Paterson, a city of New Jersey, U.S.A., capital of Passaic county, in the north-eastern part of the state, on the Passaic river at the falls, at an altitude of 193 feet. It is entered by the Morris canal, and the Delaware, Lackawanna, and Western, the Erie, and the New York, Susquehanna, and Western railways. It is built partly upon a plain, from which it stretches up the slopes of the surrounding hills. Its plan is irregular. It is divided into eight wards, and its water-supply is obtained by pumping from the river. It is well sewered, but few of its streets are paved, except with macadam. Passaic Falls, 72 feet in height, furnish ample water-power, and have induced the concentration of manufactures here. Paterson is the centre of silk manufacture. In 1900 the census enumerated 995 manufacturing establishments, with a total capital of \$43,510,481. They employed 30,190 hands, and the product was valued at \$52,287,975. Of this large total almost exactly one-half, or \$26,006,156, consisted of silk goods. In this industry there were 136 establishments, with a capital of \$19,025,564, employing 15,943 hands. Of the other manufactures, foundry and machine-shop products were valued at \$5,906,517, dyeing and finishing textiles at \$3,836,409, and malt liquors at \$1,859,537. The assessed valuation of real and personal property in 1899 was \$47,575,563; the net debt, \$3,435,820; and the tax rate, \$25 per \$1000. Population (1890), 78,347; (1900), 105,171, of whom 38,791 were foreign-born and 1182 negroes.

Patey, Janet Monach (1842–1894), English vocalist, was born in London, 1st May 1842, her maiden name being Whytock. She had a fine alto voice, which developed into a contralto, and she studied singing under J. Wass, Pinsuti, and Mrs Sims Reeves in succession. Miss Whytock's first appearance, as a child, was made at Birmingham, and her first regular engagement was in 1865, in the provinces. From 1866, in which year she sang at the Worcester Festival, and married John Patey, a bass singer, she was recognized as one of the leading contraltos; and on the retirement of Mme Sainton-Dolby in 1870 succeeded her as the prime favourite of the public, whether in oratorio or in ballad music. She toured in America in 1871, sang in Paris in 1875, and in Australia in 1890. She kept her leading position until within a very short time of her death, which took place at Sheffield, 28th February 1894, after she had put too severe a strain upon her powers in order to give an encore to an importunate audience. Her voice had great power, sweetness, and compass, and she had a true instinct for the amount of dramatic effect that was legitimate on the concert platform.

PATHOLOGY.

I. General.

THE outstanding feature in the history of pathology during the 19th century, and more particularly of the latter half of it, was the completion of its rescue from the thraldom of abstract philosophy, and its elevation to the dignity of one of the natural sciences. Our forefathers, if one may venture to criticize them, were too impatient. Influenced by the prevailing philosophy of the day, they interpreted the phenomena of disease through its lights, and endeavoured from time to time to reduce the study of pathology to philosophical order when the very elements of philosophical order were wanting. The pathology of the present day is more modest: it is content to labour and to wait. Whatever its faults may be —and it is for our successors to judge of these—there is this to be said in its favour, that it is in nowise dogmatic. The eloquence of facts appeals to the scientific mind nowadays much more than the assertion of crude and unproven principles. The complexity and mystery of action inherent in living matter have probably been accountable for much of the vague philosophy of disease in the past, and have furnished one reason at least why pathology has been so long in asserting its independence as a science. This, indeed, holds good of the study of biology in general. There are other factors, however, which have kept pathology in the background. Its existence as a science could never have been recognized so long as the subjects of physics, chemistry, and biology, in the widest acceptation of the term, remained unevolved. Pathology, in fact, is the child of this ancestry; it begins where they end.

