcal fluid material was present in the pelvic basin. A loop of small intestine, having an inflammatory ring about its neck, was found in a state of almost gangrene, from congestion and inflammation; while the loop was torn for an inch in extent in two places; the communication of the loop at both ends with the normal bowel was present, though the opening was small. Post-mortem examination otherwise negative.

HYDROPHOBIA (RABIES CANINA); FATAL TERMINATION.

BY HORACE P. STEBBINGS, M.D.,

OF ENGLEWOOD, ILL.

On Wednesday, October 20, 1886, at 4:30 P.M., I was called to see Daisy I., who had been bitten by a dog. Some one who saw her afterwards said there were thirty-five punctures: one wound on the back of the neck, one in front of left ear, one above left clavicle, one on the left leg, and the others on forearms and hands. All the wounds were cauterized with a 25 per cent. solution of nitric acid except one on the left leg, where lunar caustic (fused nitrate of silver) was used, as the wound was superficial, merely a scratch, and one above left clavicle to which a 95 per cent. solution of carbolic acid was applied. Extreme pain caused by the nitric acid was the cause of the deviation from the rule in the case of the two wounds.

The wounds were seen by me ten minutes after they were made, I am told, and work commenced on them immediately. An ordinary drop-tube was passed to the bottom of the punctured wounds and the liquid forced out of the tube until it ran over the skin about it. The wound in the skin above the clavicle was not discovered until two hours later, as the dress was untorn, it probably having been made by a claw. When seen it was treated with the 95 per cent. sol. carbolic acid as stated above.

The shock was profound, and ¼ grain morphine (sulph.) was administered by the mouth, and the girl put on a couch to rest, the wounds being only loosely covered and not dressed.

Wednesday evening.—Wounds were dressed with carbolized vaseline, then manilla paper, and roller bandage. She was much quieter, had been asleep, and was resting pretty well. Slight febrile movement.

October 21, Thursday morning.—Had passed a pleasant night; muscles very lame and wounds sharply inflamed, indurated and red, but the inflammation closely circumscribed. Wounds dressed as on night before.

Thursday night found Daisy restless and worried, for a man, a doctor, she guessed, had removed all the bandages and counted the wounds. Whoever it was failed to replace the dressings, and the lady had put them back very nicely, but the dressings had become harsh when removed and had acted as irritants until reapplied. She is having too much company. Was glad to have her wounds redressed. Added iodoform to two wounds that showed signs of suppurating. Prescribed

Tinct. ferri chlor.	
Acid phosphor. dil. āā.	℥j.
Quiniæ sulph.	℥ij.
Aquæ q. s. ad	℥iv.

directed one teaspoonful in water after each meal, also one compound cathartic pill (U. S. P.) for torpid condition of bowels.

October 22, Friday morning.—Bandages again in part removed; several wounds suppurating and looking well. Neck very lame from wound on back of the neck and the one in front of the ear. Lymphatics below this latter wound indurated and swollen. No motion of bowels yet obtained, so directed another compound cathartic pill to be taken unless a movement should occur spontaneously by noon; for inaction of kidneys, directed a mixture of spts. alth. nitros., liq. ammonii acetatis and potas. nitratis. Iodoform used on all wounds at first sign of suppuration.

Friday evening.—Bowels had moved and kidneys doing excellent work without the need of medicines of any sort. Wounds in excellent condition, and redressed with carbolized vaseline and powdered iodoform.

October 23, Saturday morning.—Tried to see a turgid condition in some of the wounds and penciled a 25 per cent. sol. of carbolic acid around some of the wounds, and redressed as before. Eating soft foods, broths and soups, as wound in left masseteric made movements of the jaw very painful.

Saturday evening.—Applied two "madstones," one green one about two-thirds as large as a hen's egg and flattened on one side; one red, looked like pipestone and had a clayey odor; this one was about half the size of a hen's-egg, irregular in form with one flattened surface, and showing bright fractures. Both stones were finely porous and adhered to any moist surface as it did to the back of the hand moistened with saliva. The stones were covered about with absorbent cotton, so as to render the wounds to which they were applied free from contact with atmospheric air. The stones were tolerated by me because family and friends all worshiped this "fetich," and the feeling of "cure" was in every mind after their use. Consent was easily obtained that no reference be made to the circumstances of the injury, to the time, nor the name of the dread disease be mentioned.

October 24 Sunday morning.—The green stone glued to dried pus at the orifice of wounds, the red one loose. The stones draw, *i. e.*, by capillary attraction produce a sense of suction and leave the wounds stimulated by their harsh feel and movement. The same dressing renewed.

Sunday evening.—Stones removed and boiled; one reapplied, the other allowed to dry during the night. Wounds redressed as before, all of them looking well.

October 25, Monday. — Wounds redressed and stones applied to any indolent-looking sores, as their presence satisfied friends and patient. Daisy had "caught cold," was sneezing badly, hands and feet cold, bowels torpid. Gave

Tinct. opii camph	℥ss.
Tinct. aconit. Rad	♏xv.
Tinct. digital	℥ij.
Aquæ chlorif	
Aquæ ää q. s. ad	℥iij.

Take 1 teaspoonful for a dose four times daily; also one compound cathartic pill (U. S. P.)

Monday evening.—Cold did not trouble her; circulation restored, and functions all perfect so far as known. Wounds doing well and redressed as before.

October 26.—Tuesday forenoon stones boiled, dried and reapplied. Wounds redressed as before.

Tuesday evening.—Wounds redressed as before.

October 27.—Wednesday morning and evening nothing to record.

October 28, Thursday.—Because of a little restlessness the iodoform was discontinued and impalpable boracic acid used in its stead. Otherwise everything as before.

Thursday evening.—Slight fever, but cake and cheese account for it. At the request of the gentleman at whose house she was given a home, I spent the day in another room without her knowledge. To day she drank five or six pints of water. Wounds looking finely.

October 29.—Spent the day at the house dressed the wounds in the forenoon as on the 28th. A diphtheritic membrane that appeared on a few wounds was destroyed with lunar caustic and in part removed. At noon she was left sitting up with the servant girl alone in the house. Seized the opportunity to eat cheese, cake, a large amount of butter and two or three ounces of syrup. Dressed her wounds on my return, and of course there was considerable restlessness and fever, but this was controlled by the mixture given on the 25th. Itching of wounds to day and yesterday, relieved with creosote water diluted to four times its volume. Uneasiness seemed to be due entirely to a healthy reparative process. In the evening her friends were worried, and desired me to call in Dr. C. H. Whitman to consider the question of removal. Wounds redressed dry with iodoform and absorbent cotton. We could see no reason for her removal, but desired the family to carry out their wishes. They concluded to remove her to St. Luke's Hospital, Chicago.

October 30.—Her wounds, which were almost all healed, were dressed dry with iodoform, as on the previous evening, and she was taken in a closed hack five miles to the hospital.

She remained at the hospital one week, during which time her symptoms were negative. The first day after her ride and getting her in bed.—"Pulse 82, temperature 99.2° F.; no pain, bowels moved. At night homesick. Appetite fair, quiet." Next day, October 31: "Temperature normal, slept fairly well." Next day, November 1: "Up all day; no pain. Bromidia ℥j nightly for sleeplessness."

Until Sunday, November 7, there is no further history, no symptoms to be recorded while under the most careful observation, and she was discharged and recorded cured; which means, I suppose, that her lacerated or punctured wounds were healed so far as to be out of danger of sepsis. On looking over her wounds she called my attention to a pimple on her left arm, exactly like several that had appeared on the back of her neck and elsewhere under the vaseline dressing, some of which I had incised. There was no infiltration or infection apparent. Until Thursday, November 11, there is no further history, and nothing of interest that can be recalled by the family.

Thursday evening, November 11, 1886, 8 P.M.—Dr. C. H. Whitman was called in to see Daisy I. Temp. 102° F., pulse 100, hard and strong, skin hot and dry, tongue slightly coated white, pupils slightly dilated. Pain in the lumbar region extending down sciatic nerves; or, as she expressed it: "My back aches and my bones ache down my limbs," making a motion down over lower part of back and down back of thighs. Prescribed of the following:

R.	Tinct. aconit. rad	gtt. x.
	Fld. ext. asclepias tuber	℥ij.
	Glycerini	℥ij.
	Water q. s. ad	℥ij.

℥j every hour.

also quinia sulph., 5 grains every four hours.

November 12, Friday, 6:30 A.M.—She had slept very little during preceding night; had been very restless. Temp. 102.5° F., pulse 110, tongue not much changed, pupils less dilated, bowels moved naturally. Urine passed about normal in quantity, of a greenish-yellow color, and with an abundant flocculent sediment which appeared soon after it was voided. A fuller account of the analysis of the urine is appended. To-day the wounds were first complained of, the new cicatricial tissue reddened, and the sites of two healed wounds broken open and discharging pus (the wounds were the one on the back of the neck and one on the left forearm). Complained of extreme pain in one of the knee joints, and there was now developed a general hyperæsthesia. To meet these indications morphine in ¼-grain doses was given every five hours until three doses had been taken, and iodide of potash was also given.

1 P.M.—No alteration.

4 P.M.—Difficulty in swallowing, and slight spasm and inharmonious action of constrictors of pharynx first noticed.

7:30 P.M.—Slight fulness of face and pallor. Temp. 100° F., pulse 90, tongue bright red (tongue of inflammation). Wound in front of left ear became painful. Hydrochlorate of cocaine gave relief. At this time and until midnight morphine alone was used. After midnight there was a troubled sleep until morning.

Saturday, November 13.—Was called at 8:30 A.M. by Dr. C. H. Whitman to see patient. Drs. Lovewell and Wilder, of this place, were also called. Found her with face bloated and pallid. She recognized me, but feared to allow any one to approach her; said it "strangled her." Abscess on left arm, areola the size of a silver dollar and a drop of healthy-looking pus

at its summit. Bite in neck aches, also the one above the left clavicle. Spasm of respiratory muscles and those of deglutition on movements toward her or when a breath of wind was felt. Wants people to approach her from head of the bed, as movements from that direction (which she does not see) do not trouble her. During forenoon commenced the use of chloroform by inhalation, which could only be used very much diluted with air because it burned her throat, as she said, and her eyes. Pulse 100, pupils normal, but once or twice momentarily very much dilated. A handkerchief was allowed to rest on the eyes, to remove all excitement caused by sight, but the moment it touched her cheek it was jerked violently away. While the handkerchief was in place the chloroform was urged a little, and 1/6 grain of curare was injected hypodermatically, she not being aware of the operation. On awaking she is unable to swallow either water or ice.

2 P.M.—Patient unchanged, except a little less excitable than in the forenoon. Wants to take the cloth in her own hand and smell the chloroform, which she is allowed to do.

Towards night, between 4 and 5, she was able to drink some water through a flexible tube, the glass being held three or four inches from her face, and she even wanted to hold the glass herself. Drank about + ℥iij, to her infinite delight, after which she felt much relief. There was some choking, but she persisted in the effort until the water was swallowed. She then submitted to another subcutaneous injection of curare (1/6 of a grain). Has taken no food; pulse 100.

November 13, midnight.—Daisy rests in comparative comfort, otherwise as excitable as ever, and allowed to remain alone, as the presence of any one makes her want to talk, and then she becomes excited and nervous. Has her cloth wet with chloroform and placed on a chair at her bedside, then she says: "now go out and I'll get it myself," and repeatedly cautions "don't fan so." At 1:30 A.M. was helped upon a chamber vessel and passed urine with a great vesical spasm; when helped back into bed she seemed very much exhausted by the effort of moving, although a lady and myself lifted nearly all of her weight. At 2:10 A.M. she made two violent attempts to clear her throat of thick sticky mucus. At 2:45 A.M. restless again and given more chloroform on her cloth, and is quieter again.

Here my notes of the progress of the disease were interrupted by her constant demands for assistance and care.

At midnight Saturday night I put on my heavy dogskin gloves and wore them constantly, for frothing had commenced, and she said to the lady who gave her a home: "Be careful, Mrs. D., for I might bite you. I wouldn't want to, but maybe I couldn't help it." Between 2:45 and 3 A.M. efforts at vomiting commenced, but only frothy mucus was thrown up. Afterwards came brownish and brownish-green matter, apparently from the duodenum. This was expectorated into a wash-bowl without violence, not more than two drachms at a time, and contained a finely curded or granular matter, undoubtedly bile.

Typhoid fever was prominent in her mind as the cause of her illness, and she asked many questions about it and if she had it. I assured her that she had, and also that I could break it up in a few days, as she was worried for the expenses of her illness to her friends.

Every movement, however deliberately it was commenced, would be finished with a jerk. There was perfect sanity whenever her mind was recalled by impression of any of the senses, but when left alone there would be a little low, busy delirium, talking to herself and low exclamations. Hearing was very acute, as were sight and feeling. The sight of the movement of a garment would cause her to exclaim "Don't fan so," before a wave of air had time to reach her, and her own breath on her hands, as they lay across her chest, caused her to complain of draughts.

From about 3 o'clock Sunday morning until death there was constant accumulation of carbonic acid gas in the blood, for there would be spasm of the epiglottis after a shallow inspiration, and the continued retching demanded more oxygen. The skin was of a dusky hue and wrinkled. In this condition, and about an hour and a half before she died, she was able to chew and swallow a little plain, soft wheat bread, and she took a little diluted fluid beef well salted; but although she liked its taste, the stomach promptly returned it. When she died there was slight spasm of the throat and chest, probably wholly of the epiglottis. There was no general spasm, and her mouth was left full of froth.

Of remedies after the development of "rabies" morphine accomplished next to nothing. Chloroform (Squibbs) gave great relief and was called for constantly. Very little was inhaled, but not much was needed. About 1½ lbs. was used in twenty hours, her attendants getting as much as she did. Curare (Merck's), while producing physiological effects, at one time numbness in one leg, and afterwards in both forearms and hands, but no further, doubtless avoided many violent spasms.

She was humored in every desire that could be fulfilled, and where it was not best for her she was satisfied with that assurance. No restraint was offered. Once a physician holding her hand and wrist lightly in his hand, did not instantly drop it when she jerked, and she glared at him, truly insane, mad, wild for the moment: "You are trying to hold me." I assured her that we would do no such thing, and she lay back in a moment soothed and quiet. She was of strong frame, well developed for her age, 15 years old, born and reared in a country town; had never menstruated; of very unusual will power and control of nerves. Mentally she was not balanced perfectly, *i. e.*, older in some regards than others, and otherwise there was a little bias.

No blebs were noticed about tongue or lips.

No post-mortem examination was held.

Examination of Urine, by Dr. Chas. H. Whitman. —Color, a greenish yellow. On cooling a white precipitate let fall, which cleared up upon boiling, also with nitric acid; this precipitate occupied one-fourth the volume of the urine. Reaction acid. Specific

gravity 1.028. *Albumen*, none. *Sugar*, none. Microscopic examination found one granular tube cast from straight uriniferous tubules, also a few epithelia from pelvis of kidney, some epithelium from bladder and some from vagina. Further than this there was found only the normal inorganic substances, *i. e.*, amorphous urates, urate of ammonia, urate of soda.

5730 Wentworth Ave., Dec. 10, 1886.

THE HEADACHE OF YOUTH AND ITS RELATION TO OCULAR DEFECTS.

BY CHARLES F. SINCLAIR, M.D.,

OF CHICAGO.

The subject of my paper is rather the relation of certain common forms of defective vision to headache in youth. The subject in general would take us over the whole field of ophthalmology, and is too vast to treat even superficially in the space allotted to my paper.

The headaches arising from defective vision are so numerous, and show such definite characteristics in connection, not only with the different forms of ametropia, but with its different degrees, that the ophthalmologist might easily furnish a terminology of his own. Instead of the usual classification into sympathetic, neuralgic, anæmic, hyperæmic, etc., another division, based solely upon the condition of the eye, might be made. This might be done, too, without regard to any faulty condition of the general system through which these errors of refraction, in many cases, first manifest themselves. And this is true especially in youth. There are headaches with certain definite characteristics which are caused not only by hypermetropia, but also by its different degrees, as there are of myopia and its different degrees. These fixed peculiarities are still more marked in the different forms of astigmatism. The severity of the pain seems in some measure to depend upon the nature of the ametropia, ranging from the dull, heavy ache in and around the eye found in the lighter degrees of hypermetropia and myopia, through the severer forms found in the higher degrees of these refractive errors, and in simple and compound astigmatism, to the intense neuralgic pain of that rare form of defective called mixed astigmatism. This latter pain may be of such severity and of so frequent occurrence as to destroy the usefulness of the life of the individual.

Such a case as this came under my care in February last, and, although somewhat of a digression, I shall take the liberty of presenting it. This patient was a young woman of 30 years of age, apparently healthy and strong. Her only complaint was about her "terrible head trouble." She had been troubled with her eyes since 10 years of age. When at school, if the sun shone brightly, she could not read her lessons, and would have to press and squeeze her eyes in order to see at all. About seven years ago her eyes were in such a condition that she could not look at any bright object, or use them for any ordinary work for months at a time. Since she was 15 years of age she has had terrible headaches in the forehead and temples, and in and around the eyes. As she stated, the pain is so intense it almost drives her mad. She can not even ride in a street car for fear the "neuralgia," as she termed it, would start up again.

These severe headaches were accompanied at times with nausea and vomiting, and these she called her "bilious attacks." At other times her "eye headache" came, when the pain seemed to be in and at the back of the eye, and which pressure relieved. At still other times the pain was located at the base of the nose, and these she called her "catarrhal headaches." In all, however, the pain in the eyes was severe. For fifteen years she has had these severe attacks regularly twice a week. They last sometimes a day and a night, and sometimes two days and two nights. She has taken medicine for biliousness and dyspepsia, and every patent medicine she could hear of for her catarrh. She has a large safe at home full of medicine bottles. Her house looks like a drug store. She has exhausted the whole pharmacopæia for lung and liver and stomach and throat troubles, and now, as a last resort, she comes to see if her eyes can be in any measure the cause of her suffering. On examination I found vision very defective, being but $\frac{2}{10}$ in the left eye and $\frac{4}{10}$ in the right. Plus and minus glasses were refused. The ophthalmoscope showed the usual distorted appearance of the disc seen in astigmatic cases, with a moderate degree of myopia in the vertical meridian, and of hypermetropia in the horizontal of both eyes. A lense of — 1.50 D spherical ⊖ + 1.50 cyl. axis vertical in the right eye, and of — 2. D sph. ⊖ + 1.75 D cyl. axis vertical in the left, improved the vision up to $\frac{7}{10}$, and apparently has cured the headache.

But it is especially in childhood and youth that these different forms of ametropia manifest themselves in all the various forms of headache. In a comparatively recent and voluminous work on the "Nature and Cause of Headache," by Wm. Henry Day, of London, a lengthy chapter is devoted to the consideration of the headaches of youth. He deplores the popular methods of education which push a child forward in the acquisition of knowledge without sufficient regard to physical training; "to the vigorous growth of the body and the stability of the frame, until some one link is broken in that mysterious chain of vital force which keeps the whole fabric in order, when the health in too many instances is undermined and life is absolutely shortened."

To one familiar with the intimate relation existing between the headaches of youth and ocular defects, and how, with the school boy and girl, all too frequently the eye is the link which first gives way, it seems strange that the author of such a work should in no instance mention ametropia as a possible cause, not alone of the severe headaches of childhood, but also, through reaction, of deterioration of the general health.

There is, however, one form of ametropia to which, on this occasion, I wish especially to refer, and which is exceedingly common among our school children. It is of slight degree and therefore easily overlooked. Indeed, it may simulate some of the less severe forms

of ametropia, and although these refractive errors may be but slight, yet they may be the cause of various forms of severe headache and of impairment of the general system. I refer to those cases of myopic and hypermetropic astigmatism of .50 D and .75 D. In these cases, for some reason as yet unexplained, the resulting disturbances are much more wide-reaching and serious than in the more common and simpler forms of ametropia.

The following cases will best illustrate the peculiar characteristics of these forms of abnormal refraction:

Case 1.—Maud W., a school girl, 14 years of age, has had severe frontal headache, and occasionally in the occipital region, almost daily for three years. It is usually, however, a severe throbbing pain through the temples and across the forehead. The severity of the pain is so great that she is frequently confined to her bed for days at a time. The headache is sometimes accompanied with nausea. These headaches became finally so frequent and severe that she was obliged to give up all her studies. Nothing during these years of suffering called particular attention to the eyes, but at last she noticed that the eyeballs were sometimes tender to the touch, and that the attacks usually began with slight lancinating pains in and around the eyes.

On examination excellent vision was found, being $\frac{9}{10}$, with some some few letters of $\frac{1}{10}$ for distance. With minus lenses of .50 and .75 of a dioptric vision improved to such an extent that $\frac{1}{10}$ was read with ease. After, however, the accommodation was paralyzed by the use of homatropin a half a dioptric of hypermetropia was found in the vertical meridian, for which a plus cylinder was prescribed, and no further complaints were made of the severe headache with which this patient had suffered for three years.

Case 2.—Emily R., 15 years of age, has had headache for a whole year, every day and every night. The pain at first was rather of the nature of a dull, heavy ache in the temples and forehead. This gradually increased in severity and extent until at times the whole head seemed numb. Two weeks before examination this dull ache turned into a sharp, throbbing, lancinating pain, shooting up through the temples and around the head toward the occiput. There was tenderness on pressure around the orbit, and especially over the supra orbital nerve. The eye-balls were also tender to the touch.

I mention this case for the reason that ordinary plus glasses were first prescribed, these permitting the patient to read $\frac{1}{10}$ with apparent ease. The patient, however, returned in a few days saying her headaches were as bad as ever. Here also, after the accommodation had been thoroughly paralyzed, a small degree of hypermetropic astigmatism was found which a × .50 D cylinder corrected, entirely curing the distressing head symptoms.

The important part these slight irregular forms of ametropia play in the headaches of youth is clearly seen in a case which came under my observation two weeks ago, in which but one eye was slightly astigmatic, the other possessing 1.50 D of long sight.

Case 3.—Lily L. has been troubled with her eyes for a year and a half. Patient looks delicate and anæmic, appetite is poor, has been very much troubled with headache—a dull, continuous ache over the frontal region, with sometimes throbbing and at other times sharp lancinating pains shooting out over the left side of the head from the left eye. During the time this patient attended school these peculiar headaches were of daily occurrence. In vacation they were absent. She is much troubled with constantly recurring attacks of vertigo and dizziness. While walking the streets these attacks are liable to come at any moment, when she is obliged to grasp some object to keep from falling.

The greater severity of the symptoms on the left side of the head seemed to find an explanation in the fact that the usual small amount of astigmatism was found in the left eye, the correction of which has apparently put a stop to both the headache and vertigo.

These are but types of, in my opinion, an exceedingly large number of cases where the most distressing symptoms, simulating, in many instances, even organic disease, may be quickly and thoroughly cured by so simple a remedy as a pair of properly adjusted cylindrical lenses. They are interesting to the ophthalmologist, as they may assume in certain cases not only the characteristics of myopia or hypermetropia, but even of normal vision; and they certainly suggest, to the general practitioner the advisability, in every case of severe or persistent headaches in youth, that not only the eye be carefully examined, but that it be examined only when thoroughly under the influence of some mydriatic.

MEDICAL PROGRESS.

HYPODERMATIC INJECTION OF FOWLER'S SOLUTION IN CHOREA MINOR.—To fairly test the value of hypodermatic injections of Fowler's solution of arsenic in the treatment of chorea minor, especially as compared with its internal administration, almost all cases of this disease admitted during the last year to St. Anne's Hospital for Children, in Vienna, service of Prof. Widerhofer, have been subjected to this treatment. For the sake of comparison a few cases were treated by Fowler's solution given internally. The results of the clinical experiment, which have been highly satisfactory, are detailed by DR. FRÜHWALD, assistant to Prof. Widerhofer, in the *Jahrbuch für Kinderheilkunde*. Equal parts of Fowler's solution and distilled water were used; care was taken to have the preparation fresh, and to have it freshly filtered before injecting it. One injection was given a day, alternately into the extremities, the needle being inserted deeply into the tissues and the surface having been well washed with thymol water. Treatment was begun by injecting up to the first division mark of a Pravaz syringe, the dose was increased day by day by one additional part until eight or ten such parts were reached, and then as gradually reduced until the original dose was again attained. In increasing the dose attention was given not only to the age of the patient and to the severity of the disease, but more

especially to the signs of improvement that became manifest.

In those cases in which the remedy was given internally the initial dose was 5 drops per diem; this was increased by one or two drops a day until 20 or 25 drops were reached, when it was as gradually reduced to the first dose. Of the twenty-five cases, almost all of which came under treatment at the height of the disease, twenty-two were treated by injection, three by the internal administration of Fowler's solution. There were eighteen girls and seven boys, aged from 5½ to 14 years, all of feeble constitution, anæmic, and of irritable disposition. As to cause, fright or some other psychical disturbance brought on the disease in nineteen, two were relapses. Only in four could a relation be traced between acute rheumatism and the chorea. At first, in three cases, redness of the skin at the punctures, and in two of them abscesses, developed, and these were subsequently treated by internal medication; but afterwards, when the injections were carefully made in the manner described above, no troublesome complications further set in.

As to the curative results obtained, both physicians are compelled, from their experience with the two ways of giving the arsenic, to give decided preference to the treatment by injection. Where it was employed pronounced improvement set in in a remarkably short time (one to two weeks), and a permanent cure was established by the third or fourth week; at least, only one relapse has been reported. They attribute this favorable result to the more rapid absorption of the preparation given subcutaneously. They regard absolute rest in bed, at least until marked improvement has set in, as a powerful auxiliary, as also a nourishing diet and tonics, especially during convalescence.

They conclude that no one should be deterred from pursuing this line of treatment by the psychical excitement to which the giving of the injection may give rise in some children, or by the slight and easily avoidable local complications, for by this method *brilliant results can be obtained in the largest number of cases, and exceedingly satisfactory results even in the most obstinate cases.*—*Memorabilien*, 2, 1886.

Osteotomy for Inveterate Equino-Varus.—In a paper on this subject read before the New York Surgical Society on December 8, Dr. Charles F. Poore says: From a study of the bones from feet affected with talipes equino-varus, it is evident that the real trouble lies not in *front* of, but *behind* the medio-tarsal joint; and that all operations on the bones are anatomically and mechanically wrong.

The only operation that of late years has commended itself to surgeons is a cuneiform osteotomy or resection of the tarsal bones in front of Chopart's joint; all others have failed to accomplish the end for which they were performed, and have been abandoned.

Tenotomy of the ligaments commends itself as one from which good results may be expected in infants, because it attacks the structure which is the chief obstacle to the normal development of the astragalus, but it has no influence on the curvature of the os calcis, and this it would seem is the cause of imperfect restitution in otherwise promising cases.

In looking at a dissection of a foot affected with the deformity under consideration, the following points suggested themselves:

1. That the inability to correct the deformity was due to changes taking place in astragalus and os calcis.

2. That, in order to bring the anterior portion of the foot into its normal position, the curvature in the os calcis must be removed and the neck of the astragalus shortened, so as to allow its head to point in the normal direction and thus carry with it the scaphoid and other tarsal bones.

To accomplish this, the following operation was performed: An incision was made from a point one inch and a half in front of the tendo Achillis on the outer aspect of the foot forward to the middle of the cuboid bone, and down to the tendons of the peroneus longus and brevis; these should be raised or pushed out of the way. Another incision, beginning from the middle of the first and corresponding to the neck of the astragalus, was made directly upward; the tissues were then raised from the bones and the periosteum incised over that part of the os calcis from which it was desired to remove the wedge. With a chisel a V-shaped piece of bone was taken away, base outward, and its apex extending to its inner border; a wedge was then removed from the neck of the astragalus of such a shape as to allow the anterior portion of the foot to be brought outward and upward. The periosteum was united with catgut and the skin with several wire sutures, because the latter held longer and gave better support.

An aperture was left posteriorly for the insertion of a drainage-tube; a plaster-of-Paris bandage was applied, extending from the toes to above the knee, and the foot was placed in a corrected position; the wound was dressed with iodoform and gauze.

The size of the V-shaped interval left after the removal of the wedge of bone should be sufficient to allow the anterior portion of the foot to be placed in a proper position without any tension on the tissues on its inner aspect. I think that a subcutaneous division of the ligaments on the inner border of the foot, when they are tense, would facilitate the correction.

The dressings should be as light as possible, not bulky; otherwise it will be found difficult to apply the plaster-of-Paris bandage firmly; a little over correction does no harm.

The advantages maintained for this operation over that of removing a wedge from in front of the medio-tarsal joint are:

1. It is anatomically and mechanically correct.

2. A smaller amount of bone has to be removed, because the operation is performed nearer the apex of a triangle.

3. No joint is opened, and, consequently, the foot is left in a more normal condition.

4. It does not practically shorten the foot in front of the ankle joint.

The class of cases suitable for this operation are:

1. Those of patients who have reached the age of

5 or 6 years with the deformity unrelieved, who have walked on their feet, and in whom the parts are rigid and the deformity marked.

2. Those cases in which, although the anterior portion of the foot can be brought into position, yet require an apparatus to retain the foot in its normal position after years of careful treatment.

3. Those cases in which the obstacle to restitution is due to elongation of the os calcis; perhaps in these patients the removal of a small wedge from that bone would accompany the result.—*N. Y. Medical Journal*, Jan. 15, 1887.

THE DELETERIOUS INFLUENCE OF ALCOHOL ON CHILDREN.—By PROF. DEMME, Berne, Switzerland (22d Med. Report of the Jenner Hospital for Children, Berne). We give the following abstract of the above very timely paper, in which this well known writer lays down his conclusions on this important subject, drawn from most careful study, and formed in a large field of observation, and we feel that in this we are doing our readers a real service, for his views in opposing, and justly opposing, the therapeutic abuse of alcohol, touch upon some very important principles in the treatment of children's diseases.

Demme first cautions against the use of alcohol, in whatever form, as an antipyretic, for although the fever-lowering power of large doses of alcohol cannot be controverted, inseparably combined with this action is the injurious influence of alcohol on the energy of the heart, on the cerebral vessels, and on the cerebral activity itself, and we have a salicylic acid, antipyrin, thallin, etc., agents of a more innocent nature, to accomplish this object.

The use of alcohol as appetizers and stimulants to digestion has been rapidly gaining ground among the people, and our nurslings are given their cognac for this purpose. As a sad consequence of such erroneous dietetic measures, and as a direct result of this too early and too abundant use of alcohol, Demme has met with two cases of cirrhosis of the liver, otherwise so rare in children. Both cases terminated fatally; in both cases the abuse of alcohol was proven, having been begun originally for dietetic purposes; and in both syphilis could be excluded. Furthermore, Demme could, in a considerable number of cases, trace a marked cessation or even a retrogression in mental development to the habitual abuse of alcoholic drinks, which in three cases led to epilepsy, while in two cases acute alcoholic intoxication terminated in this neurosis.

In addition to these five epileptics, Demme could trace twenty-one of seventy-one young epileptics, all of which had been under his own observation, to parents one or both of whom were addicted to drunkenness. An unquestionable rôle as an etiological factor the early use of alcohol played in a number of cases of night terrors and of chorea minor. Demme claims that there can be no question that there are infantile organisms in which even moderate quantities of alcohol not only prove injurious in the accepted sense, but can give rise to severe diseases of the nervous system. The introduction of alcoholic drinks into the infantile organism, be it by the people or by the profession in the usual routine manner, must be absolutely discountenanced.

Alcoholics may be administered to children *only as a therapeutic agent, after the condition of their various organs has been most carefully estimated by the physician*, as a powerful auxiliary in the medical tonic regimen in rickets, scrofula, tuberculosis, and all wasting diseases of chronic character. On account of the stimulating action of alcohol on the nerve centres, especially on the musculo-motor centre of the heart, alcoholics are mainly indicated in pædiatrics to spur on the flagging heart in infectious diseases, in asthenic pneumonia, in cholera infantum, in which latter they also serve, according to Binz, as a respiratory food. But the use of alcoholics as food or as a luxury must be positively denied to children.

A NEW METHOD OF EXCISING THE KNEE.—At the meeting of the Medical Society of London, on December 6, MR. H. ALLINGHAM read a paper on a new method of performing excision of the knee joint. The joint was opened by a long vertical incision, and the patella divided into two lateral halves, which, together with the soft parts, were slipped to the sides of the joint; the crucial ligaments having been divided, the joint was firmly flexed, and a slice removed first from the femur, and then from the tibia; the lateral ligaments were not divided. The whole surface of the joint, and the synovial pouches were then cleared of synovial membrane; the patella, if only slightly diseased, was scraped, and the two halves brought together and sutured; if much diseased, it could be shelled out of the entire quadriceps tendon without destroying the connection of the muscle with the ligamentum patellæ, and the split tendinous expansion, together with the split ligamentum patellæ, could be brought together with catgut-sutures. Drainage tubes were inserted through suitable posterior counter openings, and the wound closed with separate sutures. The operation must be performed with antiseptic precautions. Mr. Allingham claimed that by this procedure the joint was more thoroughly opened to inspection at the operation; that dislocation of the tibia backwards after the operation was prevented; that the undivided quadriceps antagonized the hamstrings; that progression was better for the same reason, and that the prospect of obtaining movement was greater.—*British Medical Journal*. Dec. 11, 1886.

BINIODIDE OF MERCURY AS AN EMMENAGOGUE.—DR. C. R. ILLINGWORTH writes to the *Lancet*, of January 29, 1887: I find the red iodide of mercury is a certain and safe emmenagogue. My attention was directed to its virtues quite accidentally some three or four years ago, since which time I have used it successfully in a large number of cases. I prescribe it in the form of mixture as follows, but should think it would act quite as effectually in pills of a quarter of a grain twice a day, or an eighth four times a day: R. Sol. hydrarg. bichlor., ℥j; potassium iodid., ʒss; ferri ammon. cit., ʒi; ether. chlorici, ʒij; aquam ad ℥viii. One teaspoonful three times a day after meals.

SATURDAY, FEBRUARY 26, 1887.

THE ARMY AND NAVY REPORTS.

The Reports of the Surgeon-General of the Army and the Surgeon-General of the Navy for the fiscal year ending June 30, 1886, have just come to hand. The Army Report is a rather miserable looking little pamphlet, without an index, while the Navy Report, though but little larger, is at least substantially and attractively bound, and has an index.

The Army report shows that the last was a year of exceptional freedom from disease, the actual number of admissions to sick report being 3,839 less than for the preceding year, though the troops on the Southwest frontier have had unusual hardships. The ratio of cases of sickness to mean strength of command was considerably lower also than for the previous year. The death-rate, too, fell to a lower rate than at any time within the history of the Army Medical Department. Of interest is the influence of length of service in determining liability to sickness among the troops: the tables show that even in this year of exceptional immunity from sickness in the Army, a greater proportion of sick was furnished by troops under thirty-one years of age; "while up to the age of twenty-five the rate proved so much above the mean for the whole that it may fairly be questioned whether the services rendered by these young men are equal to the cost of their maintenance."

It will be seen that troops in the third year of service, and up to the fifteenth year, afford less than one-half the number of admissions to strength for phthisis to those of any less service; but beyond fifteen years the rate seems to increase. Two years ago malarial fevers occupied the fourth place on the list of diseases, but it is now lowered to fifth place, the number of cases per 1,000 of strength having fallen from 147 to 120 per 1,000, and the rate of mortality .14 per cent. of the cases treated, against .17 per cent. for 1884, and .15 per cent. for the decade. This lowering seems to have been uniform, for no single month has shown any great departure from the normal. Of the 139 military stations from which reports were received 36 showed a higher rate than 120 cases per 1,000, Fort Gibson and Fort Sill, Ind. T., heading the list with 1,287 and 753 cases per 1,000. Considering the dreadfully unsanitary condition of some of the posts it seems a little remarkable that only 76 cases of enteric fever, or 3 per 1,000 of mean strength, occurred during the last year. The number of deaths was about 12 per cent. of the cases treated. During the previous year there were 156 cases, and 222 in 1883. The number of stations at which the disease continued as a result of the infection of the previous year was 19; the number of posts newly invaded was 17; and at 20 posts it ceased to exist. Of the 83 cases of acute articular rheumatism 35 occurred in soldiers under 26 years of age, or 4.14 per 1,000; and there were 41 cases between the ages of 26 and 41, or 2.86 per 1,000. Of the 32 cases of diphtheria 25 occurred at Ft. Assiniboine, Mont., with no deaths. The medical officer in charge, Dr. Henry G. Burton, reported that the task of ventilating the barracks during the winter months was almost impossible.

The report also furnishes some information concerning the health of geographical divisions of the country: "Grouping such stations as are situated on the sea coast and lakes, we find that diseases of the respiratory organs and those of the heart and its valves had a higher rate of occurrence than in either the river regions or the region of mountain and plateau. On the other hand, there was a decidedly lower rate of occurrence for diarrhœal diseases, for typho-malarial fever, and for the malarial fevers." In regard to the health of troops by military departments it is seen that the Department of Texas stands first on the list, with a rate of 1,641 per 1,000 of strength, and a constant rate of 55 per 1,000; being higher than for the previous year. The troops in this Department seem to show a special liability to malarial, diarrhœal and venereal diseases. In regard to a recently alleged antagonism between malaria and science, it may be seen from a table that the Department of the East shows a rate of admission for malaria to 1,000 of strength of 123.9, as against 33 3 for the Department of Dakota. 46.2 for the Department of the Platte, and 24.6 for the Department of California; and that while the South

Atlantic region furnished a ratio of 136 to 1,000 of strength, the North Atlantic was close upon it with a ratio of 114. Or, to speak more definitely, in regard to the number of cases the Department of the East stands second on the list, with 601. 588 of these being furnished by the North Atlantic region.

As regards rejections of applicants for the service it will be of interest to know that of 16,805 applicants 12 per cent. were rejected for general unfitness, and 57 per cent. of all applicants were rejected on the primary examination. About 4 per cent. (831) of rejections were for defective vision, one case of color blindness being discovered, 72 cases of myopia and 5 of astigmatism. The ratio of rejections among negroes was about one-half less than for whites. There were 237 rejections for diseases of the heart and valves, and 621 for varicose veins. There were 429 syphilitics, the negro applicants furnishing relatively the greater number. Of the 376 rejections for intemperance the rate among white applicants was almost four times greater than among negroes.

The report strongly recommends that a board of competent medical officers be detailed to propose a plan of organization for hospital corps suited to the conditions of the Army. This corps should be made up of intelligent and able-bodied men, who should be thoroughly trained and instructed as cooks, nurses, attendants, and litter and stretcher bearers, so that the Medical Department might be prepared for any emergency. Another serious embarrassment to the Department is the number of disabled medical officers, there being now four who have been recommended for retirement by retiring boards, and at least six others who can do no more active service. The Report ends with some special reports by medical officers, among which are one on "Acuity of Vision as shown upon the Target Range," by Asst. Surgeon, Louis A. La Garde; on "Certain Peculiar Pathological Appearances in Texas Fever in Cattle," by Asst. Surgeon Richard C. Newton; on an interesting and rare case of "Repeated Rupture of the Membrana Tympani by Discharges of Artillery," which resulted in total deafness, by Surgeon C. H. Alden; on the "Treatment of Diphtheria by the Use of Mercuric Chloride Internally and by Spray," by Hospital Steward Bernard Persh; and fifteen pages of interesting "Special Reports on Aneurism," by medical officers of the Army.

In his report Surgeon-General Gunnell says: "I have to invite your attention to the condition of the Medical Corps of the Navy. Its vacancies have not been filled for several years; resignations, deaths, and retirements having depleted it more rapidly than candidates have been obtained. The Bureau has not been willing to lower the standard of requirements; and it is imposible, with the present inducements offered, to find young medical men possessing the necessary qualifications who are disposed to become medical officers of the Navy. The Army Medical Department has qualified applicants far in excess of its needs, attracted by better pay, well-defined rank, and more satisfactory professional position. Since 1870 more than thirty young medical officers have resigned (three of them to enter the Army corps), and I cannot too strongly recommend that prompt measures be taken to increase the advantages and improve the condition of this department." It need not occasion surprise that the vacancies in this department are unfilled. For example, the pay of an Assistant Surgeon in the Navy for the first five years after his appointment is $1700 per annum when at sea, $1400 when on shore duty, and $1000 when on leave or waiting orders. The Assistant Surgeon in the Army gets $1600 per annum for the first five years, and after five years $2200. But after five years in the Navy he gets $1900 when at sea, $1600 on shore duty, and $1200 when waiting orders. This difference in pay between sea and shore duty seems unfair. But that which makes the Navy unpopular with young medical men is the undefined rank and unsatisfactory professional position, especially during the first few years of service; and may the Navy continue to be unpopular until this matter is remedied.

Most of the information concerning the Navy as a whole is embraced in a set of tables. There are, however, some very interesting "Reports and Contributions from Medical Officers," which will repay reading. Medical Director T. J. Turner calls attention, in his report upon the Museum of Hygiene, to the sad condition of the Museum as regards room for exhibits, work and library, and also to the necessity for a clerk: "The clerical duties in cataloguing, indexing, labeling, etc., utilizes most of the time of the medical officers attached to the Museum, and there is but little time left for the pursuit of scientific study." One would scarcely think it a part of the duties of a medical officer of the Navy to perform such highly intellectual and exhilarating work as is here spoken of, and especially in such a place, where there should be every opportunity for study. The Director urges that the number of officers on duty at the Museum be increased, preference being given to those officers who have displayed interest in

and are ready to work upon matters so important to the State as public health. "The tools are here but the workmen are not now on hand." Were the Museum of Hygiene in proper condition very much more good work would be done in it than is now done in matters relating to sanitary science and public health; as is shown by the work done by Surgeon Charles H. White in chemical and commercial analyses. It is proposed to investigate the slow chemistry of concentrated and preserved foods in order to determine the time when their nutritive value begins to decidely decrease and when it ceases.

Dr. Turner calls attention to the value of anacharis alsinastrum—choke-pond weed, order hydrocharidaceæ in modifying or arresting the production of malaria. "Its rapid growth and spread in marshes and rivers where it has been planted, and the cessation and disappearance of malarial and diarrhœal diseases formerly affecting villages and towns about such localities, have been grouped into a relationship. It is now suggested to cultivate this aquatic plant in marshy districts with a view to prevent the production of malaria." It might be suggested that the Government make this experiment in the vicinity of Ft. Myer, Va., Fts. Gibson and Sill, Ind. T., and Willett's Point, N. Y.

Medical Director A. A. Hoehling, gives a very interesting account of the Hôpital des Marines, at Cherbourg, of the Haslar Naval Hospital at Portsmouth, and the Victoria Army Hospital at Netley. It is also interesting to learn from him that the Spanish physicians (near Gibraltar) still bleed in "typhus" fever, and for many diseases, as well as practising the old fashioned yearly blood-letting in the spring on the peasantry. "The descendants of Spanish ancestors about Gibraltar also believe in phlebotomy, and even cattle, when purchased at a distance, are bled on their arrival in order that they may renew their blood in the new climate to which they have been brought. The cattle are said to rebel at the operation at times, which proves *their* intelligence."

Surgeon T. C. Heyl, of the "Marion," reports on that affection the parangi disease, or "Spanish pox," by which the ship was invaded at Colombo. The duration of the disease is about fourteen days. "Even when the crop of pustules was so thick as to become confluent, and the abdomen and axilla were bathed in pus, no scar remains." There are no defined prodromata. The eruption appears quickly, as a large papule, soft, becoming a pustule in twenty-four hours, with a red, angry base, the delicate epidermis only being thrust up by the pressure of pus from beneath. The true skin is not invaded. There is no odor from the pustules or contents, and after the pustules shrivel the flesh remains soft. Its period of incubation is from forty to sixty days. All that is needed in treating it is "not to meddle with it by internal medication." "Segregation, employed for three months, would efface parangi from the face of the earth."

Surgeons J. C. Wise and R. C. Persons call attention to several unsanitary conditions of the Service, and other medical officers complain of the sanitary defects of the vessels. In fact, it seems to be almost as much as one's health or life is worth to be on duty on some of our men-of war. It might be suggested, especially, that the "Mohican" be turned over to the Museum of Hygiene as an example of what a ship should not be.

The Report concludes with interesting accounts of Japan, some of the Cities of China, and Corea; and a few notes on drugs, among which may be mentioned reports on the use of the Kola nut, by Drs. Gihon and Hudson, and on the "Use of Opium in Fevers," by General Gunnell.

INTERNATIONAL MEDICAL CONGRESS—TRANSATLANTIC RATES.

In THE JOURNAL for the 5th inst. we published an official notice from the Chairman of the Committee of Arrangements at Washington, saying that reliable arrangements had been made by which members wishing to attend the International Medical Congress in Washington September 5, 1887, can be accommodated by the following steamship lines at the liberally reduced rates mentioned, viz.:

Red Star Line—$100, Antwerp-New York and return.

Inman Line—$100, Liverpool-New York and return.

Hamburg Line—$90, Hamburg-New York and return.

Royal Netherland—$80, Amsterdam-New York and return.

Since that notice we have received authentic information that the several lines named have consented to extend the same rates to the families of members, as the following letter shows:

WASHINGTON, D. C., FEB. 14, 1887.

A. Y. P. GARNETT, M.D., *Chairman of the Committee of Arrangements of the International Medical Congress:*

Dear Doctor:—I am happy to inform you that, through the

instrumentality of Mr. Edward F. Droop, agent in this city for the Lines, who has manifested so much interest in this matter, we have been able to secure from the Hamburg-American, the Red Star and the Inman Lines the offer of the same reductions for the families of members of the Congress as those I have already reported for the members themselves. Very truly yours,

J. W. H. LOVEJOY,
Chairman Com. on Transportation.

To aid the work of the Committee on Transportation, the State Department of our Government at Washington has kindly instructed the resident U. S. Consuls at European ports from which the steamships leave, to actively aid in ascertaining the number of those wishing to avail themselves of the reduced rates offered. This is more fully explained by the two following letters:

FEB. 14, 1887.

Editor of the Journal of the American Medical Association:

Dear Sir:—The following additional information relative to transatlantic transportation is furnished for publication:

The White Star Line, as well as the Cunard Line, having declined to make any reduction in fare, you will please strike out *Havre* from the list of European ports last published.

I enclose also, for publication, a copy of instructions which the State Department has kindly sent the resident U. S. Consuls at the ports of Liverpool, Hamburg, Bremen and Antwerp. Very respectfully,

A. Y. P. GARNETT, M.D.,
Chairman Committee of Arrangements for the International Medical Congress.

DEP'T. OF STATE, WASHINGTON, FEB. 5, 1887.

Sir:—The Committee of Arrangements of the International Medical Congress, which meets in Washington in September next, desire to ascertain as nearly as possible the number of delegates who will attend the same, with a view of making favorable terms for their transportation. For this purpose you are therefore instructed to bring the matters to the attention of those interested by such means as you deem best, requesting that you may be furnished with the names of such delegates as will attend and the number of ladies who will accompany them. The result of your efforts should be promptly reported. I am, sir, your obedient servant,

J. D. PORTER,
Ass't. Secretary.

It will be a great favor to all parties interested in the Congress if the medical periodicals in the different countries of Europe will give the foregoing information to their readers as early as practicable.

AN EXCELLENT EXAMPLE.—The Allegheny County Medical Society, of Pennsylvania, has unanimously voted an appropriation of one hundred dollars towards the expenses of the International Medical Congress. There are many more County and local Medical Societies, embracing a large membership, that could do the same with great propriety, and with out incurring the slightest financial embarrassment.

SOCIETY PROCEEDINGS.

ST. LOUIS MEDICAL SOCIETY.

Stated Meeting, January 15, 1887.

THE PRESIDENT, S. POLLAK, M.D., IN THE CHAIR.

FRANK R. FRY, M.D., SECRETARY.

DR. FRANK R. FRY read a paper on

ELECTRICAL DOSAGE.

The question is frequently asked now a-days by those who are becoming more interested in electrotherapeutics, but who have not especially studied the subject—can we tell the dose of electricity? Can we form a schedule of approximate doses for the various ailments in which we know this agent to have remedial effects? At the last meeting of the American Medical Association in this city Dr. Franklin H. Martin, of Chicago, read a paper on "Electrolysis in Gynecology." In the discussion of this paper Dr. George F. Hulbert, Superintendent of the St. Louis Female Hospital, is reported in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION to have said: "As well use strychnine and quinine without measuring the dose as to use electricity without measuring it with the galvanometer." From this we might infer that the doctor means to say that we can measure the dose of electricity with the galvanometer. In the same discussion, Dr. Geo. J. Engelmann, of St. Louis, in speaking of his methods of operating on fibroid tumors of the uterus by electrolysis, is credited with the following statements: "I know precisely the remedy administered." "The galvanic current must be dosed as we dose other remedies." The inference certainly is that there is a precise means of measuring the dose, and that it is employed by Dr. Engelmann in his work with electricity. Similar statements have been made by other gentlemen elsewhere.

The object of this paper is to attempt to controvert these statements, and, in a general way, the erroneous opinions that obtain about our ability to scientifically or accurately gauge the dose of electricity. It is not my purpose to discuss the results of the therapeutic use of this agent. In regard to the two gentlemen whose names I have taken the liberty to use, it is not necessary for me to say that they are to be congratulated on the results they have obtained, and commended for the amount of careful work they have done in this direction.

In the use of faradic and static machines in medicine, it is at least questionable whether we get directly anything more than mechanical effects. At any rate, we have no data that are available for estimating other effects than these. Hence, in speaking of dosage, we are limited to the galvanic current. In attempting to estimate the dose of this, these items are necessarily taken into account, viz.: the strength of the current, or the quantity passing, its density, and the length of time that it is allowed to pass. I shall consider these items as nearly separately as possible.

Quantity.—The Electrical Congress of 1881 adopted a nomenclature which is being gradually appropriated by the scientific world. Ampère is the word thus selected to express the unit of quantity.[1] It indicates the current carried in one second of time by an electromotive force of one volt through a resistance of one ohm. Most of the recent and best galvanometers are graduated in milliampères. With a good instrument, we are able to know and express, in a universally intelligible manner, the quantity of electricity passing through a patient at any given time. Unfortunately there is not a uniformity in the construction of these instruments. In fact there is no standard galvanometer, and we have no absolute measure of this kind. But we can approach one nearly enough for all therapeutical purposes. This point I may illustrate by comparing the use of galvanometers to that of clinical thermometers. If I tell a fellow practitioner that I have a patient whose temperature is 104° F., my language is perfectly intelligible to him, unless, perchance, he be one of the few unfortunate old fogies who still eschew the clinical thermometer. But he is not sure that my figure is the patient's temperature. If for some reason he wants to know it exactly, and is very confident of the correctness of his own instrument, he will try that. Even then he is not sure, and can only be so by comparing his to a standard thermometer. For ordinary purposes, however, the better class of clinical thermometers are accurate enough. The better kinds of galvanometers do not correspond as nearly in their readings as do thermometers; also they are very much more liable to become defective. But with due care in selecting and occasionally examining the instrument, a good galvanometer is of much practical use in our every day work with the battery; and, as a means of enabling us to express the results of our work to the scientific world, it is now indispensable.

Density.—With the galvanometer we cannot measure the dose. It takes no account of density, quite as important an item as quantity, practically more so. It is a fact, experimentally proved, that a current must be of a certain density before any appreciable physiological effects are produced. Hence we may expect practical therapeutical effects only from currents of considerable density. Practically we estimate the density from the area of the electrodes. To illustrate, if I take two very large electrodes, good conductors, with covers well moistened with salt water, pass a current with them in firm contact with the skin, I see that the galvanometer shows a current strength of thirty milliampères. My patient is not conscious of a current. Now I substitute for one of the large electrodes a much smaller one; when I complete the circuit, the galvanometer shows a strength of but 15 milliampères. The patient feels a tingling in the skin under the small electrode. Although there is a less quantity, the density is greater. By substituting the small for the large electrode, I have increased the external resistance. If I want to get the same quantity as with the large electrode, I must increase the electro-motive force sufficiently to overcome the increased resistance. This I do by switching in more cells, and, of course, in so doing I still further increase the density. We know that with a given quantity, the density in the various parts of the circuit will be inversely proportionate to the transverse section of the conductor. Therefore, if we know the square surface of the electrode and the quantity of electricity in the circuit, we may estimate the density on the electrode. For example, if the galvanometer shows a strength of 8 milliampères, and the electrode is 8×6 cm. ($=48$ sq. cm.), I know that I have a current of 8 milliampères spread on a surface of 48 sq. cm. It has been ingeniously recommended to express this relation in the form of a simple fraction, for the numerator of which we write the number of milliampères, and for the denominator the surface of the electrode in square centimeters. Using the figures just employed to illustrate, 8 milliampères on a surface of 48 cm. would give the fraction ($8.48=$) $\frac{1}{6}$, indicating that one milliampère is spread on 6 sq. cm. of the electrode. Hence, with a galvanometer and electrodes of known area, we can express mathematically the density on the electrode. With this fact in view, the advantage of employing electrodes of known, definite areas is apparent; as is also the convenience of standard or normal sizes, by means of which we may more readily and intelligibly express our methods of applying electricity. But we must remember that we cannot thus determine the density in the body, or portion of the body, through which the current passes. Roughly speaking, if we know the density on the electrode and the area of the transverse section of the portion of the body included in the circuit, we may approach an estimation of the density of the current in the same, mathematically. If the sectional area of such a part be 300 sq. cm., and the surface of the electrode 1 sq. cm., the density of the body will be 1-300 of what it is on the electrode. For obvious reasons this is a very unprecise calculation. The current tends to travel in straight lines, but also to spread on the conductor. This is conveniently represented in the shape of a diagram (illustrated). The density is much greater, as the lines show, near the electrodes, decreasing as we depart from them. It is also greater in a direct line between the electrodes. These differences of density we cannot estimate accurately. Before we can we must know more than we do about the resistance of the body in health and disease. This point is being now studied by prominent electricians, with more promise of satisfactory results than ever before. The showings of recent investigations would seem to indicate that there will be necessity for radical changes in the current theories of electrotonus, polarization and other phenomena connected with the application of electricity to animal organisms. I mention these facts as merely suggestive of the magnitude, as well as the unsettled condition of the problem of the resistance of the human body. Yet its importance as an item in the matter of dosage is evident.

[1] The coulomb is the unit of quantity, ampère is the unit of current, and equals a current of one coulomb per second, and is as defined above. See discussion of paper.

Length of Séance.—Regarding the length of time that the current is allowed to pass, little need be said for our present purpose. We all agree that weak currents may be continued longer than strong ones, that a séance may be longer with some individuals than with others, and that it must vary with the varying conditions of the same patient; that the length is often limited by very apparent physical defects, etc. These points are determined, and, in the nature of things, always will have to be determined, in every case, by the individual experience and knowledge of the operator. A remedy, no matter how simple, is only used to the best advantage by one having a large individual experience with it. This is more true of electricity than many other remedies. With an increasing experience, we discriminate more successfully between suitable and unsuitable cases for its use. Experience also will determine our methods of employing it. The use of very few remedies can be reduced to a scientific method, so that we may express in terms of mathematical accuracy the conditions requiring their exhibition or the size of doses. In this respect electricity conforms to the majority of remedies. Data do not exist from which we may construct scientific formulæ to guide us in making the dose for use in any of the various ways that we know empirically to be beneficial. Especially is this true when we are seeking to get its physiological as distinct from its mere physical effects. These facts should not discourage us, nor cause us to underestimate the honest, successful work that has been done. The necessary admission of them should be a stimulus to greater endeavor in attaining to methods less liable to error. In this spirit, all who are sufficiently informed on the subject, will remark with much satisfaction the increased manufacture of galvanometers available for clinical purposes, and the correspondingly increasing tendency to employ these instruments, as well as electrodes of graduated sizes. An accuracy in the application of electricity is attainable with them that without them is impossible. There is, however, much room for improvement. It will probably be some time before these more accurate means are as universally employed as they should be. As evidence of this, I offer the following: Recently I have written to a number of prominent neurologists who make a more or less extensive use of electricity in their practice. I asked each of them (1) how constantly he used a galvanometer, and (2) for what purpose or purposes he used it. They all very kindly replied. I quote some of them as follows:

Dr. ——, Cincinnati: "I always use a galvanometer with my large office battery. It is one I procured a number of years ago in London; but, for some reason I do not understand, it has lost its delicacy, and is no reliable guide in diagnosis and therapy. The most valuable galvanometers have been constructed in the last two years, but I have neglected to secure them." Dr. ——, Brooklyn, N. Y.: "I seldom use a galvanometer, and only when I wish to pass the current through the brain of a sensitive person, or some equally delicate work. I don't depend on it even in the most delicate operations." Dr. ——, Chicago: "I do not use a galvanometer constantly. I never saw one that was entirely satisfactory. I should not use one constantly if I had a perfect one, however, because they in no way assist me in making my applications further than they demonstrate to me the condition of the battery. In small operations, I find that currents of like strength, on different days and under different conditions of the atmosphere, different conditions of the parts to which the electrodes are applied, differ so much in their effects, that I have never been able to get any great good from knowing just how much electricity accomplished the given results." Dr. ——, St. Paul, Minn.: "I have a galvanometer (simply a magnetic needle surrounded by a coil of fine insulated wire), but I never use it. I depend on myself. The electrodes applied to the tongue and sides of the face is an exceedingly sensitive galvanometer, and one that never gets out of order. The time when a galvanometer would be of most value is when the current is applied to the head. But, as I said, even in those cases I am my own galvanometer."

The first of these gentlemen has been, by his own admission, negligent in this matter. The others are mistaken. The source of their mistake is, I believe, in their failure to appreciate for what purposes the galvanometer is to be clinically used, and the advantages to be thus gained. I venture the prediction that a year or two hence, if asked the same questions, their replies would be more uniform, and in substance as follows: "In private office practice I always use a galvanometer when I use the constant current, for the purpose of knowing at each and every application how much current is passing through the patient's body; in other words, what current strength I am using." This is the reply to the readers' questions received from the chairman of the committee on electrical dosage that reported at the last meeting of the American Neurological Association (*St. Louis Courier of Medicine*, October, 1886, page 325).

Stated Meeting, February 12, 1887.

THE PRESIDENT IN THE CHAIR.

DR. T. F. PREWITT presented a

PATHOLOGICAL SPECIMEN FROM A KNEE-JOINT.

It was first located below the patella, later at the left side of the joint. At first it caused little annoyance, afterwards a great deal. It was removed under antiseptic precautions. Before removal the body seemed to be but half its actual size, because only half of it could be felt through the tissues.

DR. PREWITT also presented a

COMPOUND COMMINUTED FRACTURE OF BOTH BONES OF THE LEG.

It was taken from a man who had fallen sixty feet with a falling scaffolding. The accident occurred in a brewery in East St. Louis, where ammonia is used. The pipes broke and the gas was inhaled by the patient, so that the lungs were much irritated. This

was the cause of some fever, and it was difficult to say how much was due to this and how much to the injury of the leg. The physician who first saw the case removed a great many pieces of bone; found some hæmorrhage, which he succeeded in stopping; tried to find the bleeding vessel, but failing, put the limb in plaster. About four days afterwards bleeding began. He opened the wound and attempted to stop it with styptics; got it controlled, but the hæmorrhage recurred, the patient losing much blood. He was brought to St. Louis and put in St. John's Hospital, about ten days afterwards. The wound was full of pus burrowing upwards and downwards in the the leg. I cleaned the wound to determine where bleeding came from. I was called the following morning, to find that the patient had lost a considerable amount of blood. I was satisfied that the only alternative was amputation. I had supposed that it was the posterior tibial artery bleeding, but it was the anterior. In it is an opening 5 lines in length and 3 lines in width. This is where the bleeding came from. The hole in the artery is not the result of sloughing, it is a part of the original injury. There has been a good deal of fever before and since the operation; as high as 102.8° F. The wound was in a septic condition. It was not prudent to make flaps. I made a circular amputation and left it freely open. In the last three days his temp. has been 99.8°, and I think he is in a better condition.