Recent progress. Since the article in the ninth edition of the *Encyclopædia Britannica* was written, progress in the study of pathology has been greatly facilitated by the introduction of improved methods of technique. The certainty with which tissues can now be fixed in the state they were in when living, and the delicacy with which they can be stained differentially, have been the means of opening up a new world for exploration. Experimental pathology has benefited by the use of antiseptic surgery in operations upon animals, and by the adoption of exact methods of recording; while the employment of solid culture media in bacteriology—the product of Koch's fertile genius—is responsible for a great part of the extraordinary development which has taken place in this department of pathological research. The discoveries made in pathological bacteriology, indeed, must be held to be among the most brilliant of the age. Inaugurated by Pasteur's early work, progress in this subject was first marked by the discovery of the parasite of anthrax, and of those organisms productive of fowl-cholera and septic disease. Then followed Koch's great revelation in 1882 of the bacillus of tubercle (Fig. 5, Plate III.), succeeded by the isolation of the organisms of typhoid, cholera, diphtheria (Fig. 6, Plate III.), actinomycosis, tetanus, &c. The knowledge we now possess of the causes of immunity from contagious disease has resulted from this study of pathological bacteriology, and the prosecution of that branch of treatment known as "serum-therapeutics," at the hands of Roux, Behring, Ehrlich, and others, has also followed upon it, accompanied by momentous practical issues. Before the discovery of the bacillus of tubercle, scrofula and tuberculosis were regarded as two distinct diseases, and it was supposed that the scrofulous constitution could be distinguished from the tubercular. It was always felt, however, that there was a close bond of relationship between them. The fact that the tubercle bacillus is to be found in the lesions of both has set at rest any misgiving on the subject, and put beyond dispute the fact that so-called scrofulous affections are simply local manifestations of tuberculosis. A knowledge of the bacteriology of scrofulous affections of bone and joints, such as caries and gelatinous degeneration, has shown that they also are tubercular diseases—that is to say, diseases due to the presence locally of the tubercle bacillus. At a very early period it was held by Virchow that the large cheesy masses found in tuberculosis of the lung are to be regarded as pneumonic infiltrations of the air-vesicles. Their pneumonic nature has been amply substantiated in later times; they are now regarded simply as evidence of pneumonic reaction to the stimulus of the tubercle bacillus. The caseous necrosis of the implicated mass of lung tissue, and indeed of tubercles generally, is held to be, in great measure, the result of the necrotic influence of the secretions from the bacillus. Tubercular pneumonia may thus be looked upon as comparable to pneumonia excited by any other specific agent (Fig. 3, Plate II.).

In the 'seventies, feeling ran somewhat high over the rival doctrines concerning the origin of pus-corpuscles, Cohnheim and his school maintaining that they were derived exclusively from the blood, that they were leucocytes which had emigrated through the walls of the vessels and escaped into the surrounding tissue-spaces, while Stricker and his followers, although not denying their origin in part from the blood, traced them, in considerable proportion, to the fixed elements, such as fibrous tissues and endothelia. Our present-day knowledge prompts the adoption of a middle course between the two theories. The cells found in an inflamed part are undoubtedly drawn from both sources, but while the blood leucocytes have a great tendency to become fatty and to die, those cells derived from the fixed tissues incline more to organization; the latter are, in fact, the source of the cicatrix which follows upon the cessation of suppuration (Figs. 7, 8, and 9, Plate III.). Organization and healing have been keenly inquired into, with results which seem to point the lesson that all methods of healing are to be regarded as extensions of the natural phenomena of growth. Normal cytology, of late, has become a science of itself, and has had a direct bearing upon that which is pathological.

At no time has so much been done to advance our knowledge of diseases of the nervous system as during the last thirty years of the 19th century. The localization of function in the cerebral and in the cerebellar cortex has doubtless been the main cause of this progress, and has proceeded *pari passu* with an extended insight into the structure and connexions of the parts concerned. The pathology of aphasia, as worked out by a combination of the experimental, the pathological, and the anatomical lines of inquiry, is a favourable example of what has been accomplished. The origin, nature, and propagation of neoplasms of all kinds, especially of those which are malignant, are engaging much attention. The tendency has been to refer these back to the influence of parasites,—a view, however, which has not met with universal acceptance. Much light has been thrown upon the functions and diseases of the blood-forming glands. The origin of the corpuscles, previously a matter of so much difference of opinion, is now pretty fairly set at rest, and has proved the key to the interpretation of the pathology of many diseases of the blood, such as the different forms of anæmia, of leucocythæmia, &c. The deleterious influence of high blood-pressure has engaged the attention of physicians and pathologists in later years, and the conclusion arrived at is, that although it may arise from accidental causes, such as malcomposition of the blood, yet that in many instances it is a hereditary or family defect, and is bound up with the tendency to gout and cirrhotic degeneration of the kidney. The pathology of intra-cardiac and vascular murmurs has also been inquired into experimentally, the general impression being that these abnormal sounds result, in most cases at least, from the production of a sonorous liquid vein. Pneumonia of the croupous type has been proved to be, as a rule, a germ disease, the nature of the germ varying according to circumstances. The structural changes occurring in the bronchi in catarrhal bronchitis have also been ascertained, and, as in the case of pneumonia, have been shown to be frequently excited by the presence of a microphyte. The vexed question of the diagnosis of diphtheria is now a thing of the past. Quite irrespective of the nature of the anatomical lesion, the finding of the diphtheria bacillus on the part affected, and the inoculability of this upon a suitable fresh host, are the sole means by which the diagnosis can be made certain.