Dr. Meisenbach asked what form of styptic was used by the physician?

Dr. Prewitt said he thought it was Monsell's solution, or the chloride of iron.

Dr. Pollak asked as to the condition of the lungs.

Dr. Prewitt: He had a cough and soreness about the lungs, but I have found no pneumonia. He can hardly speak above a whisper.

Dr. Dean, referring to the unfinished discussion on Dr. Fry's paper at the last meeting, would like to answer Dr. Engelmann's remarks of that evening in full, but the gentleman is not present. I understand the paper to say, "With the galvanometer we cannot measure the dose. It takes no account of the density." Then follow the experiments, first that with the two large, equal-sized electrodes, causing little feeling on the part of the subject, and secondly with one of the electrodes small, the result being a tingling of the skin under it, a less number of milliampères by the galvanometer, a less quantity of electricity and greater density.

The density in any part of a given circuit and current is inversely proportional to the sectional area of that part, and nowhere in the circuit can it be greater than in the smallest part of that circuit. The number of milliampères also of current passing through a circuit can be no greater than passes through that part of the circuit furnishing the greatest resistance. That the resistance is not mainly in the smaller sponge electrodes may be shown by applying first the large sponges, secondly the large and small sponges, directly to each other, without the intervening part of the subject, when no such disparity will be shown by the galvanometer, making due allowance for imperfect coaptation of the irregular sponge electrodes. The resistance of the circuit is mainly in the epidermis of the skin. It is the chief resistance of the body, the aggregate resistance of which is said to be more than twice that of the Atlantic cable. Increase the area of the skin under the electrode, and you decrease the resistance of the circuit; especially so, as the ducts of the sebaceous glands and of the sweat glands are better conductors than the horny epidermis. The resistance will vary if the small electrodes be applied to different parts of the surface previously covered by the large electrodes. The number of milliampères shown on the dial of the properly calibrated galvanometer will accurately indicate the current strength. Time must be considered to know the number of units of quantity administered. The resistance can be measured by the rheostat. The density of the current at the entrance of, and exit from, the skin, may be estimated from the areas of those parts of the skin covered by the electrodes. Cut the patient out of the circuit, after having noted the number of milliampères, switch in a resistance equal to that of the patient, and then apply the electrodes directly to each other, and the galvanometric deflection will be the same as with the patient in circuit, showing again that the main resistance was in the skin or person, and not in the electrodes. Of course, the chemical, physiological, physical, or therapeutical effects of electricity require taking many things into consideration. If the paper intends this, as I think its general tenor nearly proves, then I would agree with it if it stated instead: "With the galvanometer only, we cannot measure the therapeutical dose of electricity." The like is true of other dosage. With the apothecary scales only, we cannot measure the therapeutical dose. The scales do measure the actual dose of any given ingredient, and that is all that is expected of them. One or three minims of sulphuric acid, weighed or measured, are a definite quantity. If given pure, the effects will be quite different from what they would be if given diluted to 10 or 30 minims, as in the pharmacopœial diluted sulphuric acid; and then the effects will be different if this dose is largely diluted with water, and taken at the back of the mouth through a glass tube; and even then many things are to be taken into account, and cannot be fully followed, as diffusion, changes in the body, etc. We cannot send it to this or that organ or part with any definiteness. (Even in preparing the pharmacopœial dilution, it is essential to add the acid slowly to the water, and not to pour the mass of water upon the acid.)

I agree with the paper, that the mere possession and use of a galvanometer are not all of electrotherapeutics, however essential the use. Every discoverable factor must be known and used—no more so, however, than in other departments. The mere possession of a microscope, and looking down through its tube, unravel or reveal very little of the microscopic world.

Dr. Fry said he understood the point made by Dr. Dean. But in dosage the skin must be taken into account, the physical as well as the physiological effects have to do with therapeutic results. With

strong currents he had often seen neuralgias, sciatica, for instance, benefited. The current was often strong enough to blister some. He considered the good results in these cases very largely due to the physical effects. Probably the nerve was traversed by the current, producing physiological effects that helped also. He thought that Dr. Dean and he agreed. The density on the skin is estimated by the size of the electrode. This, of course, can only be done when we know the quantity, which is shown to us by the galvanometer, it being an essential means of estimating density as well as the size of the electrode.

Last Saturday evening Dr. Dean had called attention to a technical inaccuracy in the paper, in that the ampère is said to be the unit of quantity. The coulomb is the unit of quantity. An ampère is a current of one coulomb per second. The ampère, therefore, includes the coulomb. Both of these units were embraced in the old term Weber, which is now going out of use. The error had been made inadvertently in trying to use language as free from technicalities as possible.

In reply to Dr. Dean's question as to where the increased resistance was when a small was substituted for a large electrode, he said to a slight extent in the smaller electrode, but principally in the skin. We use large electrodes to overcome the resistance of the skin. Professor Stone, an English experimenter, believed this resistance could be reduced to *nil* by using very large lead electrodes, moistened with salt water.

To a question by Dr. Hurlbert, if he used the term density in the same sense as potential? Dr. Fry replied in the negative, and showed by a diagram that potential referred to the electric-level.

Dr. Hulbert thought Dr. Fry had demonstrated that it is a necessity that we use the galvanometer in the accurate application of electricity. He understood the term potential to mean the power the current has of accomplishing a certain work; the power of overcoming resistance. This term conveniently conveys to our minds a clearer idea of the effects of electricity physiologically.

Dr. Dean: Potential represents the degree to which a body is electrified. A difference of potential is a difference in electrical-level. Back of that is the electro-motive force at work within the cell that creates and keeps up the difference of potential. Work does not include the element of time. Power includes the work and time or rate. The term "tension" is dropped for potential. The term strength (of current) is supplanting the term "intensity" (of current), which is a bad imitation or translation of the French *intensité*, which, in electricity as in music, means strength.

Dr. Lee mentioned the fact that bichromate of soda was much better than bichromate of potash for use in making battery-fluid.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 26, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Thomas S. G. Morton read a paper on

ABDOMINAL SECTION FOR TRAUMATISM, WITH REPORTS OF FIVE CASES.

(See page 225).

Dr. Charles B. Nancrede said: I understood Dr. Morton to say, that the case of suture of the intestines for ball wound which he reported was the first so treated in Philadelphia. He is mistaken, for I operated on a case of gunshot wound of the abdomen some seven months ago, and reported it to the Academy of Surgery three months ago. I should like to compliment the Doctor on the immense amount of labor evidenced by his paper. I think this is a timely subject for discussion. Some three months ago I had the privilege of taking part, by special invitation, in a discussion on gunshot wounds of the small intestine, which took place in New York; and was participated in by most of those who had operated up to that time. The conclusion arrived at was that all penetrating ball wounds of the abdominal cavity demand at least an exploratory operation, and if any wound of a viscus be found its repair should be attempted. I should like to enter a protest against the evident tendency to advise the opening the abdominal cavity by any practitioner in every ball wound. Where a large tumor has been removed the abdominal walls are lax, and there is plenty of room for manipulation. In laparotomy for gunshot wounds or other injuries, the difficulties are ten-fold. You have to operate through a tight and narrow opening. In prolonged operations there is often difficulty from distention of the intestines. The difficulties in finding the wound are sometimes exceedingly great, so much so that if I had a ball wound in the abdominal cavity, unless I could be operated on by one who was in the habit of doing abdominal operations, I should rather trust to the old let-alone plan. I have seen undoubted penetrating ball wounds of the abdomen recover.

Let me say a few words about my own case which, I think, shows the important point, although I could not secure a post-mortem, that peritonitis is not the only thing we should dread. I saw the boy six hours after he had been shot. The wound was a little to the left and above the umbilicus. He vomited blood one hour and a half after admission, although the operation showed that both the anterior and posterior walls of the stomach had been perforated. I determined that the wound was a penetrating one and made an incision in the median line; and I would warn any against enlarging the existing wound, if not in the median line. I found a wound of the anterior wall of the stomach which I closed with fine silk, using a fine sewing needle. Then I found a wound in the anterior wall of the duodenum which I sutured. I next looked for and found a wound of the posterior wall of the stomach. A

large ragged wound in the posterior wall of the duodenum was also discovered. Examination from the stomach down almost to the ileo-cæcal valve revealed no other wound. A careful toilet of the peritoneum was made and the wound closed. The boy did well for forty-eight hours and never presented the least symptom of peritonitis. When peritonitis comes on suddenly there may be a profound condition of shock which will not admit of rise of temperature, rigidity of the abdominal muscles, flexion of the limbs, upon the pelvis, pain, or any of the usual symptoms, but this is not the case in slowly developing peritonitis. The boy died on the third day with a series of convulsions with very high temperature. I believe that he died of sapræmia, due to the absorption of ptomaines. The cold water coil, which was used almost from the outset in both of the successful cases of Bull, of New York, was not used, and I think more opium was given than was wise. We have long been taught to give opium in full doses in traumatic peritonitis, but I believe that many cases are killed by this treatment. When the initial symptoms are marked by collapse, low temperature, rapid, feeble pulse, and clammy skin, if you give large doses of opium simply to ward of the expected inflammation, you will probably kill the patient. If you give moderate doses of morphia with large doses of atropia, you will possibly rally the patient and carry him over the shock stage. I think that large doses of opium should not be given in peritonitis unless guarded by atropia. It should be given by hypodermic injection, for you do not know how much will be absorbed from the stomach. At the end of a peritonitis where, from the respiratory centres becoming involved and from interference with the action of the diaphragm by tympany, hypostatic congestion of the lungs is taking place, persistence in the use of large doses of opium will kill the patient. If the opium is reduced to a minimum and given with large doses of atropia, or atropia alone is exhibited you will sometimes tide the patient over.

I think we should offer a word of warning against the tendency to operate on every case of abdominal wound without proper precautions. It should be done by a skilled hand. Not every case is fitted for it. The condition of the patient should be carefully considered before such an operation is attempted, and I hope the Society will be careful how it endorses an operation of this kind as the *rule* for penetrating wounds without further light upon the subject.

Dr. S. S. Cohen said: Dr. Morton has spoken of the injection of hot water into the abdominal cavity for the purpose of restoring the pulse in cases of severe shock and collapse. It may be interesting to mention that Dr. Benjamin Ward Richardson records successes following injection of hot milk into the abdominal cavity for the purpose of restoring patients in the collapse of cholera. The same measure has been used successfully by others. Dr. Morton also stated that he knew of no case in which poisoning with boric acid had occurred. Such a case has been reported in the *Medical News*, some two years ago, by Dr. Brose, of Indiana.

Dr. G. G. Davis said: We have been taught that penetrating wounds of the peritoneum are not to be probed. The author has mentioned this as one of the means of diagnosis. If other diagnostic points are present, probing is not necessary; still, I think it is justifiable to use the probe if it is done antiseptically. The time of probing was not touched upon. This, I think, is a very important point. When called to see a man who has been shot in the abdomen or any other part of the body, the question arises whether or not it is justifiable to probe the wound at once. I believe that it is not; unless certain precautions are taken and unless the surgeon is prepared to follow up his examination, if necessary, by operation. If there is hæmorrhage it requires attention. Outside of that I can conceive of no circumstance which will require immediate manipulation of the wound. The examination should be deferred until the patient is brought to the hospital or to his home, and the examination made once for all, at the time when the surgeon is prepared to go on with the operation, if one is necessary. The indiscriminate examination of Garfield's wound was severely criticised by Esmarch, and he had good grounds for his criticism. I have not seen many cases of gunshot wound, but I can recall three cases in which the abdomen was involved. In none of these was any operation performed, and they all speedily died. If the operation is to be done, it should be done early. The cases which I have seen remained in a comparatively good condition for a few hours, but toward the end of the first or second day many of them will die, particularly if the wound is a large one. They seem simply to sink away.

As regards the use of hot water injected into the abdomen, a less radical method is the injection of the hot water into the rectum, which is frequently used, and which I employed at least six years ago. A temperature of 108° to 110° will be found comfortable.

Dr. Morton: In regard to Dr. Nancrede's remarks, they are practically covered by what I have already said. The question of what cases should be operated upon, and by whom, is still under judgment. It would seem to be the judgment of the majority that all cases of penetrating wounds should be opened. The probe would only be used where you were prepared to operate if necessary. In many cases the ordinary signs of peritonitis are perfectly worthless. The case of ruptured intestine which died presented no apparent symptom of peritonitis.

In those cases where intraperitoneal injections have been made in cholera, it has been on account of the empty condition of the blood-vessels. Here it is commended for the treatment of shock, pure and simple. It is simply the application of heat. The use of hot enemata has long been practised in the Pennsylvania Hospital, but it is not so satisfactory as large hot water irrigations at a temperature of 100° to 110°.

With regard to the question of mortality, the table shows the total mortality of cases reported. It is probable that the real mortality is even larger. Every successful case has doubtless been put on record, while it is likely that many unsuccessful

cases have not been published. The table also includes the first cases operated upon, and I think that the next three years will show a great change in the mortality. It will probably get to and remain at about 50 per cent. Many of these operations were performed without the knowledge of abdominal surgery which we now have, and many of those who operated may have had no experience with abdominal work.

Most of these cases of traumatism involve the question of murder. If we save 30 per cent., perhaps fifteen of these will be murder cases, and on the life of each of these patients would depend that of another person, so that we should really save forty-five lives.

STATE MEDICINE.

MEDICAL LEGISLATION IN ARKANSAS.

Resolutions of the Izard County Medical Society.

We have carefully examined the existing Law to Regulate the Practice of Medicine and Surgery in the State of Arkansas; and, inasmuch as it ostensibly purports to protect the medical profession and the general public from incompetent physicians, and unscrupulous charlatans and quacks, we desire to say, with due respect to the makers of the law, that it is a total failure in our opinion for the following reasons:

First. The law directs that all persons who have been in the practice of medicine for a period of five years previous to the passage of the law, be allowed to continue in the practice, provided their names be registered in the clerk's office in their respective counties. By this means all incompetent practitioners of *five years'* standing were allowed to continue under the protection of the laws of the State.

Second. The law provides that the County Judge of each county appoint a board of three physicians in his county, which shall constitute an Examining Board for all who might apply for license to practice medicine; and, which shall, at its option, grant license to any applicant. The County Judge was, in some instances, incompetent to appoint a board intelligibly; and in some instances these officials selected their boards through favoritism rather than from merit. In this way incompetent boards have been appointed. These incompetent boards more frequently make the paltry fee, than merit, the requisite qualifications for license.

Third. The law requires that all persons who have been in the practice of medicine for a less time than five years go before the board of his own (or some other) county, and submit to an examination, and pay said board a fee of six dollars before being allowed to register his name as competent to practice medicine. Here the law is *unfair* and *unjust;* it compels the *intelligent* and *conscientious* physician to submit to the indignity in some instances of being examined by an incompetent and ignorant Examining Board; it compels young men who have spent their time and money to qualify themselves for intelligent physicians to submit to the same ordeals that the most ignorant must undergo.

Fourth. There are instances in which persons who could not get license to practice medicine in their *own* counties have gone to *other* counties and obtained license, and returned to their *own* counties to practice medicine. By this means we know of no failures to get license, even by the most ignorant applicant.

Fifth. The law instead of elevating the standard of intelligence and honesty in the medical profession, has a direct tendency as far as legislation can effect it, to lower its standard by legalizing quackery and ignorance, and by lowering honesty and intelligence to the same grade with dishonesty and ignorance, thereby tending to discourage young men from properly qualifying themselves, and inviting ignorant practitioners and unscrupulous quacks into our State from surrounding States, which have passed sensible laws to prevent that class from practicing within their borders.

Sixth. The general public, confiding in the intelligence and honesty of our Legislators, and knowing no criterion but experience, have in a great measure learned an expensive lesson, for it is the public which has received the principal evil results of this most unwise law.

Now, WHEREAS, we believe the above statements are facts—that the present law encourages and protects ignorance and quackery; that it invites the incompetent class of medical practitioners from other States; that it discourages our own young men; that it elevates ignorance and degrades intelligence to a common level, as far as lies within the reach of legislation to accomplish it; that it is deceptive to a confiding public; that it is, useless, unjust, and an insult to a conscientious and intelligent medical profession, and to an intelligent and confiding public; therefore, *Be it Resolved*,

First. That the medical profession is ancient, time-honored, coeval with civilization, and has ever been an essential factor in every advance made in the development of science and in the promotion of human happiness; and that those who are worthy members of the medical profession are engaged in a grand and a noble cause.

Second. That as the medical profession has for its object the health, well being and happiness of the human race; it needs no legal protection to perpetuate its existence or to promote its progress, but it is the public which is imposed upon by quackery, that needs legal protection.

Third. That we esteem the existing law a farce, a a fraud, and as unworthy a place on the Statutes of the great State of Arkansas, and we recommend that our next Legislature repeal it; and if it must have a law, that it enact one that will protect the *public* from the numerous ignorant pretenders who are now resting under the protection of the present law.

Fourth. That we will not serve on the County Board, nor will we accept a certificate from any County Board as sufficient evidence or authority as to any physician's qualification.

Fifth. That we respectfully submit these resolutions to the medical profession of the State of Arkansas, and ask it to give them its careful consid-

eration; and if they meet with the approval of the profession we ask the various Medical Societies in the State to join us in presenting these resolutions to the next Legislature.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

The Health of London—New Remedy for Whooping-Cough—Death of Mr. Thomas Ward Jeston.

Two interesting communications regarding the health of the city and the health of London at large respectively have recently been made public. The report regarding London and its health is contributed by Dr. Lewis Parkes, who writes on the death-rate of the metropolis at large. Here there is to be found cheering news for Londoners, in the assertion that during the last forty years the death-rate has steadily diminished. Dr. Parkes's figures prove this clearly. The average death-rate per 1,000 living persons for the following periods of five years shows in each case a gratifying diminution of mortality. From 1846–1850, the death-rate as above defined was 25.4; from 1851–55 it was 24.7; from 1856–60, 22.5; from 1861–5, 24.5; from 1866–70, 24.3; from 1871–75, 22.9; from 1876–80, 22.2, and from 1881–85, 20.6. Dr. Parkes points out a significant fact in connection with the vital statistics of London, when he notes that since 1876 the birth-rate has also steadily diminished. In 1876 the birth-rate was 36.5 per 1,000, in 1885 it was 32.6. This is the lowest birth rate recorded since 1850, when it was 32.05. The result of this fall in the birth-rate, curiously enough, as Dr. Parkes points out, will be to increase the death rate. In other words, if the death-rate remains steady, as regards lowering influences and actual disease, the limitation of populace through a small birth-rate will raise the mortality returns, this result being due simply to the altered distribution of age which the population would necessarily exhibit. Facts like these afford food for thought when the constant cry of overcrowding rings in our ears. It is a possibility of the future that the adjustment of population in great centres may be wrought out on some such basis as Dr. Parkes indicates. We shall be in the position of a population which, while not excessively increasing in numbers, exhibits a tendency to longer life on the parts of its units. Grave questions of political and social economy may wait on the striking of such a balance between increase and decrease, but as the matter stands, it would appear that the character London has acquired for health is founded on a perfectly correct appreciation of its sanitary merits. Probably the area of London is so wide and so varied in its character that it presents localities for habitation suitable to many types of life and constitution. Be this as it may, the facts justify the hope that our death rate may be still further and speedily reduced.

The communication concerning the City of London is from the pen of Dr. I. Ebbetts, and deals with the sanitary state of the City proper. He reminds his readers that in more than one sense the City is admirably engineered, namely in respect of its roadways, its scavenging and its sewers. The sewers extend about forty miles in length. They have to convey the sewage of several outlying districts as well as the sewage of the City proper. This duty these great conduits discharge in a satisfactory fashion, being kept in due order by a staff of an inspector, a foreman, and some eighteen men. As regards the public carriage of waste, the City of London has little to complain of. Mr. Ebbett's protest is reserved for the private drainage arrangements of the City. The perfection of house drains is admitted the backbone of all sound sanitation, as it is the chief element in the preservation of domestic health. Elsewhere there are by-laws—the model by-laws of the Local Government Board—which regulates the fittings of house drains, and which provide especially for an air trap between the house drains and the sewer, as well as for the erection of a ventilating pipe from the highest level of the house drain itself. Again such by-laws forbid the use of the pan-closet, as well as that equally noxious appliance the D trap. So far such by-laws effect a good purpose in pointing the way to better things, and in most districts their laws are adopted. However, in London City there are practically no regulations regarding the method in which house drains shall be constructed. The commissioners of sewers are possibly appalled by the magnitude of the changes which their operation would make. Mr. Ebbetts does not advance his charges without knowing his facts. People are accustomed to speak disparingly of Parisian sanitation, to lament the odors of the sewers, but even in Paris they enforce regulations concerning drains and soil pipes, and insist on the ventilation of the drains. In the City of London neither of these provisions appears to be regarded as necessary for the health of the inhabitants. When a house is about to be constructed in the City, the builder submits a plan of the basement, showing the positions of the various rain and soil pipes, and other sanitary appliances. The commissioner's engineer settles the size of the drain which is to be laid, and the commissioners, at the owner's expense, construct the drain from the sewer to the front wall of the house. There need be no air shaft or efficient trapping. He may join or construct his pipes precisely as he thinks fit, and in a sanitary sense the builder is, within the walls of a city tenement, monarch of all he surveys. There is an iron flap, it is true, fixed, at the owner's expense, at the junction of the city house-drain and the sewer. This flap opening outwards only, is believed to prevent the access of rats and the ingress of sewer air, but as Mr. Ebbetts shows, sewer gas is far too insidious a visitor to our houses to be kept out by an iron flap. Mr. Ebbetts asserts that there is a gross neglect of the common precautions of the time against disease in the city, and shows that abutting on the city district, without drain regulations at all, there are districts regulated by at least fairly efficient by-laws.

New remedies for whooping-cough continue to

crop up. Quite recently Dr. Suckling thinks he has found a specific for pertussis in carbolic acid—or nearly so. He says he has used the glycerine of carbolic acid with great success among his out-patients at the Children's Hospital. Half a minim of the glycerine of carbolic acid given in peppermint water is sufficient for a child a year old.

Mr. Thomas Ward Jeston, J. P., the popular and well-known founder of the Reading Pathological Society, has just died at an advanced age. In early life he was an army surgeon, in the 36th regiment of foot, throughout the Peninsular war, until quite recently he took great interest in the working of the British Medical Association. G. O. M.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Social and Physiological Inequality—New York Water Supply—Abuse of Medical Charities—Manhattan Eye and Ear Hospital—Medical Society of the State of New York.

At the February meeting of the Section on Public Health, Hygiene and State Medicine of the Academy, Dr. Henry D. Chapin read a valuable paper on "Social and Physiological Inequality," in the course of which he said: The question of the hour is the social problem, and the new science of sociology overshadows all others. The air is full of the angry clamor raised by different classes, all arguing from the standpoint of their own interests. It is evident that in the present state of society many are hopelessly worsted in the effort to gain, not a competency, but a moderate sustenance. The mutterings of discontent heard on all sides have their basis largely in the belief that the fault lies in a friction resulting from an artificial social order.

It is a favorite corollary of our political system that all men are born equal. In fact, there is no such thing as equality. Two stupendous factors are present in all life, physical as well as mental, viz.: heredity and environment. These all controlling influences are present for good or evil in varying proportions in different lives. With the generation of life, heredity, whose mysterious effects we must recognize without understanding them, has done its best or worst for the beginning of existence; its potency has been in the past acting, perhaps, through long reaches of time. With commencing life comes in the new element of environment, as the complement of heredity to enhance the evil trait, or perhaps obliterate it—too often to sow the seeds of physical and mental weakness in a constitution that received a healthy start.

To insure correct environment and habit, particularly in the early years of life, is of vital importance to the well-being and efficiency of the individual. This, unfortunately, is not, and in many cases cannot be, done. Hence the fearfully unequal physical, mental and moral equipment of mankind, that allows the minority to have too much, the majority too little of the world's necessities and comforts. Such problems as how to conserve and prolong life, how to lower the death-rate in children, how to produce good hereditary development, how to strengthen the bodies and minds and enlarge the spiritual bounds of men—all these and many others are included in a conception of this subject.

No altered laws will compensate for defective knowledge or will power in the regulation of human affairs. Two leading theories have been advanced to reorganize society, socialism and communism. As human society is constituted, these are idle fancies. Legislators cannot prevent the unerring economic law due to fundamental differences in men's moral and intellectual development. Modern civilization is adapted to make the sharp sharper and the dull duller, or, in other words, conduces to condensation of wealth and diffusion of poverty. All artificial adjustments only complicate existing troubles in leaving untouched the real causes of the troubles. The lazy and criminal classes are the inevitable product of our complex civilization. They are developed by laws which it is the duty of good people to find out and obviate. It is the business of government to prevent or mitigate any environment that all experience shows will produce physical, mental and moral deterioration.

Dr. Chapin spoke particularly of the tenement-house system and its evils, and after the paper had been discussed by Drs. Spitzka, Janes, and Stephen Smith, Bishop Huntington, Mr. Charles F. Wingate, the sanitary engineer, and others, a resolution was adopted requesting the Academy of Medicine to use its influence to secure the passage of the act now before the State Legislature enforcing the registration of tenement-house owners at the Health Department, and other regulations for the welfare of the tenement-house population.

In his report to the Mayor of the work of the Department of Public Works for 1886 the Commissioner, Gen. Newton, states that during the year 5,270,000,000 gallons of water were drawn from the storage reservoirs and lakes in the Croton Basin for the water supply through the Croton aqueduct, and 2,670,000,000 gallons from the Bronx River reservoirs for the supply through the Bronx River conduit. There are now 604 miles of water mains and 14,582 water meters in use in the city. The amount of revenue from the water service in 1886 was $2,354,121; being an increase of $223,445 over the amount collected in 1885.

At a meeting of the Aqueduct Commission held February 7, it was at last definitely decided to build the great Quaker Bridge Dam, which has been so long in contemplation. It is to be 277 feet high from the bottom of the foundation and 1,500 feet long, and the estimated cost of the dam and its appurtenances is $4,027,600. The whole project, including the purchase of 4,000 acres of land, will involve an estimated expenditure of $6,743,100. The report in favor of the construction of the dam, which was signed by six of the seven Aqueduct Commissioners, was presented by Mr. Barnes, chairman of the committee on construction, and in it reference was made to the fact that some of the best hydraulic engineers

of modern times have indorsed the Quaker Bridge Dam project, and that the opposition to its construction came from only a few of the many taxpayers of the city, and from some engineers who were not usually considered of the highest rank. Gen. Newton reinforced the majority report by a supplemental statement favoring the project as the best one for obtaining a requisite supply of water for the increasing population of the city. In a minority report which was signed alone by Mr. Spencer, President of the Commission, it was claimed that the dam, besides entailing an expense of over $10,000,000, would enclose an enormous amount of water which could not be distributed through the aqueduct in a thoroughly pure condition. In answer to this sanitary point against the construction of the dam, a letter was read from Prof. Charles F. Chandler, for many years President of the Metropolitan Board of Health, commending the project, and denying that the water drained from the lake formed by the dam would be impure.

Including the capacity of the Muscoot reservoir, 2,500,000,000 gallons, and the Croton reservoir, 1,500,000,000 gallons, the new dam will make a reservoir of 38,377,935,000 gallons. When completed it will constitute the most stupendous piece of engineering of the kind ever attempted in the history of the world, and the great American Eagle will once more have an opportunity of flapping his wings over the diminished heads of the effete monarchies of Europe and all the rest of creation.

In the recently published seventeenth annual report of the Manhattan Eye and Ear Hospital, which now occupies the beautiful new building erected for it on Park Avenue, near the Grand Central Depot, are to be found some facts of special interest. From it we learn that constant and vigilant efforts are to be made to exclude from the benefits of the hospital all who are not, by reason of poverty, deserving of gratuitous care. A registrar occupies a desk near the door, and asks the following, among other searching questions, of every applicant for treatment:

"How much money have you in savings or other bank?"

"How many persons are dependent on you for support?"

"How much rent do you pay?"

"Can you afford to pay anything for medical advice?"

During the year just past 259 applicants were rejected after such inquiries, having acknowledged that they were able to pay. Moreover, after such inquiries have been made and satisfactorily answered, the beneficiaries or their friends are asked to contribute what they can to the treasury of the hospital; and it is of interest to learn that during the past year there was contributed by the acknowledged poor beneficiaries the sum of $6,614. All the money thus received was expended for the benefit of the hospital and dispensary patients.

The report contains a diâgram which gives in graphic form a digest of the 48,509 consecutive eye cases treated in the institution. In this it is noticed that the first two columns are much larger than any others. The first and largest column represents the relative proportion of diseases of the conjunctiva, and the second, the relative proportion of diseases of the cornea; and together the two columns include 51.5 of the total number of cases treated. The forceful value of these facts, the report goes on to say, will be better apprehended if we remember that the majority of the affections of the conjunctiva are either communicable or preventable, or both; as is true also, within somewhat more restricted limits, of the diseases of the cornea. Indeed, very many of the diseases indicated by the two columns under consideration are filth diseases, exterminable by proper hygienic precautions. Thousands of victims of communicable, preventable eye diseases have been found in times past in the residential schools and asylums of New York and its vicinity, as well as in other large centres of population, and have gone to make up the vast *clientele* of such institutions as the Manhattan Hospital. The medical board of this institution is a unit in believing that the faithful administration of the law entitled "An Act for the Better Preservation of the Health of Children in Institutions," which was enacted by the New York Legislature last year, will most sensibly lessen the prevalence of these diseases, which are so fatal to vision and so productive of chronic and irreparable pauperism. In this connection the Board of Managers feel constrained to call attention to the fact, however humiliating it may be, that so far as the statistics of the Manhattan Hospital go, American pauperism is relatively rapidly increasing; since of the 9,179 patients treated during the year, 5,586 are recorded as natives of the United States.

The eighty-first annual meeting of the Medical Society of the State of New York was held in Albany the first week in February, and was largely attended. The Merrit H. Cash prize was awarded to Dr. A. N. Bell, of Brooklyn, editor of *The Sanitarian*, for his essay on "Physiological Conditions and Sanitary Requirements of School Life and School-houses." The subject of the President's annual address was "The Achievements in Science and Letters of Men who have been Connected with the Medical Profession," and was delivered by Dr. Ely in the Assembly Chamber at the Capitol. Dr. Alfred L. Loomis, of this city, was chosen President, and Dr. A. M. Phelps, of Chateaugay, Vice-President, for the ensuing year.

"THE ETIOLOGY AND CURE OF ASTHMA."

Dear Sir:—In the issue of THE JOURNAL for January 29, appeared a short article under the above heading by Dr. Kuh, which is liable to mislead those not familiar with the subject.

1. With reference to the parts which the turbinated bodies bear in the etiology of asthma, the author attributes the discovery to Wilhelm Hack, and inveighs against specialists because they do not give him the credit. The fact is, that the attention of the profession was first directed to this matter by a paper read before the American Laryngological Associa-

tion in May, 1881, by Dr. William H. Daly, of Pittsburg.

Hack's articles on the subject did not appear until many months later in the *Berliner Klin. Wochenschrift*, of 1882, and in his monograph, 1883; therefore, Hack was not the discoverer, and would only ask for the honor of a place among many other faithful workers in this field.

2. In the article referred to, it is claimed that nearly all cases of asthma are the result of disease in the nasal cavities. On the contrary all laryngologists know that only a small percentage of them are so caused.

3 It is also claimed that cauterization of the nasal mucous membrane will cure the majority of cases of asthma; whereas experience shows that it will benefit only a small percentage of them. With reference to the after effects of cauterization some discussion followed the reading of the paper, but it was not sufficient to make the matter clear. By experience we have found that the amount of discomfort following the operation is dependent on the idiosynerasies of the patient, the present condition of his system as indicated by the rapidity with which wounds heal, his subsequent exposure, and the extent of the burn.

There are some individuals, who from inexplicable causes, suffer pain or develop fever from wounds which would not annoy the majority of mankind, and these are likely to have much discomfort after cauterization.

Under certain, not well-defined conditions, small wounds heal very slowly on some in whom at other times cicitrization would be rapid. In such conditions a small burn which would ordinarily cause no inconvenience may be a long time in healing. Patients who are exposed after the cauterization sometimes, in popular parlance, "take a cold," and as a result a wound which would otherwise have healed rapidly may be a long time in closing, and inflammation may extend from it to neighboring parts.

In order to guard against these unpleasant results, care must be exercised not to cauterize too much tissue at one sitting. I have never known serious complications, or great discomfort to follow a single linear cauterization the whole length of the turbinated body, or a superficial cauterization nearly as large as a nickel; therefore wounds of this size may be made when the patient is pressed for time, or when he prefers some discomfort to a second visit to the doctor's office. In no case, however, should the cauterization be more extensive, because of the danger of facial erysipelas, and other unpleasant results. Whenever time and circumstances permit it will be found better to make a linear cauterization of not more than one half the length of the turbinated body, or superficial cauterizations not more than an inch in diameter. If these precautions are followed, the author's statement that there is no noteworthy complication after the operation will be fully verified. Truly yours,

E. FLETCHER INGALS, M.D.

64 State St., Chicago, Feb. 16, 1887.

MISCELLANEOUS.

NECROLOGICAL.—Dr. B. F. Hardy died in San Francisco, November 22, 1886, of diabetes. He was a physician of more than ordinary education and professional skill, and has been a member of the American Medical Association since 1871. He leaves a wife and two little daughters to mourn his early departure. But of him could be said, "He followed virtue as his truest guide; he lived as a Christian, and as a Christian died."

DIED—January 9, 1887, in Milton, Ind., Dr. Joel Pennington, aged 88 years. At the time of his death he was the oldest practicing physician in Wayne County. He became a member of the American Medical Association in 1850. Through all his long professional life he enjoyed the confidence and esteem of both the community and the members of the profession who knew him.

EMIN PASHA, for whose relief Mr. Henry M. Stanley recently left England for Equatorial Africa, is no less a man than the celebrated Dr. Hermann Schnitzler, better known as Emin Bey, and Surgeon-General of the Equatorial Provinces under Chinese Gordon. He succeeded Gordon in the governorship, and has been engaged in bringing a barbarous region into a state of civilization. He has now been shut off from the outer world for three years by the barbarians to the north of him. He is a great linguist, and in addition to his medical learning has an intimate acquaintance with geology, botany, meteorology, anthropology, geography, etc. The little leisure which he has had for the past five years has been devoted to the sick.

THE SPRINGFIELD, MASS., CITY HOSPITAL has had bequeathed to it, in the will of the late Mr. Wm. Merrick, between $75,000 and $100,000.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 12, 1887, TO FEBRUARY 18, 1887.

Lt.-Col. Jos. R. Smith, Surgeon, detailed, in addition to his present duties, as President of the Army Medical Board in New York City, N. Y. S. O. 38, A. G. O., Feb. 15, 1887.

Major W. S. Tremaine, Surgeon, sick leave of absence still further extended four months on surgeon's certificate of disability. S. O. 39, A. G. O., Feb. 16, 1887.

Capt. Geo. McCreery, Asst. Surgeon, granted leave of absence for one month, with permission to apply for one month's extension. S. O. 35, A. G. O., Feb 11, 1887.

Capt. Arthur W. Taylor, Asst. Surgeon, relieved from duty at Camp Medicine Butte, Wyo., and ordered for duty at Ft. Laramie, Wyo. S. O. 14, Dept. Platte, Feb. 12, 1887.

Capt. M. C. Wyeth, Asst. Surgeon, ordered from Ft. Wayne, Mich., to Ft. Barrancas, Fla. S. O. 39, A. G. O., Feb. 16, 1887.

First Lieut. J. Wakeman, Asst. Surgeon, relieved from duty in Dept. Platte, to take effect on the expiration of his present leave of absence, and ordered for duty at Ft. Walla Walla, Wash. Ter. S. O. 36, A. G. O., Feb. 12, 1887.

First Lieut. Edward A. Morris, Asst. Surgeon, leave of absence extended twenty days. S. O. 35, A. G. O., Feb. 11, 1887.

First Lieut. H. S. T. Harris, Asst. Surgeon, ordered from Ft. Clark, Texas, to Ft. Ringgold, Texas. S. O. 16, Dept. Tex., Jan. 31, 1887.

THE CAUSE AND CURE OF INEBRIETY.

Delivered before The Institute of Social Science of New York, February 10, 1887.

BY T. D. CROTHERS, M.D.,

OF HARTFORD, CONN.

Approaching this subject from a scientific standpoint, it is essential to have some conception of its character and magnitude, before any clear idea of the causes and remedies can be obtained. The impulsiveness, degeneration, and insanity of inebriety are characteristics familiar to every one. The magnitude of inebriety no doubt exceeds all previous studies and conclusions. One of these estimates, which, in all probability, approximates to the truth, places the number of alcohol and opium inebriates in this country at 1 per cent. of all the population. This includes the secret drinkers and opium cases who are generally unknown, except to the family physician. With a population of 50,000,000, this would give an army of 500,000 inebriates. Inquiry in almost any direction, would seem to indicate that one inebriate to every hundred persons is not an over estimate. The mortality is very great, and is estimated at over 90 per cent. Thus, not more than one in every ten inebriates die of other disease, and the other nine die from the effects of spirits, either directly or indirectly.

The fact that inebriety is increasing, is conclusive from the fact of increased production and consumption of all kinds of spirits in this country; also the increased number of persons arrested for inebriety in the large towns and cities. These are not mere guesses or statements, but the most probable facts and best authenticated conclusions of to-day. It is clearly evident that a disorder so wide spread must have an equally wide range of causes, and many complex conditions which enter into its growth and development. It will also be apparent that a knowledge of these causes must come from a study of the history of a large number of cases. Such a study must record all the facts of heredity, of the early surroundings, training, growth, accidents, diseases, strains, drains, shocks, losses, climate, food, social and physical environment, and all the various influences which have entered into life. From a large number of such histories many of the principal causes will appear. Thus, from the records of one hundred inebriates, representing all classes, sixty will be found with defective brain and nerve organization from inheritance. Thirty or more of this number will have moderate or excessive drinking parents or grandparents. Twenty will have insane, epileptic, criminal, pauper, idiotic, and eccentric ancestry. Ten will have consumptive, rheumatic, and diseased parents. Of forty who have no prominent history of heredity, twenty-five will begin after attacks of severe disease or physical shock or injury; mental shocks or great brain perturbations, and other similar causes. In ten cases the inebriety can be traced to climatic states, to foods and occupation. In five cases no special causes can be determined; this is obviously the fault of the observer, which a better knowledge will remedy. In all these cases there is often a blending and union of causes; thus head injury and diseases with heredity are united. In another case, conditions of climate, food and occupation are prominent. Nutrient disorders, overwork and exhaustion, or mental strains and heredity, may all be found associated, and all active in the causation. A close examination will show how exact these causes are, and the laws which govern them. Thus, in direct heredity, moderate, excessive, or periodic drinking parents are always followed by inebriate children, either in the first or second generation.

The first generation will be either inebriates or rigid abstainers, and always have marks of defect of some kind.

The second generation will develop inebriety from the slightest exposure. Unless the stream of heredity is neutralized by a current of greater vigor, this generation will be found along the border line of insanity, manifesting many complex symptoms of mental defect.

In these cases some specific degeneration of the brain centres has been transmitted, with special tendency to use alcohols for relief, and low resisting power to all temptations of this kind. Many of these cases escape and never use alcohol, but they have marked defects of body and mind.

Many inebriates are found to have defective parentage, representing all degrees of insanity, eccentricity, and mental oddities; or criminals and paupers, with low intelligence, and defective characters; hysterical, ungovernable passions, and unbalanced organizations. Inebriety in the children of such characters is only another phase of degeneration. Here the drink-impulse springs up almost spontane-

ously from slightest causes; a physician's prescription, the excitement of contagion, etc.

Where the parents are consumptive, rheumatic or have some serious constitutional disorder, inebriety frequently appears in the children from most insignificant causes. In these cases a defective brain and nerve vigor exists, which seeks relief from any source at all hazards.

Another class of inebriates will develop the drink impulse after a head injury—where they are made unconscious by a blow or sunstroke; or where they have suffered from severe, protracted sickness, or sustained profound shock, either mental or physical. Fright, fear, joy, sorrow, falls of all kinds which produce sudden impressions on the organism, seems to lower the vigor, and call for relief from alcohol or or opium. Some change has taken place in the brain centres, and while alcohol and opium brings temporary relief, it hastens and increases the form of degeneration. In these cases the drink impulse may be pronounced from the first use of spirits, or it may grow up more or less rapidly and unconsciously to the victim. Of course every one subjected to such injuries do not become inebriates. Many recover without any entailment; others develop insanity, epilepsy, and various degrees of degeneration. What determining cause makes this difference is unknown.

Another class of inebriates are made so by states of climate, food, surroundings, and occupation. Thus the alternations of extreme heat and cold seem to be active causes of the drink impulse. Firemen, stokers, and others, on Southern steamers which sail from Northern ports, subject to the sudden changes from the frigid air of New York and Boston to the equator, generally become inebriates. A few years ago, Dr. Bowditch, of Boston, pointed out a drink belt, crossing the civilized world, in which spirits were used to great excess, on either side of which inebriety shaded down less and less, into comparative sobriety. In all probability climate is very active as a predisposing cause.

In a certain number of cases of inebriety, bad and innutritious food are the active causes. Thus, a child who has been underfed or overfed will have digestive disturbance and an active predisposition to find relief in some form of spirits. In adult life the same thing occurs; the starved ones and gourmands are prepared to become inebriates on the slightest exposure.

Surroundings and kinds of labor are often active causes of inebriety. This is illustrated in many ways and in almost every neighborhood in the country.

These are only the most general cases, and are combined with many and most diverse influences which develop and keep up inebriety.

Another fact appears from a study of these cases, which is somewhat startling: they all beg'n at a certain point, and pass on down the same road, and uniformly cross the same bridges, reaching the same destination. Of course there are halts, variations, and changes, but the main body of inebriates move along one progressive line, from stage to stage. The expert has only to find out where the case started, and where it is at present, to predict the future. It is here that the scientists realize that not far away, when these causes are known, inebriety will be as thoroughly prevented and stamped out as small-pox can be.

The limits of time prevent other than a mere mention of some of the great underlying causes dependent on the forces of civilization. Thus the brain strains and drains, incident to the rushing, grinding civilization of to-day; the struggle for position, wealth and power, and the effort to adapt ourselves to the new conditions and living which are constantly forcing themselves on us, are steady sources of exhaustion, and preparation of the ground for the growth of inebriety, insanity, and many allied diseases. The errors of birth, the errors of childhood, the errors of training, the errors of surroundings and occupation, all converge to cause a defective organism and unfit for living a healthy, temperate life.

While the increased culture and intelligence of the race drives out the coarser and more repulsive symptoms of inebriety, the mortality is increased, and alcohol is more used for its narcotic properties and to quiet pain. Inebriety is more concealed to-day, and is followed by more allied diseases, and is more maniacal, suicidal, and impulsive. Pneumonia, Bright's disease, heart disease, apoplexy, are some of the names given to the fatal cases of inebriety. From all exact study we find that the causes of inebriety are physical, and can be traced to clear, tangible forces. The further study in this direction establishes this fact beyond doubt, and reveals vast stretches of unknown causes and conditions entering into inebriety, awaiting some future discovery.

In the cure of inebriety there is probably more agitation and interest than ever before. The efforts of societies and parties, of the pulpit and rostrum, with the increasing books and papers from the press, have never been more active than to-day. Yet reports show that inebriety is increasing, and that more spirits are made and consumed every year.

All the temperance efforts and legal means for the cure and prevention of inebriety are based on the theory that it is a moral disorder which the victim can control at will, or a wicked habit that he can continue or put away at his own pleasure. This theory of inebriety is theoretical, and embodies the same error which follows every new advance of thought, namely, explaining all human action from some moral or theological standpoint. Thus the phenomenon of insanity was explained as a possession of the Devil, and the victims were supposed to enter into a compact with evil spirits, voluntarily. The remedy was severe punishment. Public attention was occupied for ages in persecuting and punishing the insane and epileptics on this theory of the causation. Law, religion, government, and public sentiment all failed in the cure and prevention by this means, and these diseases went on unchecked, simply because the real causes were unknown.

Inebriety is regarded in the same way as wickedness, and the same means are urged as a remedy. Over fifty thousand inebriates were sent to jail in 1886, and punished as willful and voluntary drunkards. Armies of moralists and temperance people

are pledging and praying the inebriate to stop drinking, and exercise his will, and be temperate and well again. Yet all such efforts fail, and often tend to increase the very condition which they seek to remedy. They fail because they are based on a false assumption of the causes, and not on any accurate study of the history or real condition of the patient. A new era is dawning for the inebriate. His diseased condition, and the need of special medical care in special surroundings, is a truth that is spreading slowly and surely in all directions. Not far away in the future inebriety will be regarded as small pox cases are now in every community. The inebriate will be forced to go into quarantine and be treated for his malady until he recovers. The delusion that he can stop at will because he says so, will pass away. Public sentiment will not permit the victim to grow into chronic stages; the army of moderate and periodic drinkers will be forced to disappear, and the saloons which they have supported will close in obedience to a higher law than any prohibition sentiment.

Public sentiment will realize that every inebriate is not only diseased, but dangerous to society, to himself, and all his surroundings, and demand legal guardianship and restriction of personal liberty until he recovers. When these poor victims realize that society will not tolerate their presence or allow them personal liberty in this state, they will seek help and aid before they reach extreme stages.

This is the teaching of all modern science—to check the disease at the beginning, to seize the poor waif on the street and the rich man's son, who are just at the beginning of inebriety, and force them into conditions of health and sobriety, to save the one from becoming a prey on society and a burden to the producer and tax-payer, and the other from destroying society and himself, and leaving a tide of misery and sorrow that will continue long after. When society shall realize and act on these facts, the great centres of pauperism and criminality will be broken up. This will be accomplished by the establishment of work-house hospitals, where the inebriate can be treated and restrained. Such places must be located in the country, removed from large cities and towns, and conducted on a military basis. They must have all the best appliances and remedial means to build up and restore the debilitated victim. They should be military training hospitals, where all the surroundings are under the exact care of the physician and every condition of life is regulated with steady uniformity. Besides the medicinal and hygienic treatment, there should be educational and industrial training, and each one should be employed, both in body and mind, every day. He should be placed in a condition for the best culture and building up of the entire man. Every defect of body and mind should be antagonized and remedied as far as possible. Each case should be an object of study to ascertain the real state and the means to strengthen and improve it. These hospitals should be built and conducted entirely from the license fund or the taxes on the sale of spirits. They should in a large measure, be self-supporting from the labor of the inmates, and independent of the tax-payers. These places would most naturally divide into three distinct grades. The first class of hospitals should be for recent cases, where the inmates can be committed by the courts, or voluntarily commit themselves for one or two years. The second class should receive chronic cases for longer terms of treatment—from one to three years. The third class should be for the incurables, or those who give no reasonable promise of restoration. The time should be from five to ten years and life. The latter class should be thoroughly organized into military habits of life and work, and kept in the best conditions of forced healthy living. Employment and mental occupation should be carried out literally as a stimulus to strengthen the body and mind. Where it was possible the rewards of his labor, beyond a sum to pay for care, should be turned over to his family and friends or held in trust for him. He should be encouraged to healthy work and living by all possible means and surroundings. The semi-chronic cases should be treated substantially the same way, only occupation and training of the mind and body should be more suited to the wants of each case. The amusements should also be of a sanitary character.

The recent cases should have the same exact discipline, filling the mind with new duties and new thoughts, and suited to build up the exhausted, overworked man, as well as the gourmand and underworked idler. All persons should pay for their care if possible, and, be required to render some service which would be credited on their bills. These hospitals should be literally quarantine stations, where the inebriate can be housed and protected and society saved from the losses following his career.

If ten thousand poor chronic inebriates could be taken from New York and placed in such hospitals, and made self supporting, who could estimate the gain to society, to morals, to the tax-payer, and to civilization? This can and will be done in the near future. If ten thousand semi-chronic cases of inebriety could be taken from New York and quarantined two or five years in such military hospitals, and made to pay for their care by labor, who could estimate how many would be returned to health and temperate living again? Who could estimate the relief from sorrow, misery, wretchednesss and losses? This will also be a reality a little further on. If ten thousand recent cases of inebriety could be taken out of their surroundings in New York and placed in these hospitals, where forced conditions of the highest degree of health and vigor are maintained, a large percentage would recover. The gain to society and the world would be beyond all computation. Now each one of these propositions and the practical working of a military hospital is a reality, based on evidence constantly accumulating. Every prison, penitentiary, or hospital, every asylum or home where inebriates come under care and restraint bring such evidence. They show that such a method of treatment, combining the varied experiences of all these institutions can be made practical and is the only scientific way of solving this problem. To

banish the still and saloon does not prevent inebriety or cure the inebriate; it only changes the direction of the drink current. But quarantine the inebriate in a hospital, as one suffering from contagious disease, and the victim is cured, the spread of the disease is prevented, and a knowledge of the causes ascertained, from which the remedies can be known and applied. To punish the inebriate as a criminal cannot cure his inebriety, but it always unfits him for living a healthy, temperate life thereafter. To attempt a cure by faith and prayer is to depend on false hopes, the failure of which is followed by increased degeneration. To attempt any form of treatment without knowing any other fact except that the victim drinks to excess is always to blunder and fail.

The time has come to recognize the physical conditions which enter into all cases of inebriety, and to apply exact remedies along the line of nature's laws and forces.

The late Dr. Bellows, in an address delivered ten years ago, said: "Inebriates, like criminals and insane, will all be eventually restrained in hospitals, and treated with medical and physiological skill the moment their liberty becomes dangerous to society. The terms of their confinement will be limited only by the possibilities of cure and the conditions of their disorder. Society gains nothing by holding prisoner for an hour any man who is fit to be at large. Liberty and human rights gain nothing by allowing any man to be at large for a moment who is destroying himself, his family, and his neighbors. What we need is what we are fast gaining, namely, a possession of the tests and gauges of the fitness and unfitness, and we shall be able to treat the inebriate successfully the same as in other diseases."

As scientific men the question comes to us, can this great army of five hundred thousand inebriates in this country be the outburst of a vicious element in human nature? If this is so, religion and civilization have failed. If this army of inebriates sprung from physiological and psychological causes, then the problem of cure and prevention is a question for science. If inebriety is a vice and sin, then the Church and State must apply the remedy.

Insanity has been studied for over a century by many able and learned scientists, and yet only a few facts have been established, and preparation made for more exact study. The realm of the unknown has been scarcely penetrated. Inebriety, an infinitely more complex disease, has never been studied. Only a few pioneers are approaching it from a physical standpoint, and their views of necessity must be outlines of laws, forces and facts, that are yet to be discovered. Some of these outline facts may be summarized as follows:

All accurate study of the inebriate indicates a distinct range of causes, both physiological and psychological, from which inebriety springs. When the histories of inebriates are compared, they are found to follow a regular line of progress, obeying a certain order of events, from the beginning, development, progress, decline, on to extinction. This march is governed by conditions and forces of which we have only a faint conception. Heredity, disease, injury, starvation, neglect, are only the general names for some of these forces.

In the cure of inebriety all study of cases points to a physical causation to be removed by physical means. Work-house hospitals as quarantine stations, where every condition of disease can be treated, give the greater promise of relief. Here the victim is removed from all exciting causes, and protected from himself and others; and here we can understand some of the causes beyond the saloon, and so-called free will, and deceitful heart.

From this very general review of some of the causes of inebriety, and the means of cure, it is apparent that, like the early Northman, we have only touched on the shores of a vast continent of the unknown, which, not far away in the future, the march of science will disclose.

TUBERCULOSIS OF BONES AND JOINTS.

Read before the Northwestern Medical Association, at Lima, Ohio, December 9, 1886.

BY M. STAMM, M.D.,
OF FREMONT, OHIO.

Anatomical History.—Very few subjects in surgical pathology excite at this moment as much interest as the tubercular affections of the bones and joints. This is especially shown by the many contributions in periodicals and monographs of late years treating very elaborately upon this question. That this subject is also of very great practical importance, no physician or surgeon who has met such cases will deny. The knowledge of tuberculosis of the bones may be traced to the earliest times. Hippocrates and Galen mention tubercle of bones in no indefinite terms, and the general observation that phthisis is at times the more or less direct outcome of surgical accidents or diseases did not escape their eyes. It must not, however, be imagined that they had a clear conception of its nature; they were not enabled at that time to distinguish between scrofulous, syphilitic and cancerous tubercles. In 1735 Traugott Gerber, in a treatise, ascribed the formation of spinal curvature to vertebral tuberculosis. It was, however, reserved to the genius of Laennec, who profited by the previous labors of Bayle, to demonstrate that tubercles were the anatomical basis of phthisis, and that most of the lesions, considered scrofulous, were tuberculous. Surgery took hold of this discovery, and Delpech was the first one to study it in its surgical aspects. Nichet soon wrote upon tuberculous osteitis, and Nélaton, in his memorable treatise, distinguished two forms of tuberculosis of the bones, the encysted tubercle and the tuberculous infiltration.

Like all new ideas, this theory equally had to go through the crucible of severe and carping criticism, it was opposed and defended with like vehemence by men equally high in merit and authority. Buhl had observed that acute miliary tuberculosis was in most

cases combined with old cheesy or purulent centres, and as Rokitansky had some time previously traced out the causal connection between such foci and miliary tuberculosis, the first author came to the conclusion that the latter affection was an infectious disease, due to the absorption and spread of noxious agents from old cheesy inflammatory centres of the lymphatic glands, lungs, bones, etc. A very important step was gained in this direction when, in 1865, Villemin, by way of experiment, demonstrated the inoculability of phthisical products upon animals, and showed that caseous material was just as virulent as the gray tubercle. Köster, in 1869, showed that the fungous masses in diseased joints were of tuberculous origin. He furthermore described the giant cells, which were until recently considered pathognomonic of tubercle. Subperiosteal cold abscesses were also found by Kiener to have the tuberculous character. Volkmann at the same time showed that in white swelling the foci found in the epiphysis exhibited the nature of tuberculosis. In 1878 Schüller drew attention to the fact that in scrofulous subjects traumatism had a tendency to produce the tubercular affections known as white swelling. A number of experiments upon animals, which he caused to eat or inhale tuberculous matter from various organs, and which subsequently received some bruises or injuries about their joints, seemed to confirm his views. They all exhibited about the injured joints the pathological conditions which may be brought under the term tumor albus, and in a very short time perished from general tubercular infection.

Since that time many contributions relating to this question have been furnished, chiefly from French and German sources. The germ theory was brought in connection with the etiology of tuberculosis some time before Koch made his famous discovery of the bacillus tuberculi; at least, I heard my distinguished teacher, Prof. Klebs, as early as 1871, make the prediction more than once, that in no distant future some investigator would furnish the evidence that a parasite was inseparably connected with the cause of this disease. It was, therefore, no mere accident, but the fruit of well planned work and laborious research, when Koch was able to announce to the world that he had found that destructive enemy of the human race, as well as a great part of the animal world, in the shape of a minute rod. The memory is too fresh yet to forget how this statement was received; how every microscope was called into requisition, and how every observer, whether trained or mere amateur, felt himself fully competent to pass judgment upon the correctness of Koch's observation. Suffice it to say that almost every pathologist of note, and amongst them many who at first held an opposed view on the matter, to-day look upon the bacillus tuberculi as the univocal criterion of tuberculosis. To those who are always eager for new facts and suggestions, be they of theoretical or practical import, it may be of interest to hear that Baumgarten very recently succeeded in studying the finer working of this low organism, and its way of bringing about the characteristic morbid changes. I cannot here go into the details of his method of investigation, but he succeeded in showing, by inoculation of bacilli into the anterior chamber of the eyes of a number of rabbits, that the immigration of these parasites into the tissue spaces or into the fixed cells, never into the leucocytes, is the first step. Then they begin to multiply and spread, so that in about ten days tubercles will crop up.

Tuberculosis of the bone is principally limited to the epiphysis of the joints and to the spongy tissues of the bones, as, for instance, in the short bones of the hands and feet (spina ventosa). This is somewhat in contradistinction to another infectious disease of the bones, the acute osteo myelitis, which latter affection has a predilection for the long shafts of the bones. Exceptions, however, occur in both affections, and it requires some practice to make an accurate distinction between the two. Nélaton distinguished two forms of pathological appearances, the encysted tubercle and the tuberculous infiltration, which distinction is still in use by a great number of pathologists. Kœnig, however, who has of late years paid special attention to this affection, found that in its gross aspect it presents three different forms: the granulative tuberculosis, the tuberculous necrosis, and the infiltrating, progressive form. We find in the first variety generally a small spherical or tubular defect in the bone, of the size of a hempseed to that of a large pea, or even a small hazelnut. The appearance of the contents is at times of a reddish, gray granulation, at other times of a yellow or grayish-yellow color, and not infrequently the whole focus is of a cheesy nature. We nearly always detect, with the eye alone or under the microscope, the finer residue of bone. The walls of the cavities may be soft, or there is a sclerotic, cicatricial condition. The granulations, as long as they have not assumed a pronounced cheesy character, reveal under the microscope a multitude of characteristic tubercles with epithelial and giant cells.

The second variety, the tuberculous necrosis, differs from the necrosis of the acute osteo-myelitis in its not being entirely separated from the healthy bone, as it has some slight connections with it; besides this, it is not generally found in the long shaft, but mostly in the spongy parts of bones, in the epiphyses of joints, in the vertebral bodies, also in the flat bones, like shoulder-blade or skull. It has a wedge-shaped appearance, with its base towards the joint and the apex towards the medullary cavity. As the shape of the bone is often not at all changed or enlarged, we may have some trouble in finding the sequestrum in the living bone, but its dirty-white or yellowish color and its presence of purulent fluid or soft cheesy masses, on the cut surface, will aid us greatly in its discovery. In some cases, however, it is so intimately connected with the bone, that only a very thin layer of tuberculous granulations separates it. We then may have to use some force in lifting it out, even with the chisel. The bone becomes thickened in case the joint is much used, or after a fistula is established. The resemblance of the sequestrum to infarcts, and the way in which it is formed, incline Kœnig to the belief that it is of embolic origin.

As to the fate of such tuberculous foci, they may undergo a retrogressive metamorphosis, the tubercu-

lar granulations may be transformed into simple normal granulations, and ultimately into cicatricial tissue. This is especially the case in the smaller foci at some distance from the surface of the joint. But there are cases in which the healing process is not complete, where some tuberculous granulations are left unchanged, and these may then lighten up at any time and bring about what we might call a recurrent tuberculosis. A large sequestrum will never heal. If the tubercular centre be seated right under the periosteum in the neighborhood of the joint surface it, as a rule, will penetrate into the joint and then produce the characteristic tubercular affection of the joint.

The course of the disease is very much affected by the condition of the tuberculous foci; whether they have a dry granulating, or a soft cheesy appearance. The former variety has a tendency to form cicatricial surroundings, and thereby remains localized, whereas the soft form becomes cheesy and purulent, rapidly diffuses into the surrounding tissue and there sets up identical changes; as a result we then have the chronic or cold abscess. Why we should have in one case the dry form, in other cases again see the cheesy or purulent variety, we have so far not been able to determine. We are nevertheless aware of one fact: that the quantity of matter is not dependent upon the extent of the infectious focus. We see sometimes the largest abscesses connected with the smallest tuberculous centres, and again, a number of multiple foci of granulation and sequestrum without a drop of matter. The idea that another special infection had joined hands with the tubercular infection, could so far not be verified by experiments upon animals, as inoculations of pus from such tuberculous foci produced exclusively the purest form of tubercles.

The two forms mentioned above generally preserve their original characteristic; that is, the dry form always remains dry, and should it become purulent it has very little tendency to spread. We need scarcely mention that these relations have an important bearing upon the prognosis of these local processes, but they are not less important as regards the question of general infection.

The third form, that of infiltrating progressive tuberculosis of the bones, is of rare occurrence, but still frequent and grave enough to deserve special mention here. It is especially found in cases in which tuberculosis is complicated with open suppuration. After having destroyed the cartilage of a joint it may find its way into the surface of the joint-ends, and from there penetrate deeper into the shaft of the bone. The medullary cavity especially seems to be a favorite seat for it. It chiefly characterizes itself by the irregularity of its invasion; the healthy bone may show different irregular islands of infiltration of the same color as the tuberculous sequestrum, whilst the spongy bones may be studded over alternately with yellow infiltration or small abscesses. The medullary cavity especially is apt to be filled with smaller or larger abscesses surrounded by a pyogenous membrane, so that the process is aptly described by the name "true osteo-myelitis tuberculosa purulenta." It is fortunate for conservative surgery that such cases are rare, as prognosis is obviously a bad one. From what we have mentioned before, we know in what manner the infection of the adjacent region of a focus of the bone takes place, and why we sometimes find large tubercular abscesses at some distance from the source of suppuration. The cold or tubercular abscess spreads through the cellular tissue, and its walls are formed by a fibrinous layer derived from the pus. This pyogenous membrane shows plainly the tubercular granulations, and allows us even to study the development of tubercles. The locality of the focus generally determines the question whether we are going to have tuberculosis of the soft parts or of the joint itself. The majority of cases which have been considered under the name of white swelling, or fungus articuli, owe their origin to some tubercular focus seated in the joint-ends which either directly or indirectly breaks into the joint. True, the synovial membrane may be primarily affected, but the osteal tuberculosis is much more frequent. We find there the granulative foci especially represented, which may be located under the cartilage or in the vicinity of the synovial membrane, and only a few lines of territory may decide whether they are going to break into the joint or will remain a parosteal abscess. The tuberculous sequestrum is not generally accompanied by suppuration; it remains dry for a long time and becomes polished or eburnated from extensive use of the joint. Its smoked yellowish appearance will aid in its detection.

Viewed in the light of modern pathology, the terms "tumor albus or fungus articuli" are not sufficient to cover the ground fully, and might therefore easily be dispensed with. The name *fungus* or *granulating inflammation of the joint* owes its origin chiefly to the proliferation of soft, young connective tissue which, in addition to the tubercles, is found spread over the synovial membrane. The soft tissue surrounding the joint becomes swelled, and as the fatty subserous tissue becomes atrophied the joint assumes a spindle-shaped, flabby appearance. Extensive use of the diseased limb or the presence of fistulæ, as the result of small abscesses, will increase the swelling of the joint, and finally leave the soft parts in a state of lardaceous fibrous induration. In extreme cases the periosteum becomes thickened and the indurated parts gradually adhere to the skin, which, in consequence of atrophy, then presents that smooth, shining, anæmic look which deservedly gave it the name white swelling. But we may safely assert that since such cases have received more careful treatment, principally immobilization and rest, they have become somewhat scarce. Instead of proliferation of young tissue, we may also have a dropsical exudation into the joint as the result of the same amount of irritation. This *hydrops articuli tuberculosus* is generally the result of diffuse synovial tuberculosis, and in almost all obstinate cases such a condition may be suspected. The fluid in such cases may be as clear as water, or mixed with pus corpuscles, it may also have a fibrinous deposit; in fact, exhibit all the varied products of coagulation. These coagulations may appear as a soft white membrane, or in the shape of rice bodies. At one time it was supposed that cases which showed these rice bodies were free from tuberculosis,

but recent observations seem to prove the contrary.

We should not forget to mention that condition which is embraced under the term tuberculous empyema of the joint. It should be distinguished from that form of cheesy suppuration caused by some focus of cheesy granulation. The empyema we speak of is the product of multiple miliary tuberculosis scattered over the inner surface of the synovial membrane, filling the joint with tuberculous matter and coating it with a tuberculous membrane, which can be readily scraped off. The cartilage seems to be at first exempt from tuberculous infection, it only becomes involved after the destruction of the bony or synovial parts of the joint has made progress. As a rule, the tuberculous foci are single; they may, however, appear in a multiple form in the granulating variety, and oftener still in the caries sicca. General inflammation of a tuberculous character will follow their perforation into a joint, unless the point of perforation becomes occluded by the inflammatory products of the connective tissue, as is often seen in the knee joint of children. If the inflammation involves the whole joint it may exhibit the form of fungus, dropsy or cold abscess. The tubercles are first not spread over the entire joint, even if the latter is filled up with soft, loose granulations. These granulations are simply the product of inflammatory irritation of the joint, and may be free from tubercles. The parasynovial tissue presents a gelatinous appearance, especially where extensive layers of subsynovial fat are formed.

Primary diffuse synovial tuberculosis may occur simultaneously with, but independently of, osteal tuberculosis. Its picture is varied; in some cases, where during life no sign of inflammatory change was manifested, we find subsynovial gray tubercles, and as these are mostly found in connection with acute general tuberculosis, they are more of anatomical than practical interest to us. Somewhat related to this form are the cases of dropsy with fibrinous deposits, or rice bodies. But the form which the surgeon meets most, is exhibited in the cases of diffuse tuberculous granulation. We find there numberless gray or grayish-yellow tubercles visibly distributed through the whole thickness of the synovial membrane, and even through the subsynovial tissue. The synovial sac may be filled with transparent liquid or pus, and its granulating surface be coated with a pyogenous membrane. Para-articular abscesses almost invariably owe their origin to some focus in the bone, but there are cases in which tuberculosis, which existed in the joint without suppuration, finally perforated the joint, and then ended in cheesy suppuration. Careful examination will generally detect some point of communication with the joint.

A very rare form, which will often test the diagnostic skill of a surgeon, is what we call the nodular form. If we were justified in classifying tubercles with tumors we might bring this form under the head of tumors. Its seat of preference seems to be the knee joint, also tendons and their sheath (bursa in the carpal joint). They may be of solitary growth in the capsule of the knee joint, and seem to originate from the fibrous portion of the synovial membrane, reach the size of a pigeon's egg, with flat surface. Their color is grayish red, studded with light gray, small nodules, the size of a pin head. An abundance of tubercles are found on their surface or in the richly vascularized layers. Such cases are accompanied with dropsy and fibrinous deposits.

Clinical History.—As the question of tuberculosis of the bones and joints is of somewhat recent origin, its clinical history is necessarily still incomplete. Tuberculosis may develop primarily in the bone itself, or, by way of metastasis, be transmitted there from other organs. Just how it enters into the system we have so far not been able to determine. But from experiments and from the fact that it is so frequently found in the lungs and in the thoracic duct, we may safely assume that the lungs and stomach especially serve as entrance to the virus. Very recent observations even seem to sustain the theory that tuberculosis may be communicated to healthy persons through wounds. About a dozen cases are on record which leave no doubt that the virus has been inoculated into fresh wounds. In the majority of cases we find tubercular deposits in some other organs, aside from the bursa or joints, and we may infer with some certainty that a metastasis from these organs has taken place. There is, however, a certain percentage of cases (Kœnig found about 17 per cent.), where the bone alone was the seat of tuberculosis; at all events, it was impossible to find any other organ affected. Undoubtedly it will always be difficult to say whether trauma alone in some cases, without the presence of some tubercular focus in the body, will be sufficient to produce such specific changes in the joints.

But, as we are justified in reasoning from analogy, we might use acute osteo myelitis as an example. This affection sometimes closely follows injury, and yet it would hardly be safe to assume that an infectious centre was lodged in the body previous to the attack. It would be much more plausible to think that the poison was taken up into the system about the time of injury, either by inhalation or ingestion, and carried to the place of least resistance. The question whether tuberculosis can be inherited will engage the attention of our investigators for some time yet. The opinion that it is not tuberculosis itself, but simply a disposition to it, which can be transmitted from parent to child, seems at present to predominate. Nevertheless, some recent experiments on rabbits with a view to this point have demonstrated the presence of the bacillus tuberculi in the first fœtal stages of these animals, and these experiments strongly favor the view of direct transmission of tuberculosis. We all know that scrofulous children are especially subject to affections of the joints, but at present there seems to be a tendency amongst some weighty authorities to drop this word, and to consider the changes found in such cases under the head of tuberculosis. The experiences reported by such men as Billroth, Volkmann and Kœnig, in fact, seem to justify this step. Kœnig mentions the case of a woman who suffered from fungus of the ankle when she was 10 years old; at the age of 70 the foot became so painful that it had

to be amputated. He found in the old encapsuled focus of the tibia distinct signs of tuberculosis, and patient eventually died from tuberculosis of the lungs. Volkmann reports similar experiences, and Billroth does not hesitate to say that very few such cases reach an age higher than 40 to 50 years; that secondary tuberculosis is generally the final issue. A low state of nutrition especially predisposes to such affections, but still we also meet them in well nourished subjects. Whooping-cough, measles, scarlatina, and eventually lupus, seem to prepare the soil for its development.

As to the course these tuberculous processes may take, we have already mentioned before that some have a tendency to heal, or at least become latent to such a degree that we consider the patient cured. These are especially the cases with the formation of firm granulations with a tendency to cicatrization, less so cases with large wedge-shaped sequestrum. Some cases even, where suppuration has gone on, may furnish a comparatively favorable prognosis. But with all this we must not forget the fact that, in the course of months or many years, some new exciting cause may lighten up these processes again, and finally destroy the patient under the symptoms of miliary tuberculosis.

The clinical picture of tuberculous affections of joints is by no means a uniform one; on the contrary, full of variety. It may serve a practical purpose to divide it into three distinct groups:

I. Tuberculous dropsy or synovitis.
II. Tuberculous fungus.
III. Cold abscess of the joint.

I. *Hydrops tuberculosus* is the rarest form of the three, and it may occur in cases of diffuse synovial tuberculosis with moderate swelling or with proliferating changes of the synovial membrane. In these latter forms we have fibrinous deposits in the shape of loose bodies or organized layers, which may gradually be changed into polypoid tumors. It may further occur in cases of circumscribed nodular, as well as diffuse fungus, granulative tuberculosis of the synovialis, but in the latter form the soft swelling of the membrane seems to be more prominent than the dropsy. The local symptoms are those of exudation into the joint, in conjunction with the signs resulting from the thickening or tumors of the synovialis. But as the exudation changes in quantity, the basis of clinical distinction rests more on the different forms of tuberculosis, since they are the cause of this exudation. Where the synovialis is but slightly changed, the symptoms are simply those of dropsy of the joint. The especial characteristic of this dropsy is that, after compression or puncture, it has a tendency to return after some little time. If we examine the joint after the exudation has left it, we detect a certain degree of synovial swelling, especially so in the upper recesses or near the lateral insertion of the capsule of the knee joint, there we find sometimes a solid swelling which is easily movable under the finger. In severe cases we also find, on moving the joint, a grating sound, and can detect prominences and tumors quite distinctly. Fever is not present. So far we are not able to say whether a spontaneous cure can take place or not. It seems, however, not very improbable, when we see so many cases of chronic dropsy with swelling of the capsule get well after the application of blisters, tr. iodine, or compression.

II. *Tumor albus*, or granulative tubercular form. —This is the most frequent form of joint affections, and some authors have devoted so much space and time to its description, that they were interpreted, by not a few, as denying the existence of any other form of joint affection. But even the enthusiasts admit that besides tuberculosis, other joint affections, as the result of typhoid fever, scarlatina, measles, and above all, acute osteo-myelitis or syphilis may produce similar symptoms. Surgeons skilled in differential diagnosis should, however, be able to make the necessary distinction; and moreover, you will have a hundred cases of the tubercular form before you meet with one case from the other causes. Acute epiphysial osteitis may give us the most difficulty in diagnosis, having great resemblance to this granulative form. A careful examination into the etiological factors, however, as well as the acute febrile condition, may help to clear up any doubt. In the majority of cases it will be impossible for us to decide whether we have an independent tubercular synovitis, or one resulting from affection of the bones. The knowledge that osteal processes occur a little oftener than synovial, will not serve us much as a guide in an individual case.

As we have already mentioned, this affection may exhibit clinically different forms. One form, for instance, is characterized by dry, firm granulations which have a special tendency to cicatricial contractions. This form may result in destruction of the epiphysial surface, and may in this manner interfere with the mechanism of the joint, but the tubercular process has very little tendency to spread into the parasynovial tissue, or to the formation of an abscess. If suppuration should occur, we find only the circumscribed (para-articular) abscess. Very little swelling is generally noticed; in not a few cases we even gain an impression as if the joint was in a state of atrophy, as, for instance, in the knee and hip joint of younger subjects, and especially characteristic in this respect is the shoulder joint by its rapid waste. The shoulder then loses its round shape, and we find the head of the humerus in close proximity to coracoid process, the knee becomes deflected outwards and dangling, and in the hip joint the line of the trochanter is raised, the extremity becomes slightly shortened. In another class of cases we find the tuberculous granulations soft and with a tendency to cheesy granulations. In the more advanced cases these processes perforate the synovial membrane and set up a cheesy focus or a circumscribed abscess in the para-articular tissue. The joint after much use will swell considerably and become spindle-shaped, the skin looks anæmic, from being grown to the subjacent tissue, so we have a veritable tumor albus. Fortunately, these extreme cases are to day not as frequent as they were years ago, owing to the improved methods of treatment, especially prompt immobilization. We occasionally meet cases where the granulations are so soft that it

will be difficult to distinguish it from an abscess. Practically this will be of no serious consequence, as they sooner or later are followed by suppuration. If such abscesses do not reach a large size they may, by strict immobilization of the joint, become absorbed, but more frequently they break open and leave fistulæ in different places about the joint.

So long as these fungus processes are unaccompanied by suppuration, patients are generally free from fever, except after abnormal exertion or surgical interference, as, for instance, an attempt to straighten a contracted joint. As soon, however, as we have signs of the formation of an abscess, we have a rise of temperature in the evening, and in some cases also in the morning. Various causes for contraction of a joint have been adduced by different surgeons without really explaining all the points with full satisfaction. Habit, or the way of using the joint, seems to have most to do with its position. A slightly flexed position is generally assumed to rest the joint, so it very probably, in an inflamed condition, relieves the tension of the capsule and in this way lessens the pain. Mechanical influences, as the weight of covers and the position in bed, should also be taken into account. If the contractions have established a certain degree of displacement we may infer a corresponding degree of destruction.

Pain may in some cases be only slight, whereas in others it is excruciating. In cases in which it is intense we may expect to find a grave lesion of the bone. This especially is true in the hip joint, where a quick, slight blow on the end of the foot or on the patella, with knee in a flexed position, or a push of the leg in the direction of the joint, will evince severe pain. If a joint, which has been hitherto painless, should suddenly become painful without any external cause, we may assume that an osteal depot has broken through into the joint. The presence of painful spots about the joint-ends not infrequently points to a focus of the bone. Our diagnosis becomes more definite when these spots, besides being soft and impressionable, show a circumscribed defect in the tissue, and especially complete will it be if we find a larger soft granulative focus or a small abscess. Such a diagnosis will be an essential guide in our treatment.

III. *Cold abscess, or purulent tubercular synovitis.*—In this form we generally find, after having scraped off the pyogenous membrane, the synovialis studded over with miliary tubercles. This membrane is largely distended, as we commonly find it in dropsy of the joint. It is mostly found in the knee joint less frequently in the hip, and principally amongst children. Prognosis is generally bad.

The healthy appearance of a patient should not prevent us from making a diagnosis of tuberculosis of a joint, if the characteristic signs are present. We experience most difficulty in this respect in cases which have been considered under the head of tuberculous dropsy, as their external appearance differs very little from simple dropsy of the joint. Its resistance to the different forms of remedies only, and its tendency to relapse, will strengthen our opinion on this point. Puncture of the joint may also give us some light, since the emptied fluid is not as clear as in simple dropsy, and is often mixed with decaying pus corpuscles and fibrinous deposits in the shape of grating membranes or rice bodies. It can be distinguished from arthritis deformans by making generally its appearance between the ages of 16 and 40 years, and furthermore, it leaves no deformity of the joint, is also frequently combined with tuberculosis of other organs. Cases with circumscribed tuberculous fibroma may be confounded with tumors of sarcomatous, lipomatous or syphilitic nature. Sarcomata, generally, are pedunculated, but still, in some cases, we are left in doubt until we operate. Fortunately, the treatment is the same, so that a doubt in diagnosis is of no serious consequence. In cases of syphilitic gummata, if every other diagnostic point will fail us, iodide of potassium will in a few weeks clear up all doubt in the matter.

Cold abscess of the joint occurs in persons whose system has already been reduced by tuberculous processes of other organs; it is also generally accompanied by fever, showing the curve of hectic fever. In external appearance it may resemble simple dropsy of the joint, but the synovial membrane is more thickened. The form considered under the name tumor albus, although its clinical picture is varied, generally presents no difficulty in diagnosis. Its spindle-shaped appearance is somewhat characteristic for that affection, and very little doubt is left us after circumscribed suppuration or fistula are combined with it. Acute multiple osteitis might be mistaken for it, but this affection is of rare occurrence, the processes are also multiple and found more in the shaft of the bone; in fact, in several bones, its history at the same time will be of some assistance. Syphilitic affections of the joint may show some resemblance at first, but the characteristic look of the ulcers or cicatrices usually found, will soon settle our doubts. Those forms which occur after infectious diseases carry already a valuable diagnostic factor with them in their history.

Caries sicca, where joints are in a state of dry, granulating atrophy, from cicatricial shrinking of the capsule and bones, may sometimes be mistaken for a neurosis of the joint. A careful examination, however, will reveal the wasted condition of the joint-ends, and consequently some shortening of the parts. This form is mostly found in younger persons at the shoulder, knee and hip joint.

As to prognosis, we may state that the hope of curing the local processes of a joint should not be excluded in any case. But the more these tuberculous granulations have a tendency to decay and the more extensive such a focus may become, the graver the case will be. Suppuration may also enhance the danger in a case, especially as septic infection may combine with the result. If, however, we succeed in getting a patient over this danger, cicatricial contraction may bring about a favorable termination, provided the deeper structure of the bone is not involved. But, however favorable the result may seem to be, we must never forget that tuberculosis may be present in a latent form which years after may lighten up again and lead to further destruction. Billroth's observations and those of a number of other surgeons,

although very gloomy, are no doubt correct. He found that most of his cases, which he thought cured after resection or amputation, exhibited after a few years signs of tuberculosis in other organs or had meanwhile died from that cause. He thinks that such patients seldom reach an age above 40 or 50 years. Caries sicca seems to give a better prognosis as to life, but not so favorable as to the use of the joint, since it is apt to lead to anchylosis. Children are more favored in point of prognosis than adults. As long as we find pain in the joint on pressure or after use, even after all the swelling has subsided, we must still suspect some mischief.

Treatment.—Even before the tuberculous nature of white swelling was demonstrated, surgeons, with sound instinct, instituted a treatment similar to the one followed out in tuberculosis of other organs. Preparations of iodine, preferably iodide of iron, mercury, arsenic and cod liver oil, saline and sea baths, have for a long time been in use, not on account of their specific effect, but principally with a view to raise the state of nutrition. But, after all, we are compelled to look to local treatment for better effect. Absolute rest of the joint is without any doubt the prime condition, especially in cases with a tendency to abscess. Plaster-of-Paris, or some similar bandage, unites with the immobilization of the joint the advantage of circular compression. But it is indispensable to put the leg in the proper position before bandaging and to correct any contraction. For the latter purpose weight and pulley are the best expedients in the knee and hip joint; forced redressment, however, under anæsthetic may also have its proper place—in some cases it even seems to have a more curative influence, owing to the inflammation set up by it. After contracture has been removed a plaster-of-Paris bandage is certainly the most convenient. Massage has so far not fulfilled our expectation in these cases; inunction, however, of iodine or mercurial preparations, also application of cold, may occasionally be of some benefit. Injections of carbolic acid into the joint have rapidly been abandoned. Ignipuncture of the joint, at one time highly extolled, seems only to be practised now by a few.

Whatever we may do in the way of conservative treatment, it will always require many months, and even years, for recovery, and then we find that some cases need a still more radical procedure. We may use conservative measures in younger persons, with the expectation of good results, when there is little swelling and the function of the joint moderately impeded; so also in the dry granulating form. The formation of a small circumscribed abscess, accompanied with some pain, is no special cause for discontinuing this plan of treatment. Even the graver forms of fungus may derive some benefit from it as long as there is no extensive suppuration, but if the latter should occur, with considerable pain and signs of displacement, a more radical method is called for. The social condition of a patient will also be of some influence in our decisions. A poor laborer, who has to support a family, can not well afford to be treated in such a conservative manner for a very long time, with the prospect of an uncertain result, and if the case is made plain to him he will no doubt prefer some operation which promises a fair result and within a reasonable time.

(*To be concluded.*)

A MIXED FORM OF ATROPHIC AND HYPERTROPHIC CATARRHAL INFLAMMATION (HITHERTO UNDESCRIBED), AND ITS TREATMENT.

Read before the American Rhinological Association, at St. Louis, Mo., October, 1886,

BY P. W. LOGAN, M.D.,

OF KNOXVILLE, TENN.

I desire to present briefly a general outline of a class of cases laboring under a mixed form of atrophic and hypertrophic catarrhal inflammation of the upper air passages. In these cases there exists simultaneously and conjointly, hypertrophy and atrophy of the mucus membrane of the nose, nose and pharynx, or nose, pharynx and larynx. I have observed numerous cases of this form of inflammation, some of which were apparently so slightly affected, so far as structural changes and other evidences of inflammatory action were concerned, that some observers would, on examination, conclude that the affected structures were in a healthy condition. The condition of the diseased mucous membrane, however, varies,—the structural changes being greater in some than in others, and the quantity and quality of secretion also varies. Now and then we see hypertrophy and atrophy apparently well marked co-existing in the same patient, but in many of these cases I have not noticed a decidedly pronounced morbid condition accompanied with the usual characteristic appearances present in either hypertrophic or atrophic inflammation occurring separately. In other words, this mixed form of trouble does not present the usual characteristics of either the hypertrophic or atrophic variety of catarrhal inflammation. The accompanying conditions seem to stop short of a well-developed hypertrophic or atrophic condition as described by various authors.

The mucous membrane does not appear dry and incrustated with inspissated secretions, as in the atrophic variety, yet there is not usually present sufficient secretion to normally lubricate the affected surfaces, and a dry sensation is complained of. Now and then I have noticed in children laboring under this mixed form of trouble, and in whom the hypertrophic condition predominated, excess of nasal secretion, but at the same time a dry sensation of the nose, or nose and throat was often present. In these cases I have found astringents objectionable, as they increase the uncomfortable dry sensation referred to. This effect of an application containing an astringent leads me to suspect co-existing atrophy. The mucous membrane in adult patients presents the appearance of atrophy, especially in the pharynx, seeming to be paler, smoother, and apparently thinner than the normal and healthy structure, except here and there, an occasional inflamed circumscribed spot of thickened structure with enlarged blood-vessels.

radiating therefrom, and sometimes involvement of follicles, as we see in so called follicular pharyngitis. In some patients I have noticed no appearance of disease in the pharyngeal mucous membrane, except the incipient appearance of atrophy, at the same time have observed, in the nasal mucous membrane, hypertrophy with a tendency to dryness of naso-pharynx and larynx.

A prominent, and I might say almost pathognomonic, symptom of the mixed form of trouble, is a tendency to a dry sensation of nasal or pharyngeal, and frequently laryngeal, mucous membrane. We must not be misled by the accompanying hypertrophy appearance here and there, and resort to the usual treatment for hypertrophic inflammation. In the mixed form of trouble I have usually found especially the atrophic element predominating in adults, and in children generally the hypertrophic element greatest; yet in both adults and children, treatment adapted to atrophic inflammation is, I am sure, the correct treatment for the mixed form of catarrhal inflammation.

In the management of this trouble I would not expect to succeed with astringents, but would look for an aggravation of symptoms, more especially if they were applied to the nasal mucous membrane. I am sure this class of cases is frequently improperly treated, or disposed of with little or no treatment at all, from the fact that they are many times considered so slight or trivial in character as really to require little or no treatment. Patients suffering from this variety of diseased mucous membrane are unwilling to be put aside in this way, therefore seek further advise. The lessened secretion of the naso-pharyngeal mucous membrane tends to the development of similar laryngeal involvement. Really the mucous membrane in this variety of disease does not appear literally dry, but there is, as a rule, unquestionably diminished secretion, which is generally purulent in character.

There is not sufficient secretion, as a rule, to thoroughly lubricate the mucous membrane, but enough secretion is present to prevent that excessively dry, glazed appearance which we see in a more advanced case of uncomplicated atrophic catarrhal inflammation. In cases of laryngeal involvement, patients are inclined to clear their throats, and sometimes swallow the wrong way. A hot, dry air or an atmosphere containing smoke, dust or other foreign matter seems to aggravate the trouble, especially carpet dust, which is linty, and being so, adheres more obstinately to the mucous membrane. Overheat from any source sems to aggravate this trouble, but furnace heat or dry stove heat is especially injurious, as it tends to further increase the dryness of the affected structure.

So far I believe only five distinct and separate varieties of catarrhal inflammation have been mentioned. I refer to Dr. Bosworth's classification, which is more complete than that of other authors, and indeed a good classification; but so far no author has included in his classification the mixed form of catarrhal inflammation of which I speak. This form of disease occurs quite frequently; indeed, so much so that I felt it necessary to call attention to its unquestionable existence and its successful management. Dr. Seiler, in speaking of simple chronic catarrh, says:[1] "This affection is conveniently divided into two large subdivisions, viz., into hypertrophic and atrophic nasal catarrh, which may arise independently of each other, or the atrophic may be a sequel and consequence of the hypertrophic variety. As the treatment, however, is very different, these two varieties must be considered under separate heads." This being the case, if it be true that there exists a mixed form of atrophic and hypertrophic catarrhal inflammation, how are we to meet and successfully combat these opposite coexisting conditions?

Proper classification of the different varieties of catarrhal inflammation is important, from the fact that we cannot treat them all alike. It is therefore absolutely necessary to recognize the true condition of the affected structures. A hypertrophic condition of the mucous membrane of the upper air passages accompanying atrophic inflammation of the same structure, will not yield to treatment usually resorted to in cases of uncomplicated hypertrophic catarrhal inflammation. Herein lies the difficulty of treating successfully a large class of cases, which I consider mixed in character.

Seiler[2] says, moreover: "That the hypertrophic condition may exist in one nostril and the atrophic condition in the other;" and moreover, "As the treatment, however, is very different, these two varieties must be considered under separate heads." Under this state of case, how would Dr. Seiler treat his patient who had a hypertrophic condition in one nostril and an atrophic condition in the other? According to the position taken by him, he would treat one nostril for hypertrophic and the other for atrophic catarrhal inflammation. Now if we accept the idea of a mixed variety of atrophic and hypertrophic catarrhal inflammation, and the fact that treatment adapted to the atrophic condition is correct in the management of said mixed form of trouble, I think we will succeed better than to treat one nostril for hypertrophic inflammation and the other for atrophic inflammation. Dr. Seiler also says that "Hypertrophic and atrophic catarrhal inflammation may arise independently from each other, or the atrophic may be a sequel and consequence of the hypertrophic variety." While this is generally conceded, it is not a well proven fact. It is difficult to reconcile the view that inflammation of the mucous membrane in one case will result in hypertrophy and in another in atrophy, because of the presence of organized connective tissue, when we realize the fact that this connective tissue is present in both the hypertrophic and atrophic varieties of catarrhal inflammation. Why in one case should the inflammatory process interfere with the glandular and follicular structures, and the general nutrition of the parts, as to produce atrophy and in another case give rise to increased nutrition, increased growth and increased action of the follicular and glandular structures and hypertrophy? If these conditions arise separately and independently from each other, the

[1] Seiler, "Diseases of Throat," p. 218.
[2] "Diseases of the Throat."

atrophic condition is not always Nature's cure for the hypertrophic condition. In other words, atrophic inflammation, according to this view, is not always preceded by a hypertrophic inflammation. The etiology of these two conditions seems irreconcilable. Dr. Bosworth, under the head of "Chronic Nasal Catarrh," in speaking of atrophic or dry catarrh, says:[3] "After removing from the mucous membrane of the lower pharynx, the plug of dry, shreddy mucus protruding in the median line, when the disease has resulted from the hypertrophic form of catarrh, we will find in this locality hypertrophied glandular tissues, which characterizes that form of the disease." This is an admission of the fact that we may have a mixed form of trouble, even in an advanced and fully developed case of so called atrophic inflammation.

The class of cases referred to in this paper, however, stop short of a fully developed atrophic or hypertrophic condition, with its usual accompanying symptoms when considered separately. A hypertrophic catarrhal inflammation must be treated differently from an atrophic catarrhal inflammation, after full development, and as described by *various authors*. The point I wish to make is, that we frequently meet with a mixed form of atrophic and hypertrophic catarrhal inflammation, and notwithstanding the accompanying hypertrophy, which usually predominates in children, we must, in order to afford relief, adopt treatment suitable to the existing atrophic condition, regardless of the accompanying hypertrophy. But the treatment must be less stimulating than in a case of purely advanced atrophic catarrh attended with dry inspissated, incrusted secretions, the removal of which sometimes requires the use of alkaline detergents. As a rule, in the mixed form of trouble under consideration, the usual detergents are not required. The treatment should be mild, soothing, gently stimulating, antiseptic, and protective, so far as local applications are concerned. It must be unirritating. I have obtained the most satisfactory results from applications of vaseline, containing a small quantity of oil of eucalyptus, two to five drops of the latter to an ounce of the former, which should be made hot before the oil of eucalyptus is added, after which the mixture should be stirred until it becomes cool, when it is ready for use. Some bear more of the eucalyptus than others, from the fact that the treatment should be more stimulating in some patients than in others. I usually apply, by means of spray tubes, about one-half drachm of aforesaid mixture with each tube used. Tubes necessary for nose and throat are numbered four, five, one and two, and when the larynx is involved a number seven, with which we can thoroughly spray the larynx if the patient is asked to breathe naturally or inhale deeply. In frequency of applications, and amount of medicament used, I am governed by the condition of the affected structures and the effect produced. As the affected parts improve, less treatment will be required. The mixed variety will not bear as much continuous treatment, as a rule, as the hypertrophic or the atrophic variety occurring separately. One of our best guides in the management of the mixed form of trouble is returning moisture of the mucous membrane or lessened dry sensation so often present. After having given sufficient treatment to relieve the accompanying dry sensation, the secretions being increased, and the diseased condition and appearance of the inflamed structures improved, I have usually found it best to discontinue treatment as long as the patient did well without it, recognizing the fact that the parts must be kept in a favorable condition to grow well by degrees. When improvement ceases after discontinuance of treatment, and there is a return of symptoms of the existing trouble, sufficient treatment is needed to again put the parts in a condition to improve without treatment for a time, after which a little treatment may be necessary now and then to assist the *vis medicatrix naturæ* on to final recovery. It is impossible to reëstablish a normal condition of the affected structures in a short time, hence the necessity of following up the treatment from time to time, *pro re nata*, until the parts grow well. This line of treatment, in connection with constitutional remedies, such as tonics, laxatives, and diuretics, will not only remove the accompanying hypertrophy, but will produce increased nutrition in the atrophied structures, and increased action of the glands and follicles of the diseased mucous membrane. During and after treatment hygienic measures should be observed.

While the authorities generally take the position that the atrophic condition is a consequence and result of the hypertrophic condition, and that either condition may exist separately from the other, I am inclined to the opinion that as a rule hypertrophy exists prior to atrophy, and that after atrophic changes begin in a hypertrophied structure, treatment usually resorted to in cases of hypertrophic inflammation is not suitable for the relief of the mixed form of atrophic and hypertrophic catarrhal inflammation. In other words, after atrophic changes begin in a hypertrophied structure, remedies such as I have mentioned, directed to the relief of the atrophic condition, will not aggravate the accompanying hypertrophy, but will relieve both the hypertrophy and atrophy. In the mixed form of trouble, irritating astringents, etc., usually resorted to in hypertrophic catarrh, will invariably aggravate the accompanying atrophic condition. Our treatment, therefore, must be directed to the relief of the atrophic condition always, when atrophy exists, regardless of any hypertrophy which may exist. When spraying the lower pharynx and larynx, I usually add to the mixture of vaseline and oil of eucalyptus, a few drops of the comp. pinus canadensis mixture mentioned in Dr. Rumbold's "Hygiene and treatment of Catarrh." It generally adds much to the comfort of the patient, but whenever it gives rise to the slightest dry sensation it should not be used.

MEDICAL PROGRESS.

THE TREATMENT OF PUERPERAL RUPTURE OF THE UTERUS.—F. KRONER, of Breslau, in a short but lucid communication in the *Centralblatt für Gynäcologie*, in addition to reporting a case of his own observed in 1880, has collected all cases of puerperal rupture of the uterus, in which labor was completed *per vias naturales*, *treated without drainage*, reported during the last ten years, for the purpose of studying the relative advantage of drainage or no drainage. The outcome of this investigation serves as additional proof that drainage of the peritoneum presents no advantages, a view that is at the present day being admitted as correct from a theoretical as well as from a practical standpoint.

His own case is the following: Woman, æt. 31, III-para, rachitic, child in vertex presentation; one hour after breaking of the membranes rupture of the womb, with escape of the head. Turning and extraction promptly attended to, with delivery of a dead, fully matured girl baby. The womb is torn across at its anterior attachment to the vagina. The peritoneum not torn, but peeled off from the womb for a considerable distance to the front and to the right. Manual extraction of the placenta, which had slipped between the uterus and the anterior wall of the abdomen. Irrigation of the womb with carbolized water. Treatment during the first days consisted of opium and an ice bladder to the abdomen, afterwards in emollient applications and an occasional laxative. After suffering with a diffuse parametritis for five weeks, patient is discharged cured seven weeks post-partum. Subinvolution had been normal; the womb was displaced to the right on both sides of the uterus; tense cords could be felt; Douglas' cul de sac was worn shallow and non-resistant. The forty-seven cases of ruptured uterus treated without drainage, collected from medical literature, comprise nineteen complicated with lesion of the peritoneum, with eight recoveries; ten cases uncomplicated, with five recoveries, and eighteen in which no reference is made to the condition of the peritoneum, with nine recoveries; a total of twenty-five fatal cases and twenty two recoveries.

No light is shed upon the question of drainage or no drainage by a large majority of the fatal cases, for seven perished during or shortly after labor, eleven within the first twenty-four hours, and only eight after twenty-four hours, either on the following days or weeks. Of these latter three were affected with some disease intra-partum, and four cases were in part tedious labors, in which the abnormal conditions were recognized late, and labor was terminated, after many futile efforts, in a severe and violent manner.

Of far greater importance for the solution of the question of drainage were the twenty-two cases of recovery. They were far from being all simple cases, but rupture had in all cases but one taken place *spontaneously;* and in no instance was grave infection present inter-partum. As far as the reports go to show, the lying-in differed but little from the cases successfully treated with drainage, the shortest without drainage lasting eighteen days, against fourteen days with drainage, and the longest seven weeks without drainage against nine weeks with drainage.

This proves that we are not at all justified in attributing the favorable results in the cases treated with drainage to drainage itself. *Natural* drainage, as has been emphasized by Kaltenbach, accomplishes the most good, and unquestionably the discharge of matters that have been poured into the abdominal cavity is greatly facilitated by *intra-abdominal pressure*. Hence our main object must be to favor natural drainage by a *firm and well-fitting abdominal bandage*, and by a *semi-recumbent position* of the patient. Artificial drainage, without the strictest antiseptic precautions, may be attended with more harm than good. Prognosis will be greatly bettered by a most thorough cleansing of the peritoneal or extra-peritoneal cavity.—*Memorabilien*, Hft. 4, 1886.

OPIUM IN FEVERS.—SURGEON-GENERAL GUNNELL has a note on this subject in the last Naval Report. While in charge of the temporary naval hospital at Washington, during the war, a great number of cases of fever (intermittent, remittent and continued) were received from the Potomac flotilla, which consisted of some thirty or forty small vessels engaged in the blockade of the Virginia shore. Except on the flag-ship there were no medical officers on those vessels, but most of them were supplied with a surgeon's steward or apothecary having some small knowledge of medicine. When received at the hospital the history of these cases generally was that the men had been sick for several days and had been treated with quinine, and perhaps a mercurial purgative. I adopted a uniform plan with them. The patient on admission was given a warm bath and placed in a comfortable bed with cotton sheets and gown. Most of them came from hammocks on ship board, with the stains on their bodies of the blue flannel shirts which they had worn night and day. Some soup or milk food was given to them, and effort was made to determine the time of recurrence of the chill or fever. An hour before this time a hypodermic injection of morphia, $\frac{1}{16}$ grain, was administered under the skin of shoulder or buttock. The result was invariably the same. When the time of the expected paroxysm arrived the patient was in a profound sleep, covered with perspiration; from this he awoke refreshed and ready for food, and convalescent. Not a grain of quinine was given any of those patients after reaching the hospital—generally no medicine of any kind—and the men were returned to duty after a few days in a condition of health. In some cases, where the exposure had been longer or when the remittent tended to pass into continued form, the convalescence was more slow, but the result was the same.

Subsequent experience has convinced me that any paroxysm of ague can be aborted and the attack broken up by the practice here given. I am sure that too much quinine is used in the treatment of malarial cases. Twenty or thirty grains of quinine sulph. in 5 grain doses in capsules between the paroxysms, with aperient containing 1 to 2 grains of

calomel is a sufficient preparation for the *coup de grace* of the morphia injection. After breaking the attack in the manner suggested salicin is often employed to prolong the effect of quinine, with good results. Five-grain doses in capsules, with a little pepper, black or red, or with 1 grain of quinine is very efficient.

After the beginning of the ague, when the patient is shivering in the chill stage, it can often be aborted by the inhalation of a few drops of nitrite of amyl, which will shoot the attack through chill and fever into the sweating stage in half a minute. This, of course, must be managed only by a physician, who should know with whom he has to deal before employing so powerful a remedy. I do not see why a congestive chill could not be controlled by the same agent, while the mustard frictions and hot whiskey and water in the rectum are used. But of this I have no personal experience.

[A hypodermatic injection of morphine will also abort a chill, even after the cold stage has set in.]

Treatment of Nocturnal Eneuresis. — Dr. Alexander Harkin, in a paper on this subject, says:

A mode of treatment of eneuresis founded on the theory of a hyperæmic condition of the cord as its cause, would naturally proceed on the lines of lowering the chronic congestion of the organ, and thus it is that remedies such as belladonna and bromide of potass., sometimes relieve by their power of diminishing reflex action, and causing anæmia of the cerebral organs, but their good effects are transient and not always perceptible. I have long since discarded them as insufficient, and have adopted the use of derivatives and revulsives, such as dry and wet cupping, or blisters to the nape of the neck, applied as high as possible, and as close as circumstances will permit to the neighborhood of the foramen magnum occipitale and the region of the medulla oblongata.

In my experience I have had but seldom to apply to the cupping; one full vesication being generally sufficient; a blister three inches in length by two in breadth, either by emplastrum lyttæ, or by my favorite remedy, the linimentum cantharidis of the Pharmacopœia, applied vertically, suffices. It is very seldom that a second application is required; occasionally, especially in females, after some months of respite, there may be a call for the renewal of the remedy; in obstinate cases and in grown up patients, dry or wet cupping may be requisite to complete the cure. It is of importance to note that while this infirmity is of much less frequent occcurrence in the female, it is also sometimes more difficult of cure; this may be accounted for by the anatomical peculiarities of stricture in the female organs, the urethra is only one and a half inches in length, and is much wider than in the male; it is besides unprovided with a sphincter muscle so distinctive of the other sex. It is also generally well known that females, even in waking moments, have not always complete control over the bladder, and that the slight impulse communicated by a fit of sneezing, laughing or coughing, may at any time in some individuals cause a complete evacuation of its contents. My plan of treatment has been thoroughly tested, however, in a female orphanage, and St. Patrick's Industrial School, at present containing more than 150 female children, averaging from 6 to 18 years, and the manager informs me that there has not been a single case for more than a year in the school, and that those treated by blistering had all recovered, only two having required a second application. In private practice, too, it has been fairly successful in female children. — *Provincial Medical Journal*, January, 1887.

Simple Test for Wall-Paper.—A simple and easily-applied test for wall-papers has been devised by Mr. F. F. Grenstted. No apparatus is needed beyond an ordinary gas-jet, which is turned down to quite a pin-point, until the flame is wholly blue; when this has been done, a strip of the paper suspected to contain arsenic is cut one-sixteenth of an inch wide, and an inch or two long Directly the edge of this paper is brought into contact with the outer edge of the gas-flame a grey coloration, due to arsenic, will be seen in the flame (test No. 1). The paper is burned a little, and the fumes that are given off will be found to have a strong, garlic like odor, due to the vapor of arsenic acid (test No 2). Take the paper away from the flame, and look at the charred end—the carbon will be colored a bronzered, this is a copper reduced by the carbon (test No. 3); being now away from the flame in a fine state of division, the copper is slightly oxydized by the air, and on placing the charred end a second time, not too far into the flame, the flame will now be colored green by copper (test No. 4). By this simple means it is possible to form an opinion, without apparatus and without leaving the room, as to whether any wall-paper contains arsenic, for copper arseniate is commonly used in preparing wall papers. Tests 1 and 2 would be yielded by any paper containing arsenic in considerable quantities.—*British Medical Journal*, Dec. 11, 1886.

Entozoa and Pernicious Anæmia. — Dr. G. Reyher, writing on the etiology of pernicious anæmia, points out that, as in a large number of these cases a Bothriocephalus latus has been diagnosed and expelled by means of male fern, the patients subsequently recovering, and as the anæmia of miners is now known to be due to the Anchylostomum duodenale, it is possible that all cases are due to entozoa of one kind or another, and that therefore diligent search should always be made in the faeces for the ova of tæniæ, etc. The treatment will in cases of successful search be obvious.—*Lancet*, Jan. 29, 1887.

Treatment of Diabetic Thirst.—Duchenne recommends the following mixture for the excessive thirst of diabetic patients:

Phosphate of potassium	2 parts
Water	75 "

One teaspoonful should be given two or three times a day in a little wine or hop tea.—*Nouveaux Remèdes*, October 1, 1886.

THE RED CORPUSCLE AFTER TRANSFUSION.

From a clinical standpoint the question of the normal life-duration of red blood-corpuscles is chiefly of interest on account of its bearing upon transfusion of blood. As is well-known, the lamented Panum made the first direct attempt to ascertain the life-duration of transplanted corpuscles, but by a method which was both crude and laborious—though he found that the red corpuscles were capable of living at least five days after transfusion, and that their life-duration was probably longer Twelve years after Panum's experiments Worm-Müller found by experiment that the longest possible life-duration of corpuscles after transfusion in dogs was about two or three weeks. Quincke's observations agree with this result; and experiments made by Dr. William Hunter, of the University of Edinburgh, and published as a "Report to the Scientific Grants Committee of the British Medical Association," still further confirm the accuracy of the statement. From his observations on dogs and rabbits he draws the following conclusions: 1. The duration of life of red corpuscles after transfusion varies considerably in different animals, and in the same animal at different times; 2. That the life-duration depends on two main factors, namely, the quantity of blood transfused, and the activity of the organs concerned in blood destruction; 3. That the process of blood-destruction is probably, under normal circumstances, more rapid in the dog than in a rabbit, and that this is certainly the case after transfusion of blood; 4. That the share taken by the liver in this process of destruction is always considerable, but is always greater in dogs than in rabbits; 5. Since after transfusion of blood in conditions of health, the rate of destruction of the transfused corpuscles averages from 2 to 3 per cent. *pro die* in the rabbit, and is considerably more rapid in the case of the dog, to conceive of a condition, therefore, in which after transfusion of a small quantity of blood, for example, 3 or 4 per cent., the corpuscles may remain discoverable for a period of some days, is to conceive of a condition, which, in all probability, never obtains; and, while this is true of the rabbit, it will hold still more true of the dog (and, by analogy, also of men), in which animal the process of blood-destruction is normally more rapid.

We are not so much interested, however, in the manner of conducting the experiments, as in the conclusions which may be drawn from them as to the effect of transfusion upon man; and Dr. Hunter's paper is chiefly valuable to the clinician on account of what he says on this point. We cannot, on man, transfuse such large quantities of blood as to ascertain, by actual enumeration, the life-duration of the transfused corpuscles. Again, transfusion is practised upon man only in conditions of anæmia, and here the functions of the blood-forming or blood-destroying organs are altered or impaired. "We may assume that in man, as in the dog, the corpuscles after transfusion, will be disposed of with a rapidity directly proportional to the quantity of blood injected, and varying with the activity of the organs concerned in blood-destruction, especially the liver.' If, for example, "in a person weighing 112 lbs., the quantity of whose blood would be 138 oz., we transfused 6 oz. of blood (or 4.3 per cent.), the excess of corpuscles would under normal circumstances be got rid of in all probability in a period of from one to two days." But as we have seen, it is in conditions of anæmia that transfusion is performed; and for the purposes of this discussion we may disregard traumatic anæmia. We may regard simple anæmia and chlorosis as due to a deficient blood-formation: on the other hand, anæmia may be due to increased blood-destruction; due either to greater activity of the blood destroying organs, or to lessened vitality of the corpuscles, or to both. "So far as my observations at present go, I am inclined to think that the greater number of cases of anæmia, if not, indeed all, may be referred to one or the other of the first two conditions; either to diminish production of blood corpuscles, or increased destruction." It will be understood that we are now taking no account of the blood-plasma.

As to the effects *per se* of a diminution of the number of the corpuscles, experiments on animals

show that the greater proportion of the corpuscles, may be withdrawn without serious result to the animal. We may withdraw one-half or two-thirds of the blood of a dog or rabbit, and replace it with a ¾ per cent. solution of common salt without affecting the general health of the animal. And as a matter of fact, animals fatten under repeated bleedings. Now, chlorosis "is essentially the result of a faulty formation of red corpuscles, probably in the main induced by a faulty assimilation of iron and consequent deficient formation of hæmoglobin. In such cases, in spite of the fact that the number of corpuscles may be reduced by one-half, one-third, or even more, and the hæmoglobin percentage even more reduced, the condition of the patient is far from being a serious one. But the case is quite different in other cases of anæmia, such as those to which the terms 'progressive' and 'pernicious' have been applied. When we contrast the appearance of a chlorotic patient with that of one suffering from pernicious anæmia, associated as this is with a general wasting of the body, it is impossible for us to resist the conclusion that in the two cases we have to deal with two entirely different affections, both characterized, it is true, by a great deficiency in corpuscles, but with entirely opposite tendencies. The latter condition must be regarded as essentially the result of an increased destruction of red corpuscles, mainly on the part of the liver; the condition being entirely uninfluenced by the administration of iron." These extremes of anæmia must be carefully distinguished, and it must be remembered at the same time that between the two there are many varieties of intermediate forms. But the important point to remember in all of them is "that the condition of the blood, as regards the number of corpuscles, does not in itself constitute the disease, but must be regarded mainly, if not entirely, merely as the result of disease —of morbid action in some organ or other of the body." Under such circumstances transfusion can act only by modifying the nutrition of the body, and this it can do in one or other of these ways (taking into consideration only the red corpuscles): 1. Either by the blood-corpuscles continuing to live for a certain time within the circulation, and continuing to perform during that period all the functions of those normally present; 2. By the introduction of a certain amount of oxygen along with the corpuscles at the time of transfusion, and the increased supply of oxygen brought to the tissues while the corpuscles remain in the blood; 3. By the introduction of the hæmoglobin contained in the corpuscles.

We are thus enabled to form a tolerably definite estimate of the life duration of the red corpuscles after transfusion. In the dog the rate of destruction of corpuscles in excess is 5 or 6 per cent. daily, or even more. But in man we can rarely transfuse a quantity of blood equivalent to more than 5 or 6 per cent., which is probably entirely insufficient to materially influence the general mass of the blood, for its destruction may be expected within a day or two at most under ordinary circumstances. Now, in cases of pernicious anæmia we transfuse corpuscles into an organism whose own corpuscles are perishing with undue rapidity; and "it may be fairly regarded as doubtful whether the introduction of corpuscles under such circumstances can be of the slightest value at all;" that is, if the value of the operation is to depend on the continuance of corpuscle-life for some time. "It may, however, be urged that, in other conditions of anæmia, namely, those depending on diminished production, the same argument cannot apply against the efficacy of transfusion, since under such circumstances the process of blood destruction is probably also diminished. This is probably the case, but in such conditions there is little or no occasion for resorting to such an extreme measure." But this diminution of corpuscles does not *per se* constitute an immediate danger; we know that there are cases of anæmia in which the corpuscles are reduced to 700,000 or 800,000 per cm., without the life of the patient being endangered; and we can restore the blood to its normal condition without transfusion. The amount of oxygen conveyed to the tissues by the new corpuscles may be considerable at first; but as this supply depends on the life-duration of the new corpuscles, it is doubtful whether the operation is justifiable on this ground. Most probably, thinks Dr. Hunter, the beneficial results of transfusion are due to the introduction of a certain quantity of hæmoglobin into the system, which may serve as a stimulus to the blood forming glands, and thus stimulate them to an increased production of red blood-corpuscles. This view is based on the destruction of blood in the liver, the spleen, and the bone-marrow, and the effect of an accumulation of blood-pigment in the organs on the nutrition of the animal. An accumulation of pigment in the spleen is both compatible with health and conducive to its maintenance; but the accumulation of pigment in the liver is always greatest when the animal's health has suffered most—and this is readily understood when we remember the double function of the spleen —blood-forming and blood-destroying—and that pigment accumulated in the liver is effete matter, indicating that a large amount of iron has been withdrawn

from the system. But as in all cases, says Dr. Hunter, "only a certain proportion of the blood corpuscles so introduced is destroyed by the double-function organs, the remainder being disposed of by the liver, "and those proportions are determined by the relative activities of the two sets of organs, it follows that, in most cases of anæmia, only a small proportion of the hæmoglobin so introduced can be utilized for purposes of blood-formation; and this proportion becomes infinitesimal, and the value of transfusion correspondingly lessened, in those cases of anæmia —for example, pernicious anæmia—which in all probability depend on an excessive blood-destruction on the part of the liver, a destruction evidenced, amongst other things, by the extraordinary amount of blood-pigment found within the liver-cells in that disease."

Dr. Hunter's very interesting paper, containing an account of his experiments, may be found in the *British Medical Journal*, of January 29, 1887.

RESECTION AND EXCISION.

Surgical writers, especially those using the English language, seem to have fallen into hopeless confusion, and a great deal of error, in regard to the meaning and use of the words resection and excision. This is most prominently seen in three very recent works on operative surgery, in which we read the following: "The terms excision, exsection, and resection may be applied without distinction to operations having for their object the removal of the articular extremities of bones, or of bones in part or whole" (Mears); "Excision of bone is a conservative operation, directed to the extraction of such portions of it as are inconsistent with the future usefulness or the symmetry of the part, together with the removal of the condition directly demanding the operation" (Bryant). By the latter excision is employed to the exclusion of resection, which is not used in connection with operations on bones. In a third, and still more recent work, some attempt is made to distinguish the words: "The terms resection and excision are frequently used as synonymous, but though the definitions of the two words are not unlike, there is a different and distinct meaning attached to each when properly employed. Resection strictly implies the removal of the shaft of a long bone, while excision means the removal of the joint ends of the bones, or the extirpation of a short, flat, or irregular bone" (Stephen Smith). To show how consistent the last writer is in applying the terms we may cite a few examples: "Resection of lower end of radius; excision of the extremities of ulna and radius; resection of upper end of humerus; the humerus is generally resected in part, though it has been removed entire; the scapula is resected for shot injuries, necrosis, and morbid growths . . . resection for necrosis should involve the entire bone; the spine, acromion process, and angles may be separately resected; resection of cuneiform bones; osteoplastic excision of the *foot* (possibly a new operation); the vertebræ have been subjected to frequent partial resections; portions of ribs may require resection; resection operations on the bones of the face; excision of half of lower jaw; resection of upper jaw." These are a few of the many examples which might be cited. It will be seen that the definitions practically exclude the removal of a portion of the shaft of a long bone, or of the articular extremity with a portion of the shaft, or of half of a short, flat, or irregular bone.

If we did not know where to go for information on this subject we might very properly ask for the authority upon which the words have been thus defined. In the 1874 edition of Dunglison's "Medical Dictionary" resection is defined as "Act of cutting or paring off. A name given, especially by the French surgeons, to operations in which the carious extremities of long bones, or the unconsolidated extremities of fractured bones forming irregular joints, are removed with the saw." This definition would be more nearly correct if the words "carious" and "with the saw" were omitted. Webster's definition (last edition) of resection is: "The removal of the articular extremity of a bone, or of the ends of the bones in a false articulation." This is not entirely inclusive, but shows that resection does not mean the removal of the shaft of a long bone. Excision means *destruction, extirpation*. But perhaps it may be well to go back a few years and see what has been the usage of the words: In Littré's translation of Hippocrates the words *résection* and *réséquer* are used in the sense of removing a *portion* of bone. Benivieni, in writing (1529) of an operation, uses the words *magna ossis parte resecata*. Park, who first resected the knee in 1781, speaks of his operation as total extirpation of the *joint* or *section of the extremities* of the bones forming the articulation. Thirteen months later Moreau operated on the tibio-tarsal articulation, and his son describes the operation as a *résection*, using the word in the titles of two papers (1803 and 1816). Syme wrote a "Treatise on the Excision of Diseased Joints," and this is one of the earliest authorities (if it be one) for such use of the word, except its use by James Jeffray, who also quotes Park as using it (1806). In 1812 the Faculté de Méde-

cine of Paris gave the following as the subject for a thesis: *De la Résection et du retranchement des Portions d'os*, etc. The title of Champion's *Thèse*, written in 1815, was *Traité des Résections dans la continuité des os cariés*. Since that time we find that French and German writers uniformly use the word as we claim it should be used. Fancy a German using such a term as *Gelenkexcision!*

In the Catalogue of the Library of the Surgeon-General's Office we find resections tabulated under "Excisions." But on examining the list it will be found that in about 80 per cent. of the titles resection is the word used; that the word excision occurs most frequently in English titles, though resection is used in some of these; and that German, French, Italian, Spanish, Danish, Dutch, Norwegian and Russian writers use resection almost invariably in speaking of the operations on joints. We find German writers using *Aussägung* as synonymous with resection. Wagner uses the words "*Resection und Extirpation*" in a title, showing that he distinguishes them. Finally, Ollier, of Lyons, who has made the most careful study of the subject, and everything connected with operations on bones, of any writer, says, in his *Traité des Résections:* We will only apply the name resection to the operation which consists in dividing a living bone and cutting off a considerable portion of it, preserving the soft and hard portions situated below it. By considerable portion, we mean so much as by its absence changes the external shape and relations of the bone. He does not use the word excision, because he says that some authors have used it synonymously with resection; instead of it he uses total ablation or extirpation; and he divides resections into two categories: 1. *Resections of continuity*, or *osseous resections;* and 2. *Resections of contiguity*, or *articular resections*. The term *total resection* he uses for an operation which removes "all the osseous extremities which constitute an articulation." It certainly does not seem reasonable to speak of total removal of the radius as a resection, and term total removal of a rib an excision; and at the same time use excision for the removal of the articular extremity of the radius. It is a confusion of terms, and warranted neither by good usage nor etymology. As applied to soft parts excision is always used in the sense of extirpation, destruction, total removal; and resection in the sense of partial removal. We excise the tongue, spleen, kidney, larynx, tumors; we resect the intestine, tendons, pancreas, lung, etc. There seems to be no reason for completely changing the meaning of a word according to the structure or location of a part operated upon.

NEURASTHENIA AND NEURATROPHIA.

In the *Philadelphia Medical Times*, of January 22, 1887, is a leading article in which it is said that the term "neurasthenia" was coined by Dr. Geo. M. Beard, from a term "nervous asthenia" used by Dr. Fordyce Barker, and that Dr. Beard wrote the first accurate description of the condition. Other writers have made the same or a similar error. Dr. Beard did not invent the term, nor was he the first American writer on the subject. His first contribution appeared in the *Boston Medical and Surgical Journal*, on April 29, 1869. Dr. E. H. Van Deusen, of Kalamazoo, Mich., wrote the first systematic paper on the subject in 1867, and was the first to call attention to the theory of its being associated with an underlying neuropathic diathesis (*Michigan Asylum Reports*, 1867); a theory which the *Medical Times* credits to Arndt (*Die Neurasthenie;* Wien: 1886), but which has been a profound conviction with advanced neurologists since the appearance of Van Deusen's paper. Nor did he coin the word: it may be found in Dunglison's "Medical Dictionary," Edition of 1856. In a late article Playfair objects to the term, but finds nothing better; though *neuratrophia* expresses the underlying organic condition of all forms of neurasthenia. It expresses a state of nerve starvation due to causes inherent in the nervous system itself, having its appropriate symptomatic expression in nervous exhaustion, and its immediate consequences (*Alienist and Neurologist*, July, 1882). In the *Alienist and Neurologist*, of October, 1880, may be found a paper by Dr. C. H. Hughes, of St. Louis, giving full credit to Van Deusen for his work in this field.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, January 12, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

H. M. Cutts, M.D., Secretary.

Dr. J. Taber Johnson read a paper entitled

CAN THE CÆSAREAN SECTION BE SAFELY SUBSTITUTED FOR CRANIOTOMY IN THE UNITED STATES AT THE PRESENT TIME?

(See Journal, Feb. 12.)

Dr. T. E. MacArdle said that no one listened to Dr. Johnson's paper with greater interest than himself. If two years of careful study had accomplished so much for him, he felt quite sure that he will stand

by his side before very long. I expect to hear him declaim with me against "the deliberate and cold-blooded murder of an unoffending child," and I expect to hear him teach that the child should be given a chance for its life even at some risk to the mother. I congratulate him on his near conversion. If Dr. Meadows did not convince others that craniotomy should be forever abolished from the list of justifiable operations, at any rate he seems to have enlarged the views of many who listened to him, and of many who read his burning words. All that is asked of Dr. Johnson is to teach his students what he says is the outcome of the discussion in England, viz., that whenever Cæsarean section offers the best chance it should be urged upon the family. For he contends that it always offers the best chance of saving life.

Dr. Johnson does not wish to be bound by cast-iron rules of any kind, whether medical, ethical, or theological. "Thou shalt not bear false witness" and "thou shalt not commit adultery" are about as cast iron as "thou shalt not kill;" and yet I cannot imagine my friend committing perjury or stealing his neighbor's wife, though he might, indeed, under certain circumstances, kill his neighbor's child, for fear some one would say he was bound by a cast iron rule, formulated by himself or for him by others. If, forsooth, the woman has been in labor for twenty-four hours, and he cannot successfully deliver by forceps, must he destroy the fœtus because he has been engaged to see this woman safely through her labor, and neither she nor her husband are willing to subtract anything from the mother's chances for the sake of a living child? Does not the accoucheur owe some duty to the child? Perhaps the woman, when she discovered herself pregnant, not knowing the deformed condition of her pelvis, consulted her physician to rid her of the burden she did not wish to bear. But the good physician who is bound by the cast iron rule not to commit abortion under such circumstances, because it is murder, will not hesitate to perform craniotomy, and his feelings are dreadfully hurt if you call it murder.