The part played by the thyroid body in the internal economy of the organism has also received much attention. The gland evidently excretes, or at any rate gets rid of, a certain waste product of a proteid nature, which otherwise tends to accumulate in the tissues and to excite certain nervous and tissue phenomena. It wastes in the disease known as "myxœdema," and the above product gathers in the tissues, in that disease, to such an extent as to give rise to what has been termed a "solid œdema." It is questionable if the substance in question is mucoid. The pituitary body probably subserves a like purpose. When the pancreas is excised in an animal, or when it is destroyed in man by disease, grape-sugar appears in the urine. The gland is supposed to secrete a ferment, which, being absorbed into the portal circulation, breaks up a certain portion at least of the grape-sugar contained in the portal blood, and so prevents this overflowing into the circulation in general. The transplantation of a piece of living pancreas into

FIG. 5.—Tubercular Meningitis. *a*, Arachnoid; *b*, small tubercle lying in trabeculæ between pia and arachnoid; *c*, effusion of fibrin and leucocytes into sub-arachnoid spaces; *d*, catarrhal-like cells derived from trabeculæ; *e*, tubercle bacillus lying in a tubercle of considerable size; *f*, small cell effusion; *g*, small blood-vessel obliterated by a thrombus; *h*, blood-vessel containing blood-corpuscles. (× 300 diams.)

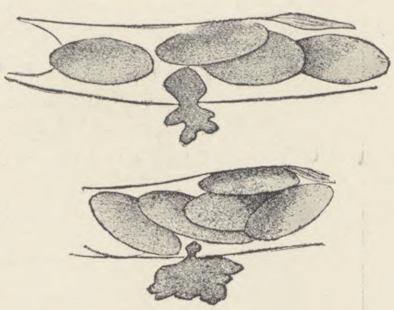

FIG. 7.—Diapedesis of a Leucocyte through the wall of a capillary, in which the blood is motionless. (Metchnikoff.)

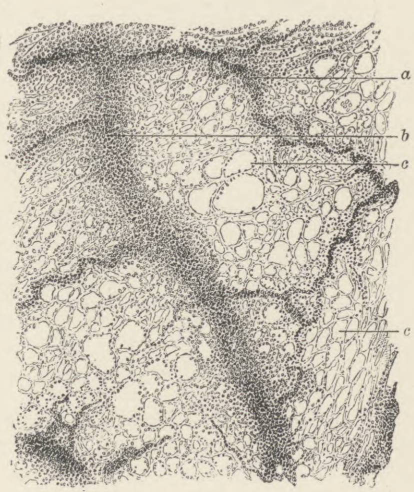

FIG. 8.—Omentum in state of acute inflammation. *a*, Small vein surrounded by escaped leucocytes; *b*, larger vein in same condition; *c*, *c*, fenestræ of membrane whose walls are covered by germinating (endothelial) cells. (× 50 diams., stained with silver.)

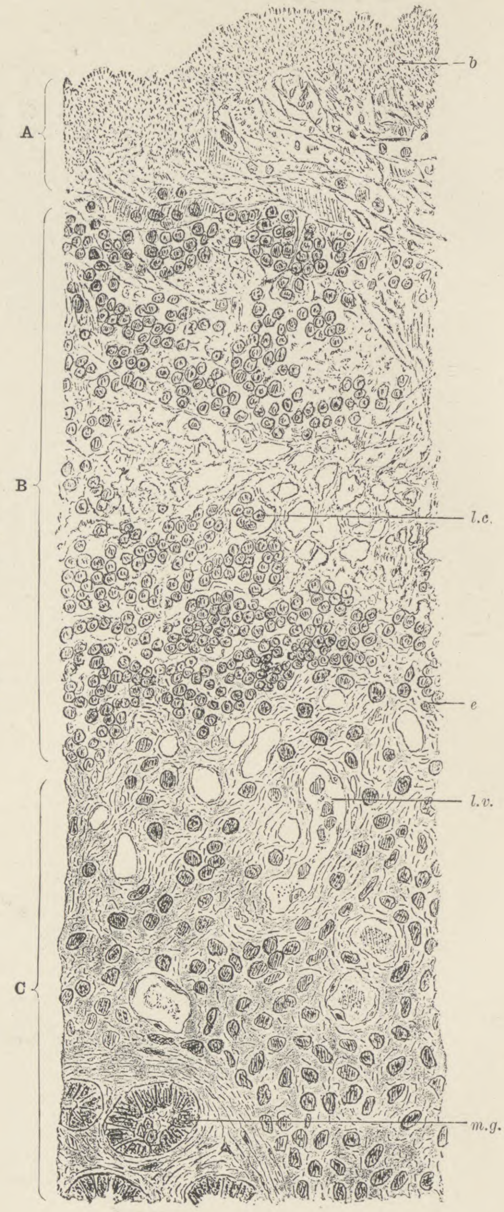

FIG. 6.—Free Surface of Diphtheritic Larynx. A, Deposit of diphtheria bacillus on surface of false membrane; B, false membrane; C, mucosa. *b*, diphtheria bacilli almost in pure culture; *l.c.*, lymph-cells in false membrane surrounded by network of fibrin; *e*, surface of mucosa deprived of its epithelium; *l.v.*, lymph-vessels containing shed endothelium; *m.g.*, mucous gland. (× 350 diams.)

FIG. 9.—Omentum in state of acute inflammation. *a*, Endothelium as yet unaltered; *b*, endothelium beginning to germinate; *c*, *c*, endothelium germinating actively. (× 300 diams., stained with silver.)

the tissues of an animal, thus rendered artificially diabetic, is said to restore it to health.

Pathological chemistry has been remarkable chiefly for the knowledge we have obtained of the nature of bacterial poisons. Certain of these are alkaloids, others appear to be albumoses. The publication of Ehrlich's chemical, or rather physical, theory of immunity has thrown much light upon this very intricate and obscure subject.

Germany and France have been in the van of progress during the period under contemplation. The success of the great pathologists of the United Kingdom has been the result of inborn merit and personal effort, rather than the outcome of a systematized method of training, whereas Continental nations have recognized the importance of fostering the subject by the endowment of centres of research and the equipment of laboratories. In Great Britain, on the other hand, pathologists have had, until quite lately, to fight the battle almost single-handed.

Pathology is the science of disease in all its manifestations, whether structural or functional, progressive or regressive. In times past it has been the habit to look upon its sphere as lying really within that of practical medicine, and human medicine more particularly; as something tagged on to the treatment of human disease, but unworthy of being studied for its own sake as a branch of knowledge. Such a view can recommend itself to only the narrowest of minds. A bearing, and of course an essential bearing, on the study of medicine it must always have. A system of medicine reared upon anything but a pathological basis would be unworthy of consideration. Yet it may well be asked whether this is the final goal to be aimed at. Our starting-point in this, as in all departments of biological study, must be the biological unit, and it is to the alterations to which this is subject, under varying conditions of nutrition and stimulation, that the science of pathology must apply itself. Man can never be the only object of appeal in this inquiry. The human organism is far too complex to enable us to understand the true significance of diseased processes. Our range must embrace a much wider area—must comprise, in fact, all living matter—if we are ever to arrive at a scientific conception of what disease really means. Hence not only must the study of our subject include the diseases peculiar to man and the higher animals, but those of the lowest forms of animal life, and of plant life, must be held equally worthy of attention. Modern research seems to show that living protoplasm, wherever it exists, is subject to certain laws and manifests itself by certain phenomena, and that there is no hard and fast line between what prevails in the two kingdoms. So it is with the diseased conditions to which it is a prey: there is a wonderful community of design, if the term may be used in such a sense, between the diseases of animals and plants, which becomes singularly striking and instructive the more they are inquired into. Utilitarian, or perhaps rather practical, considerations have very little to do with the subject from a scientific point of view—no more so than the science of chemistry has to do with the art of the manufacturing chemist. The practical bearings of a science, it will be granted, are simply, as it were, the summation of its facts, with the legitimate conclusions from them, the natural application of the data ascertained, and have not necessarily any direct relationship to its pursuit. It is when studied on these lines that pathology finds its proper place as a department of biology. Disease as an entity, as something to which all living matter is subject, is what the pathologist has to recognize and to investigate, and the practical application of the knowledge thus acquired follows as a natural consequence.

Connexion with biology.