Dr. Johnson thinks he makes a strong point when he quotes Barnes as disapproving of the action of those who wait until the child is dead before performing craniotomy. I hold such men culpable, and contend that they should make an effort to save two lives. I contend that when the child is alive, we hold its proxy, and must cast its vote in favor of Cæsarean section or one of its alternatives. I would modify Lusk a little and say "the duty of a physician is to his *patients*," and he has no right to neglect or kill either of them. Even the pagan Cicero, quoted by Parvin, deems it right to save the life which shall be of greatest service to the State. But Parvin has not proven to my satisfaction that a woman who cannot become a mother is of greater importance to the State than a child whose possibilities are unlimited. I will be greatly indebted to Dr. J. for a list of the cases in which our hands will be tied by an adherence to an inflexible rule never to commit murder.

If it be difficult, in the practice of medicine or surgery, to make correct comparisons, let us afford statisticians no chance of making them, but let us adopt the rule to know our art so thoroughly that we will recognize early enough the conditions calling for Cæsarean section or some of its alternatives. Let it be no longer said that "in Germany physicians can control the circumstances of their operations and their patients better than we do in this country; that they have better and more opportunities to perform timely Cæsarean sections than we do in the United States;" excepting, of course, the greater number of cases which are liable to occur on account of the greater prevalence of deformed pelvis. Though, fortunately, our opportunities of studying deformities of this character are comparatively limited, yet I contend that a more accurate study of pelvimetry, by means of normal pelves, will remove such blots from our escutcheon, as the recent case in Philadelphia. An early diagnosis and the consent of the patient and her friends to an early Cæsarean section, is more than half the battle, says Dr. Johnson. Very well, make your early diagnosis, and teach your students to make an early diagnosis, and teach your students that they must do away with the fear that the result will be fatal, and let them, by their words and actions, so inspire their patients that, being imbued with confidence, there shall be no delay, no golden moments frittered away. The fault lies with obstetricians, and more especially with teachers of obstetrics and writers of obstetrical text-books. They have not been properly instructed themselves, and they fail to properly instruct others, but they go along blindly, handing down the teachings of their predecessors without learning the right and then standing up for it manfully.

Professor Leopold, of Dresden, has operated nine times, saving eight women and all the children. The two maternity hospitals of Dresden and Leipzig together have had sixteen operations with fifteen maternal recoveries and the survival of all the children. Let us emulate this most successful and glorious record. Is it not good sound Yankee doctrine to let no one excel us in anything good? Have the Europeans greater skill, more brain force than we? If so, we can not begin too soon our endeavors to equal them. Do we hesitate to perform laparotomies because we cannot hope for the success of Tait? And shall we lay so much stress on antisepsis when Bantock, Keith and Tait pretend not to use them? Let physicians and patients be taught to believe that Cæsarean section is the best operation to perform, that it shall be done early, and that it does not mean sure death; let these principles be inculcated, and we open the door to a more successful future. I agree with Tyler Smith, that "Craniotomy was a rude attempt, devised in the infamy of the obstetric art, to rescue the mother at the expense of the child, in cases of otherwise insuperable difficulty."

Every great discovery in this branch of medicine stands in direct opposition to craniotomy, and has invariably tended to diminish the frequency of its performance where the child is living. Thus, as regards craniotomy, a process of diminution has been going on for ages. It remains to be seen whether the time has not arrived when a stand should be

made for its entire abolition, as a rule of practice, in cases in which the child is alive and viable.

Pelvic deformities, besides being the most frequent cause of craniotomy, have always been considered as the most justifiable excuse for its performance. But if we give due importance to measures of prevention, it cannot be denied that all such cases may be met without the necessity of craniotomizing the living child at or near the full term. But I believe that such deplorable contingencies need never occur, and that cases of this kind, when they do happen, ought to be considered as depending on some error or neglect, and to be held only as exceptions to right practice. Nothing will tend so much to diminish or prevent such cases as the establishment of the non necessity of craniotomy as the rule of practice. Considering the various means at our disposal in the way of preventing the necessity for craniotomy, I do not hesitate to express my strong conviction that, as the rule, craniotomy in the case of the living and viable child should be abolished, and that if all the resources of obstetrics in the way of prevention, management, and alternative treatment, were properly wielded, the necessity for the operation would never occur. There is no department of medicine in which, looking to what has already been done, there is more reason to be proud and hopeful for the future, than obstetrics. If facts and arguments are of any value, the diminution or abolition of craniotomy must greatly diminish the loss of maternal as well as of fœtal life. Rightly considered, the interests of the mother and child rarely, if ever, come into collision. Neither fœticide nor matricide need ever be entertained by the accoucheur.

Dr. Thomas C. Smith did not see why craniotomy should be stigmatized as murderous, and he has yet to see an advocate of Cæsarean section who was consistent in his arguments. The men that have been termed "ignorant" in this discussion are the very men who have been most successful with Cæsarean section. The country practitioner, who has to rely on his own resources, is the man who can do successfully these operations, as well as his highly educated city brother.

What are we to do in a transverse presentation with an arm presenting and a firmly contracted uterus? Is that child to be delivered by Cæsarean section? or are we to wait for the death of the fœtus and a rupture of the uterus? How is it in twins with locked heads? Are we to deliver by Cæsarean section? The man who "sacrifices" one child there is not usually called a murderer.

Dr. McArdle says, get around the necessity of craniotomy by studying pelvimetry. *When* are we to find out the diameters of the pelvis? In the virgin? Of course not.

The gentlemen advocating Cæsarean section must have things as they want them. The women must be brought for operation at the beginning of labor. Suppose such a case is attended by a midwife who, after ineffectual attempts to deliver, sends for a doctor who discovers the state of things. He sends for the surgeon, who says, "I can not save her, but if I had been called earlier I might have." We must take things as they come, we cannot have them always as we want them. What has antisepsis to do with the case? Formerly, Cæsarean section saved a good many lives in this country, but since the introduction of antisepsis we find 86 per cent. mortality among mothers. I feel alarmed for those who place so much faith in antisepsis. One cannot say much for the encouragement of Cæsarean section from its results in this city. Few women or their husbands will give consent to Cæsarean section.

Dr. S. C. Busey corrected Dr. Smith in regard to third case of Cæsarean section mentioned by him. It was in no sense a Cæsarean section. The laparotomy was done to relieve strangulation from displaced fibroid tumor. The woman had been five or six days suffering from this. The tumor had been removed, when the membranes broke and the child was delivered *per vias naturales*. The uterus contracted, but again dilated, and there was alarming hæmorrhage. The operator then removed the uterus, controlled the hæmorrhage, and subsequently amputated the uterus.

Dr. Busey asked Dr. Smith if, taking into consideration the contracted pelvis in his case of impacted head, would he do embryotomy?

Dr. Smith replied that he would; and asked Dr. Busey what he would do if the head could not be released?

Dr. Busey said that when the child's head was impacted for twenty-four hours the child would be dead, and Cæsarean section and craniotomy were not comparable under such circumstances. In a reply to the question what he would do if the child were living at the end of twenty four hours, Dr. Busey said that he would lift the head out, after having chloroformed the woman.

Stated Meeting, February 19, 1887.

The President in the Chair.

The discussion on Dr. Joseph Taber Johnson's paper was continued.

The President remarked that as several gentlemen were present to-night who were not present at the last meeting, he would say for their benefit, that in his paper Cæsarean section was made the operation of election, but at the same time craniotomy was not to be abolished. The discussion was to be upon this ground.

Dr. S. C. Busey said that at the last meeting he had no intention whatever of censuring the gentlemen named in his remarks, but, on the contrary, he desired to commend them upon their change of opinion. He desired also to congratulate himself, that so many of the profession had so nearly adopted the views expressed by him two years ago. The discussion is upon "Craniotomy vs. Cæsarean Section," and the precise issue is, not that craniotomy has been, or will ever be, abolished, but that it "should" be; and this upon purely scientific and moral grounds. He would make a few quotations from Dr. R. Barnes' paper upon the "Alternatives to Craniotomy." Dr. Barnes has hitherto been the highest authority of the craniotomists, but he seems now to have modified

his views somewhat. Barnes says: "The question we are met to discuss—'What are the Alternatives to Craniotomy?'—may be accepted as the great test of the progress of obstetrics. Or the following proposition may be stated: the more nearly we approach to the abolition of craniotomy, the more nearly do we attain perfection in obstetric practice. Tyler Smith brought the question before the Obstetrical Society in 1859 in these terms: 'On the abolition of craniotomy from obstetric practice in all cases when the child is living and viable.' To attain this consummation in the goal to which humanity points. And science in this respect, as in many others, is untiringly striding towards the fulfilment of the dictates of humanity. That science will ever achieve all that humanity longs for may be doubted; but the pursuit is a noble one, and cannot fail to bear good fruit."

Farther on he says: "Now, whether by design or otherwise, we have arrived at this point—there is a viable child; it cannot be brought living through the pelvis; a momentous question confronts us. Shall we deliberately sacrifice it, by perforation or equivalent operations, so as to save the mother from the perils attendant upon attempts to deliver *per vias naturales*, or by Cæsarean section at a time selected when the child is viable? In such a case, the Cæsarean section takes rank as an elective operation, as a real alternative of craniotomy. If the opportunity of election between the induction of labor to be completed by craniotomy, or to be evaded by Cæsarean section, has gone by, and we are brought face to face with labor at term, the pelvis deformed beyond the reasonable probability of extracting the fœtus by embryotomy with safety to the mother, the Cæsarean section has become an operation of necessity. It is not an alternative, it is the only operation." (*Brit. Med. Journal*, Oct. 2, 1886.)

I have been constantly surprised at the sensitiveness of the craniotomists whenever the term "killing" is applied to the operation of craniotomy. Something in the word, or in the suggestion of the fact that something is killed, seems to give them umbrage. A more moderate word might be found, but the act should be described as it is, "killing at will." If the operation is not done in the truest belief and the firmest conviction of its right, in the mind of the operator, then surely there can be no excuse for it. The act of destroying must be not only the result of deliberation, but of conviction, else it is criminal. Dr. Johnson's paper is not so much an argument in favor of craniotomy as an argument in defense of those who may not be competent to perform Cæsarean section, or to determine the proper relation of either to the case. Also against what he styles a cast-iron rule, *i. e.*, not to kill one that the chances of the other may be improved, but to pursue that course which gives a chance to both and saves most lives. Surely it cannot be an argument in favor of craniotomy, that it cannot be performed by unskilled surgeons. This cannot be the scientific way of regarding the question. Which is most obnoxious, to resolve to kill, or to resolve not to kill? Which is most likely to promote the killing, a rule that you may commit the act, or a rule that you will not commit the act? Is killing such a trivial act that a physician can at will determine its justice and propriety, and excuse himself upon the hypothesis that it was his right, his privilege? Our own experience, and the experience of the past, has taught that if we recognize it as a legitimate operation it will often be done, and its alternatives will be less often resorted to. The increased knowledge of the application of the forceps has already diminished the number of craniotomies, and when we have taught its various alternatives a little more thoroughly, there will be fewer in the future.

The introduction of the induction of premature labor, by Barnes, has already saved many from craniotomy, even by the advocates of the operation. The argument that we cannot recognize the deformity until term, is not against Cæsarean section or for craniotomy. Let the absolute necessity of recognizing the incapacity of the mother before term, be taught, and we shall have more induced labor and fewer craniotomies. Craniotomy is a comparatively rare operation. Tyler Smith estimated that it was done only about once in 500 labors, and now it must be even rarer. It is admitted that, with a conjugate diameter of, or below, two inches, craniotomy is more fatal than Cæsarean section. Now, if the relative merits of the two methods are to be compared, they ought to be measured by their respective results in like conditions of pelvic obstruction below the maximum conjugate, at which either is admissible, and not by excluding from the mortality of craniotomy its disastrous results to mothers in the higher grades of diminution of the conjugate and the total loss of children at all grades.

Moreover, when we consider the cases, above the minimum, at which craniotomy is permissible, which can be delivered by forceps or version, it leaves a narrow limit for craniotomy and that is covered by induced labor. Dr. Kinkead, of Dublin, at the meeting of the British Medical Association, contrasted the two operations as follows:

Causes of Operation.	Percentage of mat. mortality
Contracted pelvis, 2.5 inches and under	37.5
Pelvic tumors. Stadfelt	40.
Ovarian tumors. Playfair	46.6
Ovarian tumors, no other treatment. Playfair	60.
Carcinoma of uterus. Hermann	75.

Compare this maternal mortality with the same in Cæsarean section, and there is not only no very great disparity, but a very considerable difference in favor of the latter, when we add the children saved. The results of Cæsarean section have been:

Number.	Percentage of mat. mortality
5605, quoted by Barnes	46.
130, quoted by Harris	56.
32, quoted by Kinkead	62.5

I may put in here, as contributory evidence, the conclusions of Dr. Barnes at the end of his paper before quoted. Barnes concludes:

"1. The legitimate aspiration and tendency of sci-

ence is to eliminate craniotomy on the living and viable child from obstetric practice.

"2. The advance of hygienic rule, the improvements in forceps, in turning, in obstetrics generally, have materially curtailed the field within which craniotomy can be justifiable.

"3. In the most extreme degrees of pelvic deformity, where delivery *per vias naturales* can only be effected with doubtful success to the mother, Porro's operation is the legitimate alternative for craniotomy, it being understood that the opportunity of inducing abortion has gone by.

"4. In less advanced degrees of pelvic contraction, but still incompatible with the delivery of a living child '*per vias naturales*,' the opportunity of inducing abortion having gone by, but in which craniotomy would effect delivery with strong presumption of safety to the mother, the Cæsarean section may be a proper alternative for craniotomy. This is the most debatable point.

"5. In the minor degrees of contraction, say from three inches to three and a half or three and three-quarters inches, the opportunity of producing labor having gone by, the far greater safety to the mother obtained by craniotomy, and the prospect of living children in future pregnancies by induced labor, make craniotomy the proper course to adopt.

"6. In other emergencies than deformity, as in obstructed labor from ovarian tumors, the alternative to craniotomy is to remove the tumor.

"7. In cases of immovable tumors, Porro's operation is the proper alternative.

"8. In rupture of the uterus, the being delivered or not, Porro's operation is the alternative. There the interests of mother and child coincide.

"9. In cases of disease or tumors of the uterus obstructing delivery, Porro's operation is the proper alternative.

"10. In atresia of the cervix or vagina, Cæsarean section or craniotomy may be necessary; but incisions or gradual dilatation will more frequently be the proper alternatives.

"11. When obstruction is due to hydrocephalus or dropsy in the child, embryotomy or tapping is indicated. When the child is dead, embryotomy is indicated, and decollation when the child is impacted, and turning is hazardous.

"12. In convulsions and hæmorrhages, the proper alternatives for craniotomy are found in the more scientific methods of conducting labor under these complications.

"Lastly, but the dream of Tyler Smith, the abolition of craniotomy, will be fully realized only when hygiene shall have triumphed over disease and deformity."

Dr. Johnson would, perhaps, like to know some of the men whose opinions coincide with my own. In the discussion following the paper of Dr. Kinkead, before quoted, Dr. Lusk says he believes "that, under 2.75 inches, namely, below the limit where premature labor and version were available, modern methods of Cæsarean section were preferable to craniotomy. Cæsarean section always held out promise when performed under favorable circumstances." Mr. Lawson Tait, in the same discussion, said that he could add but little from the obstetric side of the question; but from the surgical aspect, he felt certain that the argument that such operations as that of Porro would fall largely, of necessity, into the hands of men inexperienced in abdominal surgery, was not of much value; for exactly the same thing was true of bad cases of craniotomy; and he felt certain, of the two classes, under similar circumstances, the resulting advantages would be largely on the side of amputation of the uterus." Dr. More Madden, for a long time Master of the Rotunda Hospital in Dublin, following Mr. Tait, said: "In a long experience in hospital and private practice, and as an obstetric teacher, he had not himself been able to recognize the necessity of craniotomy, and he had never resorted to it or countenanced it. . . . In cases of difficult or complex labor, in which craniotomy, which he regarded as a murderous and horrible operation, had been recommended, he had been fortunate to save life by one—or attempt the various improved methods of artificial delivery now available—namely, either by the induction of premature labor; by the modifications of Porro's operation; or by Cæsarean section; or by the timely and judicious employment of the long forceps, or version—whichever method might be adopted, it should, he said, be borne in mind that the primary object of the obstetric art was to deliver living children from living mothers, with safety to both."

Finally, Mr. Hough said, "after a large practice of over forty years at midwifery, he had only met one case in which it was necessary to perform craniotomy, and that was about forty-two years ago."

If we are to consider the question from a scientific standpoint, we must take into consideration the total number of lives saved. The lives of the mothers alone do not give a fair basis for comparison of the two operations. He has prepared a table contrasting 38 cases of Sänger's operation, given by Harris, and an equal number of supposed cases of craniotomy, thus:

Operation.	Cases.	Women saved.	Per cent. women saved.	Children saved.	Per cent. children saved.	No. lives at risk.	Lives saved.
Sänger	38	26	68.42	33	86.84	76	58
Craniotomy	38	38	100.00	None.	None.	76	38

Seventy-six lives are involved in both cases. But at the outset, only 38 lives can be saved by craniotomy, and this per cent. has never been attained. Barnes says that the percentage of deaths has been reduced to 5 per cent. in craniotomy. This cannot be maintained, for while one man may have a series of cases without a single death, another, in the same city, will have a succession of fatal ones which will increase the mortality. Nor is it fair to say that the success of the Sänger operation is due to the locality in which it is done, or to the dexterity of the operators. Undoubtedly dexterity is of value, but just as necessary as it, is the conviction of right, and the

courage of one's convictions. These, together, are what create success.

Perhaps it does require the best educated men to determine when, and where, and how to perform the operation, but experience has shown that these are the very men to get along without it, and that in their hands the operation is seldom, if ever, done.

When the profession in this country is educated up to the same high standard, but few will perform the "sacrificial" operation. In my opinion, the question may be safely left to the advance of science, and I believe that in ten years few men will do it or justify it. The craniotomists claim the right of election, when two lives are at stake, and also which of the two lives is the most valuable. But when, and how, and by whom, is this question to be decided? Certainly not by the executioner. The many alternatives which afford reasonable chances of saving both are a positive denial of such a right. Barnes says upon this subject: "Therefore, if it be still contended that the Cæsarean section should in all cases be preferred to embryotomy, it must be qualified upon other grounds. Two points must be granted, or either of them: 1. Must we abandon the old moral law, which declares that it is the mother's right to save her own life, even at the sacrifice of her child's? Are we prepared for this? It is not simply a question for medicine to decide. Religion and civil law claim a voice—a preponderating voice." Here is a positive declaration that "religion and civil law have a voice—a 'preponderating' voice" in the matter. Those who claim the right to kill, claim it upon the ground that it is done indirectly. The presumption is that the act is deliberate, and hence must be direct. No conscientious man can excuse himself upon any such hypothesis.

The child is entitled to life at the increased risk of the mother. Humanity demands it, and science clearly points to it as the line of duty. The right to destroy the fœtus is also defended upon the theory that it is the aggressor—an equally fallacious argument. Consciences that can be quieted upon such a basis must indeed be flexible. It is also defended upon the basis of individuality. It is admitted that a larger number of lives are saved by the Cæsarean section. Nevertheless, it is claimed that there are instances which absolve the operator from wrong. It is true physicians are not always permitted to do that which is proper and right, but the denial of this right or principle cannot carry with it the privilege to commit a wrong, nor can it absolve the operator from the deliberate commission of a wrong. Sentimentality, family ties, and other circumstances, may embarrass individual instances, but such considerations cannot affect the question in its scientific aspects. Many persons believe the production of abortion before the period of quickening is justifiable, but no physician will admit such a doctrine. After all, except that Dr. Johnson maintains that craniotomy is occasionally a proper procedure, our views upon the subject do not greatly differ.

Dr. Johnson has quoted from the recent work of Dr. Parvin, in which he says: "The principle of morals upon which most obstetricians rest the right to sacrifice the child for the sake of the mother is a very old one, and has met with general acceptance; that principle clearly enunciated by Cicero, for example, and sustained by moralists of all ages, is, that if two lives are in such peril that both cannot be saved, but one will be, by the sacrifice of the other, let that life which is of the least value to the State or to society perish." No such condition as Cicero defines has or ever can exist in cases where Cæsarean section and craniotomy are alternatives. No one ever has or can assert that either life will be saved by the sacrifice of the other. No one ever has or can guarantee the life of the mother after craniotomy. Moreover, who is to determine the value of the lives? The operator? the man who may be impelled to the execution because of ignorance of the other procedures, or too timid to undertake another. Who can estimate the value of the life of an unborn child to society or to the State, and who is to determine the relative valuation of such a life and that of a woman who cannot give birth to a child *per vias naturales?* The executioner? If the life of the mother could certainly and only be saved by the killing of her fœtus, and the death of both was otherwise inevitable, the execution of the child might be justifiable as the only alternative,—but such is not, and never can be, the case.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 9, 1887.

The President, J. Solis Cohen, M.D., in the Chair.

Dr. George W. Vogler reported a case of

SUPPURATIVE INFLAMMATION OF THE LIVER IN A CHILD TWELVE YEARS OF AGE; OPERATION AND RECOVERY.

M. C. S., female, æt. 12 years, of rather delicate and frail build, presented the following history:

On October 7, she first complained of intermittent pain immediately over the right hypochondriac region, corresponding to the right lobe of the liver, and at the same time began to favor the part by slightly bending forward and to the right side when standing or walking. She was still attending school, and kept up active exercise. There were apparently no other symptoms present—at least she complained of none. This state of things continued for about one week, the little patient continuing her school duties, although with much suffering and inconvenience. She now refrained from going down to recess with the other children. The pain became more severe, especially at night, producing great restlessness, and interfering with sleep. The stooped condition of the body was now permanent; walking was discontinued owing to pain; and some fever (at night particularly) also manifested itself, with marked impairment of appetite, coated tongue, thirst, cloudy urine, and constipation. Both the mother and child after several careful examinations of the part, found nothing to account for the trouble. In the mean-

while, a physician in attendance upon another member of the family was asked to look at the child. He examined her several times, but found nothing of note, and pronounced the case as probably a strain, or one of cold, for which he ordered a plaster, and some citrate of magnésia for febrile disturbance. The child continued to grow worse daily, and the same physician ordered a fly-blister to the affected part. It may be mentioned just here, that the pain, never shifted, but was always confined immediately over the area corresponding to the right lobe of the liver. Flax-seed and onion poultices were ordered to be applied by the medical gentleman upon noticing later a slight swelling over the seat of pain. Upon November 12, five weeks after the commencement of her illness, I assumed charge of the case. I found her bedfast, greatly reduced in flesh, with an anxious expression and suffering intensely. Her favorite position was a sort of sitting posture, with the body bent forward and to the right, and with the lower limbs flexed strongly upon the abdomen. The symptoms already described were very marked; also irregular attacks of chilliness or rigors; temperature was elevated every night; there was no cough, jaundice, or vomiting; there was, however, sallowness of the skin, and dark, turbid and scanty urine.

Examination revealed a dark bluish swelling, some three inches in diameter in the right hypochondriac region, bordered by the sixth rib above; the tenth below; the linea mammalis (a line extending perpendicularly downward from the right nipple), upon the inside; and the linea axillaris, on the outside. The swelling was about three-quarters to one inch in height, and presented all the appearances to sight and touch of a carbuncular development. It was hard, firm, and quite painful to the touch. There was no fluctuation. My first object was to ease the child of her enforced or assumed cramped and painful position in bed by encouraging her to occupy a rocker, or, if possible, to step about the room a little. She was put upon concentrated nourishment, stimulants, and medicinally, on syr. ferri iodidii, and bromides and chloral for the pain. The latter remedies had to be early replaced by opiates and quinine, owing to their inefficiency to combat suffering. Temporarily, I ordered an ointment applied every eight hours, composed of camphor, opium, ext. belladonna, comp. resin ointment, and cosmoline.

This plan of treatment was continued for five or six days, with the effect of markedly softening the swelling and causing it gradually to diminish in size, and the development of a central point of concentration just over the eighth intercostal space. I thought I detected fluctuation on palpation, but obtained nothing but blood on aspiration with the exploring needle. At any rate, the child seemed easier and more comfortable. Anodyne flax-seed poultices were now started, and on the 21st instant I prepared to operate, all the conditions seemingly pointing to the detention of deep seated pus. Contrary to the usual custom, I determined to treat the case by free incision, the thorough evacuation of the pus (if any), and the prevention of reaccumulation by complete drainage by means of rubber tubing.

The patient was thoroughly etherized, and after selecting a favorable point by the aid of the exploring needle, a free opening was made, one inch or more in length, down through the eighth intercostal space, about one and a half inches to the right of the linea mammalis. Immediately a large quantity of pus flowed from the wound. The amount of pus I judged to have been at least eight fluid ounces. At first the pus was "laudable," free from odor, but streaked or marked with biliary coloring matter; toward the end it assumed the very dark condition usally spoken of as "chocolate-colored pus," due to the presence of blood or disintegrated hepatic tissue. Gradual pressure over the hepatic area aided in its rapid and free evacuation, the bulging over the intercostal spaces disappeared, and for the first time the outlines of the ribs were readily reorganized. A probe was now passed through the wound under the ninth rib, and it entered in an obliquely downward direction, to the extent of four inches, toward the linea alba, and three inches obliquely upward toward the sternum, in depth perpendicularly about two and a half inches. A perforated rubber drainage tube doubled upon itself, and was introduced into the depth of the cavity, enabling free drainage; and the daily injection of carbolized oil (two to sixteen fluid ounces) through one end, and its escape through the other. Warm cataplasms were continued night and day. After some five days the tube was replaced by one of a smaller calibre, and entirely done away with the ninth day after operation. A small piece of lint dipped in carbolized oil was used a few days longer, simply to keep the cut from closing and insure through healing from within outward. Finally, carbolized zinc ointment completely healed the wound by December 8. Her improvement and rapid convalescence after the operation were wonderful. Internally she has been taking cod-liver oil emulsion with hypophosphites and syrup ferri iodidii.

December 12, she was walking and playing about her room. Of course, the marked constitutional depression due to her serious ailment, will to a considerable extent, continue for some time to come, but there is at present no doubt of her entire recovery of good health.

January 15, 1887, the child is well.

The first noteworthy fact is the *age* of the patient, viz., 12 years. Statistics show this affection to be rare in children, being seldom seen under the age of 20.

In seeking for the *cause* of the disease in this case, I am led to adopt one of a traumatic nature. Frerichs, Budd, Andral, Romis, Morehead, and others, in their collection of cases, show but a very small percentage due to external violence. Thus, Budd reports only two out of his sixty-two cases collected; Morehead, but four out of his extensive observations—318 in all. The patient revealed no previous malarial, dysenteric or metastatic history, or any other inflammatory and ulcerative process in the gastro-intestinal canal, which are generally looked upon as the chief disturbing influences or causes of suppurative inflammation of the liver. Careful inquiry elicited the following history and probable

cause: About four days previous to the commencement of her symptoms, she assisted her aunt in carrying flower plants from the yard up to the fourth floor of the house. One of these plants was, owing to its weight, entirely beyond her strength, yet, after four efforts, she succeeded in landing it on the fourth floor. She described very vividly the pain felt by the pressure, and the weight sustained over the right hypochondriac region in her struggles to complete her task. As before said, the child is of a very spare build and delicate physically, and it is quite probable that this external violence originated her painful affection.

A few words as to the diagnosis, prognosis, and treatment. I found much difficulty for a time in arriving at a satisfactory conclusion as to the *diagnosis* of the disease, and was inclined for some days to believe the case one of an unusual carbuncular development, dependent upon a very badly run-down system, and having its starting-point in the mechanical violence or external contusion referred to above. Even the exploring needle failed me in establishing a positive conclusion. It was only quite definitely arrived at in doing as Frerichs so aptly puts it: "In most cases a correct diagnosis will only be arrived at, by not relying upon individual symptoms, by taking a general view of the mode of origin and entire clinical history of the case, and, after excluding by comparison the diseases of the liver and of the neighboring parts, which may give rise to symptoms similar to those of hepatitis."

It is well understood that the prognosis is generally unfavorable in suppurative hepatitis. Frerichs says: "Suppurative hepatitis belongs to the class of severe maladies which imperil life, and which terminate in death far more frequently than in recovery." And this naturally leads to the consideration of the treatment. I candidly believe from the presence of the grave symptoms, that my patient would have died in a short time but for the prompt and energetic operation undertaken as soon as a reasonable conclusion could be arrived at concerning the diagnosis. Even when there is considerable doubt existing and the condition of the patient is serious, careful exploratory incision could be made to determine the true nature of affairs. No danger can result from this when proper precautions are used. At any rate, the aspirator should be early used as a means of establishing diagnosis. Drs. Sims, Hammond and Jimney, of Mexico, and many others, have frequently punctured the liver without any bad results.[1] It has been demonstrated time and time again, that the entrance of air into such a cavity through an incision is not necessarily attended by decomposing action and death, but, on the contrary, a complete evacuation is obtained, reaccumulation prevented, and the threatened death by exhaustion or blood-poisoning averted. Upon the other hand, imperfect removal of the pus by one or more aspirations or punctures, permitting more or less to remain behind, will, in addition to that constantly forming, undoubtedly keep up the constitutional disturbances, and, finally, produce a fatal issue by rupture or blood-poisoning, if the very rare act of absorption does not take place.

The case happily illustrates the good results of free incision, perfect drainage, and the rapid healing and antiseptic properties of carbolized oil. The method of gradually opening the abscess as recommended by Récamier, Begin, and others, by the separation of a slouch through many applications of caustic potash or soda, is very slow in operation, painful, productive of loss of tissue, and if an opening into the pus cavity is finally established air must also surely enter. Again, many abscesses of the liver open spontaneously, and though air freely enters the cavity, the patients usually go on to rapid recovery. In fact, this latter mode of termination of the disease (spontaneous opening), is very much welcomed by the physician, and has eminent advocates. I should not think after the excellent result obtained, of treating similar cases by any other plan than the one suggested. Lives are undoubtedly lost by the partial or imperfect method of the removal of foreign material, by repeated aspirations or punctures, thereby necessarily keeping up the source of trouble which must eventually end in death. The early and prompt operation happily terminated my case in recovery in about fifty days, while Rotis, in his valuable and extensive statistics, shows the average duration of the disease in cases *not* operated upon, and which recovered by bursting either through the thoracic or abdominal walls, through the bronchi, colon, or stomach, to have been 140 days.

Dr. C. N. Seltzer said: I have seen three cases of abscess of the liver, and in these cases the symptomatology was somewhat different from that of the case described. I should think that an abscess of the liver holding 8 ounces would produce more constitutional disturbance than was present in this case. The destruction of liver structure is usually greater, and the case, as a rule, requires a longer time for recovery. The three cases which I have seen all resulted fatally, and at the post mortem the liver tissue was found to be very ragged, and hanging in shreds in the abscess cavity In these cases the diagnosis was readily reached by a microscopical examination of the pus. The liver cells could be easily detected. That, I think, should have been the mode of determining whether the case was really one of hepatic abscess or not.

Dr. Joseph S. Neff said: It is well-known that pus from a hepatic abscess rarely contains liver débris, because most abscesses in this situation are surrounded by dense walls of pyogenic membrane. The cases to which Dr. Seltzer has referred, in which the liver substance projects in shreds into the abscess cavity, are cases of diffused abscess, which are very rare.

In the circumscribed abscesses of the liver which I have seen, the tendency to point has been in a different direction from that in the case reported. I have seen only one case in which the abscess was opened through the abdominal walls. That was the case of a man in the Jefferson College Hospital.

[1] Since completing these remarks, I notice in the January 1st number of the Medical News, a report of a "Case of sudden death from the introduction of an aspirator needle," by Dr. Reeve, of Dayton, Ohio.

The abscess was tapped a number of times, but as the man was evidently sinking, it was decided to open it through the abdominal wall. One of the dangers of this operation is that pus may escape into the abdominal cavity. In performing this operation, some operators at the first sitting cut down to the peritoneum. In the course of twenty-four hours there will have been some local peritonitis with the formation of adhesions, and then the operation is completed. Dr. J. M. Barton operated in my case, and after cutting through the abdominal wall with a scalpel, a white-hot knife was used in order to avoid hæmorrhage from the liver structure. After the liver had been penetrated to a short distance, the knife failed to act satisfactorily, and the operation was completed with a soft gum catheter. In the case reported, the cause of the affection and the youth of the patient are also points of considerable interest.

Dr. Seltzer said that his remarks were based on the statement, that this was an acute diffused hepatic abscess, and not one surrounded by pathogenic membrane.

Dr. Vogler said he had no doubt whatever as to the diagnosis of the case. The situation of the abscess, the fact that the pus was mixed with biliary matters, the fact the finger could be introduced through the cut two inches under the ribs, and the very grave constitutional symptoms, were sufficient to indicate the seat of the disease. I unfortunately neglected to make microscopical examination of the pus. As Dr. Neff has said, it is not necessary that disintegrated hepatic structure shall be found, for many of these abscesses are localized. I thought that in all probability adhesion had formed between the abdominal wall and the liver, and in operating I experienced no trouble.

(*To be concluded.*)

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, November 9, 1886.

The President, H. O. Marcy, M.D., in the Chair.

H. J. Harriman, M.D., Secretary.

Dr. E. C. Keller presented

CYST OF THE BROAD LIGAMENT

removed from a patient 65 years of age. Seventeen pounds of fluid were evacuated. Recovery was complete in three weeks.

Dr. Keller also presented a

SUBPERITONEAL FIBROID FROM THE FUNDUS UTERI.

Patient was 38 years of age; unmarried; menses regular; uterus free, and sound entered the normal distance. The tumor was diagnosticated as an ovarian cyst with gelatinous contents, but when the abdomen was opened a fibroid was found attached to the fundus. There was one small adhesion to the omentum. The tumor was removed by the thermo-cautery and the stump securely tied. The patient rallied well from the operation and progressed favorably until the sixth day. The temperature then went up; patient vomited and refused food, and death occurred on the seventh day.

The tumor weighed 8¾ lbs. after the blood was removed. It was not as firm as an ordinary fibroid, but to the touch was resilient and comparatively soft. These peculiarities led to a mistake in diagnosis. The autopsy revealed the fact that about five ounces of blood had oozed into the abdominal cavity, and that a localized peritonitis had existed.

Dr. H. O. Marcy presented

A DERMOID CYST WITH BONY WALL.

The interesting feature of the specimen was that a plate of real bone existed in the lower portion of the sac, from which a long spine projected into the cyst. The Fallopian tube was spread out over the tumor in the line of incision, and, being congested, it made it difficult to determine whether the tumor was ovarian and cystic. By the vagina the hard bony mass could be distinctly felt, and this fact led to the opinion that the tumor was fibroid.

In the absence of Dr. Thornton Parker, his paper, entitled

THE REMOVAL OF A LARGE VAGINAL TUMOR,

was read by the Secretary.

This case occurred in the practice of Dr. H. R. Storer, of Newport, R. I. Patient 35 years old; twice married, and has had one child at a normal labor. Health good until four years ago, when she became seriously menorrhagic. When medical aid was sought it was found that the vagina was entirely filled with a mass resembling in shape a pear with its base upwards. As the uterus could not be felt above the pubes in its natural position, it was at first thought that it was one of the rare cases of spontaneous uterine inversion. A catheter could not be made to fully enter the bladder. In the lower abdomen was found an obscure mass lying obliquely from below to the right, which moved with the tumor. With difficulty a sound was introduced into this mass a distance of 2¾ inches, thus settling the diagnosis of a very large fibroid tumor situated in the vagina. An operation was decided on and an écraseur applied, but the chain broke. The operation was abandoned for the time and no unfavorable symptoms followed. Several days later removal was again attempted and was successful. There was virtually no hæmorrhage. After the tumor was severed it could be rotated in the vagina, but could not be removed in the ordinary way on account of its size. Strong, straight hooked forceps in the grasp of a strong man failed to deliver the tumor. It was determined to produce expulsion by pressure superiorly and from within, in imitation of the powers of nature during labor. The sphincter ani having been forcibly dilated, Dr. Storer introduced his forearm into the rectum so far that the fingers entered the sigmoid flexure. The expulsive force thus applied, assisted by the vectis and forceps, was sufficient to deliver the tumor precisely as if it were a fœtal head. The vagina was then plugged. The case recovered without a single unfavorable symptom. The tumor weighed 1½ pounds, and resembled in size and shape an ox's heart. Its longitudinal circumference was fifteen inches, and its lateral circumference at point of attachment was twelve inches. Upon section the tumor was found firm, homogeneous and fibroid.

Dr. W. Symington Brown described a case of his which in some respects resembled the one narrated in the paper. In his case the fibroid was attached to the fundus uteri, and, as it was too large to be removed whole, it was cut up with the écraseur and removed in pieces. Dr. Brown thought that a similar procedure might have been adopted to advantage in this case. Putting the arm into the rectum is a barbarous and unnecessary practice. He regarded it as bad practice to attempt to remove a whole tumor when it could be more easily and safely removed piecemeal. The interests of the patient should be of first importance.

Dr. E. W. Cushing agreed with Dr. Brown. He saw no need of the écraseur in this case, and thought that the mucous membrane might have been cut and the tumor removed in pieces. He regarded the introduction of the arm into the rectum as bad surgery and a somewhat violent mode of procedure.

Dr. E. C. Keller had removed tumors similar to the one described by means of strong vulsellum forceps.

Dr. H. O. Marcy would remove such a tumor by splitting it in pieces and, as it were, shelling it out of its envelope. He mentioned a case which was presented to the Society of a similar tumor which he had removed in fourteen pieces. Dr. Marcy regarded the écraseur as a clumsy and bungling instrument, and thought that other instruments would serve the same purpose with better results. He had introduced the arm into the rectum without doing injury, and held the opinion that it was a justifiable mode of procedure in the diagnosis of some cases of obscure pelvic disease.

Dr. R. J. P. Goodwin mentioned two cases of impaction of fæces caused by eating stick cinnamon which he had successfully treated by dilating the rectum and forcibly removing the impaction.

Dr. E. W. Cushing exhibited to the Society by means of the microscope specimens of the *Gonococcus*.

BOOK REVIEWS.

Nervous Diseases and their Diagnosis: A Treatise upon the Phenomena produced by Diseases of the Nervous System, with Especial Reference to the Recognition of their Causes. By H. C. Wood, M.D., LL.D., Member of the National Academy of Sciences. 8vo, pp. 501. Philadelphia: J. B. Lippincott Co. 1887. Chicago: W. T. Keener.

The first, and only, complaint that we have to make is that it is not stated in the title-page that the distinguished author of this book is the University of Pennsylvania Professor who has given us a work on Materia Medica and Therapeutics, and who has contributed so much to the subject of fever, and to the highest class of medical literature in this country. The author need not have apologized "for trespassing upon the patience of the profession;" he is too well and too favorably known as a writer for anything he should write to be considered as a trespass upon patience.

We find on reading the introduction that this book was written for the general practitioner; and of all American works on nervous diseases which we have yet seen, this is the most intelligible to one who is not a specialist in neurology. It goes over the ground as the physician must go—from symptoms back to lesions, and not from lesions to symptoms, which is the route followed by other authors of such books. Further than this it is scarcely necessary to notice the work, except to say that the only sense in which it can be said to be incomplete is that it does not treat of the therapeutics of the conditions described. Should this be added in subsequent editions the general practitioner will be under still further obligations to Professor Wood.

Clinical Therapeutics. Lectures in Practical Medicine delivered in the Hospital St. Antoine, Paris, France. By Professor Dujardin-Beaumetz, Physician to the Cochin Hospital Member of the Academy of Medicine, etc. The Treatment of Nervous Diseases; of General Diseases; and of Fevers. Translated by E. P. Hurd, M.D. 8vo. Detroit: Geo. S. Davis. 1885.

That a book by the distinguished author of this work is worth reading goes without saying. It is most readable in style and deals with subjects intrinsically interesting. It is not a text-book, but a book rather for the practitioner than the student. It might better have been entitled a treatise on certain topics of clinical medicine than therapeutics. It is true, however, that for the most part it deals with methods of treatment, but does not ignore symptomatology and diagnosis. We recommend it to our readers with pleasure.

Chapters are devoted to the following subjects: Clinical Therapeutics; The Nervous System from a Therapeutic Standpoint; Hydrotherapeutics; Medico-Electricity; Treatment of Neuralgia; of Hysteria; of Epilepsy; of Chorea; of Meningitis; of Apoplexy; of Chronic Myelitis; The Blood from a Therapeutic Standpoint; On Blood-letting; Treatment of Anæmia: of Acute Rheumatism; of Chronic Rheumatism and Gout; of Diabetes; of Syphilis; Fever from a Therapeutic Standpoint; Treatment of Typhoid Fever; of Intermittent Fever; of Eruptive Fevers.

It is unfortunate that a work of so much interest should be marred by a few glaring typographical errors.

INTERNATIONAL CONGRESS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Washington, September 5, 1887.

SECTION ON MEDICAL CLIMATOLOGY AND DEMOGRAPHY

Scheme of Subjects for Papers and Discussions.

I. Importance of the study of Climatology and

Demography in connection with the Science of Medicine.

II. What constitute determinate climatic characteristics.

III. The effects of climate on the human race as manifested in local demographic conditions; and of the several elements of climate as shown by coincident meteorological, morbility and mortality statistics.

IV. The question of Acclimation.

V. Relative advantages of mountain and seaside resorts for recuperative purposes and as palliative or curative in certain diseased states of the system—segregation *versus* aggregation of invalids at health stations.

VI. The therapeutic value of natural mineral waters.

VII. Accurate records of prevailing sickness in any community a necessary factor in any comprehensive system of *vital statistics*. The responsibility of Governments to amply supply their people with the climatic and vital statistics of their respective countries.

VIII. *Collective Investigation*, apart from aiding the study of the Natural History of Disease, as contributive of numerical data having a demographic bearing, 1, as to the kinds and proportions of prevailing diseases; 2, as to the absolute amount of daily sickness and consequent loss of time, occupation, etc.

IX. *Medical Nomenclature* considered in its practical relations to Vital Statistics.

X. The melioration of demographic conditions effected by *Preventive Medicine*. Influence of the physical well-being of a population upon its economy. Offences against moral and civil law in their medical relations to demographic circumstances.

Those who wish to present papers before the Section must advise the Secretaries before the first of May, 1887, and furnish them with brief abstracts of their papers before the first of June.

Attention is called to the following Rule of the Congress: "*In the meetings of the Sections, no member shall be allowed to speak for more than ten minutes, with the exception of readers of papers and those who introduce subjects for discussion, who may each occupy twenty minutes.*"

Those who intend to be present at the sessions of the Section, and especially those who desire to take part in the discussions, will confer a favor by communicating with the President and Secretaries, who will be further gratified at receiving suggestions as to the work of the Section.

Albert L. Gihon, M.D., *President*,
P. O. Box 291, Vallejo, California.

MISCELLANEOUS.

Detection of Blood-Spots on Iron.—Dr. Dannenberg contributes some valuable data on detection of blood-spots on iron. Blood is easily proven on ordinary surfaces by means of the crystals of haemine, but when blood-spots on rusty iron are to be examined their detection is not so simple a matter, as the iron rust seems to form a combination with it. Dr. Dannenberg, however, states that if a few drops of a 10 per cent. solution of caustic potash be placed on the spot, and thus loosened, the rust scraped off and and treated with ammonium sulphide and water, and then handled according to the usual method, elegant extended rhumbic crystals will be formed. He considers these as conclusive proof and names them "Haemidin" crystals.

Cocaine Legislation.—On February 15, Dr. J. B. Mattison, of Brooklyn, read a paper on "Cocaine Dosage and Cocaine Addiction" before the King's County Medical Society, after which Drs. Wallace, De Lavergne and Mattison were appointed a committee to draft a bill, for presentation to the Legislature, placing cocaine on the list of poisonous drugs, and to be sold only on a physician's prescription.

Disinfecting Stations.—Several disinfecting stations were established in Berlin on November 1, and their use is compulsory by the police regulations. Within six weeks after their establishment 10,593 pieces were disinfected, mostly belonging to persons infected by diphtheria and scarlatina.

Diploma Mill in Maine.—The *Boston Herald* has recently ventilated an extensive diploma industry in Lewiston, Me., a representative of that paper, who says that he is innocent of any knowledge of medicine, having obtained without difficulty a diploma from the Maine Branch of the "Druidic University of America." As this "Branch" is incorporated under the State law, the people of the State must now pay the expenses of "a joint special committee" from the House and a few Senators, "to inquire into the expediency of repealing" the character of the Maine Branch and the Maine Eclectic Medical College.

Dr. T. Gallard, the well known gynecologist of Paris, died on January 31, of diabetes.

M. Raige-Delorme, one of the founders of the *Archives Générales de Medicine*, and one of the editors of the "Dictionnaire Encyclopédique des Sciences Médicales," died recently in Paris.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 19, 1887, TO FEBRUARY 25, 1887

First Lieut. Chas. C. Barrows, Asst. Surgeon, resignation accepted by the President, to take effect Feb. 17, 1887. S. O. 42, A. G. O., Feb. 19, 1887.

First Lieut. Chas. S. Black, Asst. Surgeon, ordered from Ft. Clark, Tex., to Ft. Davis, Tex. S. O. 23, Dept. Texas, Feb. 18, 1887.

ORIGINAL LECTURES.

THE SYMPTOMS AND DIAGNOSIS OF MULTIPLE NEURITIS; WITH REPORTS OF CASES.

Based on a Clinical Lecture Delivered at the New York Post-Graduate Medical School, January 18, 1887.

BY CHARLES L. DANA, M.D.,

PROFESSOR OF NERVOUS DISEASES N. Y. POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

A very good description of multiple neuritis was given by Leyden in 1881, again by Piersson in 1883, and by Strümpell in his "Text-book on Medicine." Dr. X. Francotti, in 1886, described it well; so also did Dr. Buzzard in the Harveian Lectures for 1885. Dr. Gowers gives a very complete account of the disease in his recently published text book on nervous diseases. Dr. M. Allen Starr will no doubt cover the whole ground in the most thorough manner in the Middleton Goldsmith Lectures on this subject, now forthcoming.

I venture to give here some notes on the history of this new development in neuro-pathology, since it has made such a change in some of the conceptions of paralytic disorders. Dumenil, in 1864, reported[1] a case running a course of four and one half months, and having the type of the subacute spinal paralysis of Duchenne. The autopsy showed diffuse lesion of the nerves, the brain and cord being normal. A second case,[2] with post-mortem examination, ran a course of several years, and started from a contusion of the sciatic. Eichhorst's case[3] came next. It was like one of acute ascending paralysis, of six weeks' duration, except that there was pain and sensory disturbance. Autopsy showed acute inflammatory nerve trouble, not a simple degeneration. Then Déjerine reported a case also resembling acute ascending paralysis. He found also neuritis, including some changes in the anterior roots. Neither Eichhorst's or Déjerine's cases are very complete. Eisenlohr[4] reported a case of subacute paralysis and autopsy. The cord was normal, the sciatic showed parenchymatous and interstitial neuritis.

Joffroy contributed a very elaborate paper to the *Arch. de Phys. Normale et Path.*, No. 2, 1879. He describes: 1. Spontaneous parenchymatous neuritis. 2. Neuritis from lead poisoning. 3. Neuritis in the course of infectious diseases. Under the first division he describes cases of multiple degenerative neuritis, with autopsy. Lancereaux reports a case of this kind occurring in phthisis, as do Desnot and Pierret.

In 1880 Leyden[5] summed up the work of his predecessors, and reported a case of his own, with autopsy. He gave a systematic clinical history of the disease, and one which is still quite correct. Leyden was followed by Melchert.[6]

In 1882 Scheube, and in the same year Baelz, showed that the nerve symptoms of beri-beri were due to a multiple neuritis.[7] Koeniger,[8] writing on this same subject in 1882 and 1884, alleged that the neuritis was only a complication. Ballet, in 1883,[9] found atrophy of the anterior cornua in beri-beri—nerves not examined. Harada[10] found neuritis and degenerative changes also in anterior nerves in dorsal and lumbar regions. M. P. Mendes[11] found lesions in the nuclei of the columns of Goll, and in the posterior columns, especially, of the cervical and lumbar cord there was atrophy of cells and parasites in vessels; also a neuritis as far up as the spinal ganglia. Tschowski[12] reported several cases, with autopsy in three. He found multiple neuritis, and also atrophic cells in the lumbar cord.

After Leyden's communication there were soon published a large number of cases, by Hiller,[13] Granger Stewart,[14] Eichhorst,[15] Strümpell,[16] Müller,[17] Vierordt.[18] Piersson wrote[19] a systematic monograph on the subject in 1883.

Roth, in 1883, reported[20] a case of acute general paralysis, with autopsy, showing extensive parenchymatous and interstitial neuritis. Dr. S. G. Webber, of Berlin, reported some cases in the *Archives of Medicine*, Vol. xii, p. 33. See also articles by

Eisenlohr,[21] Strümpell,[22] Moeli,[23] Hirt,[24] Löwenfeld,[25] E. Remak,[26] Grocco,[27] and Oppenheim.[28]

The relation of alcoholic paralysis was studied by Strümpell,[29] by Dr. Dreschfeld,[30] and by Schultz.[31] These writers give a full history of this special subject up to the date of this writing.

The relation of arsenical paralysis to neuritis was studied by the writer, and a full account of it given in *Brain*, January, 1887. In the same article the history of the relation of lead-poisoning and of diphtheria to multiple neuritis is given. In the past year a number of additions to our knowledge have been made, all of which are to be summarized and presented by Dr. Starr in the lectures referred to.

In a thesis entitled "Des Pseudo-tabes," by L. Leval-Picqueche (Paris, 1885), a very complete history of this form of multiple neuritis, from various causes, is given. Dr. Starr has also called my attention to a very complete work entitled "Paralysis Toxiques." by Broussais, of Paris.

The symptoms of multiple neuritis develop in two forms; 1st, those of atrophic motor paralysis with subsidiary sensory changes; 2d, those of ataxia and other sensory disturbances with only moderate motor paralysis. The motor form is the more common. The sensory or ataxic form occurs chiefly as the result of poisons or the infection of diphtheria.

The Atrophic Motor Form.—The symptoms generally come on rather suddenly, and are sometimes accompanied with fever, which may reach 103° to 104° F. The patient suffers from feelings of numbness, prickling or burning in the feet and ends of the fingers. These sensations gradually extend up the extremities, but rarely reach the knee or elbow. They are accompanied by sharp pains and feelings of weakness, and the paralysis steadily increases until the patient is unable to walk or use his hands. The lower extremities are oftenest and most seriously affected, the upper extremities next, and the muscles of the face and trunk least often of all. The flexors of the foot and the extensors of the hands are particularly attacked. The paralyzed muscles speedily become atrophied. The bladder and rectum are not affected. The sexual power is lessened. The pulse is generally quite rapid, owing, perhaps, to involvement of the vagus.

On making a physical examination the skin is generally found hyper-æsthetic, and yet there may be some tactile, thermal and pathic anæsthesia. Later this generally develops. Pressure along the course of the nerves and over the muscles causes much pain, as do muscular movements.

Electrical examination of the muscles shows generally a partial degenerative reaction, the muscles being less irritable than normal to both galvanic and faradic currents. The contractions are sluggish, but it is not common to get polar changes. The nerves show also diminished electrical sensibility, but furnish no positive indications of neuritis as against polio myelitis, though perhaps their irritability is less. There are not usually any marked vaso-motor phenomena except œdema. Sometimes the secretion of sweat is profuse, and in arsenical cases I have seen the feet and hands shed the epidermis as if it had been raised by a blister.

The disease reaches its height in two or three weeks, or even less. The symptoms then gradually ameliorate, and the rule is a progressive improvement ending in cure in four to six months. In some cases the spinal cord apparently becomes involved, and the sphincters are paralyzed; diabetes and various other central symptoms appear.

Some cases of multiple neuritis run a very acute course, and present the symptoms of acute ascending spinal paralysis (Landry's paralysis). Other rare cases present a slowly progressive course lasting three or four years, *e.g.*, Dumenil's case.

These types are different clinically and etiologically from the disease ordinarily known as subacute multiple neuritis.

The Sensory or Ataxic Form is spoken of by Gowers as rare, but I have seen quite a number of illustrations of it. Here the symptoms begin with burning, tingling sensations in the feet and hands, especially the former. The patient notices that his gait is uncertain. The tendon reflexes disappear, the limbs are partially anæsthetic, or areas of anæsthesia are found. There is a moderate degree of motor weakness and atrophy. In a few days the patients may develop nearly all the symptoms of locomotor ataxia. These cases are generally of toxic origin. They run a subacute course, about as does the motor form.

The symptoms may be summarized as follows: Prodromic period in some cases of several weeks characterized by some numbness and lumbar pains. Rather brusque onset, sometimes with pain.

Motor Symptoms: Progressive symmetrical paralysis, ascending, and affecting lower limbs most and oftenest. Paralysis flaccid, atrophic and painful. Partial degeneration reaction. Abolition of knee-jerk as a rule, and of skin reflexes in paralyzed limbs.

Trophic Symptoms: Muscular atrophy; œdema; rarely erythema, eczema, herpes, changes in nails and skin, local asphyxia and gangrene.

Sensory. Parasthesia; especial characteristics are burning sensations, pains of both darting and dull character, worse on movement; tenderness in limbs, and especially over course of nerves. Later some anæsthesia, general or over distribution of nerves.

Cranial Nerves: In rare cases only affected, but optic neuritis is not very rare. Rapid pulse from involvement of the vagus sometimes occurs. Sphincters not involved as a rule.

The termination is usually favorable, but death may come on unexpectedly.

Further details in the history will be brought out in the report of the following cases. These I will give here only in synopsis.

Case 1.—Alcoholic Multiple Neuritis. Sensory

Form.—The patient, a bar tender, had always been healthy, and gave no history of syphilis. In the past year he had indulged excessively in sexual intercourse, but still more excessively in alcohol, and after having been on several sprees he was taken to the hospital suffering from delirium tremens. This developed into mania, and he was confined in the asylum for several weeks. During this time he became partially paralyzed, but improved and was discharged. When seen by me soon after, he presented the symptoms of a man in the early stage of locomotor ataxia, except that he had no eye symptoms, girdle pains, bladder or marked sexual trouble. There was marked ataxia, parasthesia, areas of anæsthesia, loss of tendon reflex, some motor weakness. I learned that he later did develop some central symptoms, which lead me to think that the cord became also involved.

Case 2.—Alcoholic Multiple Neuritis. Motor and Atrophic Form.—This patient I saw at Bellevue Hospital, while visiting for Dr. Tuttle, and have shown him several times to my class. The patient was a young man aged 23 years, who for over a year had indulged nightly in sexual intercourse and very excessively in whiskey-drinking. While playing ball one day he noticed a weakness in his legs. This increased in a few days, and he was now obliged to take to his bed. When seen by me he presented the usual symptoms of alcoholic paralysis. His lower limbs were alone affected, while here the flexors of the foot were especially attacked. The feet dropped, and at one time could scarcely be moved at all. There was partial degeneration-reaction. The legs were much atrophied and there was some anæsthesia, but not much pain. There was no ataxia. The knee-jerk was abolished. The sphincters were normal. The patient got worse for several weeks, then began slowly to recover. At the end of six months he could barely walk with help. His mind remained clear.

Case 3.—Multiple Neuritis from Arsenical Poisoning. Sensory or Ataxia Form.—I have shown the class two patients who suffered from multiple neuri tis of this type (published in full in *Brain*, January, 1887). In one the patient, a young man of 25, took a poisonous dose of Paris green. Within a week he had developed very characteristic symptoms of pseudo-tabes, or arsenical ataxia. The symptoms were burning in the feet and hands, extreme ataxia, some tactile anæsthesia of limbs, combined with extreme hyperæsthesia and tenderness, especially over the course of the nerves; peeling of the skin of feet and hands; pains in the legs, especially on movement; optic neuritis; partial degeneration reaction; moderate paresis and atrophy; no girdle pains, no sphincter paralysis, no involvement of face or eye muscles. Mind clear, but patient nervous and hysterical. There was gradual improvement up to a certain point, then the symptoms remained stationary for many months.

Case 4.—In the second case the patient, a man of 45, was taking Fowler's solution in daily doses of ℥iss, and he gradually developed a pseudo tabes similar to that above recorded, but milder in type. His symptoms, too, improved, and he was finally left with simply an annoying numbness of the feet and finger tips. Two other cases have since come under my notice.

Case 5.—Multiple Neuritis from an Infection of Beri beri.—This case occurred in the service of Dr. Roosevelt at Bellevue Hospital, and through his kindness I was able to show it to my class. The case has been reported in full by Dr. Roosevelt, and will soon be published; so I will not give the details here. The patient, a sailor, after suffering several weeks from the anæmia and anasarca characteristic of the "wet form" of beri-beri, gradually developed a paralysis of the lower extremities. The flexors of the foot were most affected. The paralysis gradually involved the muscles of both legs, but to a much less degree those of the thigh. There was some pain and paræsthesia, but little other disturbance of sensibility. The muscles atrophied and showed in one leg partial, in the other complete, typical degeneration reaction. The paralysis progressed very slowly for a few weeks, then slowly improved. Judging from some of the recorded histories, beri beri may also produce a sensory or pseudo-tabetic form of the disease, but it appears to me that the multiple neuritis is not the disease, but is only one of the symptoms, or in some cases one of the sequelæ.

Case 6.—Multiple Neuritis from Rheumatic Cause.—There is no doubt that multiple neuritis may be caused by what is known as rheumatic influences; and the following case seems to illustrate it, although I confess that the diagnosis can not be made positively:

M. D. G., a Jewish ex-Rabbi, age 29, married, of Russian birth, had always been healthy, but had greatly overtaxed himself a few years ago by study. His present occupation is that of a peddler. About two months before he was seen by me he had been much exposed to cold and wet. He felt one day a great weakness coming on in the lower extremities, and to a less extent in the arms. He felt also numbness, prickling, and dead, heavy sensations in the extremities. All this increased until in a day or two he could hardly walk, and could not go up stairs. About this time he had severe pains in one knee, which lasted only a night. His symptoms did not improve, and he finally came to me. There was then the same condition of paresis of the extremities with paræsthesia; the knee-jerk was abolished; there were areas of anæsthesia over the external surface of the legs; there was considerable static and locomotor ataxia. The eye (he had but one) was normal, and he had no girdle pains or sphincter troubles. No degeneration-reaction. Urine 1026, acid, rather dark, no albumin or sugar. Under treatment he gradually improved. Nine months later I saw him again; *the knee-jerk had returned*, and all his symptoms had disappeared.

Case 7.—Neuritis Complicating Locomotor Ataxia.—I have shown to the class on several occasions a patient who had had for a year some slight ataxic symptoms, but had been able to do his work, that of a brakeman, every day, and who believed himself to be suffering only from a paralysis of the left third nerve, which was of several years duration. One

day, not feeling very well, he took a Turkish bath, and next day was in bed with an intensely painful paralysis of the lower extremities. There was exquisite tenderness along the course of the nerves, burning feet, pronounced ataxia, and abolition of knee-jerk. The symptoms seemed to point to the development of a neuritis complicating the original posterior sclerosis, and this is an accident which I believe may sometimes occur in true locomotor ataxia.

The diagnosis of subacute multiple neuritis cannot always be made with certainty. It must be based, 1st. upon the etiology; 2d, on the symptoms; and 3d, upon the course of the disease.