Since pathology is the science of disease, we are met at the very threshold by the question: What is Disease? This may best be answered by defining what we understand by Health. What do we mean when we talk of a healthy organism? Our ideas upon the subject are purely arbitrary, and depend upon our everyday experience. Health is simply *that condition of structure and function which, on examination of a sufficient number of examples, we find to be commonest.* The term, in fact, has the same significance as "the normal." Disease we may define, accordingly, as *any departure from the normal standard of structure or function of a tissue or organ.* If, for instance, we find that instead of the natural number of Malpighian bodies in the kidney, there are only half that number, then we are entitled to say that this defect represents disease of structure; and if we find that the organ is excreting a new substance, such as albumen, we can affirm logically that its function is abnormal. Once grant the above definition of disease, and even the most trivial aberrations from the normal must be regarded as diseased conditions, quite irrespective of whether, when structural, they interfere with the function of the part or not. Thus an abortive supernumerary finger may not cause much, if any, inconvenience to the possessor, but nevertheless it must be regarded as a type of disease, which, trivial as it may appear, has a profound meaning in phylogeny and ontogeny.

Health and disease.

Classification.—From the foregoing it will be gathered that the problems in pathology are many-sided and require to be attacked from all points of vantage; and the subject falls naturally into certain great divisions, the chief of which are the following:—

I. Morbid Anatomy.
 (*a*) Naked-eye or macroscopic.
 (*b*) Morbid histology or microscopic.
II. Pathological Physiology.
III. Pathogenesis.
IV. Ætiology.
V. Pathological Chemistry.

The term "Pathogenesis" has reference to the generation and development of disease, and that of "Ætiology," in its present bearing, has to do with its causes. The use of the term "Pathological Physiology" may at first appear strange, for if we define physiology as the sum of the normal functions of the body or organism, it may be hard to see how there can be a physiology which is pathological. The difficulty, however, is more apparent than real, and in this sense, that if we start with a diseased organ as our subject of inquiry, we can quite properly, and without committing a solecism, treat of the functions of that organ in terms of its diseased state.

Influences working for Evil upon the Organism.

(1) *Malnutrition.*—When the blood supply is entirely cut off from a tissue, the tissue dies, and in the act of dying, or afterwards, it suffers certain alterations dependent upon its surroundings. Thus, when the circulation to an external part is obstructed completely, as in the case of a limb where the main artery has been occluded and where the anastomatic communications have not sufficed to continue the supply of blood, the part becomes gangrenous; that is to say, it dies and falls a prey to the organisms which excite putrefaction, just as would happen to any other dead animal tissue were it unconnected with the body. Fermentative changes are set up in it, characterized by the evolution of gas and the formation of products of suboxidation, some of which, being volatile, account for the characteristic odour. In the formation of these the tissues break down, and in course of time lose their characteristic histological features. The blood suffers first; its pigment is dissolved out and soaks into the surroundings, imparting to them the pink hue so diagnostic of commencing gangrene. Muscle and white fibrous tissue follow next in order, while elastic tissue and bone are the last to show signs of disintegration. The oil separates from the fat-cells and is

found lying free, while the sulphuretted hydrogen evolved as one of the products of putrefaction reacts upon the iron of the blood and throws down a precipitate of sulphide of iron, which in course of time imparts to the limb a range of colour commencing in green and terminating in black. The temperature at which the limb is kept, no doubt, favours and hastens the natural process of destruction, so that putrefaction shows itself sooner than would be the case with a dead tissue removed from the body and kept at a lower temperature. Nevertheless, gangrene is nothing more or less than *the putrefactive fermentation of an animal tissue still attached to the body.* If the amount of liquid contained in the tissue be small in quantity, the part mummifies, giving rise to what is known as "dry gangrene." If the dead part be protected from the ingress of putrefactive organisms, however, it separates from that which is living without the ordinary evidences of gangrene, and is then known as an "aseptic slough." Should the portion of tissue deprived of its circulation be contained in an internal organ, as is so often the case where the obstruction in the artery is due to embolism, it becomes converted into what is known as an "infarction." These infarcts are most common in organs provided with a terminal circulation, such as prevails in the kidney and spleen (Fig. 10, Plate IV.). The terminal branches of the arteries supplying these organs do not anastomose; therefore, when one of them is obstructed, the area irrigated by it dies from malnutrition. Being protected from the ravages of the organisms which induce putrefaction, however, it does not become gangrenous; it is only where the obstructing agent contains these organisms that a gangrenous slough follows, or, in the case of the contaminating organisms being of a suppurative variety, ends in the formation of a so-called "pyæmic abscess," followed by rapid dissolution of the dead tissue (Fig. 11, Plate IV.). In ordinary circumstances, where the artery is obstructed by an agent free from such organismal contamination, the part becomes hard and well defined from the precipitation of the fibrinogen contained in its liquids (coagulative necrosis), and at a later period assumes a yellow colour. Its condition, in fact, comes to resemble very closely, if it is not identical with, the caseation of a tubercular nodule. Examined microscopically, it is found to be very granular, and minute oil-globules show themselves within it, the result of a fatty degeneration of its tissue elements. Later, it is absorbed, and, as in the case of all such dead tissues left in the midst of living surroundings, apparently by a double agency—in the first place, by the histolytic influence of the tissue liquids, and, in the second place, by the phagocytal cells at its margin.