Diagnosis from the Etiology.—Painful symmetrical progressive paralysis, with atrophy coming on after an attack of rheumatism, is probably neuritic.

The same may be said regarding attacks coming on in alcoholic patients. The post mortem evidence collected by Dreschfeld, Schultz, Francotte and Bernhardt shows that almost all cases of alcoholic paralysis are of peripheral origin. Some are, however, I believe, myelo-neuritic.

The paralysis from arsenical poisoning, bi-sulphide and oxide of carbon, and in some cases after the use of lead, are peripheral. The pseudo-tabes after diphtheria and in diabetes is neuritic, but glycosuria may occur in true tabes.

The paralysis and pseudo-ataxia after infective diseases, diphtheria, variola, pneumonia (*Virchow's Archiv*, Vol. 68), measles, typhoid, and occurring in the course of acrodynia and beri-beri, are neuritic.

It is not yet demonstrated that multiple neuritis occurs in children except from beri beri, although Webber and Chapin have reported cases which appear to belong to this category.

Diagnosis from the Symptoms.—Rather sudden onset with marked pains in legs and arms, and sometimes fever, followed by rapid symmetrical atrophic paralysis, are the main characteristics of subacute multiple neuritis. Hyperæsthesia is present at first, with great tenderness of muscles and along the course of the nerves. Later tactile and thermic anæsthesia of moderate type develops.

The specially characteristic symptoms in detail are: Symmetrical ascending paralysis affecting the lower extremities most, and especially the flexors of feet and extensors of arms.

Diagnostic Electrical Reactions.—E. Remak reports a case of generalized neuritis with marked electrical alterations of non-paralyzed nerves and muscles. It was in a woman of 30 years, and followed acute rheumatism. This was followed by burning pains and numbness of the legs and arms, with intention-tremor and some atrophy of hand muscles.

Clonic movements, intention-tremor or athetosis. Muscles of face and extremities, though not paralyzed, only react to severest electrical currents and give polar changes.

Erb noted the degeneration-reaction (milder form) in non-paralyzed muscles—head paralysis (*Arch. f. Psych.*, 1885, v, p. 445). Also Bernhardt (*Berlin. klin. Wochenschr.*, 1878, Nos. 18 and 19), and Buzzard (*Brain*, 1878, vol. 1, p. 121).

Kahler and Pick found the severe form of degeneration in lead paralysis. Beiträge zur Path. u. Path. Anat. des Central nervensystems; Leipzig: 1879; p. 131. So did Kast (*Centralb. f. Nervenheilk*, No. 8, p. 137).

Kahler and Pick (op. cit.) also found these changes in a case diagnosticated at the time as polio myelitis anterior subacuta, but which gives much such a history as that of Remak's case. Bernhardt has also described such a case (*Virchow's Archiv*, 1879, Bd. 78, p. 274). In Schultz's case of alcoholic neuritis marked diminution of E. l., but no qualitative changes.

Rapidly developing atrophy of muscles. Partial degeneration-reaction.

The usual formula being—

Faradic current over muscles—*E*, sensibility lessened; *E*, irritability lessened or absent.

Galvanic current over muscles—*E*, sensibility lessened or absent; *E*, irritability lessened, contractions sluggish. Generally in reversal of poles, but KaCC > AnCC.

Œdema is often marked, without albuminuria. The pulse-rate is high. Sphincters not involved; no decubitus. The face and eye muscles are rarely involved, but occasionally there is optic neuritis. Optic neuritis has been noted by Eichhorst (*Virch. Archiv.*, 1876, Bd. 69, p. 69); Strümpell (*Archiv f. Psych.*, Bd. 14. p. 339); Löwenfeld (*Ueber Multiple Neuritis*, 1885, p. 15); E. Remak (*Neurol. Centralbl.*, No. 14, 1885); Dana (*Brain*, June, 1887).

The burning hands and feet, the peeling of the skin of the extremities, the sometimes sharp demarkation of the paræsthesia of the extremities, are diagnostic points to be noted.

Favorable termination favors the diagnosis of multiple neuritis. The presence of degeneration reaction with retention of voluntary movement favors polio-myelitis. Localization of paralysis in physiological groups of muscles favors polio-myelitis, symmetrical ascending paralysis or poly-neuritis.

The diagnostic points in a case of Schulz's seen by Strümpell were: The multiplicity of the processes attacking the extremity nerves; high grade atrophic paralysis, with highest grade diminution of electrical irritability, without quantitative changes; the slight paræsthesia without anæsthesia; the joint affection; the absence of the tendon-reflex with presence of skin reflexes; tenderness over the great nerve trunks; pains on starting to walk; the eventual return of the tendon-reflexes and normal electrical irritability. The bladder and rectum were, however, somewhat affected.

Diagnostic signs given by L. Löwenfeld in a case of rheumatic multiple neuritis with athetosis were: Motor weakness with fever and sensory disturbance limited to certain nerves; girdle sensations and great sensitiveness of the back muscles; absence of pupillary, bladder, rectal and sexual symptoms; girdle sensations about the extremities; electrical reactions were those of partial degeneration-reaction; there was striking diminution of electrical irritability to both currents, with slight polar changes. This has been found by Brenner and Bernhardt also.

The ordinary course of an acute poly-neuritis is, according to Roger:[32] Sharp attack, with severe pains in extremities, oftenest in lower; often a fever; then paralysis, without contractures, with rapid atrophy. Hyperæsthesia is followed by anæsthesia; tenderness; electrical degeneration reaction.

Initial pains, early, marked sensory disturbances, combined with degenerative muscular atrophy and paresis of extremities, *following acute articular rheumatism*, point to subacute multiple neuritis.[33]

Some particulars may be given regarding the diagnosis of the different forms of multiple neuritis:

:. *Alcoholic neuritis* runs a less acute course, is less progressive, and the paralysis is more confined to the extensor groups. The legs alone are often affected. There is a characteristic hyperæsthesia and hyperalgesia. Cerebral symptoms are frequent. The gait in the pseudo-tabitic cases is modified from that of true tabes by the fact that, the extensors of the feet being paretic, the foot is brought down flat.

The diagnostic signs of *alcoholic neuritis*, as given by Oetlinger (loc. cit.), are: The symmetrical paralysis, almost always beginning in the lower extremities, and affecting especially the common extensors of the foot and the extensor hallucis. Bladder, rectal, facial and eye paralyses are not present. Ataxia is not constant, nor are contractures. In chronic forms there is hyperæsthesia; in acute forms analgesia. Generally there there is œdema and trophic disturbances of the skin. Tendon reflex always absent.

There are three forms: mild, chronic and acute. The prevalence in women was not observed by Oetlinger. The ataxia was static only in a case described by Lilienfeld.

Besides the points given, the alcoholic patient may suffer from central scotoma; tabetics have a more general narrowing of the visual field (Bernhardt).

Optic neuritis is seen in acute myelitis, multiple sclerosis, multiple neuritis, and alcoholic neuritis, but never in true tabes.

There are mental disturbances in alcoholic cases, and women are oftener affected.

The degeneration-reactions are temporary, and only noted at the height of the disease. The ataxia is static only in some cases. There may be rapid pulse and hyperidrosis.

In *arsenical neuritis*, a characteristic trophic disturbance is the entire shedding of the epidermis of the feet and hands. A hysterical mental condition is sometimes present. The paralysis may be motor and atrophic, or may take a pseudo-tabetic form, the last being rare.

A multiple neuritis of the sensory or ataxic form is differentiated easily from locomotor ataxia usually, by the changed electrical reactions (high grade diminution of E. irritability, with or without qualitative changes). In tabes, at the beginning, there may be an increased E. I., which later decreases without any degeneration-reaction.

There is an ataxic neuritis seen in early atrophic paralysis.

The pupillary symptoms, girdle-pains, bladder and rectal disturbances are, as a rule, absent in neuritis.

There may be slight pelvic symptoms in ataxic neuritis.

The tendon reflex, though apparently absent, may be brought out sometimes by Jendressik's method in neuritis; never in tabes (Moeli).

In *post diphtheritic multiple neuritis* there are generally paralyses of the soft palate first, then general muscular feebleness, ataxia and loss of tendon-reflex. In a few cases the external eye muscles are affected, causing exophthalmoplegia externa.[34]

Subacute multiple degeneration neuritis is to be distinguished clinically from *acute ascending spinal paralysis* (Landry's). In the latter disease there is, it is true, a multiple neuritis, in some cases at least, but its cause and course, as well as the anatomical changes in the nerves, are different.

Myelo neuritis.—Multiple neuritis may be combined with a polio-myelitis, and then symptoms of both diseases may be present. Leyden, Rosenthal and Déjerine have found cases running a course like that of multiple neuritis, with, on autopsy, evidences of both neuritis and myelitis. Eisenlohr has reported[36] a case that is particularly striking. J. J. Putnam reports two cases of painful myelo-neuritis.

Central spinal lesions predispose to neuritis. Déjerine reports[36] two cases of tabes with extensive degenerative neuritis.

Illustrations of symmetrical ascending neuritis and myelitis are given by Grainger Stewart,[37] who reports three cases. The patients showed the signs of multiple neuritis with ascending paralysis, beginning in all four extremities. Post-mortem examination showed secondary degeneration of the columns of Goll and of the direct cerebellar tract.

TUBERCULOSIS OF BONES AND JOINTS.

Read before the Northwestern Ohio Medical Association, at Lima, Ohio, December 9, 1886.

BY M. STAMM, M.D.,

OF FREMONT, OHIO.

(*Continued from page 262.*)

Cases of tuberculous dropsy of the joint should, as soon as diagnosis is possible, be operated upon, as all other means will have little effect. This operation generally consists in making incisions into the joint, removing the swelled synovialis. After having washed out the joint with disinfecting fluid, dust it over with iodoform, put in drainage-tubes, etc. The idea of preventing the spread of tuberculosis from an affected joint is less an indication for operative measures than the local condition itself. Such measures, amputation especially, may sometimes be called for to cut off the dangers of septicæmia, pyæmia and amyloid degeneration of the kidney and other organs; it is indeed surprising to see the rapid general improvement of the patient following amputation.

Where we are certain of a large osteal focus or some partial destruction of the joint, we are not necessarily compelled to make a typical resection or amputation, but, thanks to the excellent effect of iodoform in such conditions, a partial resection, that is, the removal of the affected parts only, gives very satisfactory results.

A small circumscribed abscess may, after the joint is immobilized, heal spontaneously and leave a fistula only for a short time. Should it, however, be necessary to open such an abscess, the best way is to make an incision, and should you have to find your way deep between the muscles or in the neighborhood of the blood-vessels, dilate with a pair of forceps, which may be passed along a probe. After being able to introduce a finger you may scrape off the tuberculous granulations with the nail, sponge, or sharp spoon. Then, if necessary, you make a counter-opening for drainage-tubes, rub in some iodoform, and apply some antiseptic dressing. Should, however, the whole joint be filled with matter, simple incisions will be of no avail, since the synovial tuberculosis is more diffuse and has a tendency to cheesy decay. We may, in cases of children, at times succeed by making large incisions and removing the affected synovialis; in adults, on the contrary, resections, or more often amputations, are the only resort.

In most cases of tuberculous fistula it would be bad practice to introduce a spoon and try to scoop it out, as we never can be certain whether we have removed all the diseased parts. It is much better in such cases to open the joint freely and remove whatever is affected with knife and chisel; this can often be done without damaging the function of the joint. It is scarcely necessary to say that this should be done by the bloodless method. After the affected bone and synovial membrane has been removed, we should irrigate the joint with some disinfecting fluid (carbolic acid, corrosive sublimate or salicylic acid), under some pressure, in order to clean it from small spicula of bone or shreds of tissue, then dry the parts and rub some iodoform into the walls of the joint. We then introduce drainage-tubes and apply antiseptic dressings, which should exercise some compression to prevent hæmorrhage after the rubber bandage is loosened. The leg should for the first day or two be kept in a raised, almost perpendicular position, to prevent loss of blood. The results in purely synovial fungus are not so favorable, owing to the impossibility of removing the capsule of the joint completely without resection of the epiphysis; typical resection is therefore the only curative way.

It cannot be denied that there are cases so grave in which local resection, right from the start, would be the best resort. But, unfortunately, diagnosis will not always come to our aid at the right time, since only when the symptoms do not improve; if pain, instead of subsiding, increases after a long course of rational treatment, our suspicion, that extensive destruction of the bones by a large granulative focus or a large wedge shaped sequestrum are the underlying causes, becomes hardened into a fact. At such a time, then, we are generally obliged to make a typical resection or amputation. Perhaps it is hardly necessary to add that in younger patients the conservative plan should not be so easily abandoned as in older individuals, especially above 50 years of age, as it is well known that resections in children leave bad functional results; and moreover, these processes have a better tendency to heal at an early age than in later life. The fact, also, that children can better afford to sacrifice three or four years' time for treatment than grown persons who have to earn a living, should have some weight with us. But steady fever as a sign of suppuration and fistula, acute nephritis or amyloid degeneration of some organs, are, even in youth, a vital indication for resection or amputation.

A large cold abscess calls for an early resection, although amputation in most cases, especially above the age of 30 years, will be the best measure. The technique of resection should be carried out with a view to remove all the pathological parts of the joint. Long incisions, usually more than one, should be made, in order to expose all the synovial folds, as it is important to remove whatever is diseased with the knife, forceps or scissors. These incisions can generally be so managed as to obviate any transverse cut or section of the muscles, so that, if it was only necessary to make a partial resection, the function of the joint would not suffer too much by it. We should make it a rule not to remove of the bone more than what is really affected or is necessary to get free access to the diseased synovialis, in order to remove that portion fully. The latter can be removed better with forceps and scissors than with the sharp spoon. Ligaments and periosteum may, as a rule, be left intact. The affected bone is best removed in children with the knife, in adults with the chisel, saw or spoon, and we should not hesitate to leave an irregular surface where only a part of the epiphysis is affected. The bloodless method, as well as the application of iodoform, have essentially improved our results in such resections.

Tuberculosis of the Hip Joint.—We occasionally meet some slight subacute forms of this affection in the hip joint, which may recover in the course of some weeks or months after the application of ice or tr. iodine, also after the use of pulley, Taylor's splint, or Hutchinson's plan (high-soled shoe on the sound leg with a pair of crutches). But these cases have a great tendency to relapse. There are probably some small foci which do not lead to extensive infection. The majority of cases, however, are of a grave nature, as the bony parts, acetabulum and head of the femur, are generally greatly disorganized. Caries sicca presents yet a comparatively favorable prognosis, although it has, by virtue of its cicatricial atrophy, a tendency to stiffen the joint and, as it occurs principally in youthful subjects, also to shorten the limb from one-half to two inches. A conservative treatment is best indicated in these cases. A plaster of Paris bandage, as long as there is no contracture, is of great advantage. We should not forget to tell the family that a very long time is required for a cure. Taylor's splint answered very well in a few of my cases, and gave also satisfactory

results in the hands of others. Contractures are best reduced under anæsthesia, if necessary in several sittings. In the majority of cases we find cheesy granulation with suppuration. The localized abscess generally points at the front part of the joint; much less frequently along the iliopsoas muscle near the lesser trochanter, and we sometimes find great difficulty in tracing the fistula to its origin.

Of very great consequence are those cases which break into the pelvis. Resection is the only safe means to give an outlet to the matter, but it should at the same time be combined with an incision near the anterior superior spinous process. Multiple abscesses with fluctuation in front and behind the joint, as well as fistulæ that have no tendency to heal, also demand resection. The diagnosis of the grave osteal processes is difficult before they burrow into the joint. In localized foci of the neck or head of the femur, also of the upper rim of the acetabulum near the inferior spinous process, we obtain good results, without injury to the function of the joint, by careful removal.

Spontaneous luxation of the joint in these cases points to disorganization of the bony parts, principally the acetabulum; and here we need not wait for the formation of an abscess, but resect at an early time. Children, even at an age of 1½ years, seem to furnish good results after resection, and we should not feel altogether discouraged in cases even above 50 years of age. We should never neglect to remove all the diseased portions of the acetabulum or capsute of the joint. The incision is best made in a line drawn from the posterior spinous process to the middle of the trochanter, it should be made deep down to the bone and can, if necessary, be extended further. Should the acetabulum be affected, the chisel is the best instrument to remove whatever is diseased. Should an iliac abscess be the result of perforation, it should be opened below the anterior superior spinous process by a large incision, in order to free its inner walls from all tuberculous granulations, a drainage-tube may then be left in there, and one also near the trochanter. If we use iodoform, the first antiseptic dressing need not be disturbed for eight or ten days, the others can be left even for a longer time, so that we seldom have to change it more than three times before the wound is healed. Extension to the leg is commonly used in some way or other for the after-treatment.

Knee Joint.—In the knee joint we find all the different forms of tuberculosis described in this paper. Tuberculous dropsy seems to have almost an exclusive seat in this joint. As a characteristic feature of this joint we may mention that grave osteal processes even have sometimes a tendency to isolate themselves. A partition is, so to say, formed by the inflammatory tissue, almost amounting to a new synovial sac, which keeps in this way the other half of the joint intact. The diseased patella may also adhere to the femur by a ring shaped septum. This explains why a comparatively good function is left even after a protracted course of disease. A great tendency is shown for contracture; early treatment, however, can do a great deal to prevent this. In patients up to 14 years about the same frequency is observed between osteal and synovial processes, whereas in adults osteal processes seem to predominate. The femoral condyles are more often involved than the head of the tibia. Amputation should be reserved for old people, or for patients who have a complication with nephritis or septicæmia; eventually also for cases in which the leg is so shortened and deformed that no good use can be expected from resection.

We have already seen that a number of our best authorities raise their voice in condemnation of a typical resection of the knee joint in children below 14 years. But still this is no cause for remaining idle in such cases, as a vast deal of good can be accomplished by the sharp spoon or by partial resection. These partial resections are best made by a curved incision at the inner side of the joint, beginning at the tibia near the insertion of the ligamentum patellæ, with the convexity inwards; after having reached the upper part of the joint turn towards the middle line, where you readily find the distended synovial sac. As it is necessary to get free access to the synovial membrane, another incision at the outside, in front of the lateral ligament, should be made. Very little difficulty is thus found in the removal of the anterior part of the capsule, cartilage or bone. If this is not sufficient, we may nip the ligamentum patellæ slightly, and pull it outwards; or, if necessary, cut the internal and crucial ligaments, which will give us all the room desired after flexing the limb.

A very ingenious method has been recently reported by Israel, which was followed by no less brilliant results; brilliant because he succeeded in preserving the function of the joint after having removed the capsule of the joint completely. He made a flap starting from the condyles and reaching below the tuberosity of the tibia, then by means of the saw he separated the tuberosity in an oblique direction from the tibia, so that it remained with the ligamentum patellæ attached to the flap. As the synovialis was found thickened and covered with tuberculous granulations, it was totally removed in connection with the crucial ligaments and the semilunar cartilage. After having inserted the drainage-tube, he nailed the tuberosity to the tibia. As soon as the wound healed by first intention patient was induced to use passive movement of the joint. The operation was performed in March, 1884, and patient is now about 10 years old; he can bend his leg at an angle of 100°, has full strength in its use, with no shortening and with natural shape of the joint.

Typical resections can be made by different methods. A transverse incision across the middle of the patella, and then dividing the latter with the saw, is very much in favor with some surgeons. The patella has, of course, to be wired together at the completion of the operation. In one case I followed Hahn's method, which consists in making an incision at the inner side, starting from a point as far back as possible at the line of the joint, cutting the quadriceps muscle close above the patella, and ending at the outside at a corresponding point. The advantages of this method seem to be that the wound heals faster,

as it is nowhere in immediate contact with the bone; it also enables better drainage and you get freer access to all the parts of the joint. The patella also stays better in its place, and not as many blood-vessels have to be cut as in other methods, so there is no danger of secondary hæmorrhage. Steel nails about three inches long, one end shaped like the point of a trocar and the other with a small head, are now used to unite the joint-ends more firmly. I kept my patient in a plaster-of Paris bandage with wire frame.

Ankle and Tarsal Joints.—The osteal processes seem to predominate in the tarsal joint; tuberculous dropsy is found in but a few cases. In children a sequestrum of the tibia gives a characteristic clinical picture (thickening of the tibia, fistula, and consecutive swelling of the whole joint). A cheesy, granulating depot or sequestrum of the astragalus may cause perforation into the ankle, talo-calcaneus or navicular joint, and from there extend into the different bones. Suppuration occurs frequently; we find the abscess distending the extensor muscles in front, posteriorly it is buried under the tendo Achillis. Milder forms may heal spontaneously in children, less so in adults; there some operative interference is generally imperative. Swelling below the malleoli, at the upper border of the calcaneus, points to an affection of this bone. Swelling over the neck of the astragalus, to the region of the scaphoid bone, signifies affection of the navicular joint. Taking these points into consideration and finding pain on moving the different joints, we will be enabled to diagnose with some accuracy the extent and seat of the affections of the several joints.

Treatment of the milder forms is best carried on by means of the plaster-of-Paris bandage, but if extensive suppuration should set in, we better resort to some kind of operation. Destruction has in some cases gone so far that no better choice than amputation is left us. Last year I had to amputate the leg of a young man, in which all the tarsal bones and the largest part of the shaft of the tibia were disorganized. But cases where the epiphysis of the tibia, fibula and astragalus, even part of the os calcis, are affected, quite often furnish very good results after resection. During the last two years I resected the ankle joints of two young men with very satisfactory results. In one case I excised one inch of the astragalus, one-half inch of the tibia, and left the fibula intact; the wound was healed by first intention on the tenth day, except the drainage openings. Two weeks after operation patient rode home (about twenty-two miles) in a wagon without the least discomfort. Both of the patients have now good use of their legs. I followed in this case Koenig's method, which I enthusiastically endorse. This consists in making an incision immediately in front of the inner malleolus down to the scaphoid bone; a similar incision is made in front of the external malleolus down to the talo-navicular joint. This gives you ample scope for the removal of the bones and capsule. The same holds true in affections of the tarsal bones. I removed four years ago in a man sixty-four years of age, both cuneiform and part of the first metatarsal bones with excellent result. Last summer I had to remove, in a lad 16 years old, part of the scaphoid, cuboid, both cuneiform and first metatarsal bones; only a shell was left of all these bones. Patient suffered before the operation for three years, and is now able to walk without a cane and do some work in the field.

Shoulder Joint.—This joint is not so subject to tuberculous affections as the other joints, and we are not able to give any definite reason for this. As we have mentioned before, caries sicca seems to have quite a predilection for this joint, but all the other forms are occasionally found. In most of the cases we are obliged to resect, provided there are no distinct signs of phthisis present. About four years ago I made a resection on a man 44 years old; the joint was distended with matter; the glenoid cavity had to be scooped out, and about 2½ inches were removed of the humerus. The patient is well satisfied with the use of his arm. It is best to make the incision in front of the acromion process, along the intertubercular groove, and about four inches long.

Elbow Joint.—Osteal tuberculosis seems to be the most frequent in this joint, principally at the olecranon, less often at the condyles of the humerus, and very seldom at the radius. Conservative treatment seems to promise poor success, this seems to be due to the complicated mechanism of the joint. We should therefore not postpone resection too long, as it is almost devoid of danger, and the functional result equally as good as after protracted conservative treatment. Partial excisions in some cases are accomplishing all we can reasonably wish for. Israel had splendid results even after removing the entire capsule of the joint. The typical resection is best made by an incision about four inches long over the inner side of the olecranon; the periosteum should, if possible, be saved.

Carpal Joint.—The synovial membrane seems in this joint to be more frequently affected than the bones. So long as such affections remain circumscribed, or occur in children, a cure, although often with some deformity, may be brought about by the compressive bandage. In adults, however, where the whole joint is involved, tuberculosis of the lungs is threatened quite early. In such cases resection should soon be called into requisition. This is best made by an incision about three inches long, running, at the dorsum of the hand, from the ulnar side of the second metacarpal bone over the epiphysis of the radius. After having cut the skin, you get down between the extensor indicis on one side, and the extensor carpi radialis brevis and extensor pollicis longus on the other side, then you divide the carpal ligament and capsule of the joint. push the tissue towards the ulna, and when you get at the bones try to save of the periosteum as much as possible. In persons above 40 years, where there is extensive caries of the bones and considerable infiltration of the soft parts. running along with chronic bronchial catarrh and profuse night sweats, fever and pain, yellow color of the face, we should not temporize with any other measure, but proceed to amputation without delay.

THE CLIMATIC TREATMENT OF DISEASE.

Read before the Chicago Medical Society, February 7, 1887.

BY JOHN A. ROBISON, A.M., M.D.,

OF CHICAGO, ILL.

ATTENDING PHYSICIAN FOR THROAT DISEASES, PRESBYTERIAN HOSPITAL; ATTENDING PHYSICIAN COOK COUNTY HOSPITAL.

There is probably no field in therapeutics in which the general practitioner becomes so quickly lost as that of the climatic treatment of disease. He seldom has the time or opportunities to investigate the subject personally, and what little knowledge of the subject he possesses has been gleaned from the voluminous literature written by various authors on this topic. Even this knowledge is ill defined. There is a great difference of opinion among writers on climatology as to what should be the altitude, temperature, dryness or moisture, etc., for the treatment of various pulmonary diseases. The purpose of this and following papers will be to formulate the desiderata for climates in the treatment of various pulmonary diseases.

Inasmuch as phthisis pulmonalis constitutes the largest class of these diseases, we will first briefly note what eminent authorities say are the requisites in the climatic treatment of this disease.

I quote the opinion of Dr. C. J. B. Williams: "Our great object in consumptive diseases is to give the patient as pure an atmosphere as possible, of such thermometrical, hygrometrical, and other qualities, that it can be breathed safely and freely by him. It should therefore be free from extremes, humid or dry, and neither too still nor too windy, and its influence on his frame should be furthered by frequent exercise of various kinds carried out in cheerful sunshine, uninterrupted by rainy, misty, or windy weather. For consumption originating in septic influences, a climate of great pureness and dryness would seem to be indicated, and this is to be found at considerable heights above the sea level. In these cases a mountainous climate is recommended."

Professor Ludwig Buhl, of Munich, a high authority on tuberculosis, says: "For commencing or already established chronicity, the (I might almost say) *principle cure is pure air*. There must be plenty of air, and it must be free, properly changed, without dust, rather dry, and not subject to great changes of temperature: this latter is particularly necessary in a medium degree of moisture. The residence should be in a spot well sheltered from the wind, and on well drained soil, with large airy rooms. South of the Alps (in Europe), if possible, and during the summer, an elevation of from 2,500 to 3,000 feet should be sought. In the spring and autumn this may be changed for an elevation of from 1,500 to 2,000 feet. In winter the patient may dwell either near the sea, or at an elevation of from 500 to 1,000 feet."

Dr. J. Hughes Bennett says: "What is really required is a cool temperate climate, which should range from 55° to 66° F. during the day, and 45° to 55° at night. The air should be dry or with only slight moisture, little rain, and a clear bright sun. Such an exhilarating climate, in which exercise can be taken almost daily in the open air during the winter and spring months, is the best for the consumptive patient."

From the opinions of these authorities we can tabulate certain facts:

1. The climate must be such as to insure *pure air free from dust, or poisonous germs.*

2. Such air is more apt to be found at an elevation of 1,000 feet, or more, above the sea level.

3. There should be an equable temperature, neither too warm nor too cold, the air should be in continuous motion and yet there should be no wind storms.

4. There should be plenty of sunshine.

5. The landscape should be pleasing.

6. The health resort should be easily accessible and home comforts with congenial society easily obtained.

7. The patient should be able to take almost daily outdoor exercise without fatigue.

When patients are able to find homes in climates which nearly fulfil all these conditions, clinical observations demonstrate that consumption may not only often be arrested but cured. It is a well-known fact in mycology that a modification of the environment often prevents bacteria from thriving and multiplying, and this may account for the improvement which often follows the residence of a consumptive in a pure climate where he can take exercise. Bodily nutrition is increased, the power of resistance to disease is augmented, and the germs of consumption die. The disappearance of the disease is heralded by the improvement of the appetite and the digestion, the increase in force of the circulation, the stimulation of the respiratory functions with increase of normal oxidation and bodily heat. Thus with the improvement of the general bodily nutrition is favored that condition of the lung where there is absorption of the inflammatory exudates present in incipient phthisis, or the formation of cicatrized tissue in the later stages of the disease.

Having thus considered the climatic conditions favorable for the treatment of consumption, we wish to pass in review the claims which certain localities in the United States present as being suitable places to send consumptive patients. The first locality we will notice is

ASHEVILLE, N. C.

In western North Carolina, between the Blue Ridge on the east and the Alleghanies on the west, lies one of the most picturesque valleys in the South. In this valley is the village of Asheville. It is on the line of the Western North Carolina Railroad and has about 5,000 inhabitants. It has long been known as a summer resort, and for this reason its popularity as a health resort has not grown rapidly. But there are many reasons why it should attract the attention of the profession more. In the first place the altitude of Asheville is 2,250 feet above the sea level. The air in the summer is pure, cool and invigorating, and in the winter mild on account of the latitude. The climate is pleasant and salubrious. There is a large proportion of sunshiny days so that outdoor ex

ercise can be taken daily, except when it rains. After a rain it is not easy to take exercise on account of the clay soil retaining the moisture for some time. However, the precipitation of moisture is quite evenly distributed throughout the year, being excessive at no time. What little snowfall there may be seldom remains long, even on the mountains, and its stay in the valley may be measured by hours.

The average rainfall in inches of the different seasons for a period of eleven years is shown to be as follows:

Spring	10.1	inches.
Summer	13.5	"
Autumn	7.1	"
Winter	9.5	"
Total	4.02	"

Temperature.—The record at Asheville shows the following mean temperature for the seasons:

Spring	54.3	deg. F.
Summer	71.3	"
Autumn	55.3	"
Winter	27.2	"
Yearly mean	55.3	"

In a series of nine years the mercury did not rise above 90° F. any day in the summer. During this season the nights are always cool, permitting refreshing sleep. In winter it is very seldom that a zero temperature is reached, while the air is comfortable, dry, clear and invigorating.

Dr. H. O. Marcy, of Boston, who has personally investigated the claims of this region, says he has sent a large number of patients there with excellent results. And there is not wanting testimony from many physicians who have seen the benefits which result from a residence there during the spring and summer months.

However, there are places more accessible to persons living in the North. One point that is easily reached by Northern tourists is

MARIETTA, GA.

This village is on the line of the Western and Atlantic Railroad, about twenty miles northwest of Atlanta and 120 southeast of Chattanooga, Tennessee. Its altitude is 1,132 feet. About ten miles from the town is the Kennesaw Mountain, from whose top Gen. Sherman made the famous signal to Corse: "Hold the fort; for I am coming." This mountain has an altitude of 1,800 feet. The scenery about Marietta is delightful. For outdoor exercise one can take pleasant rambles, or can secure good livery at low figures and take the most delightful drives. If the rural scenery becomes too monotonous one can go to Atlanta, which is one of the most beautiful cities in the South. But for amusements it will seldom be necessary for the invalid to leave the village, for the proprietor of the Whitlock House, the health resort at Marietta, is ever providing for the social enjoyments of his guests by excursions, drives, etc. The air is so fresh and invigorating that the temptation to take outdoor exercise cannot be resisted. Malaria is unknown. The drinking-water is pure, as has been attested by Prof. W. S. Haines, of Rush Medical College: "The specimen of water from Marietta, Ga., submitted to me for examination, has been carefully tested and found to be of excellent quality for drinking purposes. It contains but a small amount of mineral matters and only a trace of organic compounds."

The society in Marietta is composed of cultured, kind hearted and hospitable people. And the fact that most interests the invalid is that here can be found all home comforts. It is not a place where the necessities, not mentioning the luxuries, of life are absent.

The temperature of Marietta is mild throughout the year. In 1885 the lowest mean monthly temperature was in January, 30.3° F. The yearly mean temperature was 59.4° F. During the winter of the same year there was no snow at Marietta. Snow seldom falls and only remains a very brief period. Of course this place is as yet little known, and yet it would seem to afford a place where those who wish to find a quiet home where the climate is pleasant, where the air is somewhat rare and pure, and where outdoor exercise can be taken, can live comfortably.

However, a large number of consumptives, when they go to a quiet health resort, suffer from homesickness, and become so despondent that they refuse to take the exercise so essential as a remedial measure in this disease. If they could find a locality where there is a combination of all the requisites of a perfect climate for consumptives, and also the opportunity to enjoy city life with all its attendant evidences of civilization. they could be placed under the ideal requirements for treatment. The only locality that I know of where there is the possibility of such a combination is

LOOKOUT MOUNTAIN, TENN.

This mountain has been memorable since Hooker fought his battle on its summit in mid-air, but it is only recently that it has been thought to be desirable as a health resort. For this reason we cannot give any records of temperature, humidity, etc. But it matters little, for temperature charts do not always prove to be of much value. Again, we cannot give extensive statistics as to the benefit to be derived from a residence on this mountain, but we can enumerate the features which will commend themselves to all fair-minded physicians as those demanded in health resorts for consumptives.

This mountain has an altitude of from 1,500 to 3,000 feet. The altitude is somewhat greater than that of Marietta or Asheville. The advantage in this is that it insures a greater purity of the atmosphere and increases the activity of the respiratory functions. As for the scenery that greets the eye of the observer as he stands on this elevation, it is not in our power to give you a word picture of it. Suffice it to say, that to the lover of nature are presented views of which he will never weary, nor forget. Daily rambles over the sides of the mountain disclose new beauties in the landscape, and urge one to take the wonted exercise.

The sunshine is abundant, and the temperature,

even in winter, seldom is low as is evidenced by the fact that during this winter there has been almost no perceptible snow on the mountain.

Recently there has been completed a cable railroad winding up the mountain, thus connecting it with Chattanooga. The trip from the top of the mountain to Chattanooga can be made in twenty-five minutes. This enables one to live on Lookout Mountain and transact business, attend church or places of amusement, or do shopping in Chattanooga.

Chattanooga is now a busy, enterprising city of about 30,000 inhabitants, having doubled its population in the last twelve years. Northern enterprise has invaded the city, and the result is a grand development of her resources. Wealthy residents are building their suburban residences on Lookout Mountain, and the construction of the cable road was the outgrowth of the demand for building spots on the mountain. And yet this will prove a boon to sickly humanity. It enables the consumptive patients of the North, South, East and West to go to a place where are as nearly combined as it is possible on earth all the requisites for a climate in which consumptives should live. On Lookout Mountain cottages can be built in which patients can reside the year round. The cottage hospital plan secures to their inmates quiet, purity of air, such temperature in each room as each patient demands, home comforts, especially when the patient's family is along, and independence of action. By a residence on this mountain there are secured the following advantages:

1. Purity of air.
2. A proper elevation above the sea level.
3. Equable temperature, and air in motion, yet no wind storms.
4. Sunshine.
5. Outdoor exercise, pleasing landscape, home comforts and the advantage of close proximity to a city.

That these advantages can be secured is not merely an assertion, but fact that is susceptible of proof, and in due course of time the proof will be forthcoming.

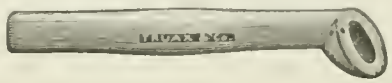
MODIFIED INTUBATION INSTRUMENTS.

Exhibited to the Chicago Medical Society, February 7, 1887,

BY F. E. WAXHAM, M.D.,
OF CHICAGO.

I wish to say a few words this evening in regard to intubation of the larynx in connection with the specimens and instruments I have to present. About thirty years ago a new operation was proposed as a substitute for tracheotomy, by M. Bouchut, of France, and so great was the opposition to this new operation, which was styled tubage of the larynx, that a committee headed by Trousseau, appointed by the Academy of Medicine, reported adversely in regard to it, and the operation was so deeply buried in oblivion, that early operators in this country were not even aware of the attempts and failure of Bouchut.

The most earnest advocates of intubation do not consider that the instruments are perfect, indeed the operation is yet in its early infancy, and it may be years before the method is fully and perfectly developed. One of the chief objections to the operation, indeed the only valid objection, is the difficulty of swallowing, the danger caused by the falling of food and fluid into the bronchial tubes through the canula, and the too frequent occurrence of broncho-pneumonia. I would not exaggerate this danger, but certainly it is true that many patients die of broncho-pneumonia from this source. To overcome this difficulty I have had Messrs. Charles Truax & Co., of this city, modify the O'Dwyer tubes, by making them with smaller heads.



Cut No. 1.—O'Dwyer Tube.

Cut No. 2.—Waxham's Modified Tube.

The tube is prevented from slipping into the trachea, by a rubber collar. (See cut No. 3.) To

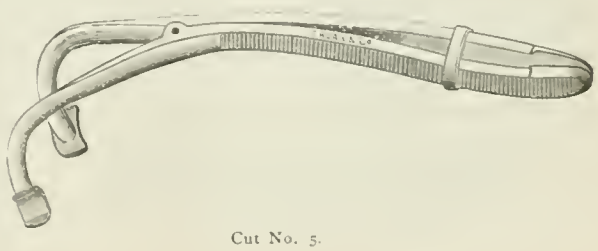
Cut No. 3.

this rubber collar is attached a flap, or artificial epiglottis. (See cut No. 4.) During the act of degluti-

Cut No. 4.

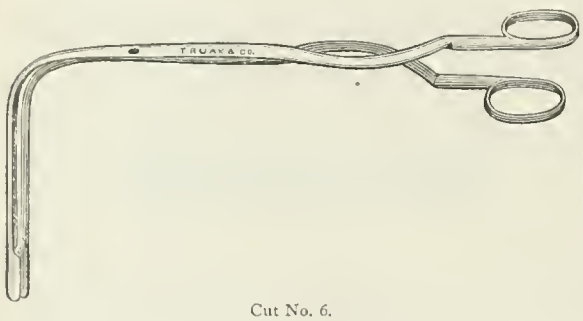
tion the larynx rises and presses against the base of the tongue and the epiglottis, and the pressure of the epiglottis holds the rubber cap, or artificial epiglottis, over the aperture of the tube, thus preventing the dropping of solids into it, and as deglutition ceases, the larynx falls and the elasticity of the rubber throws it upwards. This rubber attachment does not entirely prevent the falling of liquids, of water particularly, into the tube, but it is of very great assistance in swallowing solids and semi solids. I have used this modification in a number of cases with good results, and I have now a little patient convalescing from a desperate attack of diphtheritic croup, in which this modification was used.

I would also present a modification of the mouth gag. (See cut No. 5.) In the old gag the extremities are



Cut No. 5.

liable to strike the shoulder, especially if the child is not held well and is allowed to slip down in the lap of the attendant, the extremity of the gag striking the shoulder and throwing it out of the mouth. This gag passes back of the head and we avoid the danger of the gag being displaced by pressure of the shoulder. This gag was first suggested by Dr. McWilliams, of this city, and has been in the market for several months. There is still another danger that may follow the introduction of the tube, and that is the detachment of membrane below the tube, or the pushing of membrane down ahead of the tube when it is introduced. An accident of this nature occurred to me recently; a tube was passed down into the larynx and the respiration at once ceased, the child turned blue and seemed upon the point of death. The tube was at once removed, but the respiration was only slightly improved and the tube was again introduced, with the same result. It was again removed and the trachea forceps (see cut No. 6) that I have devised for



Cut No. 6.

this purpose were introduced into the mouth and a mass of membrane, a perfect cast of the trachea and the two larger bronchial tubes, removed. After the removal of this cast the tube was again introduced, and respiration was easy. Without these forceps an immediate tracheotomy would have been necessary.

In this connection I present to the Society a membranous cast from the trachea, larynx and bronchial tubes of the late Dr. Newton. This specimen is remarkable not only for its thickness and its extent but for the rapidity of its growth; it was produced within three or four days after the invasion of the larynx. The fate of Dr. Newton, whose early death we all regret most sincerely, teaches us a sad lesson; it teaches us the danger that besets the faithful physician, and the necessity of taking every possible precaution against the contraction of this hydra headed monster, this justly dreaded disease.

To those practising intubation I would advise that an ordinary rubber cot with the end cut off should be slipped over the forefinger, and then during the operation, if the gag is displaced, the finger is protected; as an additional protection, it will be well for the operator to use a respirator, (see cut No. 7.) an ordinary pad of antiseptic gauze with tape attached to secure it in place. This pad should be passed over the mouth and nostrils and should be used by the physician when inspecting the throat or when operating upon a bad diphtheritic case. I believe it is a duty that every physician owes to himself, his family and friends, to take these precautions, especially in the treatment of bad diphtheritic cases.

Cut No. 7.

NEURITIS PLANTARIS; A CLINICAL RECORD.

Read before the St. Louis Medical Society, March 5, 1887.

BY C. H. HUGHES, M.D.,

OF ST. LOUIS, MO.

This rare, painful and formidable malady of the terminal distributions of the two popliteal nerves in the foot is worthy of the physician's especial study. It comes on as the sequel, usually, of a low form of blood-depraving fever, like typhoid or protracted malarial, with typhoid-like depression, or in the latter stages of phthisis; but it may be the sequel of an exhausting, long-continued rheumatism, or possibly of a badly-managed or neglected and chronic gonorrhœa, as Ross asserts, though I have never seen this as a result of that disease. It appeared as a conjoint symptom in some of the cases of caisson disease at the time of the building of the St. Louis Bridge, and I have seen it follow upon a residence in the high altitudes of Colorado, and an attack of the so-called mountain fever of that region. It comes upon a nervous organism, shattered and tremulous, and choreic, and the painful paroxysms are agonizing. The patient cries out with pain, and often cannot rest at night, even after prolonged wakefulness, without powerful anodynes. The slightest touch, such as the application of local anodynes with the hair pencil, to the painful parts, often cannot comfortably be borne. A peculiar burning sensation, without thermometric evidence accompanies the pain. The pain is usually localized in the balls and the tips of the three toes supplied by the internal plantar nerve, and in the heel and plantar arch of the foot, but sometimes implicates also the two smaller toes, which are supplied from the external branch of the plantar nerve, the fifth toe being supplied exclusively by the external plantar, while a filament from the internal joins with the external, in giving the fourth its æsthesiodic supply.

Misleading vasomotor disturbances, suggesting erysipelas, or incubating abscess, are sometimes associated with this form of neuralgia, but in those intensely severe cases which have fallen under my observation, the feet have been pale and dry. A sour sweat has been mentioned as associated with some quite similar cases described by Ross. I have never observed this.

Poulticing does not help these cases, and the metatarsal and tarsal swelling, and fluctuation which usually follows this procedure, sometimes excites the fear of forming abscesses, but this soon subsides if the poultices are not renewed. Intense dry heat or a draft of cold air alike painful to the patient, and

the weight of the bedclothes cannot be tolerated by the toes, or even a feather pillow, sometimes, by the soles of the feet; but hot water beginning with a temperature of 100° and gradually raised from 130° to 150° is often a source of comfort to the patient. Ether and Goulard's extract give a little temporary relief, but are often too painfully cold: chloroform does better but is sometimes too burning. A paint of equal parts of chloral and camphor with morphia or belladonna is pretty well borne in some cases, and gives considerable, and sometimes complete local relief for a time. Cocaine, likewise, but is usually too painful when first applied. Iodine is not worth much, nor is oil of winter-green, and the latter after a poultice is excruciatingly painful to the patient. In fact, to precede these applications when they can be borne with poultices is apt to make them unbearable.

Wier Mitchell was the first to describe an affection similar to this but not the same, under the name of erythemomegalalgia. He regarded it as a rare vasomotor neurosis of the extremeties, and Ross, the only neurological writer, who, to my knowledge, refers to this subject, regards it as plantar neuralgia, "inasmuch as the vasomotor disorders are preceded and accompanied by some paroxysms of pain." My cases may possibly have been more exclusively neuralgic or neuritic, for there was no redness in any of them. The present case is the third or fourth well-defined case of this kind coming under my observation. They are very rare, as Mitchell says, in the description of his cases. Anstie makes no note of them, and the cases described by Elliotson, which Ross thinks were plantar neuritis from gonorrhœa, were probably cases of gonorrhical rheumatism, involving the tendonous portions of the muscles of the sole of the foot and plantar fascia.

The history of the following case is somewhat unique, and while it might be described as a newly discovered disease, I think it well to group it as only a variety of the already noted cases of plantar neuritis and tarsal hyperalgesia.

About the 1st of August, 1886, G. B., a young man of 19 years, was taken sick in the mountains of Colorado, thirty-six miles west of Gunnison, at or near Dry Fork, of Gunnison River, with a chill. A low form of fever followed, called in that section, mountain fever. He was brought to his home in Illinois. After, or about the end of the fifth week of his illness, he had sharp, lancinating pains in the toes and under the plantar fascia. The tips of the three inner toes, supplied by branches from the internal plantar nerve, could bear not the softest wet sponge of an electrode to touch them without a little flinching, and only a very mild, constant current passed from these to the internal malleolus could be borne. The temperature of the foot was not above normal. The patellar tendon reflex and tendo-Achillis reflex were exaggerated in both extremities, but much more so in the left than in the right leg. No effort at eliciting the reflex phenomena was attempted till after the hyperalgesia and hyperæsthesia had disappeared from the feet.

Without fever and without evident organic lesion of the heart, the heart beats continued throughout two months of his sickness at 120 per minute, except when modified by treatment. A tenderness, on pressure, at the sacrum persisted after the pain had left his foot.

The patient was much emaciated and very feeble when he came under our observation on September 23. He had lost much of his hair and his nails were changed to a dirty brown color. The movements of the upper and lower extremities were tremulous and choreic on attempting exertion. The paroxysms of pain in the feet recurred every few minutes without exciting cause, but a touch or draft of air, or putting the feet pendant, would start the pain immediately. The pain was often in the two feet at the same time, but most frequently alternated. The most comfortable attitude the patient could assume was to flex the thigh on the abdomen, and to grasp the leg below the knee with locked hands, while lying recumbent or holding his knees up in that way.

Under a treatment which consisted mainly of rest, a liberal diet, judicious galvanism, belladonna, aconite, gelsemium, quinine, arsenic and the bromide and muriate of ammonia, with occasional doses of morphia and chloral, the patient became practically convalescent of the neuritis by the 7th of October, the pain paroxysms having ceased to recur, no tarsal or plantar pain to touch, and but a little tenderness to firm pressure remains, October 12, over the sciatic notch. The patient has increased a good deal in flesh, rests well at night without hypnotic aid, and takes a nap or two during every day, while active treatment for the neuralgia is almost entirely withdrawn. But there remains the irritable heart, a lame step in walking, to accommodate the left side, and some incomplete rheumatic and malarial symptoms have appeared. October 24, the patient was sent home for a few days, free from pain, but still walking somewhat lame, and with a pulse of 120 per minute.

On October 29, the patient returned for treatment, without pain, but still with a lame step and an abnormal heart-beat, and remained under treatment till the 4th of November, when he was discharged convalescent, with a slightly lame step, no pain, and a heart-beat when sitting, of 84 per minute. There was no history of venereal disease in this case.

A case came under my care last June not preceded by any pronounced form of fever, but by a general *malaise*, irritable heart and a masked intermittent, in which there was only restless sleep and night sweats, in the person of an old lady of 65 years, who has had a chronic stationary ovarian tumor for over thirty years, which Dr. Jesse Judkins, of Cincinnati, thought it not advisable to operate upon. This trouble was followed, on the 1st of July, with a dysentery which lasted till about the middle of September.

Dr. Elsworth Smith, of this city, succeeded me in charge of this case on the 24th of July (when I took my vacation), and the patient, by our joint advice, went East, to the sea shore. After her return, in September, the foot trouble reappeared, and was

much like one of Wier Mitchell's typical cases of erythemomegalalgia. The skin in this case was red over a certain area of the sole of the foot and the great toe, and the two adjoining lesser toes, and peeled off. The nails were not discolored, but the ball and tips of the great and adjoining toes were intensely painful. An ointment of acetate of lead and belladonna was however well borne, and this and quinine and belladonna internally gave relief. The patient is now (November 25) quite well for one of her age and other local infirmities, and has gained in flesh, appetite, sleep and strength.

There was no persisting accelerated heart action in this case. While I regard these cases as all belonging to the same category of peripheral nerve irritability from inflammatory states of the nerves or their sheaths, or conditions approximating inflammation and due to blood states, as other forms of neural pain and nerve-sheath inflammation after fevers, they may also precede, as well as follow poison or depravity of blood, and the effect is not always, nor do I believe ever, altogether spent on the peripheral nerves, though it is there usually most apparent. In the case first above described, there was pain in the sciatic on pressure, near its point of emergence, from the pelvis under the pyriformis muscle, and lower down between the trochanter major and the ischium. There was also some sense of constriction complained of about the waist, even after the pain had left the foot, so that what Ross says of this disease, viz., that it is sometimes progressive, and in its later stages may be associated with evidences of spinal disease, such as girdle pains and partial paralysis, muscular atrophy is not a future impossibility with our patient, though we shall endeavor by judicious management of the case, if permitted, to avoid so dire a result.

The efforts of pathologists have, of late, been in the direction of establishing them as febrile sequelæ, as they most usually, but not invariably are, as MM. Pitrès and Vaillard (*Revue de Médecine*, December 10, 1886,) have lately shown in regard to post-typhoid neuritis and in regard to post-neuritis tuberculosa. They belong to the same category as those extremely sensitive states of teeth, and nails and hair roots which sometimes are seen to precede, but more often to follow, certain states of depravity—or poison of blood; the clinical cachæmias and toxhæmias.

Neuritis plantaris, as I have observed it, is seldom displayed in the constitutionally neuralgic, like sciatica and tic-douloureux, and singularly does not suddenly migrate from one branch to another of its great nerve root, the posterior tibial, or of the popliteal bifurcations of the great sciatic, in imitation of neuralgia trifacialis and other forms of transitional neuralgia. It does not even alternately pass to and from the external and internal plantar, which bifurcate from the posterior tibial, but is exclusively confined in all the cases I have seen to the digital branches of the internal plantar, extending no further outward than the distribution of the nerve to the inner aspect of the ball of the fourth toe, and the toes all seem to be more or less conjointly rather than alternately painful, as is usually the case in true neuralgia of central origin of the common terminal branches of a certain nerve-trunk. This gives it the character of peripheral neuritis rather than of simple neuralgia. But why neuritis plantaris should select the internal plantar nerve about the point of its bifurcation, and at its distribution in the toes is only conjectural. It may be due to the fact, that it is larger than the external, has more to do in the movements of the foot and toes, and is more pressed upon in standing and walking than its outside neural neighbor.

Ross, we think, has justly criticised the name erythemomegalalgia, given by Mitchell to these cases, "inasmuch as the vasomotor disorders are preceded and accompanied by severe paroxysms of pain," though the name given by Mitchell is certainly very descriptive of his own cases, as they all had erythema as well as intense pain, and the flushing over the painful area is quite characteristic in many cases, though by no means in all.

MEDICAL PROGRESS.

HYDATID CYST OF THE SCROTUM.—A case of hydatid of the scrotum came under the care of MR. PHILIP E. MUSKETT in the Sydney Hospital during the course of last summer, and as this is an example of a very rare condition a brief note will be of interest. The patient, aged 25, had been in Australia since he was 3 years old, and in a sheep district where the water was very bad for four years before the swelling appeared; this was first noticed eight years before he came under treatment. During that time it had been tapped twice, and on the second occasion also injected with iodine. When admitted to the hospital "there was an intra-scrotal tumor, about the size of a large emu egg, on the right side. It was smooth in outline and its general contour nearly oval. The tumor was tense and dull on percussion, but gave to the fingers on palpation the sensation of fluid within. There was no impulse on coughing, and it was irreducible. The position of the testicle at its posterior part was made out by the presence of testicular sensation. The cord could not be clearly defined at the upper portion of the swelling. Light was transmitted by the ordinary manner of procedure, and, finally, the history had been that of an eight years' growth: painless except from its mere weight." The cyst was tapped on the day following admission, and about an ounce of "serous-looking fluid" of pale yellowish tinge evacuated. Suppuration followed this tapping, and thirteen days later, about 6 ounces of purulent fluid were drawn off. After this pus drained away from the puncture for eleven days, than a hydatid sac partly forced its way out and was partly extracted through this opening. The sac was greyish in color, translucent, and elastic, and its sunken condition would about fill an egg-cup. The swelling gradually subsided, the sinus closed, and the patient left cured.—*Lancet*, Jan. 29, 1887.

SATURDAY, MARCH 12, 1887.

THE TREATMENT OF PUERPERAL CONVULSIONS.

Within the past six months several papers on the treatment of puerperal convulsions have appeared in different journals, and among the various measures and remedies suggested and praised for treating this affection, we have seen no mention of one of the most powerful means for controlling these convulsions—hypodermatic injections of morphine. It is now almost twenty years since Professor Loomis began the use of morphine subcutaneously to control uræmic convulsions. We need not stop here to discuss the pathology of puerperal convulsions, and to inquire as to the difference between them and the convulsions of ordinary nephritis. Loomis makes no distinction between them when he writes: "From the histories of quite a large number of puerperal and non puerperal cases of acute uræmia, in which morphine was successfully used, I have reached the following conclusions: *First.* That morphine can be administered hypodermically to some, if not to all, patients with acute uræmia, without endangering life. *Second.* That the almost uniform effect of morphine so administered is first to arrest muscular spasms by counteracting the effect of the uræmic poison on the nerve-centres; second, to establish profuse diaphoresis; third, to facilitate the action of cathartics, and diuretics, especially the diuretic action of digitalis." We know that in puerperal convulsions, as in uræmic convulsions of nephritis, the functions of elimination are held in check; and under such circumstances morphine may be administered with the view of "holding the patient until the normal eliminating process shall be re established."

In a recent communication Dr. Joseph D. Eggleston, of Worsham, Va., writes: "I have used morphine in these cases for sixteen years, and I began its use on account of its antispasmodic effect. I was afraid of chloroform because it caused too much coma, and had tried chloral, veratrum viride, and other drugs in place of venesection, which reduced the patient so much that I was anxious to find something that would lessen the use of the lancet. By using morphine I found that I could dispense with chloroform altogether, but not with chloral, the effect of which was more lasting, and the drug could be continued indefinitely without injury to the patient. I have not had a case of puerperal convulsions for five years; and this I attribute to the use of bitartrate of potash as soon as there is the slightest swelling of the feet or legs of a pregnant woman. I have yet to find one show the slightest symptom of uræmia after beginning its use, two teaspoonsful every morning, in water. If, in spite of this, amaurosis occur, I order chloral in 10 grain doses three to six times a day, with very decided effect. In an experience of thirty-six years (thirty cases with thirty recoveries) I have found nothing equal to morphine and chloral, by which we can treat the cases without the loss of blood, and consequently with better and easier after-recovery. Morphine does not increase coma when used during convulsions; it is easy to see whether the pupils are inordinately contracted. So far from the coma being increased it will be found that in thirty minutes, at farthest, it is lessened, and in many cases the patient fairly on the road to recovery. Should I have a case of puerperal convulsions today, the first thing I would do would be to use a commanding dose of morphine and atropia hypodermatically, and give bromidia or chloral; and if this did not act promptly I would bleed. One would be surprised to see the effect of morphine in these cases—as if bringing the dead to life. It does not stupefy the patients, but renders them brighter."

Leading obstetricians seem to be agreed that chloroform is the first remedy in puerperal convulsions, some placing it above all others as a continuous remedy, others using it to control convulsions until other drugs begin to act. While formerly it was recommended that it be used in full anæsthetic doses, so as to paralyze the motor centres, it seems to be agreed, on this side the Atlantic at least, that it should not be pushed except when labor is nearly at a close; except in this case "it is advisable to restrict the chloroform to the pains, and to the restlessness which is often the preliminary to a fresh seizure." It seems to be more widely and exclusively used in

England than in this country. From the excellent work of Professor Lusk one would gain the impression that he first bleeds, then gives chloroform, and afterwards uses such remedies as chloral and bromide of potassium; but it is difficult to see the necessity for both venesection and chloroform. Most of those who advocate the use of morphine advise that it be given in small doses, though there seems to be no good reason for this; but at the same time the dose recommended by Clark, a grain and a half, seems unnecessarily and dangerously large. Smith, of Melbourne, who reports that no case of puerperal convulsions has died in the Melbourne Hospital since the introduction of the morphine treatment, gives ¼ to ⅓ of a grain hypodermatically, and says that it should not be combined with atropia; though why atropia should be left out does not appear (quoted by Parvin). This injection is repeated in a few hours, but with a smaller quantity of morphine, if the patient has another fit. Nitrite of amyl has given signally good results in these cases, but alarming hæmorrhage may ensue if given during labor. Pilocarpine has been highly recommended by a few, but the results do not seem to be very encouraging, and its action on the heart seems to contra-indicate it. Nitro-glycerine is said to be promising as a resource; but there does not seem to be very much promise in a drug which must be given in one minim doses every hour to get an effect when time is all important.

In conclusion, it seems that too little attention has been paid to the morphine treatment of these cases; and this seems to be due to the strong prejudice which has existed against the use of opiates in general cases of renal disease. It may be said that a patient is much more manageable, so far as giving other drugs is concerned, when under the influence of morphine than while under chloroform. And while chloral cannot be readily dispensed with in these cases, a patient is brought under the influence of a subcutaneous injection of morphine much sooner than under the influence of a rectal injection of chloral; and if we wish to give chloroform until the narcotic takes effect, it is easily seen that a considerable time of chloroform inhalation is cut off by using morphine. Veratrum viride has also been endorsed as an efficient remedy in these cases; though such recommendation is by no means new. Dr. Eggleston writes that twenty-five years ago, when its claims were first put forth, it was used in one case (post-partum) to the amount of 1 ounce of Norwood's tincture in three hours, but without the slightest effect. Besides its uncertainty, its safety in large and repeated doses is by no means established. It seems scarcely necessary to say that when the convulsions have been controlled, even temporarily, "every effort should be made to re-establish the functions of elimination. Digitalis is especially serviceable throughout. Active cathartics should be given without hesitation, as these are usually very efficient aids, not only on account of their eliminative action, but also because they lessen the congestion of the nerve centres," (Purdy). "As a subsidiary measure the lower bowel should be cleared out with an enema, and a cathartic (a drop of croton-oil, or calomel and jalap in case the patient is able to swallow) should be given by the mouth" (Lusk). Croton-oil is especially valuable, as it may be placed on the back of the tongue when the patient cannot swallow.

LEGAL REGULATION OF MEDICAL PRACTICE.

This is the season of the year when the Legislatures of many States are in session, and not a few of them are considering Bills, or amendments to laws already existing, having for their object the regulation of the practice of medicine. Copies of Bills or Acts have been sent to us from several States, which had been introduced into one or both houses of their respective Legislatures, but in only one instance had they been acted upon and acquired the force of law. While these numerous attempts at medical legislation show a popular desire, both in and out of the profession, to protect the people from medical charlatanism and ignorance, they show a very general failure to comprehend either the true basis for legislation, or the skill to adjust the details for obtaining the best results. Hence we invite the attention of all parties interested to the following simple propositions: 1. The only legitimate ground on which the law making power of a State or nation can presume to regulate, or in any way to interfere with, the practice of medicine, is the presumed necessity of protecting the people from being imposed upon and injured, by impostors and ignorant practitioners. 2. To accomplish this purpose the law-making power must first clearly define, in unequivocal terms, the minimum amount of education, both general and medical, necessary to qualify a person to practice medicine; and, second, provide a reliable executive tribunal or board for determining in a uniform manner when each person proposing to commence practice has actually attained the standard of education specified in the law. The same standard of qualification and the same executive board must apply to all parties proposing to enter the profession.

For the law making or political power of the State

to attempt to recognize medical theories or discriminate between so-called schools of medicine, or in any way influence the private judgment of the practitioner, is to commit a radical error, as untenable as it would be to enact laws discriminating between the several sects or denominations in religion. Not only should there be one standard of requirements for all, but there should also be one and only one standard of eligibility for appointment on the executive or examining board, on which is to devolve the execution of the law. To proscribe one class of practitioners simply because they may be teachers in medicine, and to dictate that a certain number shall be selected professing one pretended theory of medicine and a certain number professing another theory, is a species of class legislation of the most odious character, and invariably injurious in its results. It would be entirely proper and consistent for the law to specify, for the guidance of the appointing power, that no person shall be eligible for appointment as member of the executive Board whose general and professional education has not been fully equal to the standard of requirements specified in the law, and who had not been a practitioner, and a citizen of good reputation, at least five years in the State. With this plain and fair rule of eligibility for the profession, and the appointing power vested in the Governor, with the right of confirmation in the Senate, there would be no danger of having the State Board made up of inferior men or mere theorists.

THE BENEFITS OF MOUNTAIN-CLIMBING.

As more and more attention seems to be paid each year to the climatic treatment of disease, it seems well to mention the increased benefit which the patient may receive by climbing gradual and steep ascents while seeking a renewal of health in suitable climates. Jaccoud has called attention to this in his admirable work on the "Curability and Treatment of Pulmonary Phthisis:" "Walking is not the only form of exercise which should be taken; if the character of the country is suitable, constant ascents, proportionate to the age and strength of the patient, should be prescribed. These ascents should be made with slow and measured steps, so as to occasion no fatigue to the respiratory organs, and there should be occasional rests on the way. If it is wished to expand the lungs as far as can be done, the person should be advised while climbing to place a stick between the arms, which are thrown back, and the dorsal region of the back. In this position the transverse diameter of the lower part of the chest is completely expanded, the fixed position of the upper limbs causes the whole action of the auxiliary inspiratory muscles to be combined in raising the chest, and the upper part of the lungs, whose expansion is always measured by that of the chest, dilates as far as possible at each inspiration, which is necessarily exaggerated by the effect of the ascent. When carried on in this way, such a plan constitutes a true and useful kind of pulmonary exercise."

But phthisis is by no means the only affection which may be benefited by judicious mountain exercise and climbing. In the *New York Medical Journal*, of February 26, Dr. L. Barkan, of Brooklyn, gives some very interesting information on this subject—interesting both on account of his remarks as to the value of pure air in the treatment of disease, and on account of the records of cases. The best inhalation apparatus, baths, and medicaments, he says, are of but temporary value if no compensation is made for the loss of vitality and of muscular tone, especially that of the heart and vessels; if the blood-stasis in the glands and other organs does not yield to an increased flow of blood in the arteries and veins; if the thinned blood does not become thicker and more rich in albumin; if the accumulating carbonic acid is not expelled by a more plentiful supply of oxygen; if the fat deposited in the body is not more rapidly oxidized; and if the kidneys are not made to act more efficiently. But all these effects are produced more certainly and more generally by mountain climbing than in any other way. Those who have had any opportunities for observation must know that after several weeks spent in mountain excursions the condition of the patient is changed, and radically, for the better—mentally and physically.

The cases reported by Dr. Barkan may be briefly given as follows: Man of 40 years, weight 230 pounds, circumference of waist 120 ctm., of chest 116 ctm. The first walk caused him to pant for breath so that he was almost obliged to stop every three minutes. On the second day the breathing was easier, and he had to stop every five minutes. The secretions were increased in amount, and the torpid condition of the bowels was corrected. The walk was lengthened each day. At the end of a month climbing caused but slight acceleration of respiration, which was inaudible, he could walk for a quarter of an hour without stopping, and he could climb for four hours a day. The cardiac contractions were full and strong, and he had lost the feeling of oppression and dyspnœa. At the end his weight was 208, circumference of waist 107 ctm., and of chest 121 ctm. The second was an old case of neu-

ralgia of the left facial nerve, resulting in numbness of the affected cheek. After a three weeks' excursion the numbness entirely disappeared, and has not returned. The third patient had suffered for thirteen years with rheumatism. At the end of two weeks of treatment he could climb hills, and after doing this for a week and a half his rheumatism had permanently disappeared. The fourth patient was plethoric and hypochondriacal, and had hæmorrhoids. Improvement was noticeable at the end of two weeks: after four weeks the hæmorrhoids had entirely disappeared. His weight was reduced from 211 to 185 pounds; his waist measure from 108 to 98 ctm., and his chest measure increased from 104 to 109 ctm. The fifth patient had chronic gastric catarrh. There was noticeable improvement after one week, and after three weeks the stomach was in good condition. A bronchial catarrh, which had given trouble, was much improved the first day, and disappeared on the third day. He gained fifteen pounds during his trip. In a sixth case psoriasis disappeared permanently in twenty-four days. In another case a chlorotic girl of 19, who had amenorrhœa, improved markedly in two weeks. In still another case a weak, hysterical woman, who had not menstruated for two years, was much stronger, not hysterical, and menstruated, after eight weeks of this exercise.

CRIMINAL ABORTIONS.

On this subject a correspondent makes the following suggestion: "When we shall have passed a law binding all physicians, upon their honor, to make public the desire of any person who may ask the performance of an abortion, we can then hope to check, in a measure, the wholesale murder of the unborn. Secrecy in regard to patients who come to us for advice should be sacredly observed, but the audacious insult of requesting an honorable physician to procure an abortion should be publicly resented by openly reporting the party."

It is doubtful whether an attempt to carry the suggestion of our correspondent into practice would prove either an efficient remedy for the evil or an agreeable one for the physician. Only a small proportion of those who desire to have a pregnancy aborted go to a physician and, admitting the pregnancy, directly ask him to procure an abortion. On the contrary, three-fourths of the whole number simply acknowledge that their menstrual periods have ceased to recur, and they plead for something to restore them, and render every excuse they can think of before acknowledging the *possibility* of pregnancy. A considerable number of this class, when positively assured that they are pregnant by the physician, and faithfully warned of the dangers, physical and moral, liable to result from any and all methods of producing an abortion, at once abandon all further efforts in that direction. For the physician to publish such cases would be manifestly unjust; and certainly there should be no law compelling him to do so. But admitting that the other parties persist in desiring the performance of the abortion, and the physician not only refuses to do it, but actually makes public their application. will it deter a single one of them from seeking out the professional abortionist who, for the stipulated fee, will proceed with his murderous work just as readily as though no publication had been made. The proposed law to him would be of no consequence, except in making all parties desiring abortions more cautious to seek him first instead of going primarily to the regular physician. Again, very few of those who apply to physicians for aid in effecting an abortion take a reliable *witness* with them, or consult the physician in the presence of others, and should the physician, under such a law as proposed, make public the application of Miss A. or Mrs. B., and a libel suit should follow, by whom is he to prove the truth of his public statement? We fear such a law would prove more dangerous to the honorable physician, than helpful to the cause of public morals and humanity.

OFFICIAL REPRESENTATIVES TO THE NINTH INTERNATIONAL MEDICAL CONGRESS.—It was announced several weeks since that Dr. Leopold Servais, of Antwerp, had been appointed by the Belgian Government as representative to the Congress in Washington. More recently we learn that Deputy Surgeon-General Jeffrey A. Marsten, M.D., of the British Army, has been designated a representative by his Government; and the Government of France, through the Academy of Medicine, has designated as representatives Drs. Charpentier, Dujardin Beaumetz, Léon Le Fort, Trélat and Vallin. From all directions, at home and abroad, the indications of a very large and interesting Congress are of the most gratifying character.

CONTRIBUTORS TO AND CORRESPONDENTS OF THE JOURNAL are earnestly requested to remember that brevity of style and conciseness of statement facilitate early publication. Prolixity is a great bar to publication, however interesting or valuable the communication may be.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, February 7, 1887.

THE PRESIDENT, EDMUND J. DOERING, M.D., IN THE CHAIR.

DR. W. E. QUINE, Chairman of the Committee appointed to convey to N. S. Davis, M.D., LL.D., a formal expression of the Society's estimate of his labors and character, prefaced the presentation of the report, by a few well chosen words of congratulation to Dr. Davis on his arrival at the fiftieth anniversary of the date on which he received his diploma to practice medicine. The report of the Committee, which had been engrossed on parchment, was then read and presented to Dr. Davis, who responded in a feeling manner.

DR. J. A. ROBISON read a paper on

THE CLIMATIC TREATMENT OF DISEASE.

(See page 289.)

DR. F. E. WAXHAM exhibited

MODIFIED INTUBATION INSTRUMENTS.

(See page 291.)

DR. JOHN BARTLETT said: Dr. Waxham has given us the position of the O'Dwyer tube when *in situ*, indicating that the beveled facet on its upper extremity should present upwards and forwards. Now by several practitioners in this city the tube has been introduced contrariwise; that is with the bevel of the flange looking upwards and forwards. And this position of the tube, it is maintained by those who prefer it, has an advantage, namely, that when it is so placed, the patient's ability to swallow is appreciably greater than when it is inserted as intended by Dr. O'Dwyer. The anatomist, Professor Hoadley, prefers this reversed position. He has now introduced the tube in this manner in eight cases, and in seven of these, the patients directly after the operation, could swallow fluids without the least difficulty. Dr. Hoadley maintains that the flange of the tube as placed by him deeply within the vestibule of the larynx, in no wise interferes with the functions of the epiglottis, or the aryepiglottic folds. Confusion in regard to the proper position of the tube, has arisen here from earlier cuts of the instruments accompanying some of the cases; these erroneously represented the tube placed with its longer margin forward. I desire to say a word in regard to feeding these patients. There are reasons for believing, that by the use of a French condé catheter of proper size, introduced some distance into the gullet through the nasal cavity, thorough alimentation could be secured without distressing the child, or, a suitable stomach tube, might be introduced through a stomach tube director without greatly distressing the patient. Stress might be properly laid upon the fact that pultaceous food, as bread soaked in milk, is swallowed more readily than water, or fluid nutriment.

DR. CHARLES WARRINGTON EARLE said: I think Dr. Waxham, who is certainly the most successful in this operation, should warn the general practitioner who has had little experience, against trying this operation without some one standing at his elbow to show him just how to perform it. There are few who do it well, and I know of excellent surgeons in this city who may be trusted in everything else, but who have tried to do this operation and signally failed. And, although Dr. Waxham talks as if it was very easy, I think no person should try the operation for the first time without having some one by him who is particularly skilled. I remember very well trying to perform the operation, and I had Dr. Waxham right there. I tried my best to introduce the tube but could not, and Dr. Waxham took the instrument out of my hands and did it in two seconds. I think he should not try to make it appear so easy.

DR. WAXHAM, in closing the discussion, said: I would say a few words in regard to feeding patients. I think one of the secrets of success is proper feeding, and the attending physician should superintend the feeding of the child. He may tell the people to feed it *bread* and milk, or semi-solids, and if he investigates the matter he will find they are giving it half a teaspoon of milk with a little bread, and the milk trickles into the trachea and the bread is rejected. If they are told to make a custard they make it so soft and fluid that it will *trickle* into the trachea. It is very important that the physician should superintend the feeding personally. It is well not to give the child liquids, a small piece of ice placed in a piece of cloth held in the mouth will quench the thirst, and it should not be allowed to swallow for several hours, when it will swallow very much better than if the feeding is attempted at once. I have always made it a practice to introduce the tube with the bevelled portion directed forwards and the projecting shoulder backwards, and I think this has been one reason of my success. To me it seems a reasonable method of placing the tube because, if the higher portion is directed backwards the epiglottis can more perfectly close over the aperture of the tube than if the high portion is introduced forwards. Little or no difficulty is ordinarily experienced by the expert in removing the tube. It has been removed over and over again in two seconds, and yet occasionally, if the tube becomes turned in the larynx, or if from the small size of the tube it sinks to the bottom of the larynx, it becomes difficult even for the expert to extract the tube, and in such a case after two or three careful attempts, we should give the child an anæsthetic so as to have it entirely quiet while the extractor is passed into the tube. In extracting the tube it is best to place the finger over the base of the tongue, when the child will gag and the tube will rise to the finger and it can be caught with the extractor.

Stated Meeting, February 21, 1887.

THE PRESIDENT IN THE CHAIR.

The discussion of Dr. J. A. ROBISON'S paper on

CLIMATIC TREATMENT OF DISEASE

being in order,

DR. JOSEPH P. ROSS said: I am called upon to open the discussion of the treatment by climate of consumption, one of the most frequent and fatal diseases that afflict our race. Statisticians tell us that more than three million persons die annually of this disease. Dr. G. B. Wood, in his "Practice of Medicine," states that north of the tropics one-sixth of all deaths are caused by this disease. And upon consulting Zeimssen I find that the author of the article on consumption makes the statement that two-sevenths of all the deaths in the world are caused by pulmonary tuberculosis. Since this disease is so general, and since treatment by medicine does not accomplish as much as hygiene, which includes climatic treatment, it is very important that we discuss the subject.

In the excellent paper read by Dr. Robison at the last meeting, he quoted the opinions of three leading medical men with reference to the kind of climate which is appropriate for the treatment of consumption, and I think their views with reference to the appropriate climate, which were adopted in the paper, are correct. From my study and observation of the effects of various climates upon tubercular patients, I believe that, although you cannot say any particular climate is suitable for every case, you can say that for cases in general the air should be pure and dry, should be neither too hot or cold, should not be variable, and should be somewhat rarefied; for instance, such an air as would exist at an altitude of from 1,000 to 3,000 feet above the sea level, and lastly, the air should be invigorating, because of its containing an additional element, probably ozone. It may be that this invigorating quality is due to an *electrical* condition of the air, but I think it is more likely due to ozone. I waive the discussion of each of these elements appropriate to a good atmosphere, but will speak more particularly of different localities that are known as health resorts, and will state what facts my experience and study has taught me concerning these localities.

In the first place, I will briefly refer to Colorado. Twenty years ago I began the study of the Colorado climate. You will remember that at that time the eyes of the medical profession were turned to this region as offering the best promises for a good climate for tubercular patients. I thought that in Colorado we have a climate where there is a pure, bracing air, with an altitude high enough to secure rarefaction of the air sufficient to invigorate the respiratory functions. I sent a large number of patients there, and the following is an almost typical history of the course many of these cases took: Mrs. H. had been ailing six weeks. Her symptoms were cough, profuse expectoration, fever and night sweats. Physical exploration revealed a consolidation of a limited area in the apex of the right lung, supposed to be tubercular. This exudation did not extend much below the lower border of the second rib. Being in affluent circumstances, she was sent to Denver, where she was surrounded by every comfort and luxury. She embraced every opportunity to improve her health. In two months she returned to Chicago, her strength having improved, and having gained eleven pounds in weight. To all outward appearance her recovery seemed assured, but on physical exploration of her lungs I was surprised to find that the area of consolidation had extended until it involved almost the half of the right lung. She went to Denver again, but did not improve much. She remained there about two months and returned with the exudation rapidly breaking down, and only lived two or three weeks after her return home. I have observed this fact: that while the patients seem to improve in their general health, the exudate increases rapidly, and if softening occurs it takes place also very rapidly. This is probably due to the high altitude. I have also observed that in the high altitudes patients who have a tendency toward hæmorrhages are apt to be unfavorably affected in this way. Therefore, in the later stages of tuberculosis, the high mountains of Colorado and New Mexico are objectionable. For this reason I have carefully selected all cases that I have advised to go to Denver, Colorado Springs, Pueblo, Raton Pass, Las Vegas, Santa Fè and Albuquerque.

I next selected San Antonio, Texas, as a health resort, and sent patients there for a few winters. During the first winter some seemed to improve, but a large number of them complained that the sudden cold winds from the north, or northers, as they are called, caused severe attacks of bronchitis or pneumonia. In the spring or summer there is a great deal of malaria. But barring the northers and malaria, a great many cases do very well there, and during the months of December and January, I believe it is a very good climate for consumptives. But during the summer months the heat has too depressing an influence on the patients. While I believe that in January the patients were a little better in San Antonio than in Chicago, still they did so poorly that I stopped sending any patients to Texas.

I sent many to California, and, all things considered, I think the best climate and opportunities for treating this disease are found in California. I sent a brother, a son, and a servant boy with advanced consumption to Long Valley, California, all of whom recovered. I had quite a number of patients who recovered in the valley north of Virginia City, just below the Summit Range. And a number of my patients regained their health on the other side of the range, in the foot hills of the Sacramento valley. With reference to Southern California, probably for two months of the year it would be desirable to send patients down to Los Angeles, Riverside or San Diego, but taking that climate all the year around it is not the place, because the air does not contain something that should make it essentially invigorating; it is not light enough, and seems to lack ozone. I think patients affected with ordinary catarrh will do well there, but consumptive patients do not improve in Southern California all the year round. If one could live in the southern climate for two months in the year, and then go up into the Sacramento valley, where you can find almost any altitude, I think probably it would then be the best climate for cases of consumption in general on the continent. One objection to sending patients there is the distance from Chicago.

Afterwards I made a study of the Gulf coast and Florida, and after going all over and investigating these regions, but Florida more especially, I hold the same view in regard to that climate that I obtained when I was there last year. I visited Palatka, on the St. Johns River, and called on Judge B. and asked him what kind of a climate for consumption they have in Florida. "Well," he said, "I will express my views candidly. If you want to send your consumptive patients down from Chicago to have them put in the ground, send them along." I think the climate of Florida is a failure for the treatment of consumption, for this reason: patients go there having a cough, being debilitated by disease, and the air is balmy, and they say, what a beautiful air. They do not cough so much, but they sit around and take no exercise, for there is nothing to cause them to take active exercise. There is something lacking in the air; it does not brace one up, and I never saw a patient there that improved the least from day to day, The atmosphere is warm and moist, and very depressing, while malaria abounds.

With reference to the regions mentioned by Dr. Robison, I have investigated the climate of the mountains of Tennessee, Georgia and North Carolina, and have been to the places mentioned in the paper: Asheville, N. C., Marietta, Ga., and Chattanooga, Tenn., and I fully agree with the remarks made by the author. I think the climate of these regions is suitable for the treatment of consumption. I think it is well for us to consider the favorable features of this mountainous region of Tennessee, Georgia and North Carolina, which is called, and I think correctly, the Switzerland of America. In the first place, let us contrast the climate of that region with ours at the time of year when our climate is bad. It is in the spring from the January thaw until June that our climate is bad; the latter part of winter and spring. Now, it is a fact that at an altitude of 6,000 feet above the sea level, as at Denver and Colorado Springs, the air is too cold, and when we have bad weather here you will find bad weather in Colorado, extending from the January thaw until near June. During these months when our climate is bad, you consider the question of sending patients away from Chicago. In Great Britain and the north of Europe they consider that the bad time of the year is from January to June, and they send patients down where the Alps dip into the Mediterranean Sea and where they find the climate mild, about the same conditions of climate that we have down South. All the rest of the year we have a good climate; in fall, summer and early winter, the Chicago climate is not bad, it is only in the spring, and then you want to consider where you should send your patients. You might send them to Texas, and it may be that in January they might be a little better there, but for the whole time it does not seem to me they have a climate with which they succeed in curing patients. You might send them to California, but if you do not want to send them so far away, the other localities mentioned in this paper are good places. I endorse what was said about the favorable climate in the South. I have spent spring, summer and winter months down there, and I find that at an altitude of from 2,000 to 3,000 feet above the sea level you have a good climate, and it is near home, and so convenient that if anything should happen friends can go to the patient, or he can return home, in a few hours, which is another reason why we should think favorably of this latitude. During the past fifteen years I have had considerable experience in sending patients to these regions, and they return as much improved as I ever had them return from any other point on the continent. I have had patients go to Chattanooga when they were not able to climb Lookout Mountain, and they would come back wonderfully improved. I felt deep regret four years ago at sending a lady down there, for I did not believe she would ever return alive. I knew she could not live here three weeks, having all the symptoms of advanced tubercular trouble, with almost complete consolidation of the lung, but in four months she came back almost cured, and to-day I met her on the street, and she is to all appearances robust and healthy. The question comes up with reference to the most desirable points. Asheville is in North Carolina, and it takes a day and a half to go there; Marietta takes thirty-two or thirty-three hours to reach; while it takes twenty-one hours to go to Chattanooga. I think, as Chattanooga is a little nearer home, it would be desirable to try that point, and if that does not suit the patient he can move on to Marietta. On Lookout Mountain the scenery is perfectly grand and beautiful, and lends an interest to a residence on the mountain. The scenery is varied from every point of observation. As they have a cable railroad on the mountain, if you get tired you can run down into Chattanooga, a town of 30,000 inhabitants (and in a few years they will have 50,000), in a few minutes.

I have no personal interest in the matter, but I wish to say that Mr. and Mrs. Carter, of Chicago, have rented a most beautiful home on Lookout Mountain and will run it as a health resort. They opened our County Hospital in this city twenty-five years ago and were managing it beautifully until the war came, and then it was taken away from them; but they demonstrated their ability to manage a hospital. They have accommodations for entertaining about 200 guests, and I think it is the best place to regain health I have ever known. If the patients should tire of Lookout Mountain House, kept by Mr. Carter, they can go to Marietta in a few hours, and here is a pleasant health resort. I never passed a more pleasant week than at the Whitlock House in Marietta. Mr. and Mrs. Whitlock are the most genial host and hostess I ever met. They look carefully after the interests of their guests and provide them with every comfort.

Now, allow me to epitomize my rambling remarks. My reasons for recommending the South as a place to send consumptives are:

1. When the climate in Chicago is unsuited for consumptive patients, the climate is mild and favorable in the South.

2. The nearness of Chattanooga, Marietta and Asheville to Chicago and the North. The trip can be made in a few hours.

3. The results of a limited experience have convinced me that my patients do as well, if not better, at these points than at any other.

In conclusion, I wish to add that the reason I prefer Lookout Mountain to the other points is on account of the extent and variety of the scenery, and its proximity to a city, and greater nearness to Chicago.

Dr. J. J. M. Angear said: I endorse nearly all that Prof. Ross has said and most of the paper. There are a few points in the paper that I think might be amplified and supplemented profitably. The author speaks of home comforts, pleasing scenery and congenial society, and these three things, I think, demand a good deal of our attention. We are all aware of the fact that there is some truth in the old saying: "Laugh and get fat." It is an impossibility for any one to do well who is constantly under a cloud; it has a depressing influence upon the mind, I care not how good the climate. And here comes one of the greatest difficulties which we have to contend against in all diseases. Let us imagine for a moment the head of a dependent family who fears consumption. The physician advises him to leave home for a more salubrious climate, and under the pressure of circumstances he takes his departure. It may be that he begins to think as soon as he has bought his ticket: there is $25 or $100 that my children will need. This is a big load. He thinks he is going to be gone for a month or two, and he estimates what his services would be worth to his family, and if anything should happen to him his widow will need it; and this is another big load. We can readily see that it is impossible for his frail frame to bear up under these burdens. It is probable that there would be more cheerfulness at home than away among strangers, no matter how desirable these places may seem. These things must be taken into consideration. I have thought, for a number of years, that the benefit of our watering places was not from the water, but because the patient leaves home, leaves business cares and has a gay, good time. He goes to Saratoga with plenty of money in his pocket, enjoys the fine music, enters into the gaieties of the ball and the festivities of the occasion, light as a feather, buoyant as the mountain air. Sadness of heart has melted away, that patient can "laugh and get fat." There is something here for us to study, the tranquility and peace of mind so that nutrition can go on undisturbed.

The idea is advanced in the paper that in good environments bacteria cannot thrive. If they cannot thrive they are not able to do their mischief. There may be something in this which we do not understand. We do not believe that laughter will ever get rid of a tapeworm; we do not believe that cheerful society and good music will cast out or put a check upon the ravages of trichina, but we are compelled by force of circumstances to acknowledge the truthfulness of the assertion that good environments will check, if not destroy, the influence of microbes, and if we are convinced that microbes are really the cause of tuberculosis, then we want to place the patient in such an environment, which will check, if not destroy their ravages. It may be wise for us to select pure air, the right temperature, and sunshine; but unless the patient can carry contentment with him, sunshine in his soul, it would be better for him to stay at home; and unless he has abundant means so that he may not feel pinched, and can enter into the gaieties of the place, he had better stay at home.

Dr. J. G. Kiernan said: The point raised by Dr. Angear, as to the mental condition having an influence on the progress of the disease, is valid as to principle, but he has ignored the mental peculiarities of the consumptive patient. Hope has been known as a characteristic for a long time, but the suspicious element is a less known and as frequent characteristic. In removing a patient who has tuberculosis from the surroundings of his home we are doing the best possible for that patient, from a moral standpoint.

Dr. R. G. Bogue said: Some years ago it was my fortune to spend a few years in the South, the greater portion of them in the mountain regions of Tennessee, Northern Alabama and Northern Georgia; all of one winter, about six months, in Chattanooga. I can bear testimony to the wholesomeness of the entire region for the greater part of the year, and in the mountain regions for all of the year; in the valleys there are about two months in the summer season when malaria is quite prevalent, but up in the mountains it is eminently a healthy country. The air is pure, the water is good, the scenery is magnificent; there is everything to entertain and amuse one so far as scenery is concerned. The region of Chattanooga is peculiar and delightful from the variety of the mountain and valley scenery. The entire year, or very nearly so, it is practicable for people to be out of doors. During the latter part of December, all of January and the early part of February, the temperature is subject to considerable variation; it is reasonably cold and there are some storms, but after the middle of February, with the exception of now and then a short storm, the climate is delightful, extending thus through the whole summer. The altitude in the mountain region is such as to render the summer not oppressive. I fancy that for the colder and stormy portion of the winter the region south of Atlanta might be better for consumptive patients than north of the Atlanta, although personally I do not know as I was not so far south. There is Macon, and that part of Georgia fifty miles north of the coast, and extending through Georgia and Alabama to the region of Mobile. Quite early in the spring one can come northward, coming north of that range of mountains into the valley this side of the Atlanta, to Marietta, and find a delightful spring climate, with a great deal of sunshine, and a forest filled with bloom for two months in the spring, and everything, as far as climate and scenery are concerned, to delight even a sick person. There is much to recommend the region of Chattanooga to invalids, and if they are not satisfied with Chattanooga or the vicinity, there are other points, Marietta, Atlanta, and north of the Tennessee river, the region of Huntsville, and north from that as far as Nashville, so that consumptive patients or invalids

may be in a mild invigorating temperature, really all the year in the space of a couple of hundred miles.

Dr. Wm. T. Belfield presented a

PROSTATIC MYOMA—A SO-CALLED "MIDDLE LOBE" OF THE HYPERTROPHIED PROSTATE—REMOVED BY SUPRA PUBIC PROSTATOTOMY.

The patient, a man 73 years old, had for several years experienced difficulty in urination, and for nearly a year had been practically dependent upon his catheter. There was found symmetrical enlargement of the prostate per rectum, dilatation and catarrh of the bladder, and an impediment at the bladder neck to the entrance of rigid instruments. Exploration of the bladder by supra-pubic incision revealed a solid prostatic outgrowth, or "middle lobe," as large as a hazel-nut and of flattened pear-shape, springing by a short, narrow pedicle from the vesical orifice. The pedicle was twisted off with forceps and the growth removed. Recovery was uninterrupted, the fistula closing entirely on the seventeenth day. Patient has since urinated freely without a catheter, and can now almost completely empty the bladder; the cystitis has subsided.

Dr. Belfield also presented specimens of

MUCOUS CASTS FROM A CASE OF MEMBRANOUS ENTERITIS.

The patient was a nervous, rather hysterical lady about 35 years of age, who for several years had at intervals suffered from severe intestinal colics, followed in a day or two by diarrhœa with the expulsion of these casts; for several days thereafter much soreness and tenderness of the abdomen was experienced. The casts appear under the microscope as amorphous pseudo membrane enclosing cast-off epithelial cells. They are said by DaCosta to give the chemical reactions of mucin. This patient improved materially under small doses of bichloride of mercury and pills of iron, arsenic and strychnine.

Dr. Belfield also exhibited a

FOREIGN BODY FROM THE BLADDER;

a roll of chewing gum, two inches long, partially encrusted with urinary salts, which had been removed from the bladder of a young man by Dr. T. W. Miller. The patient, suspecting he had a stricture, had explored his urethra with a well-masticated roll of chewing-gum stuck upon the end of a broom straw. When the straw was withdrawn the gum had disappeared. Acute cystitis ensued. Attempts to detect and extract the gum with a small lithotrite having failed, perineal urethrotomy was performed and the gum extracted by the finger. Patient entirely recovered in two weeks.

Dr. Belfield also presented a

FRAGMENT OF THE OCCIPITAL BONE

of irregular quadrilateral shape, three inches long and two and one fourth inches broad, its longest edge serrated for articulation with the right parietal bone. The fragment was removed by him from a young man who had suffered a compound comminuted fracture of the skull, by a blow with a sharp iron instrument which had penetrated the brain to depth of over an inch. On admission to the County Hospital over a teaspoonful of brain substance was found among the hair; the scalp and dura mater were badly lacerated. The fragments of bone were removed, the wounds in the brain substance cleansed and drained, and the scalp wound sewed up. After the fourth day the temperature remained normal; the wound was entirely healed in a month, the dressing having been changed four times during that period. The scalp is depressed over the seat of fracture, and still pulsates with the brain.

Dr. Belfield also presented a specimen of

INTESTINE COVERED WITH MILIARY TUBERCLES; DEATH FROM MILIARY MENINGITIS.

This specimen is a piece of intestine the peritoneal covering of which is full of miliary tubercles. This case was a girl about twenty years old, who had always had excellent health. Three sisters are still living, and neither they nor the parents, nor any of the relatives so far as known, have ever shown symptoms of tuberculosis. The present generation are examples of perfect health, and this girl was in many respects apparently the healthiest of the lot. Until five days before her death her health was as usual; then she complained of feeling ill one evening; her head ached; she vomited without apparent cause; she lay down, drank a cup of tea, and was all right. The same thing happened the next day, and she complained of extreme headache. On the third day, with the exception of severe headache and vomiting without cause, she maintained her usual health. The evening before her death she was at the theatre, and came home about 11 o'clock, going to bed with one of her sisters. During the night the sister was several times awakened by the extraordinary breathing of the patient, which was very hard and loud. She shook her and the abnormal breathing ceased. In the morning it was found impossible to wake this girl; she was breathing very deeply and slowly and could not be roused. Physicians were summoned and all of them pronounced it a case of opium poisoning. The symptoms as related to me were stertorous breathing, sometimes as slow as four or five per minute, contracted pupils, a suggestion of strabismus, and rather warm surface. The pulse was remarkably good, about 80, similar to the pulse of a healthy person; the skin was not moist and clammy. The physicians instituted the usual measures for opium poisoning; they gave mustard at once, and as soon as a tube could be procured pumped out the stomach. They injected minute doses of atropine hypodermically, the patient receiving about a fortieth of a grain in three injections. The breathing improved very much after these injections, coming up to twelve and fifteen per minute; the pulse also quickened; suddenly the pulse flickered and went out, and the breathing stopped.

On the following day the Assistant County Physician and myself made a post-mortem examination, which included the head and abdominal cavity only. The brain was not hyperæmic, there was no venous congestion, the pupils were widely dilated; the membranes of the brain were adherent to the brain sub-

stance, and on stripping them off and examining them there were found numerous miliary tubercles. On opening the abdominal cavity the intestine bulged out, its surface thickly studded with miliary tubercles; there was extreme tuberculosis of the peretoneum and the mesenteric glands were large and cheesy; there was a ruptured cyst of the right ovary, about as large as a fist. That the rupture was antemortem was evident from the fact that the inner surface of the cyst was intensely congested; there was a good deal of coagulated blood in its cavity. While it would be impossible to say that no opium had been taken, yet it seems probable, when we consider that the pulse was natural, that the surface was not cool and clammy, and that there was a tendency to strabismus, that her death resulted from the tuberculosis, perhaps rupture of the cyst. There was no morphine found anywhere around, and her general disposition and circumstances were such as to forbid the conception by her friends that she could have taken poison. The case seems to have been another instance of sudden coma incident to tubercular meningitis. It is of extreme interest as showing how insidious miliary tuberculosis of the serous membranes may be. The only abnormal feature known to her family was an unusual fulness and hardness of the abdomen, developed during the last year of her life.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, January 19, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

H. M. Cutts, M.D., Secretary.

Dr. D. S. Lamb presented specimens of

CANCER OF THE SUPRARENAL CAPSULES AND ADDISON'S DISEASE.

The following three cases are reported to illustrate cancer of the suprarenal capsule contrasted with that lesion of the capsule, viz.: cheesy degeneration, which is so usually found in Addison's disease.

Case 1.—General Cancer, attended by Drs. D. W. Prentiss and Frank Baker; in which I made the necroscopy assisted by Dr. Baker. The patient, Mrs. Rosina M., white, age 61, died September 22, 1882. The following lesions were noted at the p. m. ex. Petechiæ on anterior and inner surfaces of thighs; upper limbs emaciated; lower limbs markedly œdematous. Cicatrices of pregnancy on abdomen. Head not examined. Thoracic viscera normal except a small cicatrix at apex of right lung. Abdomen contained many soft white flakes of lymph and yellowish serum. Greater omentum contracted, thickened and contained cancer nodules. Stomach contracted to six inches in length and three in breadth; middle portion adherent to adjacent viscera and walls occupied by a thick hard cancerous mass, deeply ulcerated; the ulcerated surface was shreddy, and dark from hæmorrhage. Intestines normal. Liver small, congested and in an anterior part, showed several cancer nodules. Gall bladder much distended with bile. Spleen small, soft, firmly adherent to adjacent organs, and contained one hard cancer nodule. Pancreas and kidneys normal. Suprarenal capsules much enlarged and converted into a cancerous mass. Ovaries atrophied and undergoing colloid degeneration. Lumbar and left iliac glands enlarged and cancerous. Microscopical examinations of the several organs by Dr. J. C. McConnell of the Museum showed cancer as stated.

Case 2.—Cancer.—Woman, age 35, was five days in Freedmans Hospital, in this city, where she died. She was anæmic, constipated, urine albuminous; and had convulsions. She was attended by Dr. F. J. Shadd, of the hospital, who made the necroscopy and contributed the specimen. This consists of the right kidney which is normal; and its suprarenal capsule, which is converted into a soft cancerous mass, 4 inches by 3.5 by 3 and was adherent to liver. Renal vein and inferior vena cava were occupied by blood clots, which were closely adherent to the walls; in some places the inner coat was thickened as by incipient cancerous growth. Left kidney normal.

Case 3.—Addison's Disease.—Attended by Dr. J. T. Young; Mrs. Lucy W., white, widow, age 31. tailoress. First noticed a discoloration around her mouth three years before death, that is, in 1872. This extended but little until the summer of 1874; afterwards it spread rapidly until the whole body was affected. Black spots appeared in January, 1875. The patient's previous health had been pretty good except that her monthly periods had for a long time occurred every three weeks, and were sometimes excessive in quantity. She had never been pregnant, though married seven or eight years. About the beginning of the winter of 1874–5, she began to complain of feeling week, could not work regularly, and working was followed by prostration. After January 1, she gave up working altogether. Her feet and legs became swollen; she had constant pain in her back and left side, and had dyspnœa on going up stairs. Dr. Young first saw her in March, 1875. On the 25th of that month. fæcial erysipelas set in and lasted six days. April 5, there was uncontrollable nausea and vomiting, which continued. She could take but little nourishment, had severe pain in epigastrium and constant tired feeling; sleeplessness; pulse small and weak. Died April 15.

I made the necroscopy and found lesions as follows: Face a faint yellowish-brown color, and showed many black spots from one-eighth to one-fourth of an inch in diameter, some slightly elevated, some of a uniform tint, others darkest in the centre: body and limbs of a lighter color than the face, and showed a few similar black spots. Head not examined. Abundance of fat in subcutaneous connective tissue; one inch thick over the abdomen. Right lung collapsed, congested posteriorly, contained several calcareous deposits; firm old pleuritic adhesions. Left lung similar to right; calcareous deposits more numerous and larger; adhesions more extensive. Heart flabby, contained a few small clots and a little blood. Large

calcareous mass in a greater omentum. Stomach and intestines normal. Liver extended up to third rib, was dark-red and somewhat flabby. Gall bladder full of dark green bile. Spleen normal. Kidneys dark. Suprarenal capsules contained cheesy masses, larger in the right. Firm adhesions of omentum, liver and spleen to abdominal wall. Posterior adhesions of uterus. Bladder empty.

The diseases to which the suprarenal capsules or as they are also called, the "adrenals" are subject, are mainly secondary to similar lesions elsewhere; sometimes by extension, by contiguity at others, by infection from distant organs. Thus we have lardaceous degeneration, cheesy degeneration, tuberculosis, cancer, embolism, abscess.

The glands may also be affected by direct violence. The only lesion which appears to cause definite symptoms is the cheesy degeneration. It is generally admitted that the disease known as Addison's disease is intimately related to this form of degeneration of the suprarenal capsules. The exceptions are very few in number.

In the first case, here reported, of cancer, the greater omentum, liver, spleen, stomach, lumbar and iliac glands and adrenals, were all involved in the disease; it is probable that the primary disease was in the stomach, the other organs being affected by secondary infection. No history is given, but there is nothing in the necroscopy to suggest Addison's disease. And the recorded cases of cancer of the adrenals rarely, if ever, do give clinical symptoms such as are found in Addison's disease. The second case is reported only to show how very large a malignant growth of the glands may become; there is no history, but it is probable that the case was one of general cancer like the first. It is interesting to note that the kidneys were not affected by the disease in either case.

The third case is a typical one of Addison's disease. As is usually the case, both capsules are involved; one is somewhat atrophied, the other enlarged; both show the characteristic yellow caseous degeneration in what was doubtless a firm whitish mass. The prominent symptoms connected with this lesion are: 1. Discoloration of skin, often but not very correctly called bronzing; 2. Progressive weakness; and 3. Nausea and vomiting. The case reported shows these well marked. The discoloration began three years before death, the woman then being 28 years old, progressed slowly at first, but rapidly during the last nine months of life. At death the whole body was of a faint yellowish brown hue, the color being deeper on the exposed parts; the abundant black spots, on which stress is laid by Dr. Greenhow, were also present. Progressive weakness marked the case more especially during the last four months of life. Instead, however, of being accompanied by emaciation, there was abundance of fat everywhere. About ten days before death the nausea and vomiting became uncontrollable. As is often the case, although the discoloration began so long before death, the other prominent symptoms were noticed only during the last few months.

The probable cause of the disease is obscure. The women's occupation, tailoress, suggests no explanation. The theory of Greenhow, that the disease is most often found in those who do severe manual labor, of course, is not supported. His further theory, that the cause may be found in the history of some strain or other injury, especially in women, is not confirmed, simply because it is not known if this woman ever was injured. Dr. Fagge, like Virchow and Rindfleisch, regards the disease as tubercular; and in this case calcareous deposits were found in both lungs and in omentum, suggesting obsolete tubercule. Attention was not drawn to the semilunar ganglia by any peculiarity of appearance; this is the more to be regretted in view of the opinion of some that the ganglia are responsible for the nausea and vomiting, and progressive weakness; it is not likely, however, that the discoloration is in any way due to them.

BOOK REVIEWS.

THE REFRACTION AND ACCOMMODATION OF THE EYE AND THEIR ANOMALIES. By E. LANDOLT, M.D., Paris. Translated, under the Author's Supervision, by C. M. CULVER, M.A., M.D., formerly Clinical Assistant to the Author, Member of the Albany Institute, Albany, N. Y. 8vo. Edinburgh: Young J. Pentland.

The appearance of a new edition in English of Dr. Landolt's work on the "Refraction and Accommodation of the Eye," is an event in ophthalmology, and has attracted the attention of the numerous English and American physicians who frequent the Paris hospitals. This treatise may be compared favorably with that of Donders, published in 1864 by the New Sydenham Society. The author's aim, however, is different from that of the eminent physiologist of Utrecht. The book is not intended for scientists only, but seeks also to supply students and practitioners with a manual elementary and practical, but at the same time exact and complete. The author possesses the rare ability of bringing within the reach of every one questions which are too often obscure, owing to their being too learnedly exposed. The "Manuel d'Ophthalmoscopie" of the author is simply a *chef d'œuvre* of its kind. It may be asked whether this particular quality may not be found wanting in the profound exposition of a subject so vast as the "Anomalies de la Réfraction et de l'Accommodation." But the proof is before us that one can treat these complex questions, in all their details, and with remarkable clearness, avoiding at the same time not only long mathematical demonstrations, but nearly all the formulæ of inverse value, which are the stumbling blocks of so many beginners in ophthalmology.

To facilitate the mastery of a subject so vast and complex, the author has divided it into three headings: 1. the *Physical* portion; 2. the *Theoretical*, which perhaps might have been better named the *Physiological* portion; and 3. the *Clinical* portion. The first part forms an elementary treatise upon optics, which enables even a beginner to understand the ac-

tion of the surfaces and refractive media upon light, from its passage through a plane surface, up to its complicated transmission in the dioptric system of the eye. It is scarcely necessary to say that the questions of lenses and spectacle glasses meet with special attention. This section may be read with advantage even by those who are not acquainted with algebraic formulæ, as the author gives the solution of those problems also by simple construction with diagrams. Nevertheless, the reading of this chapter is not indispensable in order to understand those following it. The latter form, so to speak, a separate work, a treatise of refraction and accommodation without mathematical formulæ and therefore very easy to read.

The second part gives a description of the dioptric system of the eye and its definition. The definitions of emmetropia and ametropia, the anatomy and physiology of accommodation and convergence and their reciprocal relations.

An excellent chapter is devoted to the methods of visual examination. All the principles of optometry are clearly discussed, but only those methods of optometry which have a real practical value are described in detail. Astigmatism, both regular and irregular, are treated by the author in a manner clear and original; he may be congratulated for having condensed all that relates to this anomaly of refraction, properly so called, into a single paragraph, instead of dividing it into two headings, theoretical and clinical, as for hypermetropia and myopia, which are due to imperfect conformation of the eyeballs rather than of the dioptric apparatus.

The Clinical chapter, as might be expected from the author's aim, is the most important. If the first two sections are remarkable for their clearness and conciseness, the third commends itself by its abundance both of clinical relations, and original and judicious views of the author. The novel classification of matter above mentioned indicates, in itself, an independent thinker. Far from making an absolute distinction between ametropia as a pathological condition, and emmetropia, the only normal state of vision, the author classes as "normal" eyes the slightly hypermetropic and myopic, together with the emmetropic. Clinically these *slightly* ametropic eyes are fairly normal, and suffer little or nothing from their defects of refraction. With the medium degrees of ametropia it is otherwise, and these comprise the hypermetropic from two to four, and the myopic from three to six dioptrics. Here not only is correction of the optical defect indispensable, but what is chiefly remarkable is the difficulty of coöperation between the eyes which characterize this medium degree of asthenopia, ametropia, and find their expression in spasm of accommodation, convergent and divergent strabismus, etc. The author calls much more attention than has hitherto been paid to the relation which exists between the functions of the two eyes, on the one hand, and accommodation and convergence on the other. These have already been studied in the physiological portion of the work, but the author here indicates new methods of mensuration (Landolt's dynamometer), and enters into fuller details of a clinical order. The analysis, and the treatment of muscular asthenopia, both palliative and radical, by means of strabotomy and muscular advancement, belong entirely to Landolt. The "metre angle" first proposed by Nagel, and which is here adopted as the unity of measure of convergence, gives clearness to the descriptions, and precision to the author's methods, some of which have already been published.

After the medium, we come to the higher degrees of typical ametropia. Here the organ of vision is in a truly pathological condition. Eyes strongly hypermetropic are arrested in their development, and those which are strongly myopic are generally affected by a series of morbid conditions of the uveal tract.

Another happy idea is the separation of typical ametropia from curvature ametropia, what the translator terms atypic aphakia, etc.

The last chapter treats of the anomalies of accommodation, of myotics and mydriatics, and an appendix only, a kind of postscript, is devoted to presbyopia. It is somewhat surprising to find an anomaly of refraction which has hitherto met with universal recognition dismissed in this summary fashion, but Landolt goes still further. He would, as he has already pointed out in his "Manual on the Examination of the Eyes," abolish the term altogether. He explains that the word presbyopia implies necessarily a fixed distance for near vision, and this conception may lead to serious errors: there is only one exact way of adapting the eyes to the visual distance, whether it be long or short, and this is by a careful examination of their statical and dynamic refractions, and the functions of the motor muscles. From these data alone can the question of corrective glasses be settled, and it is unnecessary to resort either to a given distance of near vision, or to standard diagrams for presbyopia. Landolt is the more authorized to do so, as he was the first to study the quota of accommodation and convergence; that is to say, the quantities of these two functions which the eyes can dispose of for prolonged work.

To conclude, this work is full of new ideas and means of investigation, and operative methods devised by the author. It will be read with profit not only by students, but also by ophthalmologists, and will doubtless become one of our standard text books.

Manual of Operative Surgery. By Joseph D. Bryant, M.D., Professor of Anatomy and Clinical Surgery, and Associate Professor of Orthopedic Surgery, Bellevue Hospital Medical College, etc. With about 800 illustrations. 8vo, pp. xxvi, 530. New York: D. Appleton & Co. 1887. Chicago: A. C. McClurg & Co.

One does not read very much of this book before finding that its author is impressed with the necessity of a surgeon knowing his anatomy; anatomical relations are frequently and carefully given, so that the reader will not have to turn alternately from the book in hand to an anatomy. In very many respects the book is an excellent manual of operative surgery; it is well written, and the illustrations are

good. But some matters which may be regarded as important are omitted: for example, no mention is made of the treatment of stricture of the urethra by electrolysis, of the operation of shortening the bones in extensive injury to soft parts; the very important details of correct operative procedures in cases of rupture of the bladder are omitted. The directions for the Wladimiroff Mikulicz operation (which is ascribed to Mikulicz, and is called "osteoplastic amputation of heal and ankle) are incompletely given, as are the indications for it. In the account of litholapaxy the evacuators of Bigelow, Thompson and Otis are described and illustrated, but no mention is made of the continuous current evacuator of Professor Edmund Andrews, described and illustrated in THE JOURNAL of June 5, 1886, the advantages of which should be apparent to anyone who has been annoyed by the churning of the other instruments. With these and some other defects remedied the book will be much better. It is, nevertheless, a good guide to the performance of surgical operations.

ASSOCIATION ITEMS.

AMERICAN MEDICAL ASSOCIATION.

Section of Medical Jurisprudence.

In THE JOURNAL for February 12, 1887, page 196, the Chairman of this Section published a list of writers and the titles of these papers, at that time offered for his Section at the coming meeting of the Association, the first week in June, 1887. We are now requested to add the following:

"On State Regulation of Medical Practice. Its Value and Importance." By Dr. K. C. Markham, Independence, Iowa.

"On the Medico-Legal Relations of Alcoholic Liquors, Fermented and Distilled." By Dr. N. S. Davis, Chicago.

"On the Jurisprudence of Mental and Nervous Diseases." By Dr. S. V. Clevenger, Chicago.

"On the necessity of a Uniform Standard of Education, Especially more Detailed Pathological Instruction to Unity of Professional Action in Forensic Medicines." By Dr. Frank S. Billings, Lincoln, Neb.

"On Mental Responsibility in Inebriety." By Dr. T. D. Crothers, Hartford, Ct.

"On Paralytic, Aphasia and Apoplectic Conditions in Return of Testamentary Capacity." By Dr. E. C. Spitzka, New York.

"Report on the Present State of our knowledge Concerning Concussion from Railway Accidents." By Dr. N. E. Brill, New York.

[Who of the officers of Sections will report progress next?—EDITOR.]

MISCELLANEOUS.

MILK INFECTION: A SUGGESTION.—Dr. James F. Allen, medical officer to the Corporation of Pietermaritzburg, has written a very suggestive report on the causes of enteric fever in that city. Pietermaritzburg, he says, is in fair sanitary condition. It has a public water supply, and the houses in which enteric fever made its appearance were not those in which any local condition of house construction could give rise to it. Last year this disease broke out round a small dairy on the outskirts of the town, the occupants of the farm entirely escaped, so far as he could ascertain. In this dairy specific enteritis among the calves had been very fatal; all the calves contracted the disease, and in each case it ended fatally, eight or nine dying altogether. The proprietor of the dairy states that the pasturage round his house is very unhealthy, and last year the calves were therefore kept tied up; nevertheless they did not escape the disease; but Dr. Allen notes that full-grown animals are exempt from it. As a rule, the calf disease made its appearance in this farm late in the summer, but last year the first calf must have died about the end of July or the beginning of August. Thirteen cases of enteric fever occurred altogether among persons resident in the neighborhood—one in August opposite the affected dairy, the family of the sufferer receiving milk from this source. In another house five cases occurred among a household of seven. This household did not receive milk from the suspected dairy, but they used for fuel cowdung collected in the neighborhood—not from the affected calves, for these were tied up; but perhaps from other animals suffering from the same disease. In another family two cases occurred, and in this house cowdung was also used for fuel, the source from which it came being unknown. Another case occurred in the person of an infant at its mother's breast, but this child, the mother states, received no other milk than her own. Concerning the household, no distinct mention is made of the fuel used for burning. The remaining four cases were all in one house; milk was not received by this household from the suspected dairy knowingly at the time of the appearance of the first case, but during this child's illness this dairy supplied the milk for the rest of the family, but it was at this time regularly boiled. Later, however, this precaution was neglected, and three other persons then contracted enteric fever. There is to be found in these cases nothing more than a suggestion that the bowel discharges from the animals in the dairy may have been concerned in the production of some of the cases of enteric fever in the neighborhood. Dr. Allen has omitted to state the total number of households using for fuel the material which he suspects has given rise to disease, and the whole facts are therefore not sufficiently before us to enable any positive opinion to be formed on the subject; but Dr. Allen's story is well worth bearing in mind in any further investigation into the etiology of this disease. In another report Dr. Allen insists upon the simultaneous appearance of enteric fever, among the inhabitants of the neighborhood of the farms, and the appearance of what he describes as specific enteritis among the calves. He states that he examined the mesentery and small intestines of one of these animals; that he found the mesenteric glands

enlarged, and in the intestinal mucous membrane evidence of the same diseased action as is to be found in that of human beings after death from enteric fever—thus ulceration and patches of inflammation involving Peyer's glands are to be found in both diseases; and he asserts that the two disorders in Pietermaritzburg at least are always found together.—*Lancet*, Nov. 20, 1886.

Health in Michigan.—For the month of February, 1887, compared with the preceding month, the reports indicate that remittent fever decreased in prevalence. Compared with the preceding month, the temperature in the month of February, 1887, was higher. The absolute humidity, the relative humidity, the day ozone and the night ozone were more. Compared with the average for the month of February in the nine years, 1879–1887, intermittent fever, pneumonia, diphtheria, consumption of lungs, and influenza, were less prevalent in February, 1887.

For the month of February, 1887, compared with the average of corresponding months, for the nine years, 1879–1887, the temperature was slightly higher, the absolute humidity was more, the relative humidity was much more, the day ozone was slightly less, and the night ozone was less.

Including reports from regular observers and others, diphtheria was reported present in Michigan, in the month of February, 1887, at thirty four places, scarlatina at forty-two places, typhoid fever at sixteen places, and measles at twenty-four places. Reports from all sources show diphtheria reported at twenty-two places less, scarlet fever at six places more, typhoid fever at two places more, and measles at three places more in February, than in the preceding month, January, 1887.

Michigan State Board of Health.—At the 276th meeting of the Brooklyn Pathological Society, held at the Brooklyn Eye and Ear Hospital, February 24, 1887, the following resolutions was unanimously adopted.

Whereas, the State Board of Health of Michigan, has been for many years a pioneer in the investigation of disease and the collection of vital statistics, and

Whereas, the result of these investigations and of the collection of these statistics, has been to stimu men and boards of health throughout the country to undertake similar work for the public good, therefore be it

Resolved that the Brooklyn Pathological Society heartily endorses and commends the course so admirably planned and so efficiently followed by the State Board of Health of Michigan, and respectfully but earnestly, appeal to the legislature of that State to be liberal in its support to its State Board of Health, and to widen its influence and usefulness by appropriating the necessary funds to establish and maintain a Laboratory of Hygiene.

New Medical Journals.—*The Journal of Obstetrics and Gynecology* is the Anglicized title of a new Russian medical journal, the organ of the Obstetrical and Gynecological Society of St. Petersburg.

The *Revue Générale de Clinique et de Therapeutique*, the first number of which appeared on February 17, is a weekly which, according to the preliminary notice, will be on the plan of the *London Medical Record*.

Capital Punishment by Electricity is now proposed, and is receiving favorable consideration by a legislative commission appointed by the New York Legislature to inquire into various devices for putting murderers to death.

"Pilocereus Senilis" is the title of a volume of the collected writings of the late Dr. Walter Moxon, of Guy's Hospital, which has been recently published by Sampson Low & Co., of London.

Vaccination in Africa.—Archdeacon Farrar, of Magila, writing from East Africa, says: "We have just saved the whole district of Magila from an invasion of small-pox, vaccinating everybody, at the rate of about fifty a day, until all have been vaccinated; so that while other districts have suffered considerably around us, there has not been a single case of small pox in the Magila district, with its hundreds of villages, and thousands of people. This, of course, has commended our medical science to the people, and they come in numbers."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 26, 1887, TO MARCH 4, 1887

Major Chas. R. Greenleaf, Surgeon, ordered for duty in the office of the Surgeon-General of the Army. S. O. 41, A. G. O., Feb. 18, 1887.

Major D. L. Huntington, Surgeon, relieved from duty in the office of the Surgeon-General, to take effect March 1, 1887. S. O. 41, A. G. O., Feb. 18, 1887.

Major David L. Huntington, Asst. Surgeon, ordered for duty at San Diego Bks., Cal., and granted leave of absence for one month from March 1, 1887. S. O. 45, A. G. O., Feb 25, 1887.

Capt. Robert H. White, Asst. Surgeon, on being relieved by Major Huntington, to proceed to Angel Island, Cal., and report to commanding officer for duty at that point. S. O. 45, A. G. O., Feb. 25, 1887.

Capt. Louis S. Tesson, Asst. Surgeon, ordered for duty as attending surgeon at hdqrs. Div. of the Missouri and examiner of recruits at Chicago. S. O. 44, A. G. O., Feb. 24, 1887.

Capt. Wm. W. Gray, Asst. Surgeon, leave of absence for seven days extended twenty-three days. S. O. 13, Dept. Dak., Feb. 21, 1887.

First Lieut. Chas. F. Mason, Asst. Surgeon, resignation accepted by the President, to take effect March 25, 1887. S. O. 44, A. G. O., Feb. 24, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE FIVE WEEKS ENDED MARCH 5, 1887.

Guitéras, John, P. A. Surgeon, granted leave of absence for twenty-one days. Feb. 28, 1887.

Pettus, W. J., Asst. Surgeon, to proceed to Charleston, S. C., for temporary duty. Feb. 28, 1887.

THE PRACTICE OF MEDICINE AMONG THE GREEKS PRIOR TO THE AGE OF HIPPOCRATES; A CONTRIBUTION TO THE HISTORY OF MEDICINE.

BY J. M. BALL, JR., M.D.,
OF WATERLOO, IOWA.

At a time when Egypt, Chaldea and Phœnicia were enjoying the benefits of an advanced civilization, the early inhabitants of Greece, called Pelasgi, were living on the acorns of the forests, clothing themselves with the skins of wild beasts, and sleeping in caves. The arts and sciences were carried to Greece by the emigration of successive parties from Tyre and Memphis. It is said that Inachus, the victim of a revolution, conducted the first Egyptian colony to Greece, where he founded the city of Argos, 1,856 years before the common era. The indebtedness of Greece to the civilization of Asia and Africa was amply repaid by the Ionian migration.

Of all the Greek peoples the Ionians were the most intellectual, and they were so, not through any inherent faculties in themselves, but simply from the force of circumstances. At a remote period in their history they were forced to leave their homes on the shores of the Corinthian gulf, and to seek a new abode. For a short time they took refuge in Attica, whose territory was found to be too small to support the increase of population. Accordingly, they resolved to seek new settlements in the East, and in their passage across the Ægean Sea they colonized most of that group of islands called Cyclades. On reaching Asia Minor, they took possession of that strip of country lying between the rivers Hermes and Meander, together with the islands Samos, Cos, Lesbos, Chios and others. This migration was of great subsequent importance. While their kinsmen in Attica were struggling for a bare subsistence, and were often hard pressed by the neighboring tribes, the Ionians, having settled in a fertile and luxurious country and among a race wealthier, but far inferior to themselves, soon found those means of ease and leisure which, to a certain extent, seem necessary to the development of intellectual culture.

It is the object of this article to describe the condition of medical practice among the ancient Greeks prior to the age of Hippocrates. The writings of Homer present us with a vivid picture of the state of Europe a thousand years before the birth of Christ. A twilight was dawning on the most eastern verge, in the countries adjoining the Hellespont, but the West and the North were immersed in darkness. "In the intellectual infancy of a savage state, man transfers to nature his conceptions of himself, and, considering everything that he does is determined by his own pleasure, regards all passing events as depending on the arbitrary volition of a superior but invisible power."[1] The white race at that period was like a child. To the Greek, no fiction was too marvellous for belief, if it was separated from his view by a hundred years or a hundred miles; the exaggeration of tradition confirming it in the one instance, and the difficulties of travel in the other. Every hill had its supernatural legend, every forest its phantom, and even the mouth of hell was said to be on the farther side of the Euxine. The medical mythology of the Greeks is remarkably full, and the learned Le Clerc,[2] with commendable zeal, has searched through history, poetry and inscriptions, hoping to find something which would shed light upon the origin of our science. He details the names of more than thirty gods and goddesses, heroes and heroines who possessed a knowledge of medicine.

The first of the Greeks who immortalized himself by his wonderful cures was Melampus, to whom altars were erected by his grateful patients. He is said to have lived 200 years before the Trojan war. His most famous cures were performed upon the daughters of Proteus, King of Argos, who were afflicted with outbreaks of mania, during which they imagined themselves transformed into wild beasts and ran raging through the forests. The cure is said to have been effected by the administration of hellebore.[3]

Medicine was brought to Greece by the sage Chiron. There is much mystery attached to his character and to everything connected with him, but what we may consider as the most probable conclusion is that he was a prince of Thessaly, who lived a short time previous to the siege of Troy, that he was far superior to his contemporaries in knowledge, and that, after the manner of his countrymen, he was so frequently seen on horseback as to give credence to the fabulous story of his being a centaur.[4] He held his school in a grotto in Thessaly and, if the chronicle may be believed, no philosopher of antiquity, no

professor in modern times, could count in his audience as many celebrities as the centaur saw in his cave. He instructed Jason, Theseus, Castor and Pollux, the subtle Ulysses, the fiery Diomedes, the pious Æneas, and the invincible Achilles: all heroes who distinguished themselves either at the capture of the fleece of gold or in the Trojan war. He taught Apollo music, Æsculapius medicine, and Hercules astronomy. He cured Phœnix, son of Amyntor, of a blindness supposed to be incurable, and obtained great fame in the treatment of ulcers. He was shot in the knee by a poisoned arrow and prayed Jupiter to take away his life. The god heard his prayer and translated him to the heavens, where he is said to shine in the constellation Sagitarius[5]

It is to Æsculapius, the pupil of Chiron that, by common consent of antiquity, is ascribed the merit of having first devoted himself to the cultivation of medicine and of having made it a distinct object of pursuit. He passed for the son of Apollo by the nymph Coronis, and is said to have been born at Epidaurus, a city of Argolis, where he had a temple and famous oracle.[6] In passing, it may be well to remark that the ancients cherished a great veneration for the medical character. The poetical mythology of Greece shows how great was the respect and gratitude rendered to those who practiced the healing art. This is nowhere better exemplified than in the noble origin which is assigned to it in their fables. No less a personage than the god of light himself, Helios or Apollo, who created and maintains all living nature, is said to have been the father of Æsculapius, the god-like teacher of medicine. The same tradition makes Circe to have been the sister of Æsculapius.