Where the malnutrition is the effect of poorness in the quality of the blood, the results are of course more widespread. The muscles suffer at an early period: they fall off in bulk, and later suffer from fatty degeneration, the heart being probably the first muscle to give way. Indeed, all tissues when undernourished, either locally as the result of an ischæmia, or generally as from some impairment of the blood, such as that prevailing in pernicious anæmia, tend to suffer from fatty degeneration; and at first sight it seems somewhat remarkable that undernourished tissues should develop fat in their substance (Figs. 12 and 13, Plate IV.). The fatty matter, however, it must be borne in mind, is the expression of dissimilation of the actual substance of the proteids of the tissues, not of the splitting up of proteid or other carbonaceous nourishment supplied to them.

A part deprived of its natural nerve-supply sooner or later suffers from the effects of malnutrition. When the trigeminus is divided (Majendie), or when its root is compressed injuriously, say by a tubercular tumour, the cornea begins to show points of ulceration, which, increasing in area, may bring about total disintegration of the eyeball. The earliest interpretation put upon this experiment was that the trophic influence of the nerve having been withdrawn, the tissue failed to nourish itself, and that degeneration ensued as a consequence. The subsequent experiments of Snellen, Senftleben, and, more lately, of Turner, seem to show that if the eyeball be protected from the impingement of foreign particles, an accident to which it is liable owing to its state of anæsthesia, the ulceration may be warded off indefinitely. The bed-sores which follow paralysis of the limbs are often quoted as proof of the direct trophic action of the nerve-supply upon the tissues, yet even here the evidence is somewhat contradictory. Still, there are facts which, for want of a better explanation, we are almost bound to conclude are to be accounted for on the direct nerve-control theory. Thus a fractured bone in a paralysed limb often fails to unite, while another in the opposite sound limb unites readily, and an ulcerated surface on a paralysed limb shows little healing reaction. A salivary gland degenerates when its nerve-supply is cut off; and the nerves leading up to the symmetrical sloughs in Raynaud's disease have been found in an advanced state of degeneration (Affleck and Wiglesworth). It is just a question, however, whether, even in instances such as these, the nutritional failure may not be explained upon the assumption of withdrawal of the local vasomotor control. There seems to be little doubt, notwithstanding, that one of the chief functions of the nerve cell is that of the propagation of a trophic influence along its axon. When a nerve-trunk is separated from its central connexion, the distal portion falls into a state of fatty degeneration (Wallerian or secondary degeneration). That special trophic nerves, however, exist throughout the body, seems to be a myth. It is much more likely, as Verworn alleges, that the nerves which influence the characteristic function of any tissue regulate thereby the metabolism of the cells in question—in other words, that every nerve serves as a trophic nerve for the tissue it supplies. It is a significant fact that neoplasms contain very few nerve-fibres, even although growing luxuriantly, and there is a doubt whether the few twigs contained in them may not merely have been dragged into their midst as the tumour mass expanded (Young).

(2) *Senile Decay.*—It may naturally be supposed that as old age is approached the tissues fail to regenerate themselves, so as to make up for the ordinary wear and tear to which they are subject, with the same readiness as in youth. They lose also a certain amount of their power of assimilation. From both these causes a certain shrinkage is liable to occur, more evident in some parts of the body than in others. Thus the brain falls off in bulk, and the muscles become attenuated, and in no muscle is this more notable than in the case of the heart. A tendency to pigmentation also develops in certain tissues of the body, such as the nerve and muscle cells. As a result of these various senile degenerations, the functions of the body deteriorate, the faculties become blunted, and the muscular energy of the body is below what it was in earlier life, while the secreting glands in certain instances become functionally obsolescent.

(3) *Overwork.*—The effect of overwork upon an organ or tissue varies in accordance with (*a*) the particular organ or tissue concerned, (*b*) the amount of nourishment conveyed to it, and (*c*) the power of assimilation possessed by its cells. In the case of muscle, if the available nourishment be sufficient, and if the power of assimilation of the muscle cells remain unimpaired, its bulk increases, that is to say, it becomes hypertrophied. The hypertrophy in this case is due chiefly to the numerical increase of the muscle fibres, partly to slight augmentation in their bulk. Where hypertrophy of muscle takes place from increased blood-supply, as sometimes happens, the enlargement is partly due to numerical increase, but chiefly to increase in bulk of the individual fibres (Zielonko).