The manner in which Æsculapius was ushered into this world was entirely in harmony with his divine character, and was of itself sufficient to show that he was no ordinary mortal. According to Ovid, he was cut out of the womb of his mother, Coronis, by Apollo after he had destroyed her for infidelity. Apollo received the information respecting the unfaithfulness of Coronis from a raven, and the angry god is said by Apollodorus to have changed the color of the raven from white to black, as a punishment for his unwelcome officiousness. The story of the unnatural manner of birth is thus related by Ovid:

> "Ut tamen ingratos in pectore fudit odores,
> Et dedit amplexus, injustaque justa peregit;
> Non tulit in cineres labi sua Phœbus eosdem
> Semina; *sed natum flammis uteroque parentis*
> *Eripuit*, geminique tulit Chironis in antrum."
> —*Metamor.*, lib. ii, v. 626.

In infancy, Æsculapius was exposed upon a mountain in Thessaly, and was suckled by a goat and defended by a dog. A shepherd having for some time missed his goat and dog, went to the mountain to seek them, and found the child possessed of extraordinary beauty. He raised the boy with the greatest care and gave him into the hands of the sage, Chiron, by whose instructions he profited so well as to far surpass his master in fame.

[6] Renouard: History of Medicine, translated by Comegys.

Marvellous stories are told of Melampus and Chiron. These, however, are insignificant when compared with the feats of Æsculapius. In addition to many other astonishing powers, he was gifted with a remarkable faculty, peculiar to himself, of raising at pleasure the dead to life. Not less than six or seven instances are on record of distinguished corpses that were benefited by the exertion of this happy talent. It is impossible to say how far the bounds of science might have been enlarged by so mighty a genius had not Pluto taken alarm at his progress, and presented a memorial to Jupiter, humbly showing that if a stop were not put to the career of this officious mortal, people would soon cease to die and hell would become a desert; whereupon Jupiter killed Æsculapius with a thunderbolt. It is probably for this reason that the modern children of Æsculapius abstain from working miracles.

We find Æsculapius first mentioned in the Homeric poems as a Thessalian king, not as a god, although divine honors were paid to him in later times. There is no sign in the writings of Homer of the subordination of medicine to religion which is seen in ancient Egypt, nor are the priests charged, as in that country, with medical functions. These are facts which throw grave doubts upon the commonly received opinion that medicine derived its origin in all countries from religious observances. Although medicine among the Homeric Greeks was quite distinct from religion, yet the worship of Æsculapius as the god of healing demands some notice. Sick persons repaired, or were conveyed to the temples of Æsculapius, in order to be cured, just as in modern times relief is sought by a devotional pilgrimage, or from the waters of some sacred spring. Then, as now, the healing influence was sometimes sought by deputy. The sick person or his representative, after prayer, sacrifice and ablution, was made to sleep upon the hide of the sacrificed animal, or at the feet of the statue of the god, while sacred rites were performed. In his sleep the appropriate remedy was indicated by a dream. The record of the case was inscribed on the columns or walls of the temple. Æsculapius obtained in antiquity a veneration which was almost universal, and his worship, which passed from the Greeks to the Romans, extended to all countries subjugated by the two nations. Fifty years after the destruction of the kingdom of Priam, there was erected at Titanus, a city of Peloponnesus, the first temple in his honor. This edifice was reared by the grandson of Æsculapius, Alexanor, the son of Machaon. The worship of this god spread with great rapidity.

The noted asclepia were very numerous, and in the work of Schulz more than sixty of them are described.[7] Among the many temples consecrated to this god, those at Epidaurus, and on the island of Cos, were particularly famous. The island of Cos, for centuries, remained the Mecca of medicine. None but the initiated could enter these holy shrines, and the exclusion of all unholiness extended to all other temples. Only the priests could look upon the columns of Hygeia at Ægeum; no dog was permitted to enter

[7] Schulz: Historia Medicinæ a Rerum Initio ad Annum Urbis Romæ, DXXV. Lipsiæ, 1728.

at Delphos; no child could be born at Epidaurus, and no one was allowed to die within its grounds. In the last temple there was a statue of colossal size, the handiwork of Trasymedus, made of gold and ivory, which represented the god of medicine in the form of an old man seated on a throne, holding a staff in one hand and resting the other upon the head of an enormous serpent. A dog, the emblem of vigilance, lay reposing at his feet. The whole figure bore a striking resemblance to that of Zeus.

The serpent was always the chief symbol of Æsculapius, and all the coins stamped in his honor are thus marked. From time immemorial the snake has been the symbol of craft and prophecy. Moses erected a snake in the desert of Arabia; the natives of Guinea still worship a holy serpent, and the Phœnicians and Egyptians always regarded it as divine. There are many reasons for this reverence: The snake was formidable in appearance on account of its fiery eyes and the activity of its poison; it moved quickly, and in moving described curious, mystic figures upon the ground; it had a long life, with apparent capacity for rejuvenation. Being found in grottoes and holes by the side of springs and healing waters, it came to be regarded as the guardian of these trusts. The Asclepiadæ kept tame snakes which licked the hands of the sick with their tongues or twitched their ears with their mouths. The Epirotes kept snakes in the grove of Apollo, and every year a virgin, naked and alone, entered the grove to feed them. We are told that around Epidaurus there were serpents of a yellowish-brown color, whose bite was not poisonous, and that these were used by the priests in those supernatural performances which filled the people with fear and astonishment.

Although the accounts which have been transmitted to us respecting Æsculapius would lead us to conclude that he was a real personage, who possessed a greater degree of skill than his contemporaries, yet his whole life is so involved in fable and mystery that it is impossible to obtain any correct ideas of the details of his practice. We have no direct evidence to show how far internal remedies were administered, and it may be supposed that the Greeks at this period relied largely upon the use of magical arts and incantations. Although we have reason to believe that certain vegetable products were employed as internal remedies, yet we are scarcely able to ascertain what was the object of the practitioner and what were the plants used. The poet Pindar, who lived 800 years later, was the first to comment upon the practice of this personage, which he described as follows: "Æsculapius cured the ulcers, wounds, fevers and pains of all who applied to him, by enchantments, calming potions, incisions and external applications."[8] It is said that Æsculapius obtained from Minerva the blood which flowed from the veins of Medusa after the latter had been beheaded by Perseus. With that which flowed from the left side he destroyed his enemies; while that obtained from the veins on the right was used for the benefit of his patients.

The practice of medicine remained for a considerable time hereditary in the family of Æsculapius, and his descendants, called Asclepiadæ, were the priests who presided over the temples erected in his honor. The temples were built in salubrious localities, sometimes on the summit of a hill or on the side of a mountain; sometimes on the sea shore, or near a thermal or mineral spring, and in spots where groves of trees could refresh the sight of the sick and afford them cool and solitary retreats.[9] In the selection of the sites for the temples, the priests displayed the shrewdness which has characterized them ever since. Thus we see that they were erected under circumstances not a little resembling those found conducive to health by the invalids of modern times. Some of the practices enjoined by the priests were of a dietetic nature and were directly conducive to temperance and cleanliness. The isolation and seclusion of the temples was well calculated to excite the reverence of superstitious and credulous minds, and this feeling was greatly heightened by the preparation of fasting and prayer which was made a necessary preliminary to entering the gates. The temple at Orophus was open only to him who had first fasted for several days; no wine could be drunk for three days, and no food tasted for twenty-four hours before admission to the temple at Pergamus. In addition to these preparations, offerings were made of a cock or a goat, as in the sacrifices of Socrates; prayer attended the ceremonies, and the service was further sanctified by music. The patient was bathed, subjected to frictions and manipulations, and then anointed with oil. Apollonius anointed himself, before entering the temple, by pouring oil of amber upon his head, so that the body smoked, and physician and patient were enveloped in a halo. After enwreathing themselves, the patients entered the temple amid the singing of hymns and the playing of harps. In the sleep which followed, Æsculapius appeared in a dream and indicated the proper treatment. All antiquity had faith in dreams, and their interpretation was the business of the priests. Sacred and profane history are full of examples which attest the universality of this belief. The Asclepiadæ did not stop with interpreting the dreams of their patients; when occasion required, they even dreamed for them themselves.

In return for their services in behalf of suffering humanity, the Asclepiadæ received no direct emolument, but were paid by presents from the patients. These were often of great value, such as vessels of gold and silver; often casts of the affected member, the so-called anathemas, were made from these precious metals and donated to the priests. At Amphianus it was customary to throw silver coins into the sacred springs. In some places paintings of the diseased parts were suspended from the walls of the temple, or the name of the patient with a description of his disease, the remedies employed and the result attained, were engraved on metal tablets (tabulæ votivæ), doorposts, or columns. Six such columns, with Doric inscriptions, were still standing in the time of Pausanius, in the asclepion of Epidaurus. As soon as an important remedy was discovered, the mode of preparing it was written on the gates and

[8] Pindar: Third Pythian Ode.

[9] Lessing: Handbuch der Geschichte der Medizin. Berlin, 1838.

columns of the temples. Thus, a celebrated anti dote for snake-bites, the contribution of Eudemus, was recorded on the door of the asclepion at Cos, and a noted eye-wash was affixed to a similar place at Ephesus. Those who invented surgical instruments deposited them within the temple. Thus Erasistratus, according to Cœlius Aurelianus, presented one to the temple at Delphos, intended for the extraction of teeth. In this manner the temples gradually became centres for medical instruction.

Gruter[10] has given a copy of several votive tablets which were unearthed on the Isle of the Tiber, on one of which the following was inscribed in Greek: "Lately a certain Caius, who was blind, came to consult the oracle. The god required that he approach the sacred altar to perform adorations; at once he passed from the right to the left, and having rested his fingers on the altar, he raised his hands to his eyes and immediately recovered his sight. The people rejoiced to see such marvels accomplished under the reign of our august Antoninus." It is more than probable that Hippocrates, the central figure of ancient medicine, obtained much of his knowledge from reading the votive tablets and inscriptions found in the temples.

Statues of Æsculapius were to be found in all the temples. The god of healing was always figured in the form of a strong and venerable man with full beard and gray hair, who in earnestness and mildness of expression bore a striking resemblance to Jupiter. Although sometimes seated, yet generally he was seen standing erect or leaning on a staff, around which a snake was seen twining its spiral coils. He was usually covered with a pallium with regularly disposed folds resting upon his right shoulder and exposing the greater part of the chest and abdomen, whose well-formed muscles showed him to be possessed of great strength. Rarely was his head covered, but frequently it was adorned with a laurel wreath or a nimbus. At his feet was a mystical globe. Sometimes he was seen bearing a strobile of pine. The animals most frequently seen with Æsculapius were the cock, which Socrates mentioned in his last hours, the owl, the eagle, the hawk, the ram, or, what to him was most sacred, the serpent. Sometimes he was figured alone, but frequently one of his daughters, usually Hygeia, accompanied him. She is represented as clad in a long folded garment of white, holding in her left hand a serpent, while the right contained a shallow dish or patella, filled with consecrated food to which the snake is directing its attention. Between these two figures often stood another of dwarfish aspect and doubtful origin, the child Telephorus, or the Harpocrates of the Egyptians. His finger pressed to his lips was symbolic of the secrecy which appertains to the mysteries of the art.[11]

The practice of medicine in the temples of Æsculapius may be divided into two epochs. In the first, which extends to the time of Hippocrates, the Asclepiadæ, although for the most part employing superstitious means, rendered a service to science by the custom developed among them of observing the phenomena of disease. In those barbarous times medicine could make more progress in the hands of a secret order like the Asclepiadæ than if it had been a domestic and popular art. It was not to be expected that at this remote period, when all knowledge was in an infant state, a man of genius could be raised up, who would elevate medicine to the rank of a science. In the second epoch, which extends from the time of Hippocrates to the institution of Christianity, the influence of the priests gradually declined, and the practice of medicine in the temples was little better than a gross superstition.[12]

The remembrance of the benefits of Æsculapius was perpetuated by the institutions of feasts which were celebrated with much solemnity at Epidaurus, Ancyra, Pergamus, and Cos, and at which the greater part of the inhabitants of the cities of Asia Minor congregated at certain periods.

The course of instruction among the Asclepiadæ was in conformity to the national habits. Young men, about to commence the study of medicine, were not allowed to enter until after the completion of a preparatory course of three years, from the fourteenth to the seventeenth years, but the sons of physicians began earlier, and with both the medical training continued seven or eight years. The neophyte was conducted into his art with all the secrecy and exclusiveness that had prevailed, from the remotest antiquity, among the handicraft associations and religious orders, and which, at a later period, was to be found in the political clubs and schools of philosophy. Some of these societies were for charitable purposes, some for the promotion of commerce, some for the cultivation of knowledge, while others were for the purpose of controlling the affairs of state. In each of them, the ceremony of initiation, however distinctive it might appear to be, was modeled after that of the Eleusinian mysteries. Of these mysteries there were two grades, the greater and the lesser; and of each division there were several degrees. The celebration of the greater began at Eleusis on the fifteenth day of Böedromion, the third month of the Attic year, and lasted over nine days. The eighth day was called Epidauria, in honor of Æsculapius, who arrived on one occasion from his native city, Epidaurus, too late to attend the grand ceremonial of the sixth day. The Athenians, unwilling to disappoint so distinguished a benefactor of mankind, added a supernumerary day. In these sacred mysteries there were three stages of advancement, or degrees, which answered to the three scholastic degrees conferred by the universities in mediæval times. The candidate for medical honors, having passed a suitable preparation, was obliged to subscribe to an oath which was similar to that in use among the Pythagorians. At the completion of the term of study, the ceremony of coronation took place and corresponded to the modern graduation. It was an evidence of the recipient's fitness for assuming the duties of the profession, and conferred upon him the privileges of fellowship and the right

[12] Gauthier: Recherches Historiques sur l'Exercice de la Médicine dans les Temples. Paris, 1844.

of initiating others. The ceremony of placing a wreath, cap or crown upon the heads of those who were admitted into full fellowship in these ancient schools was continued down to the middle ages, and was the usual form of admission at Salernum, the earliest of the mediæval schools of medicine.[13]

In accordance with the custom of that age, Æsculapius transmitted his profession to his sons, Machaon and Podalirius, who were as skillful in the sciences and in eloquence as in the healing art. Machaon and Podalirius belong equally to history and mythology, and their biographies are a mixture of probable and fabulous narrations. Their existence cannot be doubted, for the Homeric songs and other ancient writings represent them as skillful physicians and valiant captains, who took an active part in the siege of Troy; but the statement of their genealogy does not admit of the same confidence. They are said to have been the sons of Æsculapius, while we know that there are grave doubts as to the existence of this celebrated individual, and besides, the words, "children of Æsculapius," are often used figuratively by ancient writers to designate members of the medical profession.

Machaon, who was regarded as the elder of the two brothers, must have been skillful in dressing wounds, if we may judge of the value which was placed upon his services by the Grecian army from its anxiety to have him properly cared for when he was wounded in the shoulder by a dart. "O, Nestor, pride of Greece (cries Idomeneus), mount, mount upon thy chariot and let Machaon mount with thee! Hasten with him to our ships, for a warrior who knows, as he does, how to relieve pain and cure wounds, is himself worth a thousand other heroes."[14] This renowned hero was killed by Eurypylus in single combat under the walls of Troy.

Podalirius survived his elder brother and assisted in the ruin of the kingdom of Priam, but on the voyage homeward he was shipwrecked and cast upon the coast of Caria, where he was rescued by a shepherd. Learning that he was a physician, the shepherd conducted him to the king, Damætus, whose daughter had fallen from the top of a house and was insensible. This skillful surgeon bled her and saved her life, this being the first recorded example of blood-letting.[15]

The sons of Æsculapius were both surgeons, as witness the lines of Homer:

> "Of two famed surgeons Podalirius stands
> This hour surrounded by the Trojan bands;
> And great Machaon, wounded in his tent,
> Now wants the succor which so oft he lent."
> —*Iliad*, lib. xi.

The other members of the family of Æsculapius are all fictitious beings whose symbolical names remind us of some attribute in medicine. Thus the name of Epion, his wife, means to quiet; those of Hygeia and Panacea, his daughters, express respectively health and a remedy for all diseases. Many of the gods and goddesses of Olympus fulfilled medical functions. Apollo, or Phœbus, the father of Æsculapius, assumed the privilege of preventing or causing epidemics, and Juno was said to preside at accouchments, at which times she was called Lucina, Ilithyia, or Natalis.

It is in the immortal poems of the Iliad and the Odyssey that we find the only certain traditions respecting the state of medical practice in Greece prior to the time of the Peloponnesian war. From these writings it appears that the profession of medicine and surgery constituted a kind of sacred occupation, the practice of it belonging only to privileged persons, and that in the armies, the highest princes gloried in dressing the wounds of those who had fought the battles of their country. From these poems we learn that the duties of those who devoted themselves to the divine art were mainly confined to the dressing of wounds, and that the imaginary power of enchantment was joined with the use of topical applications. The priests of India, the physicians of China and Japan, and the jugglers of the savage or half-civilized tribes of the old and new worlds, constantly associate, with drugs and manual operations certain mysterious rites and practices, upon which they especially rely for the cure of their patients. Such doubtless was the character of medical practice among the Greeks in the remote times.

The heroes engaged in the Trojan war evidently understood the means of arresting hæmorrhage. Homer, in describing the treatment of the wound of Eurypylus by Patroclus, says:

> "Patroclus cut the forky steel away;
> Then in his hands a bitter root he bruised;
> The wound he wash'd, the styptic juice infused.
> The closing flesh that instant ceased to glow,
> The wound to torture, and the blood to flow."
> *Iliad*, lib. xi.

Eurypylus, when asking the professional services of his friend, thus addresses him:

> "But thou, Patroclus, act a friendly part,
> Lead to my ships, and draw this deadly dart;
> With lukewarm water wash the gore away;
> With healing balms the raging smart allay;
> Such as sage Chiron, sire of pharmacy,
> Once taught Achilles, and Achilles thee."
> *Iliad*, lib. xi.

It is to be regretted that we have so little information regarding the political condition of the physicians of Greece. All that we know has been gathered from a few obscure passages in various writers. In a State so polished as Athens, the physicians would necessarily be subjected to certain laws. Plato seems to insinuate that at his time the physicians of Greece, as formerly those of Egypt, directed the treatment of diseases according to certain formulæ and precepts marked out for them, and that they were responsible to the state for all deaths caused by their negligence. A passage in Xenophon also proves that the young men, before establishing themselves on the territory of the republic of Athens, were obliged to ask permission, in a public discourse, in which they explained their previous education and practice.

Anatomy could not be studied by the Greeks be-

[13] Watson: The Medical Profession in Ancient Times. New York, 1856.
[14] Iliad, lib. xi.
[15] Sprengel: Erster Theil, p. 106.

cause they condemned, and regarded as a crime worthy of great punishment, all conduct towards the dead which was contrary to public prejudices. These prejudices had their origin in the belief that the soul, when freed from its earthly covering, was forced to wander on the banks of the Styx until the body was buried or cremated. Hence the celerity with which sepulture was performed on the dead to insure the rest of their souls, the duty imposed on all travelers of covering the dead bodies met with, the religious respect in which the burial spots were held, and the severe punishments inflicted on all who dared to profane them.[16] The extreme veneration in which the dead were held may well be illustrated by the following incident: In the twenty-sixth year of the Peloponnesian war (406 B. C.), Callicratidas, who succeeded Lysander as the admiral of the Lacedæmonian fleet, was defeated by the Athenians in a sea fight off the Arginusæ islands. At least a dozen Athenian vessels were left floating about in a disabled condition after the battle; but owing to a violent storm that ensued, no attempt was made to rescue the survivors, or to collect the bodies of the dead for burial. Eight of the ten generals were summoned home to answer for their conduct; six of them obeyed and were denounced by the Assembly, sentenced and compelled to drink the fatal hemlock. Socrates alone defended them, but his eloquence was in vain when pitted against the deep-rooted prejudices of the people.[17] Even during the Trojan war it was customary to declare a truce to allow the dead to be burned:

> "Next, O, ye chiefs! we ask a truce to burn
> Our slaughtered heroes, and their bones inurn;
> That done, once more the fate of war be tried,
> And whose the conquest, mighty Jove decide."

Scanty and imperfect as is our knowledge of the state of medicine in the age of Æsculapius, after his death and that of his sons, we have a long period extending over several centuries, during which we have still less information respecting the history and progress of the art. We have not a single improvement of any kind recorded as having taken place during this interval, nor have we the names of any individuals handed down to us who were of sufficient eminence to be distinguished above their contemporaries. We learn that the practice of medicine was entirely in the hands of the Asclepiadæ, and that the temples were gradually converted into schools of medicine, among the most celebrated of which were those at Cos, Cnidus and Rhodes.

The priests connected with the two rival establishments at Cos and Cnidus devoted their attention, from the outset, to different objects; those of the former asclepion assumed more of a philosophical caste, attempting to unite reasoning with experience, while the latter devoted themselves solely to the observation and collection of mere matters of fact. Hence it would appear that thus early in the history of our art a foundation was laid for the two great sects, the Dogmatists and Empirics, which long divided the medical world. The priests in the temple of Cnidus professed to depend on experience alone in the treatment of disease. They argued that if reason taught differently from experience, it was injurious, but if it taught the same it was unnecessary. Thus the very source of medical teaching was contaminated with the germs of sects and systems.

Several centuries elapsed during which the Asclepiadæ religiously adhered to the traditions of the Egyptian school, which allowed them to transmit their doctrines only to the members of their caste and to such strangers as fulfilled satisfactorily the initiatory tests. Under the control of the priesthood, medicine had remained stationary when, at last, it began to be cultivated by a class of persons much more likely to produce improvement, and from whom, in truth, it received its first impulse. Previous to the time of the philosophers, medicine had been exercised for the most part for the purpose either of direct emolument, or for the still more selfish purpose of maintaining the influence of the priests over the minds of the people. And, indeed, it was time that things were changed. The era of brute force, of hand to hand conflicts with monsters and brigands, had passed away, and the reign of intelligence, of strategy in war and politics, had become conspicuous. The mythological heroes whose labors were so much boasted such as a Perseus and a Bellerophon, were succeeded by those great men whose names have been justly celebrated in history, as Leonidas, Miltiades, and Themistocles. Long before the Asclepiadæ revealed their knowledge of medicine, and previous to the dispersion of the philosophers, the art of healing was extensively practiced in the gymnasia. Of the physicians connected with these establishments, there were three orders: the gymnasiarchs, who regulated the diet of the athletes; the gymnasts, to whom was intrusted the medical treatment of the sick; and the jalaptres, whose duties were mainly surgical.

The revolt of the Pythagorians at Crotona was an event of great importance in the history of medicine, for it was followed by the disruption of the sect and indirectly contributed to the advancement of our science. When the storm of persecution had driven the philosophers into different parts of Greece, many of the members being no longer under an obligation of secrecy, revealed the workings of the order, taught publicly the art of healing, and thus originated the general practice of medicine. About 440 B. C. Metrodorus, a former member of the Pythagoreans, exposed their secrets, and set himself up as a teacher of medicine. About the same time the practice originated among physicians of migrating from place to place and of making a public declaration of their skill. The same custom prevails to-day among us, who are supposed to far exceed the ancient Greeks in wisdom and judgment. The people of antiquity called these itinerant physicians periodevtæ, while the moderns name them charlatans.

When the disciples of Pythagoras had revealed the secret of their mysteries, and the philosophers had dared to teach and discuss publicly the principles of morals, physics and theology; when the itin-

[16] Sprengel: Geschichte der Arzneikunde, Erster Theil, p. 141, Halle, 1792.
[17] Wm. Smith: History of Greece, p. 366.

erant physicians and professors of the gymnasia had acquired the confidence of the public, the priests of Æsculapius could no longer keep silence, under the penalty of seeing the sceptre of medicine, which they had held till then, depart from their hands. They were forced to bring to the light of discussion the principles and rules of their medical practice. It was in this manner that our science came forth at last from the shadow of the sanctuary.

The priests who served in the temple of Cnidus were the first to follow the impulse of the age, and they issued a small repertory of medical facts called the "Cnidian Sentences." These are said to have been written by Euryphon,[18] a contemporary of Hippocrates. The Asclepiadæ of Cos were not slow to follow their example, and they published a series of treatises which, at a later date, were collected under the name of the "Hippocratic Works." This production, which overshadowed all other medical publications at that period, constitutes one of the most precious monuments of ancient medicine.

Thus it was that the spirit of medical inquiry outgrew the confines the temples which, long after medical instruction had ceased to be given in them, remained the strongholds of religion and still maintained their ancient mysterious ceremonies. The asclepion of Cnidus is known to have been in existence down to the time of Constantine, by whose command, in common with other relics of paganism, it was razed to the ground. The Asclepiadæ of Cos gradually lost their influence over the multitude; their sacred groves and fountains were forsaken; and, at length, during the lifetime of Mark Antony, the Roman prefect, Turullius, regardless of the divinity which had once ruled within the precincts of its hallowed shade, cut down the groves and of the timber made his ships. Such was the fate of those noted temples of medicine. Although long since destroyed, they have left an influence upon our art which will last as long as time itself. It was from this family of priest-physicians, the Asclepiadæ, that Hippocrates, the Father of Medicine, was descended.

THE THERAPEUTIC VALUE OF OXYGEN.

With Reports of Cases Treated.

BY SAMUEL S. WALLIAN, A.M., M.D.,

OF NEW YORK.

Regarding the availability and applicability of factitious oxygen as a therapeutic agent, there has prevailed, and still prevails, a very general professional misconception. This stereotyped estimate is based on the reports of early investigators, particularly those of Lavoisier, who asserted that his birds, dogs, rabbits and guinea-pigs, when immersed for a short time in an apartment or receiver filled with crude oxygen gas (derived from and doubtless tainted by the bungling decomposition of an oxide of mercury,) became excited and preternaturally lively, which condition was followed by more or less physiological depression. Considering the crude state of chemical science at the time, and the questionable processes employed, it is easy to understand that these results were not necessarily attributable to the newly discovered gas, the nature of which was being eagerly and none too honestly investigated. These hasty and superficial impressions seem to have been accepted without question and without satisfactory verification; and, what is more surprising, they have ever since remained as accepted dogmas in the world of physiological chemistry. In the century that has since elapsed chemistry and physiology have both been revolutionized; but with all the progress made in this direction few text-book authorities have thought it worth while to investigate from a fresh standpoint, or to disturb the fossiliferous strata of scientific thought handed down from the latter end of the eigteenth century.

The later French and German authorities have not added much to our knowledge of the agent, their experiments partaking more of the brilliantly curious than of the practical form. Some of them have shown, at least to their own satisfaction, that there is a saturation point of the blood beyond which it refuses to absorb any more oxygen; overlooking the imminent and practical fact that the average human being, living under ordinary civilized circumstances, seldom approximates the saturation point; and that ordinary mortals are in about as much danger of being translated as of damaging themselves by an excess of the vital element in question. To this dead-level of authorities there are a few notable exceptions. Phillips cautiously, but convincingly, combats the prevailing misconceptions, and our own Dalton refutes many of the absurd conclusions which had so long prevailed. It is now known that the decarbonization of the blood is not the principal office of the oxygen derived from atmospheric inspiration. The experiments of Magnus show that from ten to twenty-five per cent. of the oxygen inspired by a human adult is absorbed directly and in a free state, into the blood. The affinity of blood, arterial as well as venous, for oxygen is shown to be very great. Compared with that of water the ratio is as 2½ to 1. This is doubtless the key note to the action of oxygen, therapeutically exhibited.

Dalton has shown that the carbon dioxide constantly exhaled by all animal bodies is not all formed by contact of the circulating fluid with the oxygen of the air. *It already exists in venous blood before it reaches the lungs.* Hence, it is constantly being formed in the tissues themselves, as well as in arterial blood; since the same authority shows that both carbon dioxide and free oxygen exist in arterial blood. According to Magnus there is a nearly constant relation between them, the mean proportion being, by volume, as 10 to 25 in arterial, and as 10 to 40 in venous blood. If these premises be accepted, and no one has as yet disputed them, carbon dioxide is not, as generally taught, wholly the product of respiration. No doubt a small portion of that expired is formed at the moment of contact of atmospheric oxygen with the carbon-loaded blood as it reaches the air-cell, but more of it already exists in the circulating fluid. The venous system is thus seen to be a col-

[18] Schulz: Historia Medicinæ, p. 148.

lector of waste products—the complete sewerage of the vital economy. In the pulmonary circulation oxygen is freely and promptly absorbed, and carbon dioxide given off, while in the systemic circulation oxygen disappears and is constantly being utilized in the various processes of reconstruction.

It is evident that the ancient assumption respecting vital combustion is very imperfect as an explanation of the office of oxygen. In fact, modern physiologists have proved that the whole theory of heat production in the animal system, considered as a direct result of combustion, is lame and unsatisfactory. It is a well known law of physics as well as the result of common observation that slow oxidation is not the source of any considerable degree of heat, and vital caloric has another explanation than that of the combustion of carbonized material within the system.

What becomes of the 10 to 25 per cent. of oxygen so constantly absorbed by the blood? Is its office to supervise the general processes of metamorphosis, without which the animal cannot exist? Does it preside alike over digestion and assimilation, and does the absence of it render possible all the various forms of mal-assimilation, including those which result in glycosuria, lithæmia and the various diathesis—even the tubercular? Does it incidentally, here as elsewhere in nature, intercept toxic tendencies, destroy septic and putrefactive germs, prevent degenerative changes and retard or render inert the slowly forming elements of malignant growth? Is it used in the end as an essential *materia elimentaria?* These are questions which have been asked, which are, in fact, constantly being insinuated by science, but have been as yet only empirically rather than satisfactorily or scientifically answered.

A large class of physicians at the present time flippantly dispose of the question of the therapeutic value of oxygen by citing the current saw about the saturation of the blood. They repeat that scientific stupidity which assumes that the free oxygen in the blood cannot be increased beyond the limited quantity which it constantly and readily receives from the ordinary atmosphere; and hence. that any attempt in this direction is not only uncalled for but practically futile. Granting that this assumption is true, the objection practically falls flat. If the human race could be turned adrift, in a body, and should lapse into the primitive life of nomads, it might be feasible for each individual to realize his due quota of the vitalizing element. Unfortunately civilization implies a sort of human hibernation, and the average modern individual is compelled to eke out his disease-pestered days on one-half this allowance, or even less. The result is inevitable. Functions are imperfectly and incompletely performed; changes and metamorphic processes, though initiated, necessarily flag and result in half formed tissue, or in products inimical to the healthy organism. Toxic, carbonaceous elements accumulate, degenerative processes are set up, and chronic disease is the inevitable result, if even malignant demonstrations do not end the disastrous history.

These are homely facts, and they have no glamour of superficial laboratory erudition or bacillus-staining to give them mock dignity. Nevertheless, they appeal to the hard common sense of every practitioner of medicine who realizes how helpless he is to relieve the many and multiplying forms of disease, constantly being analyzed by the aid of the scalpel and the microscope, with a minuteness of detail which is fairly bewildering, and which are the direct or remote results of this universal oxygen famine.

Inspired oxygen passes in a free state into the arterial blood and is distributed throughout the entire system, thus coming into intimate contact with every remotest tissue and cell. Keeping in view this fully admitted fact, how can its ultimate influence on the vital economy be estimated? It would be a waste of time to prove that the blood can and does, under certain circumstances, absorb an unwonted increment of oxygen, since as already asserted, a large majority of the race live under conditions which positively prohibit the utilization of anything like a normal supply. That medical mountebanks have made capital out of the word oxygen is no concern of ours. They did the same for electricity, for hydrotherapy, movement cure, and massage; which, once extolled as panaceas, are now universally recognized as valuable and sometimes indispensable allies. But in spite of drawbacks in the shape of prejudice, time, care in manipulation, and expense, the medical use of oxygen and its principal ally *nitrogen monoxide*, is steadily on the increase. A large number of reputable practitioners in this country are quietly experimenting with these agents, and carefully noting results. Abroad there is even more interest shown. The subject is yet without a literature, but materials and data for this was steadily accumulating. Lately, Dr. Powell, of this city, read a suggestive paper before the New York Academy of Medicine on the use of ozone in phthisis. The February number of the *South-Western Medical Gazette* has a short paper on the subject, by Professor F. C. Wilson. The *London Lancet*, of recent date, contains a short, but pertinent paper on the remedial value of oxygen. Thus, a slow but steady progress in this direction is being made.

It is evident to the most casual observer that the medical science of the future must be largely based on a study of natural therapeutics. The artificial, and far fetched are daily losing caste. The profession long since lost faith in dispensatory routine, and the lay public is gradually becoming infected with the same skepticism. The heyday of pharmacomania has passed and the inevitable reaction has already set in. The routinists no longer take front rank. They must henceforth become the rear-guard and camp followers of the army of progress. Without realizing it the profession is quite generally commending oxygen. Every patient sent on a sea-voyage or to the mountains, is a walking certificate as to its efficacy. Every argument in favor of open air life, roughing it on the plains, a sojourn in Southern California, Italy—in short all travel, is a plea for oxygen. Many of the newer antiseptics and parasiticides have been found to depend on free oxygen liberated during decomposition within the system, or

in contact with the tissues The terebene group may be cited as an example. Theories, however, are not so important as clinical facts. A few brief sketches of further cases treated are appended:

Case 21.—Mrs. S., age 32, suffering from chronic gastric catarrh of unusually severe type. After six weeks daily use of oxygen (modified and diluted,) together with hot water drinking—very little attention being paid to her diet—she fully recovered, and became more robust than for many years.

Case 22.—Mrs. C. R., age 63. Suffered some years since with spinal meningitis and has never fully recovered. Convalescence was followed by epileptoid convulsions and hysterical phenomena of various kinds. At present is subject to paroxysms of dyspnœa, simulating œdema of the lungs. Each paroxysm it is thought will prove fatal. Modified oxygen was carried to the bedside in rubber bags, twice daily, and during the intervals the patient was kept supplied with a solution of hydrogen dioxide which was vaporized and inhaled.

This treatment was continued for three weeks, with the gratifying result of clearing up the lungs, removing the dyspnœa, and greatly aiding the digestion, which had become seriously disordered. Nor was there any relapse on leaving off the remedy. This patient died six months later from degeneration of the cord, (at least so reported by the attending physician) the dyspnœa not having returned.

Case 23.—P. E., age 22. Subject to periodic headache of so severe a type as to have injured his memory and caused ocular troubles. The paroxysms are generally a true migraine and of fairly explosive violence. They recur from once to three times per week quite regularly. Placed this patient on a mixture of O, N_2O and common air, viz.:

℞. O, two volumes.
N_2O one volume.
Common air three volumes. M.

Of which two to four gallons were inhaled night and morning.

Two weeks treatment greatly relieved the paroxysms, and in four weeks patient assures me he is no longer troubled. The head is cool, the eyes clear, and the paroxysms do not now recur.

Case 24.—Miss W. M., age 24, teacher. Has severe and constant cough, with "soreness" of the lungs, loss of appetite and general malaise. Is very much frightened lest it be already incurably seated "consumption." The family history is not favorable.

October 20.—Not being able to come to the office for treatment, is placed upon the daily use of the portable variety. Continuing the inhalations carefully night and morning for four weeks, she reports that her cough is gone and appetite excellent. The soreness no longer troubles her, and she has given up "dying of consumption" for the present.

Case 25.—Mrs W. A., age 62. Has been for years subject to constant neuralgia—trifacial—of the most aggravated form, accompanied by severe chronic dyspepsia. Stomach tolerates very little food of any kind, and her sufferings are agonized in the extreme. It is hardly thought that treatment will do much for her, especially since her circumstances do not permit the most efficient form of office treatment. Contrary to expectation, the thorough use of the portable form of oxygen four times a day is followed by marked and immediate relief of the paroxysms. The digestive system also promptly responds, and within a week or ten days she is enabled to partake of nourishing diet, and to digest it. In connection with the inhalations this patient is directed to take internally, of the 15 volume solution of hydrogen dioxide, a teaspoonful, well diluted, before each meal.

This treatment is still being followed and improvement is steady in all directions.

491 West Twenty-Second Street.

A REMARKABLE RESULT FROM AN OPERATION FOR STRANGULATED HERNIA.

Read before the Wayne County (Indiana) Medical Society.

BY S. S. BOYD, M.D.,

OF DUBLIN, IND.

On May 17, 1886, I was called to see John Leeson, aged 52 years, who was suffering from direct strangulated inguinal hernia of the right side. The tumor below the ring was about five inches long and two inches thick. The symptoms which ordinarily accompany strangulated hernia, such as intense pain, sickness and vomiting, being absent, and as I had, two months before, reduced a similar strangulation in the same patient, of four days' standing, by taxis after anæsthetizing with ether, I thought it safe in this case to make an effort at reduction by the same means. Being assisted by Dr. H. B. Boyd, we had the patient placed on a broad board, which was inclined at an angle of about thirty degrees from the horizontal, with his head downwards, his head and shoulders being supported by pillows, I resorted to the usual manipulations. After pursuing this course three and a half hours we abandoned the effort in that direction.

Dr. C. N. Blount was then called in consultation, when we concluded, as the symptoms were still not urgent, to try the topical application of ice. During the next eight hours blocks of ice of about a lb. weight were continuously applied over the tumor, and warm water enemata frequently injected into the bowels during the same period. That night a slight nausea was developed, though there was little pain or other unfavorable symptoms. The pulse, which had not been over 80 per minute, was not increased, and the temperature did not rise above 100°.

On the morning of May 20, the fifth day after the strangulation occurred, believing that without the use of the knife the obstruction would not be removed, we determined on an operation. When the sac was opened it was found to contain omentum only. The distal end of the contained omentum was dark, but not gangrenous. But, in accordance with later teaching on that subject, and from the fact, as we believed, that omentum which has been strangulated over four days will not likely have its circulation restored if returned to the abdomen, we decided to ligate and excise it. We therefore ligated the protruding omentum

in four parts, as near the point of stricture as possible, then incised the omentum as near the ligatures as practicable, and after enlarging the stricture, we returned the stump into the abdomen. After placing three deep sutures in the wound, the usual dressing completed the operation. The removed omentum weighed nine ounces. It was about four inches long and one and one-half inches thick, and nearly round, being a little larger at the proximal end.

On the 21st the patient was resting well; pulse 100, temperature 100°. On the 22d the pulse was 110, temperature 100. Pulse and temperature declined from last date until the 27th, when warm water enemata were freely used. On the 28th, after having removed, mechanically, a large amount of impacted fæces from the rectum, the bowels were freely evacuated. On the 29th the temperature rose to 102°; pulse to 100, but both fell back to nearly normal during the next three days.

Up to this time the patient had been nourished entirely on milk diet. After this a little bread was added to his three meals per day.

On June 6, seventeen days after the operation, the patient passed per anum one of the ligatures used in ligating the protruding omentum above mentioned, and at the same time there was found in the stool of the patient a piece of what was supposed to be a part of the omentum devoid of its fatty substance. The pulse and the temperature again rose to 100, but fell back to normal the next day. Three days later another one of the four ligatures used in the operation was found in one of the patient's stools.

At no time during the treatment of the case did the patient suffer much pain; and there was but little swelling of abdomen. Opium was freely used from the time of the operation until the patient was considered out of danger. It is now nearly nine months since the operation, and the patient is well and pursuing his occupation as a farmer.

UNUSUAL CARDIAC ANOMALY.

BY A. M. HAYDEN, M.D.,

OF EVANSVILLE, IND.

I wish briefly to record a case of cardiac anomaly which is altogether different from any case that I have ever seen, and so far as I can find there is no similar case on record. The case is as follows:

I was called to see the child when one week old. I found it fairly well developed, weighing eight or nine pounds, with more or less incomplete, though marked, cyanosis. Breathing was labored, and there was a slight cough. I made a diagnosis of non-closure of the foramen ovale, and gave an unfavorable prognosis.

I was superseded by a physician of considerable reputation, who pronounced my diagnosis incorrect.

Thirteen months later I was again called to see the child. I found that it had grown but very little, and was much emaciated, not weighing more than ten or twelve pounds. It was suffering with a well-marked case of chronic bronchitis, mucous râles being distinctly heard on both lungs. I now concluded that I was mistaken in my former diagnosis, as the child was not cyanosed, the skin having regained its normal color. I treated the case for bronchitis.

Heard nothing more from case until a few days ago, when I was called on to make a post mortem examination, the child having died from the effect of disease at the end of the sixteenth month.

Autopsy revealed chronic bronchitis, with hepatization of lower lobes of both lungs. Heart enlarged. Hypertrophy of walls of ventricles. Foramen ovale pervious. Right auriculo-ventricular foramen normal. Left auriculo-ventricular foramen normal. Foramen one half inch in diameter connecting right and left ventricles. Auricles slightly dilated. *The pulmonary artery took its origin from both right and left ventricles*, the cavity of the artery dividing in the wall of the heart into two equal parts, one terminating in each ventricle. The aorta took its origin from left ventricle, and seemed to be normal. The pulmonary veins emptied into left auricle.

I report the above case with the hope of eliciting comment, both as to the probable cause of the condition, and as to the manner in which the circulation was carried on so as to sustain the life of the child for sixteen months. I would also like to hear of any similar cases, if there be any on record.

Evansville, Ind., December 17, 1886.

MEDICAL PROGRESS.

Treatment of Hernia by Subcutaneous Injection.—At the meeting of the New York County Medical Society on December 27, Dr. W. B. De Garmo gave a brief history of the treatment of hernia by methods purporting to be subcutaneous, the object of all of which had been, up to the time of the publications of Heaton's method, to cause obliteration of the hernial sac. Heaton had been practicing his method, and obtaining many cures, since 1843, but he refused to make it known until 1877. Heaton made no attempt to destroy the hernial sac; the whole object of his operation was to so fortify the fibrous tissue surrounding the canal that protrusion would not occur. His method stood alone; it differed in every way from previous methods of subcutaneous treatment; the fluid injected was astringent and mildly irritant, and its action was brought to bear upon the muscular and tendinous structures of which the inguinal canal was composed, and upon the connective tissue which bound these layers together. That improvement and practically cures would result from injections of this oak-bark solution the reader had had abundant evidence, and he could also state that it was practically without danger, at least when correctly employed. Several years ago he stood almost alone in indorsing the method, but since then it had been adopted by many others. That frequent failures had occurred was beyond question. To throw light upon the cause of some of the failures was a principal object of the paper.

In the first place, too much had been expected of the operation, and this was in great part due to the manner in which Heaton placed it before the profession. It was quite natural that he, after so large an experience, should have met with greater success than the general operator. Then the method had been put to unfair tests. For instance, he had known patients to be allowed to go about immediately after rising from the bed, seven or ten days after the operation, without any support. They had even been instructed to cough or strain in order to test whether or not the hernia would recur. A second error was the anticipation of a cure in old herniæ by a single injection. In these herniæ the sac was largely dilated and the canal shortened, and there was a funnel-shaped opening at the internal ring —conditions most favorable for the protrusion of the hernia—and it was very necessary to continue wearing a support. It was cases of oblique inguinal hernia of recent date, in which but few pathological changes had taken place, that were most readily cured by this method. That many errors had been committed in the performance of the operation he had abundant evidence. One error in operating consisted in puncturing the scrotal tissue invaginated by the finger, instead of inserting the needle directly into the canal. In order to enter the canal without injuring the cord he deflected this for convenience to the outer side, instead of to the inner, as advised by Heaton. Immediately and for some moments after withdrawing the needle he made firm pressure over the point of entrance to prevent the return of the fluid in the track of the needle. Some English surgeons laid the sac open and smeared it with the fluid, but there was nothing to be gained by this method, while it added danger. The reader had never observed abscess develop from subcutaneous injection. He employed a particular syringe to make the injections. The subsequent management of the case was as important as the manner in which the operation was done. The strengthening of the walls of the canal was a slow process, and not to wear a support, at least for some time after the operation, was only to invite a return of the hernia. On the other hand, too firm pressure was to be avoided as tending to weaken the tissues which it was desired to strengthen. The patient should be confined a week or ten days, and longer in extreme cases. He had usually employed during this time the bandage devised by Heaton. Last March he had called attention to a modification of Heaton's method which he believed to be important. It consisted in making repeated injections of a small quantity of the fluid when the patient had to continue at his business, and causing him to wear a truss in the meantime. His conclusions from seven years' experience with Heaton's method, during which time he had employed it in over a hundred cases, were: 1. That it was free from danger. 2. That over 45 per cent. of all cases could be cured by it, and in select cases 50 to 75 per cent. 3. That many extreme cases uncontrollable by means of a truss could be brought under control by the operation. 4. That it was followed by improvement in almost every instance. 5. That children not cured by mechanical means could in almost every instance be cured by Heaton's operation.

Dr. R. F. Weir said that the last time he looked over his records he had performed Heaton's operation seventy or eighty times, and the proportion of cures was between one third and one-half—nearer one-third than one-half. At first he had made some of the errors in operating mentioned by Dr. De Garmo; in one instance he had inserted the needle so far as to inject some of the fluid into the abdominal cavity and set up inflammation. The patient died some months later from another cause, and at the autopsy there was evidence of his having injected the fluid into the omentum. He employed Heaton's bandage sometimes, but he preferred superimposed strips of adhesive plaster. Where the hernia was large, he thought the open method was the better. In general, his experience confirmed the views of the author.—*New York Medical Journal*, Feb. 19, 1887.

Artificial Abortion by Evidement.—In the *St. Petersburg Med. Wochenschrift*, No. 45, 1886, Weidemann, of St. Petersburg, calls attention to a plan for rapidly emptying the pregnant womb, that in the two cases in which he has used it has proved eminently safe, prompt and in every way satisfactory. A case of incessant vomiting of pregnancy, in which he had had great trouble in inducing abortion once before, caused him to study anew the various means for producing abortion and to try to find a safer and prompter method than the ones usually employed. The case was as follows: A woman, æt. 26, applied to his clinic in December, 1885, for relief from incessant vomiting. She had given birth to five children, without any complications except some moderate vomiting during her pregnancies. One year before, being again pregnant, vomiting became incessant and refused to yield to treatment. At that time Wiedemann had induced abortion. He had dilated the cervical canal with sponge tents, introduced the sound, perforated the membranes, and made hot vaginal douches every four hours. Although these procedures had been repeated daily for six days, they merely brought on pains lasting for several hours. On the sixth day he had chloroformed the patient and had scooped out the contents of the womb with the Simons' curette, though not completely, for after twelve hours hæmorrhage with pains set in and some shreds of placenta came away. Although he had been careful to work antiseptically, an endo-parametritis gave rise to fever for a week. She is now again two months gone in pregnancy, and the vomiting again refuses to yield to treatment, even the much-lauded cocaine fails of action. She is rapidly sinking, her pulse is 120–150, and the temperature is subnormal. The patient's condition being so low, his previous experience having shown that her womb reacts so badly, and the chance for infection being so great, made him adopt a method by which he could empty the uterus of its contents more promptly.

Thinking that the condition of the womb during the early months of pregnancy must be similar to that of placental polipi, which we are in the habit of

treating by forcible dilatation and curettement, he concluded to empty the womb in this manner. Accordingly, on December 23, 1885, the patient was chloroformed, the parts disinfected with corrosive sublimate solution, and the womb drawn down with vulcellum forceps. The cervical canal being dilated to admit the index finger by means of Fritsch's dilators, the fœtus and its adnexa were removed with Martin's spoon, and under continued irrigation with thymol solution all parts of the placenta and the decidua were completely taken away. Hæmorrhage was very slight and ceased with the completion of the operation. Time from beginning of the dilatation to complete removal of the ovum and its membranes, twenty minutes. It was not possible at this stage of pregnancy to remove the ovum in toto, for on account of the length of the cervical canal his finger could not be carried up to the fundus uteri. The lying-in was normal in all respects. No fever, the pulse rapidly became lower, the vomiting stopped at once, subinvolution progressed normally, the lochia were serous by the second day and ceased by the ninth day, when the patient was dismissed with much improved strength. As a matter of interest, he would add that four months afterwards he was asked by the woman to again perform abortion on her, but refused her, as he could find no indications for the operation.

On May 6, 1886, abortion was performed at his clinic by the same method on a married woman, æt. 23, pregnant twelve to fourteen weeks, who had a contracted pelvis with a conjugata of 6.0 cm., and who refused to have abdominal section performed at term. The operation was as successful as the first, duration twenty minutes, very slight hæmorrhage, lying-in normal.

Wiedemann thinks that the method recommended by him, forced dilatation in narcosis and èvidement of the ovum, has not heretofore been used for the purpose of interrupting pregnancy, and hopes by this report to induce his colleagues to give it a trial, for he believes that this operation, so frequently employed for other purposes, should be especially adapted to produce artificial abortion, as it is simple, rapid and safe, and enables us to avoid many of the dangers of abortion.

Infant Feeding.—Soxhlet starts from the premises that milk in the glands is free from germs, as shown by Eister and Escherich, and that the germs that give rise to fermentation enter the milk after it has been taken from the glands. He finds the reason for the fact that infants thrive on mother's milk, and are so apt to suffer from digestive troubles and to lose ground when fed on cow's milk, not in the slight difference in the chemical constituents of the two milks, but in the manner in which they get to the child, the former direct from the breast, the latter only after it has had all opportunities to become contaminated with impurities and fermentative producing causes. To avoid this danger when it becomes necessary to feed an infant on cow's milk, he advises that it should be *sterilized* as soon after milking as possible. To accomplish this the milk should be put into bottles, closed with rubber stopper through which a hole is pierced, the bottles placed in a vessel with water, and heat applied. As soon as the milk in the bottles has expanded to its highest degree, a well fitting glass plug is inserted into the hole in the cork, and the water is then made to boil for thirty-five to forty minutes. This may be repeated two or three days, and *such milk may be kept in a cool place for three or four weeks without turning acid.* Before using the milk the bottle is placed in a vessel with water and heated to 97½–98½° F., the stopper is removed and a clean nursing apparatus is attached to the bottle. Milk left over and milk in open bottles must not be fed. The bottles and nursing apparatus must always be kept scrupulously clean. Soxhlet affirms that he has evidence to prove that milk preserved in this manner does not exert the least injurious influence on the infant's digestive tract, and that thus one of the main obstacles to infant feeding is obviated.—*Memorabilien*, Hft. 4, 1886.

Inoculation of Tuberculosis in a Child.—The custom of the Jews of sucking the wound after circumcision, the sucking being done by the operator, by a relative, or by an acquaintance, has frequently given rise to syphilitic infection of the child, and many such cases are on record. On the inoculation of tuberculosis in this manner we have only the communication of Lindmann (*Deutsche Med. Wochenschr.*, 1883, No. 30, ten cases), and that of E. Lesmann (*Deutsche Med. Wochenschr.*, 1886, No. 9, et. seq., ten cases, all infected by one person). Elsenberg reports in *Gaseta Sekarska*, No. 18, another case, which is interesting because only the discovery of tubercle bacilli by the microscope enabled the observer to differentiate the affection from syphilitic infection, the surface of the ulcer being gray, the lymphatic glands greatly swelled and suppurating. The operator who had infected the child, to outward appearance seemed healthy, though he coughed a little. Tubercle bacilli were found by Elsenberg, in the operation, and also by Prof. Hoyer. Laryngoscopic examination revealed some true tubercles on a somewhat infiltrated base in the interarytenoid space.—*St. Petersburg Med. Wochenschr.*, 1887, No. 1.

Torsion of an Incisor Tooth.—Mr. Smale mentions in the *British Journal of Dental Science* the case of a boy, aged 8, who had the right upper central incisor twisted so that the mesial surface presented towards the lip. The tooth was grasped firmly by a pair of straight-bladed forceps and twisted into a good position, care being taken to press the tooth firmly into the socket during the operation. It was tied to the surrounding teeth with silk twist in order that it might not return to its old position. A week afterwards it was quite firm, the tooth could be tapped, and he could distinguish between hot and cold applications. There was no discoloration, and the gum was quite healthy. Torsion may be used freely before the patient arrives at the age of 12 years, and should be always done at one operation. It is only applicable to the incision.—*Lancet*, Jan. 20, 1887.

THE PATHOLOGY AND TREATMENT OF EPILEPSY.

At a recent meeting of the New York Academy of Medicine Professor Wm. H. Thomson, of the University Medical School, read a paper on the "Pathology and Treatment of Epilepsy," based on notes of sixty consecutive cases in practice, in which he advanced some rather unusual views, among which was the opinion that all convulsive seizures of an epileptiform character, whether due to a temporary peripheral irritation or not, as convulsions from dentition, for example, really belong to true epilepsy.

Dr. Thomson regards *suddenness* as the invariable and essential element in epilepsy; it is the single truly sudden disease, the only affections resembling it in this particular being laryngismus stridulus and spasmodic asthma, though in these the suddenness is found not to be absolute as in epilepsy. Apoplexy, hemiplegia, sunstroke, etc., being accidents, cannot be strictly compared with epilepsy: nor are hysterical and neuralgic attacks so sudden as those of epilepsy. Furthermore, Dr. Thomson regards *petit mal* as the most real form of the disease. In regard to the cell discharge or explosion theory, the views of Hughlings-Jackson, and Nothnagel's "convulsive centre," he thinks that if no other form of epilepsy than *petit mal* had ever been observed the explosion theory would never have been proposed. With Jackson and Gowers he is willing to grant that there is a motor discharge in every convulsive seizure; but that it is a different matter to say that an attack of epilepsy is a motor discharge. He believes all motor phenomena except the voluntary to be under the control of sensory impulse, and a sudden suspension of the regulating sensory impression may result from a variety of causes. Any irregular motor phenomena are therefore due to a loss of the customary sensory influence; and this, he thinks, explains the clinical facts of epilepsy without the necessity of supposing any additional nervous force being called into action.

He considers the phenomena of epilepsy to be the effect of an afferent sensory impression when some abnormal condition of the nerve centres is present. What this condition may be he is not prepared to say, but it seems most probable to him that it is one of malnutrition. If asked if he would assert that all cases of epilepsy are attended with sensory impressions in the face of the well-known fact that in certain instances there are definite lesions of the brain present, he would reply that we do not get rid of the sensory element when we enter the cranial cavity. A syphilitic gumma of the brain may be as truly an excitant of sensory irritability as an external impression. He does not hesitate to acknowledge that a motor centre may be excited by the application of an electric current after trephining the skull; but the explanation of the phenomena noted he believes to be found in the fact of a wholly unaccustomed irritation in a centre habituated to act in response to sensory impressions. The hypothesis of a sudden suspension of the ordinary suspensory functions, he thinks, fully accounts for all the phenomena observed in epilepsy.

As regards his treatment of epilepsy Dr. Thomson says that of late years, since he has based his therapeutic measures on the hypothesis that the lesion of epilepsy is to be found in the sensory, rather than the motor, centres, he has grown much less skeptical of the advantages of treatment in this disease than formerly. The first thing to be aimed at is the improvement of nerve-nutrition; and by far the best agent for this purpose is cod-liver oil, which he prescribes as regularly in epilepsy as in phthisis. Phosphorus is also a useful remedy in this connection. Like the great mass of physicians, he has found the bromides the best agents for controlling peripheric irritation, and he has found cod-liver oil of very good service in counteracting their debilitating effects. When there is persistent cortical irritation, as indicated by muscular twitchings during sleep, he employs, with happy results, the bichloride of mercury, or the oleate by inunction. He uses belladonna or oxide of zinc in all cases in which the attacks show any connection with disturbances in the alimentary canal, and when there is reflex irritability he uses chloral hydrate or Hoffman's anodyne, in addition to the bromides. Digitalis he uses in all cases characterized by vas-

cular disturbance, or where there is involuntary discharge of urine during the attack. He is also in the habit of using, in a certain proportion of cases, a red pepper pack at night; 1 drachm of capsicum being used to the pint of hot water for this purpose. In one case a patient who ordinarily had two epileptic attacks a day did not have a single one for seven weeks after this measure was resorted to; the disease being completely arrested by the peripheral excitation thus secured. In his opinion, an important part of the treatment is the total exclusion of all butcher-meat for a period of two years; though poultry and fish are permissible. Animal diet, he believes, predisposes to convulsions in direct proportion to the quantity in which it is used. The tendency to convulsions in the carnivoræ, and the absence of this in herbivorous animals, are apparently due to the respective diet in each class. Another thing to be avoided is eating fast, as the too rapid mastication and swallowing of food seems to act directly on the convulsive centre of the medulla oblongata. It is possible that the habit of eating too fast may thus induce confirmed epilepsy. These points show, he thinks, the direction in which efforts should be made by which better results may be expected in the future, and the treatment thus be relieved of the grievous burden of suspicion which it has borne so long.

It could scarcely be supposed that such views as to the pathology of epilepsy could be expressed before the Academy without discussion. It may be questioned, as Dr. Putzel remarked, whether anything can be considered epilepsy unless the convulsive habit is established. But we cannot so certainly draw a line of demarkation between infantile convulsions and true epilepsy, as Dr. Putzel seems to think, as clinical experience shows that the tendency to convulsions in children is closely associated with the epileptic diathesis, and that accidental convulsions are often the beginning of lifelong epilepsy; and we also know that many cases of epilepsy give a history of convulsions in childhood. But a consideration of the pathology of epilepsy, and epileptiform convulsions, would carry us beyond the limits of this article.

With one exception it seems that Dr. Thomson's views as to the treatment of epilepsy were generally endorsed. Dr. Wm. H. Draper, however, did not agree as to the danger of animal food; on the contrary, he is inclined to think that the origination of an attack is more likely to follow the ingestion of starchy foods, and he prefers that his patients should use animal food and milk, and a diminished quantity of the carbo-hydrates; and from this he has had very good results.

At the same meeting of the Academy Dr. A. D. Rockwell read a paper on *The Value of Electricity in the Treatment of Epilepsy*, in which, among others, he drew the following conclusions:

Electricity possesses a certain value in the treatment of epilepsy.

It is not claimed that it can alone cure the disease, but in many instances it is of great service as an adjuvant to the bromides.

In the nocturnal variety its good effects are especially marked.

The methods of application to be used are central galvanization and general faradization.

It is important that the agent should be administered with great care. Anything like a shock should be avoided, and the applications should not be continued too long at a time.

The treatment should be kept up, with suitable intermissions, for two years after all epileptic symptoms have disappeared.

MEDICAL LAWS.

In another department of this number of The Journal may be found a copy of the new law adopted by the Legislature for regulating medical education and practice in the State of Minnesota. As a whole the law is much better adapted for the accomplishment of its legitimate purposes than most of the State laws hitherto enacted. Section 3 of the Act, by enumerating the *branches* required to constitute a minimum standard of medical education; by requiring the candidate to furnish proof of having attended three annual courses of Lectures of not less than six months each, and to undergo a full examination, both scientific and practical, by the State Board of Examiners, without any regard to college diplomas, is in strict conformity with correct principles of Legislation as briefly stated in The Journal for March 12, 1887. The *Section* would have been more complete and efficient if the term of study had been specifically stated as not less than three years, and if to the branches of study required, had been added, attendance on Hospital Clinical Instruction during the second and third courses of Lectures. Section 1, which requires the Governor of the State to appoint a State Board of Medical Examiners consisting of nine members, and defines their tenure of office, is very defective in some respects, and in direct violation of sound principles of Legislation in

others. For instance, the *Section* makes no allusion to any standard of qualifications, professional, moral, or social, necessary to render a person eligible for appointment by the Governor as a member of the Examining Board. So far as the language of the law is concerned, he may select at least *seven* out of its nine members from the ranks of mechanics, merchants, lawyers, or saloon-keepers, or he may select physicians who have not been out of college six months or practised in the State six days. And yet, as if to show the climax of inconsistency the law specifically declares that "no member of any college or university having a medical department shall be appointed to serve as member of said board," but at least *two* of the board *must be* "homœpathic physicians," whether two such can be found in the State or not. Doubtless the Legislature of Minnesota intended that the Board of Medical Examiners should be composed of members of the medical profession, and quite probable that the Governor will make his appointments in accordance with that intention. But it would have been very much safer, more in accordance with correct principles of Legislation, and more consistent with the equality of citizenship, if the law had clearly required the Governor to appoint a State Board of Medical Examiners consisting of nine members of the medical profession, of good general and medical education, of good reputation, and not less than five years resident practitioners in the State, and avoided all invidious distinctions not founded on personal qualifications.

THE TREATMENT OF WOUNDS OF THE LIVER.

Traumatic lesions of the liver have but a small place in surgical literature. When deep, especially, they are usually considered necessarily fatal on account of the resulting hæmorrhage, and on account of the peritonitis which will most probably result from the hæmorrhage. There is a reported case in which in a deep stab wound of the liver followed by hæmorrhage sufficient to distend the abdominal cavity, laparotomy was performed, the peritoneal cavity cleansed, and sutures placed in the liver wound. The patient rallied from a state of profound shock and collapse, and remained in an apparently good condition for about twelve hours, and then died suddenly. The peritoneal cavity was clean, the liver wound was closed, and there were no signs of peritonitis. According to Elder the mortality of wounds of the parenchyma of the liver is 78 per cent. for incomplete ruptured wounds, 39.7 per cent. for shot wounds, and 37.5 per cent. for cut and stab wounds; but Meyer regards this estimate as too low.

From a paper by Burckhardt, in the *Centralblatt für klinische Chirurgie*, No. 7, 1887, it seems that modern antiseptic principles applied to wounds of the liver will considerably diminish the high mortality. The case is of sufficient interest to give rather fully: In March, 1886, a workman was stabbed in the left epigastric region, a little below the border of the ribs, and after receiving temporary medical attention he was taken to the Stuttgart Hospital. On admission he had not lost consciousness, but there were all the symptoms of considerable internal hæmorrhage. In the left mamillary line, on a level with a free border of the ribs, was a wound about two and a half centimetres long, in which two sutures had been placed. The belly was distended; and there was dulness in the lower abdominal region, but above and to the fifth rib on each side percussion was tympanitic. The patient was chloroformed, the wound reopened and enlarged to 12 or 14 ctm., and search was made for the origin of the hæmorrhage. When the peritoneal wound was opened a large quantity of black blood escaped. Several loops of intestine were replaced and carefully sponged. The situation of the wound was such as to give the idea that hæmorrhage proceeded from a large mesenteric or gastric branch, and the liver was not thought of, as no portion of this viscus was perceived. The knife had entered transversely, however, and on drawing the liver towards the wound Burckhardt found a wound in the left lobe of the liver 3 ctm. long, from which a considerable quantity of blood was flowing. The probe showed that the parenchyma of the organ was penetrated, below and to the right, to the depth of 5 or 6 ctm. The state of the patient was now such that it was necessary to terminate the operation as soon as possible. He introduced and pressed into the wound of the liver six or eight pieces of iodoform gauze, letting the ends hang out. The abdominal cavity was then cleansed, the intestinal loops again cleansed and replaced, and the external wound sutured in its whole extent, leaving, however, a place above for the introduction of a drain and for the removal of the pieces of iodoform gauze. A complete antiseptic dressing was then applied. The patient rallied well, and gained, in spite of a pneumonic complication, probably the result of an embolic detachment from the liver. When the first dressing was taken off there was a small escape of blood, the remains of the peritoneal extravasation, which was soon followed by a small quantity of bile. On the sixth day the gauze was removed and replaced by a new drain. On the twelfth day bile ceased to escape, and after nine weeks there was only a small

fistulous tract, caused by a piece of gauze which had been forgotten; when this was removed recovery was soon complete.

Burckhardt calls attention to the value of tampons of iodoform gauze as an excellent means for arresting hæmorrhage, and, in such cases, of preventing the escape of bile into the peritoneal cavity. In spite of the friable nature of the liver sutures are perfectly practicable, as experiments on animals have shown; but they are seriously inconvenient. An incised wound of the hepatic parenchyma must involve some of the bile-ducts, and it is unlikely that these could be sutured with convenience or success; and to simply suture the liver tissue about them would result in escape of bile into the peritoneal cavity. But a piece of iodoform gauze placed in the wound will arrest both hæmorrhage and escape of bile.

American Medical Association.—We invite the attention of our readers to the official notice of the next meeting of the American Medical Association in another column of this number of The Journal. The general sessions will be held in Central Music Hall, most conveniently located and admirably adapted for the purpose. There are gratifying indications of renewed interest in the Association in the most widely separated parts of the country. Let full delegations come from the East, the South, the West and the North; Chicago has room for all, and will give to all a cordial welcome.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, January 26, 1887.

The President, Jos. Taber Johnson, M.D., in the Chair.

H. M. Cutts, M.D., Secretary.

The discussion on Dr. Jos. Taber Johnson's paper on

CÆSAREAN SECTION

(see pages 189 and 270), was continued.

Dr. J. F. Hartigan said that although he had listened attentively throughout this discussion, nothing had been said to change his first impressions as to the proper procedure to adopt when confronted with such a calamitous situation. The Cæsarean operation is so ancient that its origin can hardly be traced. 'Tis enough to say that it was performed on the undelivered dead woman centuries before it was resorted to on the living. So far as he could ascertain, the first published histories of this operation on the living female—400 years ago—are just as misguiding as recent statistics; for the reason that only those have been reported that showed the most success, and we are left in the dark as to the numerous failures. In other words, more than 75 per cent. of the cases published have perished; while if the same pains were taken to bring to notice *all* the unfortunate cases, the supporters of this most formidable operation might be reduced to a minimum. The discussion of this subject has been going on elsewhere lately, and much of it seems to have been inspired by certain religious sentiment. But this is not a body of religionists. We meet to discuss medical subjects on a purely scientific basis, and to stand by those who place their lives in our hands, and *trust* us with them. He asked if it was right that a valuable life should be placed in further jeopardy in order to attempt to save one that has at most but a precarious existence. We will suppose that the operation is performed, and the child survives; it has only even chances of living up to the fifth year, and would such survival fill up the void left by the death of its mother? No, sir; our first and sacred duty is to the patient. In that terrible hour of trial we all have heard the cry, "Whatever you do, Doctor, save my wife!" Is there a man in this room who would turn a deaf ear to such an appeal, or who would any longer hesitate as to where his duty laid? He said he was no craniotomist, but the teachings of ages, as well as the dictates of conscience and humanity, compel us to treat our patients as we would treat ourselves, and to save that life which is of the most value.

My position on this question is best expressed in the following extract from Cazeaux and Tarnier, just published: "This operation may be practiced on the living female whenever the natural passages through which the child has to pass are so narrow, or so obstructed, that a delivery by the application of the forceps, or by symphysiotomy, is wholly impossible; and when the mutilation of the child itself would not permit its extraction without exposing the mother to the greatest dangers. It may likewise be resorted to for the purpose of saving the infant when the patient dies in the advanced stages of gestation."

Dr. G. Wythe Cook said that although we consider lives of equal value, still if confronted with the problem of an unborn child, the sacrifice of whose life was necessary in order to save that of the mother, there could be no doubt in his mind as to the choice. If more lives can be saved by the Cæsarean section than by embryotomy, then Cæsarean section is the operation to be done, for it is a serious thing to take the life of an unborn child, or even to teach that it may be done. Successes in Germany indicate that much may be hoped for in the direction of Cæsarean section, though the statistics of England and this country are not so encouraging.

He said that he spoke feelingly upon the subject, as some twelve or more years ago he was so unfortunate as to be called to a case in the country in the care of a midwife, in which the arm had been pro-

truding for twelve hours; the shoulder was impacted, but the child was still alive. Being unable to turn and deliver it, a consultation was called, the physician attempted to turn, but was unsuccessful, as Dr. C. had been, though the patient was completely under the influence of chloroform. The consultant agreed that the child could not be born alive, but would not consent to Dr. Cook's proposition that embryotomy should be immediately done, as the child was still alive, and advised delay. Dr. Cook said that under the circumstances he could but wait. The child finally died, and was removed by embryotomy. The mother had septic fever, and died also. Here was a case in which both mother and child might have been saved by Cæsarean section. It is certain that nothing was gained by not performing embryotomy. When it is taught that Cæsarean section is the operation to be done in most of these cases, when the child is alive and can not be delivered *per vias naturales*, there is no doubt in his mind but that the country practitioner will have the nerve and the skill to perform the operation, and his successes will compare favorably with those of his metropolitan brother.

Dr. S. C. Busey said that he must defend himself from having made any distinction between the relative ability of the country and city practitioner. In his remarks he spoke of the "ignorant" as a class, and made no distinction as to where they lived.

Dr. T. E. McArdle thought that the Cæsarean section is being taught as *the* operation. At a meeting of the New York Academy of Medicine, June 8, 1886, Dr. Charles Carroll, Secretary, read a paper on the "Future Influence of Surgery and Surgical Resources upon Obstetrics." In the discussion, as reported by the *Medical News*, June 12, 1886, Dr. Polk is quoted as saying: "Before the obstetricians of to-day lies the grandest problem that can possibly engage their attention, viz., that in connection with the Cæsarean section I do not doubt that within the next two years it will be possible to eliminate entirely from practice the most repulsive of all procedures, the destruction of the life of the fœtus by craniotomy. When this has been accomplished there will have been achieved the greatest work ever done in surgery, and the honor of it will belong to the obstetrician."

Dr. Hartigan said that out of 164 cases, according to Heyner, 102 mothers were lost, or sixty-two per cent. But there were only 101 children survived, the rest being still-born, and as only one-half are expected to attain the fifth year, this leaves only fifty children saved of the 164—showing and infantile mortality of seventy per cent. So that, out of the whole number—328—only sixty-two mothers and fifty children survived—112 in all. Now had craniotomy been performed, it is not unreasonable to suppose that at least 150 mothers would have been saved. Therefore, without regard to the relative value of the lives, who can sustain the Cæsarean section in the face of such figures?

Dr. J. R. Brownell said that, believing that the operation of craniotomy, on the living fœtus, is a perfectly justifiable operation under certain conditions, and that, in the present state of medical, surgical, or obstetrical science and human deformity, it cannot be abolished without the sacrifice of life, which cannot be saved in any other way, he could not permit to go unchallenged some of the statements made. Dr. McArdle calls it "a deliberate and cold-blooded murder," and classes it with criminal abortion. That those of us who have been forced to the operation of craniotomy on the living child should not be accredited with a conscience, rather surprises me. Quoting from the debate of the last meeting we have the following: "The life of the child must always be considered, even at the expense of increased risk to the mother." "Who will compare the unlimited possibilities of the unborn child with the life of a woman who cannot bring a viable child into the world?" I contend that, if the two operations afford only equal chances of saving the life of the mother, it is our duty to give the child a chance for its life, and perform Cæsarean section. If, however, there is greater risk to the mother in submitting to Cæsarean section, or, as is often the case, all odds are against her, we must endeavor to save her by sacrificing the child, who has no certainty of life by the Cæsarean section. Shall we only consider the life of a woman of value because she can bring a live and viable child into the world? Is she only to be considered as a child-bearing machine? If so, a man is justifiable in putting away the wife who cannot bear him children, and seeking until he finds one who can. He who acts under such "conscientious discharge of duty" presumes beyond his prerogative in constituting himself jury, judge and executioner. I would ask if it may not be as much the fault of the child's head in being too large, as of the pelvic diameters in being too small, the woman having already been a mother, with little less than a normal pelvis? Have not instances occurred where the descending head was so large as to be out of all proportion to a perfectly normal pelvis? Increase our knowledge of pelvimetry until we can ascertain, with mathematical exactness, the diameters of the pelvis, and yet we have no positive means of measuring the size of the child's head in the mother's womb until it is too late to do anything but sacrifice it, that we be not responsible for two lives instead of one. Will the most thorough knowledge of pelvimetry prevent the necessity of craniotomy, or embryotomy, in the case of locked heads in twin births? the retained after-coming head in breech presentations? or in transverse presentations, when the membranes have ruptured? the distorted body forced low down into the pelvis, so low down as to preclude all possibility of moving it? All this occurring before we saw the patient, possibly due to her living at some distance from us, and consequently unavoidable. Are not these instances, if there were no others, in which the operation of craniotomy on the living child would be justifiable? When version and forceps have failed, or are rendered impossible from the peculiar nature of the case, the woman's life slowly, but surely ebbing away, from protracted pain and suffering, her life further jeopardized by damage threatened to the lower uterine segment and soft parts through protracted continued pressure, the child under any other circumstances immovable, the disproportion between

the head and the pelvic diameters so great as to preclude all possibility of its passing, and when Cæsarean section, under such circumstances, shows a maternal mortality of from 80 to 90 per cent., if we hesitate we will be responsible for two lives instead of one.

DR. BUSEY disclaimed any intention on his part of discussing the subject upon personal or religious grounds, and he had so stated at the beginning of his remarks.

DR. J. TABER JOHNSON, in closing the discussion, said that while one was at a disadvantage in closing a discussion which had lasted over three evenings, there were several points to which he wished to call attention. In the first place, he desired to thank Dr. King for his kind and complete endorsement of his paper. Dr. Thompson had said that I recommended craniotomy in the United States and Cæsarean section in Germany, where there were better operators. Then he says that craniotomy must sometimes be done even to save the mother. In this last remark we agree, so that it needs no discussion.

My paper was confined entirely to Cæsarean section in the United States, of which I had full data; and, knowing the feeling upon the subject, I entitled it "Can the Cæsarean Section Supplant Craniotomy in the United States at the Present Day?" To this the answer was, No. Now, while I endorse all that has been said in favor of Cæsarean section, my conscience would not permit me to agree that craniotomy should be entirely abolished. In my opinion, there is no comparison between the value of the life of the fœtus and its mother, and our duty is to her first. Save them both if we can. Dr. Thompson says that the Cæsarean section is a "cleaner and more perfect surgical procedure"—these words occurred in my paper, so there again there is agreement. The statistics quoted in my paper were not made by me, but by the surgeons of the United States who performed the operations. These showed that of nineteen Cæsarean sections done in the United States during the past ten years, seventeen of the women had perished and fourteen of the children were still-born, and that of the five Sänger operations performed within the last five years all of the mothers died. That is not a brilliant showing for our operators, especially when compared with the results obtained in Germany.

Dr. Busey blames me, and also Dr. King, for stopping the wheels of progress by teaching that a child could be "killed at will." Until there is a better average than 90 per cent. mortality for Cæsarean section in our country, no one ought to be blamed for holding on to craniotomy a little longer. To use Dr. Busey's own way of arguing, let us compare the last nineteen Cæsarean sections in the United States with nineteen imaginary craniotomies. In the former, with the possibility of saving thirty-eight lives, only seven were preserved; while in the latter, although we start with only a possible nineteen, the number of saved would not probably be as low as seven. Harris says of this mortality in the United States that "it makes him sick at heart to think of it;" and Parrish says "it is a terrible mortality, and should make American operators hang their heads in shame." I do not think that Dr. Thompson himself would do or favor the repetition of an operation in general surgery that had 90 per cent. mortality, or, as Dr. Busey would put it, out of thirty-eight lives involved, one that would only fail to "immediately kill" seven.

Dr. Meadows has been quoted as being in favor of totally abolishing craniotomy. On p. 270 of his book, however, he states that he has performed "sixteen craniotomies with only two deaths." He probably could not have saved as many mothers by the Cæsarean section. In speaking of the Cæsarean section, on p. 292, he refers to a patient as "leaving her to the terrible prospect of Cæsarean section;" and on p. 293 says: "I fully share Dr. Barnes's dread of the Cæsarean section." This does not look as if Dr. Meadows was a very ardent supporter of Cæsarean section, whatever his opinions of craniotomy. For his part he would agree with Bedford when he says: "The man who would *wantonly* thrust an instrument of death into the brain of a living fœtus would not scruple, under the mantle of night, to use the stiletto of the assassin." Those who would *wantonly* kill a child; those who speculate in human life; those who "kill at will," are the ones he would condemn. The term "murderer" is a rather harsh one to apply to men who are acting as conscientiously as those who do the Cæsarean section. Who does the "killing" when Cæsarean section is done when delivery is impossible except by craniotomy, and both mother and child die? Might not the broad-minded physician have saved the mother? The question is submitted to the husband, and we hear the cry, as Dr. Hartigan says, "For God's sake save my wife!" There is no love for the unborn child under the circumstances, while the husband does love his wife and would oppose the risking of her life. Who of the audience would submit his wife to the "increased risk" favored by one speaker? Where do we go for our authority in these matters? and if we had a suit at law, to whom or what should we refer? To the text-books—and there is not a text-book published to-day that does not tell how and when to perform craniotomy. If we were to pass a resolution to-night, declaring that the doctors of the District should never do craniotomy, and should adhere to it, the people would not have us in their houses, because they would consider us men who did not know our duty to humanity; or if we did, would not perform it.

Prof. C. Braun, who has successfully performed several Cæsarean sections, and the Porro operation three times, states, on p. 691 (Lehrbuch der Gynäkologie) when the operation should not be, as well as when it may be done. He says: "This operation is not permissible when the parturient woman, in full consciousness and without indirect coercion, declines the Cæsarean section. Further on he says: "It is not right to subject her to this operation without her consent, when she has been rendered unconscious by disease, anæsthetics, poisons or intoxicating drinks." In this Braun differs somewhat with Drs. Busey and McArdle, and agrees with me that craniotomy should sometimes be done. Dr. Busey says that craniotomy is inadmissible in the justo-minor pelvis, and quotes Lusk and Taylor to prove this assertion. As a mat-

ter of fact, they only condemn it in what we call the higher grades of the deformity. As against this assertion Merkel reports, out of 100 craniotomies, thirty-seven in the generally contracted pelvis with only two deaths. Also we find that C. Braun, Spaeth, Schroeder, Créde, Spiegelberg, Charpentier and Barnes explicitly advise the performance of craniotomy in the lower grades of the generally contracted pelvis. I would add to these Cazeaux and Playfair, and refer to the views of Parvin as quoted in my paper. Dr. Busey quoted four men as taking ground against craniotomy. Of these Lusk (p. 482), says that, under certain conditions, "delivery of the child without perforation is often impossible," and I personally know that Mr. Tait does not believe in the total abolition of craniotomy. Dr. Busey has discussed the question from the proper standpoint of its scientific aspects, and left out personalities, which is difficult to do in such discussions. For my part, I desire to discuss it in the same spirit. Drs. Bromwell, Hartigan and Cook have also viewed it from the same aspect. The latest speaker says, however, that "no man is able to say which life is of most value." Perhaps if the mother were a relative of ours there would be no difficulty in making up our minds. But Dr. McArdle, at the last meeting, was not quite so impersonal. In his written remarks, he quoted largely from my paper. Dr. McArdle was the first in this city to suggest the total abolition of craniotomy, and therefore deserves the title of reformer. I cannot endorse his position, and have not the time and patience to discuss the peculiar points made by him.

The public and the profession are not yet ready for the abolition of craniotomy, and even most of those who talk against it admit that there are cases in which it gives the best, and perhaps the only chance to the mother. When there is a doubt in a case as to which operation is the most expedient, one always wants advice and counsel. What is the use of sending for a man who will not judge by the symptoms in the case, but who is bound by a cast iron rule never under any circumstances to perform craniotomy, whose opinion you know is adverse? You are aware that it cannot be changed by evidence or reason, and are thus debarred from sending for him. In the case reported by Dr. Cook a living child was *allowed* to die by delay and then delivered by embryotomy. Its mother died also as a result of this policy. If embryotomy had been done sooner, in accordance with Dr. Cook's wishes, and with proper arrangements, the woman would probably have been saved. Dr. McArdle makes it appear that Polk teaches that craniotomy should be abolished. Polk only says that he *hopes* it will be abolished in two years; and I unite with him and all those who would utterly abolish craniotomy in hopes that medical science may, sooner than that even, arrive at such a state of perfection as to render "sacrificial midwifery" unnecessary; but at present, as argued in my paper, I cannot favor its *complete* abolition. I would join hands with the half-dozen who agree with Drs. Busey and McArdle, and work with them to that end—but I believe now with Barnes, "that as yet the total abolition of craniotomy is an aspiration, not an accomplished fact."

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 9, 1887.

(Concluded from page 278.)

THE PRESIDENT, J. SOLIS COHEN, M.D., IN THE CHAIR.

DR. H. A. KELLY presented the

RESULTS OF SOME GENERAL WORK IN ABDOMINAL SURGERY WITH CASES AND SPECIMENS.

Many here to-night remember the time when the large cystic ovarian tumor was considered the only indication for abdominal section, and, if other conditions were accidently discovered, the incision was simply quietly closed. The dangers of the operation itself were so great that surgeons were loath to interfere until the wretched condition seemed to warrant the risk. As, however, our race cultivated a familarity with the peritoneal sac, and learned its limits of toleration and intolerance, a bolder and more successful work was entered upon. With dropped pedicles, innumerable ligatures for hæmorrhage, peritoneal toilet, drainage tube, and above all, an unremitting care to secure *microscopic* cleanliness throughout, we have become masters of the situation, and our failures, when they occur, are no longer *mysteries*. And with these improvements has come a recognition of greater variety of indications for abdominal section, until, as to-night, I am able to present, out of twenty eight successive cases, at least nineteen separate morbid conditions.

In the removal of small tumors in the pelvis, in the removal of ovaries and tubes not to the naked eye diseased, we are most often compelled to operate for *pain*. The patients themselves, *seeing* nothing amiss, are very loath to submit to "being opened" until their misery makes life a burden—at least this has been my own experience with women, to whom I always explain, in the fullest possible manner, the exact nature of what I propose to do, and its consequences. It is gratifying to the operator, who has finally been driven to this expedient, to find gross lesions suitable for class demonstrations, but the most typical relief often comes where the disease cannot be so easily demonstrated; and in cases where there are palpable tumors, the surrounding infiltration and cellulitic inflammation are often serious enough to delay convalescence, for a long time defeating the operator. Thus, if I were asked, in my own work, which of my cases had given the most gratification—that is, where had the relief been most typical and striking from a condition of suffering—I would point out a patient who was for more than two years unable to take a step on account of the great pain in the right ovarian region; in addition, she was a most wretched sufferer throughout the whole time. There were no gross lesions in the ovaries, and it was long a question with me whether she had not some other serious organic disease, which question I debated under the most varied and patient efforts at general and local treatment, until, with the removal of ovaries here shown, she rose up as if a great weight had been lifted off her, and went

home to her parents and friends, a walking miracle.

Another case, well illustrating this point, is that of Mrs. W. She suffered ever since her first menstruation, from pains which left her a most degraded picture of misery when she came to my office. I found the remains of chronic ovaritis and the wiry tubes of a chronic salpingitis and perisalpingitis, which had contracted down so tight and adhered to so many surrounding structures that they were exposed and removed with the utmost difficulty. This patient has gained eighty pounds since the operation. These results, and some others I might detail had I time, are undeniably brilliant; but cures are not always so typical, and I am still often satisfied in this, my work, if I can but remove one element (perhaps the most distressing) of my patient's sufferings. If my patient can only come back to me and say, "you have taken away that dreadful pain in my back and stomach; life is now bearable, before it was unbearable," I am well content. One of my patients exhibits this well. She had a rapidly growing tumor in the right ovarian region, which seemed in a most unaccountable manner, to prostrate her general health. I decided this to be a case of extrauterine pregnancy, and I believe my section proved it. She is now like another woman, although still under treatment for an induration of the left apex, undiscoverable before operation.

I do not claim wonders for this field of work. I claim for it what is asked for other fields of our art—that the *results* justify the means. It is of *results* I wish now to speak, with a brief preliminary as to *difficulties*. The difficulties encountered in handling small pelvic tumors are often very great, far exceeding that of removing an ordinary cystoma.

First, the abdominal walls, which have never been distended, press tightly down upon the contents, and the recti pinch the fingers like a vice, utterly defeating any effort to catch or raise pelvic viscera, and this in spite of ether and chloroform. I have been obliged twice to overstretch the recti before I could proceed.

Secondly, in case of chronic peritoneal inflammation, the bleeding from the more superficial vessels of the abdominal wall may be extreme.

Thirdly, the intestines, in this close sac, often cling to the fingers until they feel as if they were clothed with several pairs of gloves, and just as useless.

Fourthly, when the patient is very obese, the embarrassment of the operator is greatly increased, requiring a much larger incision, prolonged manipulation, with difficulties of closure and subsequent dangers.

Fifthly. Cellulitis, so common a concomitant, so draws down and anchors everything in the pelvis, that the structures are elevated with extreme difficulty, and only a pedicle in the *technical* sense, can be secured. The dangers of secondary hæmorrhage from this kind of a tie is, I know, very vividly before the minds of all operators of experience. It is, at times, about like tying the apex of a broad-based pyramid. I tied off some broad ligament structures on a fibro-cystic tumor the other day, which impressed me for all the world like putting a ligature on a paper wall.

Lastly. These smaller diseased structures often become parasitic on neighboring tissues and organs for their blood supply, and when they are torn loose, the bleeding is alarming; and it may be deep down in the pelvis, possibly requiring an enlargement of the original incision, and then only seen with the utmost difficulty of exposure and illumination.

[DR. KELLY then read a table of his operations in 1886.]

In one of the patients operated on in 1886, I did what has, I believe, never been done before: opened the abdomen upon a diagnosis of hypertrophic cirrhosis of the liver, with the intention of puncturing—hepatophlebotomy. The patient, about 40 years of age, had a very large ascites, which had been treated for some weeks, but never tapped; and with full confidence in the safety of a simple incision, I made a free opening, large enough to admit two fingers, just below the umbilicus, thoroughly emptied the peritoneal cavity of two bucketfuls of fluid, and on reaching the liver found the organ contracted and hob-nailed; I consequently closed the incision, which healed perfectly. The fluid reaccumulated very slowly until the man died, some weeks after, in the natural course of the disease. My friends, Dr. R. P. Harris, and Drs. Freeman and Bradford, residents of the Episcopal Hospital, were present. I had long intended to use this direct method of abstracting blood from the liver, in view of my experiences in hospital and private practice since, before Dr. George Harley recommended plunging a trocar into the liver through skin, subcutaneous tissues, and two coats of peritoneum, in the right hypochondrium, with the same end in view—hepato phlebotomy. If, however, I am going to draw blood from this organ in a state of inflammation, I prefer an incision free enough to allow me to handle the organ, and, under full control of the eye and touch, to direct the trocar to the proper place, free from the danger of wounding other structures or large vessels. The incision should be made just above the umbilicus.

As to another case, that of my office nurse, I will content myself by briefly remarking, that she suffered constantly for four years with a dragging pain in the left side, and two years ago last December, she was tapped for what was believed to be a large ovarian tumor. The fluid was straw colored and coagulated spontaneously in the bucket. She came to me from Ogdensburg, N. Y., twenty months ago. There had been no reaccumulation of the fluid, but she suffered constantly with dragging pains in the left side. I found here masses attached to the left cornu uteri, which I mapped out in my book; but, to my astonishment, I found in the course of a few weeks, while under treatment, that the tumor diminished and seemed to have shifted its site. Bimanual examination, while still revealing well-defined masses in the neighborhood of the uterus, yet yielded such a different find that I was disposed to distrust my records. As her suffering increased, I made an incision last spring, and found the intestines universally adherent, like one great sac, but free from the abdominal wall; the pelvic structures were so bound up that I could define nothing. Some serous fluid oozed up into the

incision and coagulated *in situ*. This was carefully cleaned out of the whole peritoneum, a piece of membrane, containing isolated tubercular granulations, snipped off for microscopic examination, and the incision closed. She apparently made a perfect recovery, and returned to New York, doing a great deal of hard work all summer, (had not been so well for twelve years). She returned to me upon my return from Europe, and, until seven weeks ago, remained in perfect health The old pain then began to distress her again, and with it was a continuous elevation of temperature. After waiting until it was impossible for her to drag herself around any more, I again made an abdominal section, by a smaller incision to the right of the old incision, for the purpose of cleaning out the cavity and dusting well with iodoform. She insisted upon preparing everything for the operation herself, and lay down upon the table and submitted to the section *without* a general *anæsthetic*. I made multiple hypodermatic injections of a few drops of a 4 per cent. solution of cocaine in the line of the incision. The pain of the incision was but slight. It increased with the introduction of two fingers within the peritoneum, but was easily bearable. In fact, once she warned Dr. R. P. Harris, who was present not to make her laugh. The only severe pain felt was in handling the matted structures in the left side of the pelvis. Sixty-two grains of pure powdered iodoform were sprinkled over the peritoneal surfaces, the incision closed, and the patient put to bed without the slightest shock or discomfort. She insisted on unbuttoning the jackets worn by the operator and assistant, and was as comfortable from that moment until she rose on the sixth day, to take a drive on the seventh day, as if there had been no operation. All trace of the induration has disappeared and she has since felt perfectly well, although the ultimate result remains very doubtful.

Dr. Jos. S. Neff read the report of a case of

PERFORATING ULCER OF THE STOMACH, WITH CHRONIC PERITONITIS.

Alfred Reed, colored, stevedore by occupation, 45 years old, was admitted to the Medical Ward of the Philadelphia Hospital, December 12, 1886. The family history was indefinite; he had had the ordinary diseases of childhood; pleurisy when about 19; enteric fever a few days later; says he had relapsing fever about twenty years ago, since which time he has often had pains and stiffness in the joints, but not severe enough to prevent him working. During the last year he has had occasional attacks of indigestion, rarely accompanied by nausea and vomiting. Last spring he vomited blood; had sensations of burning heat in the stomach, and other evidences of indigestion, with extreme acidity of the stomach; there was very little pain until the latter part of July or the first of August, at which time it was confined to the abdomen (?), and was constant, but more marked after eating. From this time he vomited after almost every meal, and it was not long before he could retain only liquid food. At first the vomited matter was simply the undigested food, later small quantities of a slimy, watery fluid as well. From that time up to admission he vomited blood, dark in color, small in quantity, but once or twice.

Does not remember any sudden onset of pain, chill, or any symptom pointing to perforation of the stomach, or acute peritonitis. His weight last winter was 190 pounds, but at date of admission he was much emaciated, complaining of severe and constant pain over the upper portion of the abdomen, especially in left hypochondriac region, not being able to bear the slightest pressure. There was a small prominence, slightly firmer than the rest of the abdominal wall, situated below the margin of the ribs, one inch to the left of the median line, ovoid in shape, the horizontal diameter being three inches, the vertical diameter two inches in length. Over this area the percussion note was somewhat dulled—*i. e.*, on light superficial percussion; the motion of the diaphragm was not imparted to the mass. He referred to this point as the source of pain which radiated over the entire abdomen and through to the back.

Physical examination showed the heart to be of normal size, first sound absent, second accentuated, more marked over aortic valve; no murmurs were heard; the temporal and radial arteries were firm and hard, not compressible, with no perceptible pulse in the wrists. A systolic bruit was heard posteriorly over the thoracic aorta.

The lungs were normal, but many mucous râles were audible in the bronchial tubes.

No increase in the liver or splenic dulness could be made out, as he could not bear any pressure below the diaphragm.

His general condition improved somewhat for a short time after admission; the pain, however, remained constant, and vomiting was of frequent occurence.

He died of exhaustion on January 1, 1887. During the time he was under observation no change of note occurred. The temperature ranged from normal to 95.5°. He vomited blood once only, on December 15, small in quantity, and dark in color. Paroxysmal spasm of the diaphragm commenced December 16, and lasted with intermissions until death. A loud systolic murmur was detected on the 19th, with area of intensity over the apex. The urine remained normal throughout, and much reduced in quantity; specific gravity 1.032; reaction markedly acid, and of high color. No albumen or sugar.

The diagnosis was made of cancer of the pyloric end of the stomach with secondary peritonitis, induration with inflammatory infiltration, and adhesions between the diaphragm and the stomach.

Autopsy.—External Appearances.—Body much emaciated. Abdomen scaphoid.

Thorax.—Lungs were normal, except hyperæmia, and were firmly adherent to the diaphragm. No other pleural adhesions.

Heart.—Pericordial sac obliterated by adhesions. Left ventricle large, firmly contracted. Right ventricle small, and partly filled with a firm clot. Valves normal. Aorta shows marked chronic endarteritis

throughout its whole thoracic portion, and extending to abdominal aorta. Left ventricle was small, wall thickened, red, and firm.

Abdomen.—Peritoneal cavity contained a quantity of purulent (?) matter. Peritoneum inflamed, the coils of intestine extensively adherent to each other, and to the liver, spleen, stomach, and diaphragm. There was a sac formed at the hilus of the liver by adhesion of the duodenum with the gall-bladder and under-surface of the liver. This cavity contained purulent (?) fluid with thickened walls. The gall-bladder was flattened from pressure, and contained a small amount of thickened bile. The meso-colon showed inflammatory thickening. The upper surface of the liver was extensively adherent over the right lobe to the diaphragm. The left lobe was intimately connected with the stomach. There was a cavity formed by the anterior surface of the left lobe of the liver, the anterior surface of the pyloric end of the stomach with the diaphragm forming its roof. The right wall of the cavity was formed by the suspensory ligament of the liver, the anterior wall by adhesion of the liver and stomach, the left wall by adhesions between the diaphragm and the anterior wall of the stomach. The cavity was filled with a grumous material, its walls being indurated and inflamed. In the floor of the sac there was an opening a half inch in diameter through the anterior wall of the lesser curvature, about half way between the cardiac orifice and the pylorus, and a half-inch to the left of the left edge of the left lobe of the liver. There was also another sac formed by adhesions between the diaphragm, spleen, and cardiac end of the stomach. This appeared to be a blind cavity having no communication with the one just described, or the stomach; it contained a similar looking thick grumous fluid.

Stomach.—Walls were greatly thickened, more marked at the lesser curvature. In the neighborhood of the perforation noted the wall was thinner, the orifice presenting a rounded edge. When opened the mucous surface throughout appeared greatly rigid and mammillated, general thickening being most marked at the pylorus. There was no indication of neoplasm.

Spleen.—Adherent throughout its whole surface, very small, firm, with dark-red fibrous pulp.

Liver.—Right lobe large, the left being small. Flabby cut surface shows a slightly congested parenchyma.

Pancreas.—Normal.

Kidneys were firm, cyanosed, normal in size; capsule slightly adherent; some small cortical cysts; thinning of cortex, and interstitial thickening.

The point of interest clinically is in connection with the diagnosis from malignant disease. The constant character of the pain, the persistency of the vomiting without remissions, the small amount and character of the hæmorrhage, the gradual loss of flesh, with apparent cachexia, and the presence of a painful, non-fluctuating tumor, would warrant a diagnosis of cancer. I should mention, too, the presence of constipation as being of some value.

The circumscribed cavities noted were the result evidently of inflammation from the passage of the contents of the stomach into the peritoneal cavity, the secondary adhesions binding the organs together in such a form as completely to shut off the small cavity in the left side from any outlet, while the larger in the right side still had direct connection with the anterior of the stomach. The cause of the immobility of the tumor upon deep inspiration was undoubtedly due to the fact of the diaphragm itself being thoroughly adherent to the chest-wall over a considerable extent of its surface, and therefore having very little play during the respiratory movements.

Dr. Henry F. Formad said: The case of Dr. Neff's is of great interest, from the fact that the patient's life was considerably prolonged by the formation of a sac which retarded the development of peritonitis after the rupture of the ulcer. The case is also interesting, from the fact that it occurred in a male. In some twenty-two cases of gastric ulcer in which I have made the post-mortem, in about seventeen the subjects were females. This agrees with the experience of others. Gastric ulcer is not a rare condition, but many cases are overlooked because physicians are in the habit of opening the stomach through the smaller curvature, and it is here that the ulcer is most frequently situated. In the majority of cases that I have seen, the death was sudden, being due to perforation. In some the death was apparently due to shock, the whole of the contents of the stomach having in many instances escaped into the peritoneal cavity. Death occurred before there was time for the establishment of inflammation. In some cases there was free hæmorrhage, and in one case there was a complete blood cast of the stomach.

Some of the cases that I have seen have been in drunkards, some have been in hysterical women, and some in the insane. Three of my cases came from the Insane Department of the Philadelphia Hospital. Dr. Dercum informs me that he has met with several cases of gastric ulcer among the inmates of the Norristown Insane Asylum.

Dr. Addinell Hewson said: I wish to express my opinion in reference to certain points in connection with the paper read. The speaker stated that he has resorted to the operation for the relief of pain in cases where the diagnosis was not definite and the existence of a tumor not positively made out. In an experience of over three hundred cases, I have not seen one in which relief of pain was not directly afforded by the application of clay. In reference to the stretching of the cicatrix, it has been my lot to see a good many cases of hernia following laparotomy. In one three or four large herniæ protruded. In this case I resorted to the use of a 50 per cent. solution of silicate of soda applied on strips of gauze, such as the late Dr. Paul Beck Goddard used in his collodion dressings.

Dr. J. M. Baldy said: I would first refer to the case in which the uterine appendages were removed for metritis. This is a new indication for the operation, and it seems to me that it would be a unique case in which such a procedure would be justifiable. There are many men of large experience who have

not seen an uterus which they were unable to reduce to a normal size without recourse to surgical procedure. In regard to cystomata, it is important that as soon as they are diagnosed they should be removed. It has been claimed that rupture of the cyst is followed in a shorter or longer time by malignant disease not only of the appendages and peritoneum, but also of other organs. It is important in pyosalpinx that the appendages be removed on both sides.

I have seen a good many cases of pyosalpinx operated upon, and in some cases where the disease was unilateral the unaffected tube has been left. In a recent case operated on by Dr. J. Price this was done, and two months later the second tube became involved; on opening the abdomen it was found impossible to remove it on account of the adhesions present.

As a rule, we can discover no disease. There are cases, however, which will tempt most of us to operate. Dr. Kelly's case of simple chronic salpingitis in which he had such happy results is a case in point. A case operated on by myself was just such a one and terminated just as happily.

Dr. J. Price said: In Dr. Kelley's cases it is as yet too early to speak positively with reference to hernia, but his incisions have been short. In the December number of the *Lancet*, Mr. Tait gives a review of this whole subject and of hæmatocele. I wish to argue against the removal of the appendages for defective involution. We have many other methods of treatment which will surely accomplish the same result without resorting to such bold measures. I consider this an unjustifiable procedure.

At present, the surgeon simply presents numbers and percentages of recoveries as representing the exact measure of his skill in operating and care in the after-treatment. Too great importance has been given to bare statistics. The conditions inherent in the patient which determine the result beyond the control of the surgeon are barely considered, nor faults of omission or commission on his part. Perfect evacuation of pus, the utmost cleanliness, and perfect drainage—I mean a high degree of surgical cleanliness.

The growing tendency to hold the surgeon strictly responsible for every unfavorable result has stimulated abdominal operators to great care, and the most careful study of every detail. Hence, the methods of abdominal surgery have become well-nigh perfect.

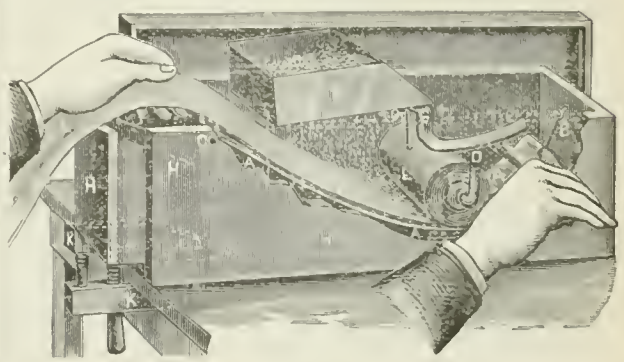
Dr. Kelly said: I have had no practical experience in the treatment advocated by Dr. Hewson; if it can be shown to be practicable in such cases as I have detailed this evening, I will try it. My efforts, however, have been directed toward the establishment of a cure, and not palliation. With reference to the case of enlarged painful uterus, with endometritis, of which Dr. Price has spoken, I desire to make the following statement, and at once prevent any further misconception upon so serious a subject. I hesitated in reporting this case lest I should be misunderstood. I do not wish to recommend a sectional operation for subinvolution or metritis in general. I am weekly treating many such cases without any idea of operative interference. In this particular instance the patient had not only been long under treatment in one of our first hospitals, but I had faithfully tried every means at my disposal for two years—counter-irritation, douches, packing large wedge-shaped excision of the cervical lips, and an Emmet operation on the perineum, hoping by this support, free depletion, and rest in bed to secure a permanent advantage. She was only slightly benefited, remaining a miserable sufferer until I operated, removing tubes and ovaries. The uterus decreased *at once* in size, and is now three inches, with a small hard cervix, and reclines in the sacrum rocking-chair fashion. She has no local tenderness whatever. I attained here a perfect result which I was unable to reach in any other way, and under similar circumstances I should repeat the procedure. If permanent, this will be one of the most gratifying of my cures.

Dr. H. Augustus Wilson presented and described:

A NEW APPARATUS FOR PREPARING DRY GYPSUM BANDAGES.

Rolling the dry plaster-of-Paris bandages by hand, the method usually in use, is unsatisfactory, and under the most favorable circumstances a dirty process. It was to avoid the inconveniences and irregularities of that method that I devised this apparatus, which I have had made by A. G. Gefvert, orthopædic apparatus manufacturer.

It consists of an ordinary box-bandage roller, with addition of the following: A movable bottom, A, A, A, held in contact with the outermost layer of the bandage as it is rolled, by a rubber band B, and the other end by a hinge-joint C. Upon this movable bottom, and just in front of the crank, is a flood-gate or distributor, not shown in the illustration, which equalizes the distribution of the plaster and presses it into the bandage from above, while the movable bottom prevents the gypsum from passing through the meshes. The proper tension is applied by two rubber bands.



A hopper, E, is provided with an arm, F, bent in such a manner as to be raised by the crank at each half turn, and upon being released, it falls, throwing down a quantity of the powder upon the bandage in front of the distributor. A compartment, H, H, H, occupying the otherwise waste space under the mova-

ble bottom, is utilized as a receptacle in which may be kept the gypsum when the apparatus is not in use.

A scoop accompanies the apparatus in which to take gypsum from the compartment and fill the hopper. The entire affair can be securely held to a table by a clamp, K. Elastic bands are used for springs, because they are inexpensive and can be very readily replaced when worn out.

The method of using is, first to pass the end of the bandage to be rolled over the movable bottom, under the distributor, and attach to the crank. The hopper is now to be placed in position and, by means of the scoop, filled with a sufficient quantity of gypsum. While the crank is turned with the right hand the left guides the bandage, which may be watched, over the hopper, as it is being rolled.

The bent arm of the hopper is so arranged that the fall of the hopper may be sudden or gradual, and upon this depends the quantity of powder discharged. When the crank is turned very slowly the hopper is raised slowly and descends with the motion of the crank, and scarcely any gypsum is precipitated, and, of course, the converse follows. This being clearly understood, a very slight experience will enable any one to control the action of the hopper with the crank.

When a bandage is finished, the crank is withdrawn sufficiently to disengage it from the bent arm of the hopper, and while the left hand holds the bandage a quick reverse turn of the crank enables it to be easily withdrawn. The gypsum remaining on the movable bottom is now discharged into the compartment by placing the hopper to one side, detaching the spring, B, and raising that end.

The apparatus is applicable to the rolling of the ordinary surgical bandage by detaching the rubber spring, B, thus allowing the movable bottom to drop out of the way. It prepares the dry gypsum bandages evenly and quickly. It is very simple in its construction and action. It cannot get out of order, except by the breaking of the rubber bands. It is inexpensive. Possessing these advantages, I hope it will be of service and facilitate the preparation of the dry gypsum bandages in the hands of other physicians as it undoubtedly has in mine.

STATE MEDICINE.

REGULATION OF THE PRACTICE OF MEDICINE IN THE STATE OF MINNESOTA.

[The following is a copy of the law for regulating medical practice, etc., adopted by both branches of the Legislature of the State of Minnesota during the recent session, and signed by the Governor. It is to become operative July 1, 1887.—Editor.]

A BILL

To regulate the practice of medicine in the State of Minnesota, and to license physicians and surgeons, and to punish persons violating the provisions of this act.

Be it enacted by the Legislature of the State of Minnesota.

Section 1. The governor of the State shall appoint a board of examiners, to be known as the State Board of Medical Examiners, consisting of nine members, who shall hold their office for three years after such appointment and until their successors are appointed;

Provided, That the members thereof first appointed under this act shall be divided into three classes, each class to consist of three. The first class shall hold office under said appointment for the period of one year, the second class for two years, and the third class for three years from the date of their appointment.

It is further provided that no member thereof shall be appointed to serve for more than two terms in succession, and no member of any college or university having a medical department shall be appointed to serve as a member of said board, two of which are homœpathic physicians.

Sec. 2. Said board of medical examiners shall elect a president, secretary and treasurer, shall have and keep a common seal. The president and secretary shall have the power to administer oaths. Said board of medical examiners shall hold meetings for examination, at the capital of this State, on the first Tuesday of January, April, July and October of each year and such other meetings as said board may from time to time appoint. Said board shall keep a record of all the proceedings thereof, and also a record or register of all applicants for a license, together with his or her age, time spent in the study of medicine, and the name and location of all institutions granting to such applicants degrees or certificates of lectures in medicine or surgery. Said register shall also show whether such applicant was rejected or licensed under this act. Said books and register shall be *prima facie* evidence of all of the matters therein recorded.

Sec. 3. All persons hereafter commencing the practice of medicine and surgery, in any of its branches in this State, shall apply to said board for a license so to do, and such applicant at the time and place designated by said board, or at the regular meeting of said board shall submit to an examination in the following branches, to-wit: Anatomy, physiology, chemistry, histology, materia medica, therapeutics, preventive medicine, practice of medicine, surgery, obstetrics, diseases of women and children, diseases of the nervous system, diseases of the eye and ear, medical jurisprudence, and such other branches as the board shall deem advisable; and present evidence of having attended three courses of lectures of at least six months each; said board shall cause such examination to be both scientific and practical, but of sufficient severity to test the candidate's fitness to practice medicine and surgery. When desirable said examination shall be conducted in the presence of the dean of any medical school or the president of any medical society of this State. After examination said board shall grant a license to such applicant to practice medicine and surgery in the State of Minnesota, which said license can only be granted by the consent of not less than seven members of said board, and which said license shall be signed by the president and secretary of said board

and attested by the seal thereof. The fee for such examination shall be the sum of $10, and shall be paid by the applicant to the treasurer of said board, to be applied by said board towards defraying expenses thereof—and such board may refuse or revoke a license for unprofessional, dishonorable or immoral conduct.

SEC. 4. The person so receiving said license shall file the same or a certified copy thereof with the clerk of the district court in and for the county where he or she resides, and said clerk of the court shall file said certificate or copy thereof, and enter a memoranda thereof, giving the date of said license and name of the person to whom the same is issued, and the date of such filing in a book to be provided and kept for that purpose, and said clerk of the court shall each year furnish to the secretary of said board a list of all certificates on file in his office, and upon notice to him of the change of location or death of a person so licensed, or of the revocation of the license granted to such person, said clerk shall enter at the appropriate place in the record so kept by him a memoranda of said fact, so that the records so kept by said clerk of the court shall correspond with the records of said board, as kept by the secretary thereof. In case a person so licensed shall move into another county of this State, he or she shall procure from the clerk of the court a certified copy of said license, and file the same with the clerk of the district court in the county to which he or she shall so remove, said clerk shall file and enter the same with like effect as if the same was the original license.

SEC. 5. This effect shall not apply to commissioned surgeons of the United States Army or Navy, to physicians or surgeons in actual consultation from other States or Territories, or to actual medical students practicing medicine under the direct supervision of a preceptor. Physicians whose practice extends into the teritory of this State from an adjoining State or Territory shall comply with the provisions of this act, and shall record their certificates with the clerk of the county in this State, whose county seat is nearest the residence of such applicant.

SEC. 6. Any person practicing medicine or surgery within this State without first having obtained the license herein provided for or contrary to the provisions of this act, shall be deemed guilty of a misdemeanor, and upon conviction shall be fined not less than $50 nor more than $100, or by imprisonment in the county jail not less than ten nor more than ninety days, or both fine and imprisonment. Any person shall be regarded as practicing, within the meaning of this act, who shall append the letters "M.D." or "M.B." to his or her name, or prescribe, direct, or for a fee recommend for the use of any person any drug or medicine or other agency for the treatment, care or relief of any wound, fracture or bodily injury, infirmity or disease. Justices of the peace and the respective municipal courts shall have jurisdiction over violations of the provisions of this act. It shall be the duty of the respective county attorneys to prosecute violations of this act.

SEC. 7. Chapter 125 of the General Laws of 1883, is hereby repealed. It is, however, provided that all persons licensed under said act shall be taken and considered as licensed under this act. And the secretary of the board herein provided for shall enter the names of such persons upon the register so kept by him as licensed physicians and surgeons, without application or fee upon the part of the person so licensed.

SEC. 8. This act shall take place and be in force from and after the 1st of July, 1887.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York County Medical Association—The International Congress—Proposed County Association in Brooklyn—Spastic Ataxia; the Scleroses of the Cord—General Shaler.

At the stated monthly meeting of the New York County Medical Association, held February 21, Dr. Charles A. Leale, who has for the past two years filled the position of President with so much credit both to himself and the Association, delivered an able address, on retiring from the chair, which was followed by one of like character by the President-elect, Dr. John Shrady. In his remarks Dr. Leale referred to the fact that from its membership was chosen the one not only to deliver the Address in Medicine at the last meeting of the British Medical Association, but who was also unanimously elected to be the President of the next International Medical Congress. "We miss his genial face to-night," he said, "but the name of Dr. Austin Flint will ever remain upon our records as the representative man." The Association, he went on to say, had now completed its third year, and those who had been constantly connected with it since its birth had great reason to rejoice at the amount of excellent work its members had accomplished, and at its continually increasing power.

In the course of his address Dr. Shrady said: I beg to call your attention to the coming International Medical Congress in the autumn, to which every Fellow, in common with the profession at large, is expected to give his moral support. Happily, the difficulties which beset the preliminary committees, and which were exaggerated with a purpose, have been overcome. Individual and sectional jealousies have been allayed. The unduly ambitious were rebuked by the prompt acceptance of resignations, and the embarrassments which were supposed to forebode defeat—and I regret to say that many were unpatriotic enough to desire it—have only ended in the attainment of harmony of action. Some needed the lesson that there was to be no background for the display of incandescence, and that sometimes even the electric light might cast green and annoying shadows. Our Medical Republic is now at peace, and amply able to receive visitors from abroad, and render their stay agreeable, as well as perhaps profitable.

It is worthy of note that a movement is now on foot to organize a County Association in Brooklyn,

like that in this city, which shall be in affiliation with the State Medical Association and support the National Code of Ethics. A very satisfactory informal meeting of the Fellows of the State Association residing in Brooklyn was held in February to consider the advisability of such a step, when, by a unanimous vote, a committee consisting of Drs. Edward R. Squibb, chairman, Joseph C. Hutchison, Avery Segur, and E. H. Squibb, with power to add to their number, was appointed to draft a plan of organization and call a meeting by circular of all physicians in the city in accord with the principles of the Association.

At the last meeting of the New York Academy of Medicine the paper of the evening was by Dr. C. L. Dana, one of the ablest and most studious of our neurologists, whose subject was *Spastic Ataxia, Functional and Organic, and the Combined Scleroses of the Spinal Cord.* The form of disease to which he referred was that interesting one so admirably described under the name of ataxic paraplegia by Dr. Gowers in a clinical lecture delivered at University College Hospital London, February 23, 1886; and the object of the paper, he said, was to call attention to a class of cases, not very rare, which corresponds to some extent to ordinary progressive locomotor ataxia, and to a much more marked degree to spastic paraplegia. These it was important to recognize both on account of the prognosis and treatment. He had been able to collect forty five cases of combined sclerosis, observed by various authorities, and among them were two which, with their autopsies, were reported for the first time in the present paper. All but sixteen of the number he felt obliged to exclude on account of various circumstances which he thought prevented them from properly coming under the head of the class of cases now under discussion.

In describing the symptoms Dr. Dana said there was gradually increasing weakness of the limbs, with some loss of power of coördination; but the lancinating pains of tabes were for the most part entirely absent, while the patellar tendon reflex was increased, instead of being lost, as in the latter affection. The "Argyle-Robertson" pupil was also seldom seen. As the disease advanced, the muscular power became more and more impaired; while the incoördination did not proportionally increase, but was overshadowed by the increasing paralysis. The increased myotatic irritability continued, and stiffness and rigidity developed as its consequence. "Thus," as Dr. Gowers had graphically described it, "the aspect of the patient comes to be that of spastic paraplegia; the feet drag as the patient walks, shake from clonus when he steps, and the legs are hauled forward with visible effort at each step." Sexual power was often lost early in the disease. The sphincters were frequently impaired, but the impairment rarely reached a considerable degree. There was, as a rule, no wasting of the muscles, and no change in their electrical excitability.

The pathological condition found *post mortem* by Dr. Dana was chronic cervico-dorsal myelitis, affecting the lateral columns primarily, the gray matter secondarily. In a case the drawings from which he exhibited, there were secondary degenerations in the lateral columns, and ascending and descending development of sclerosis in the columns of Gall. In addition, there was sclerosis of the crossed pyramidal tracts, most marked in the dorsal region, and sclerosis in the cerebellar tracts to a moderate extent. The sclerosis in the columns of Gall was most marked in the cervical region. According to Gowers, in all cases the spinal cord has presented sclerosis of both posterior and lateral columns; but the precise extent and degree of the degeneration seem subject to considerable variations. As a general rule, he says, the sclerosis of the posterior columns differs from that of tabes in two particulars: First, it is not more intense, and often is less intense, in the lumbar than in the dorsal region of the cord. Sometimes, indeed, in the middle and lower parts of the lumbar region the posterior columns may be free from sclerosis, although it is considerable in the dorsal region and at the junction of this with the lumbar enlargement. The second difference is that the sclerosis has rarely the special intensity in the root-zone of the postero-external column that characterizes the lesion of tabes.

The prognosis as to life, Dr. Dana remarked, was better than in simple tabes dorsalis. The disease has little tendency to cause death; indeed, according to Gowers, the fatal cases have, for the most part, been untypical, and do not convey an accurate idea of the disease. The chief danger to life was said to be from the accidents common to all chronic spinal affections, and especially from kidney disease secondary to retention. So far as the prospect of recovery was concerned, the prognosis was unfavorable, and one case, Dr. Dana said, was on record in which the affection had already lasted thirty years.

The treatment did not vary greatly from that of locomotor ataxia. Rest was a very important element, and electricity, both static and in the form of the Faradic current, was useful. Orthopædic appliances to support the tottering limbs were often of great service. Antisyphilitic treatment should always be given a thorough trial, and large doses of iodide of potassium were not infrequently called for. In conclusion, Dr. Dana said that while no name had as yet been found which properly described the disease clinically, he thought the designation "combined fascicular sclerosis" was applicable from a pathological point of view.

In the discussion of the paper Dr. M. Allen Starr, who recently delivered the Middleton Goldsmith lectures, under the auspices of the New York Pathological Society, on "Multiple Neuritis," objected to the name proposed by Dr. Dana; claiming that the changes in the cord met with after death were not entirely fascicular. The diagnosis between tabes and combined sclerosis, he remarked, was often very difficult; and, again, the occurrence of general paresis in connection with tabes sometimes made us hesitate in arriving at a diagnosis. Dr. E. C. Seguin related a case of his own in which he said the lesions seemed to show that there were instances in which pathological changes present were intermediate between fascicular sclerosis and disseminated sclerosis. Dr.

Jacobi suggested that perhaps the sclerosis followed the course of minute blood-vessels whose extensive network, it had been shown, served to connect and bind together the various fasciculi of the spinal cord. This anatomical fact, he thought, might offer a satisfactory explanation of these mixed forms of sclerosis. He regarded the subject of the paper as one of great importance to general practitioners, on account of the frequency with which disease of the spinal cord was now met with.

The Governor has at last given his official approval of the order made some nine months ago by Mayor Grace removing General Shaler from the office of President of the City Board of Health. P. B. P.

SAENGER'S CÆSAREAN OPERATION.

Dear Sir:—In his excellent paper entitled "Can the Cæsarean Section be Safely Substituted for Craniotomy in the United States at the Present Time," published in THE JOURNAL of February 12, 1887, and in the scientific conclusions of which I fully concur, my friend, Dr. J. Taber Johnson, in one place mentions me in a way that may give rise to misunderstanding, if not corrected. He says: "To quote from recent authority, in the October number of the *American Journal of Obstetrics*, page 1021, by Garrigues, who claims that the Sänger method should as properly be called by his name as by Sänger's, and further, that there is really nothing in this 'method' after all, as the most successful operators get on better without it—Garrigues says," etc. To those who have not read my paper, or who have forgotten the particulars of it, the first assertion looks as if I had laid claim to the so-called Sänger method, but a reference to the passage alluded to in my paper will clearly show that this is by no means so. I said: "When he (Sänger) says that American physicians might as well call the improved Cæsarean section mine as his, I quite agree with him, but I make haste to add that *one thing would be as ridiculous as the other*. The improved Cæsarean section is a beautiful outgrowth of general surgical and special gynecological development, an evolution due to the combined efforts of many men working independently in different countries."

The second assertion put into my mouth, viz., that there is really nothing in this "method," after all, will be very apt to be misunderstood. The cause of this that the words, "Sänger's method," have a double meaning. I show, in the paper referred to, that the only original idea of Sänger was the resection of the two slices of muscular tissue of the uterus contiguous to the incision made in that organ, but unfortunately, not only German, but English, French and American writers have got into the habit of calling the whole improved Cæsarean section, with its manifold steps due to different men, by Sänger's name. In the above-mentioned quotation from Dr. J. T. Johnson, it must be well understood that in the first sentence he refers to the whole improved Cæsarean section, while in the second he has only in view that part of Sänger's so-called method which really belongs to him, namely, the resection of muscular tissue of the womb, and by no means all the other points entering into the composition of that which is erroneously attributed to Sänger. It is Sänger's original proposition which is objectionable, and has been given up, while all the res of the improved Cæsarean section is, in my opinion, highly recommendable.

Very truly yours,

H. J. GARRIGUES, M.D.

155 Lexington Ave., New York, March 10, 1887.

"THE ETIOLOGY AND CURE OF ASTHMA."

Dear Sir:—In the issue of THE JOURNAL for Feb. 26 appeared a short review, under the above heading, by Dr. E. F. Ingals, which is likely to mislead those not familiar with the subject. I was astounded at the manner in which Dr. Ingals perverts the meaning of my words. *Firstly*, he claims priority for Dr. Wm. H. Daly against Hack. As the paper of Dr. Daly, quoted by Dr. Ingals, deals exclusively with hay asthma, and as my paper and quotations from Hack entirely exclude the consideration of hay asthma, there can be no discussion as to priority.

If Dr. Ingals is still confused on this point, I should earnestly advise him to read Hack's writings before discussing them.