It may be advisable to define exactly what is meant by "hypertrophy," as the term is often used in a loose and insignificant sense. Mere enlargement of an organ does not imply that it is in a state of hypertrophy, for some of the largest organs met with in morbid anatomy are in a condition of extreme atrophy. Some organs are subject to enlargement from deposition within them of a foreign substance (amyloid, fat, &c.). This, it need hardly be said, has nothing to do with hypertrophy; enlargement is simply one of the

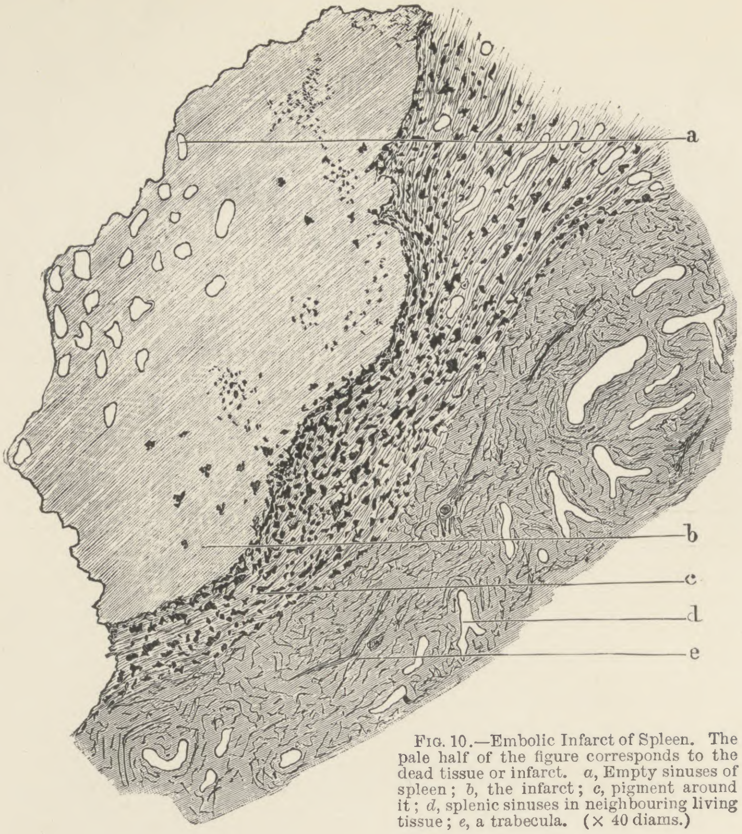

FIG. 10.—Embolic Infarct of Spleen. The pale half of the figure corresponds to the dead tissue or infarct. *a*, Empty sinuses of spleen; *b*, the infarct; *c*, pigment around it; *d*, splenic sinuses in neighbouring living tissue; *e*, a trabecula. (× 40 diams.)

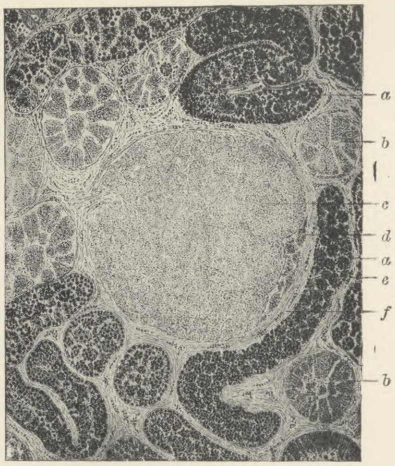

FIG. 12.—Catarrhal Nephritis, showing fatty degeneration of epithelium of the tubes of the kidney. *a*, *a*, Convoluted tubes filled with fatty epithelium; *b*, *b*, convoluted tubes with epithelium still in stage of cloudy swelling; *c*, glomerulus very swollen, granular, and probably œdematous; *d*, a few catarrhal cells in the intracapsular space; *e*, spindle-shaped lymph-spaces in interstitial tissue filled with oil globules; *f*, same in Bowman's capsule. (× 350 diams., stained with perosmic acid.)

FIG. 11.—Pyæmic Abscess of Lung. *a*, Walls of alveoli; *b*, effused small cells; *c*, fibrin lying in alveolar cavities; *d*, cell entangled in meshes of same; *e*, *e*, *e*, masses of micrococcus (staphylococcus) lying in the exudation; *f*, effused cell becoming fatty. (× 350 diams.)

FIG. 13.—Fatty Degeneration of Nerve-fibres of Phrenic Nerve in Diphtheria (Meyer).

PLATE V.

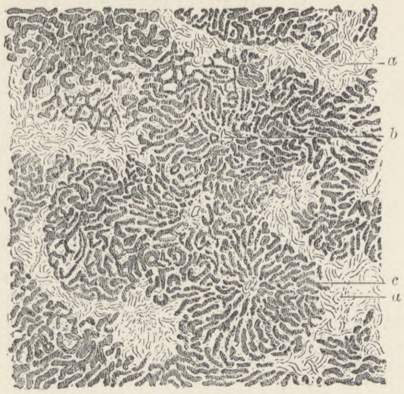

FIG. 14.—Atrophy of Liver from Valvular Disease of Heart. *a*, *a*, Distended capillaries of hepatic vein with entire disappearance of liver-cells from atrophy; *b*, branch of portal vein; *c*, liver-cells still left in portal vein area. (× 60 diams.)

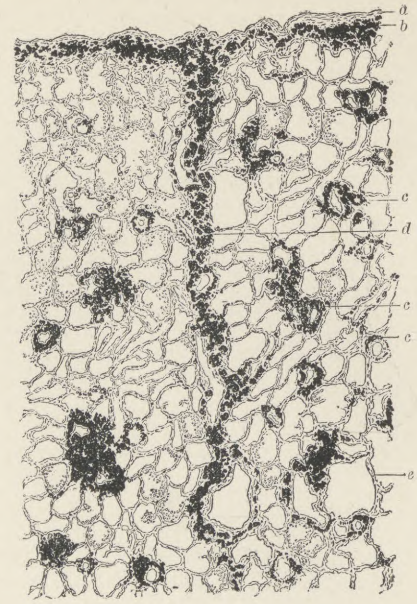
FIG. 15.—Anthracosis. *a*, Superficial layer of pleura free from pigment; *b*, deep layer much infiltrated by it; *c*, *c*, *c*, accumulations of pigment round branches of pulmonary artery; *d*, interlobular septum, much pigmented; *e*, alveolar walls. (× 20 diams.)



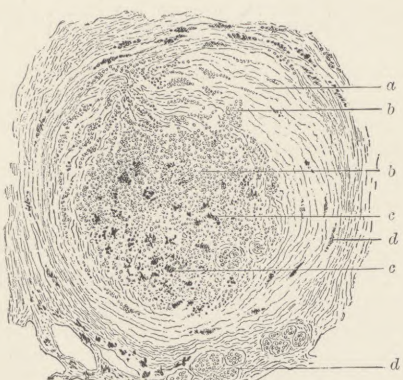


FIG. 16.—Lithosis or Stone-mason's Disease. Section through a nodule in the lung. *a*, Concentric fibrous tissue of the nodule; *b*, *b*, stone particles; *c*, *c*, soot particles mixed with those from stone; *d*, *d*, soot particles at periphery of nodule. (× 300 diams.)

FIG. 17.—Healing by First Intention. Cicatrix ten days old, Linea alba, ovariotomy. *a*, Neighbouring epidermis; *b*, corium continuous with cicatrix (*e*); *c*, *c*, neighbouring tissues; *d*, united epidermis; *f*, portion of same included in cicatrix; *g*, fat-cells in side of wound. (× 50 diams.)

FIG. 18.—Healing by Second Intention. Perpendicular section through edge of healthy granulating wound, old ulcer of leg. *a*, The discharge; *b*, the bluish-pink pellicle of young epidermis; *c*, older epidermis; *d*, granulation-tissue; *e*, injected blood-vessels; *f*, deep organizing layer beneath cicatrix; f_1, same beneath granulations. (× 50 diams.)

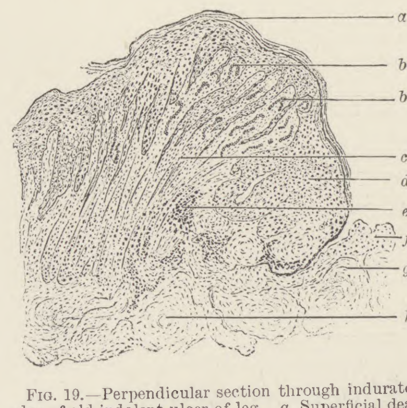

FIG. 19.—Perpendicular section through indurated edge of old indolent ulcer of leg. *a*, Superficial dead epidermis; *b*, *b*, granulation-loops; *c*, half-organized granulation-tissue beneath the edge; *d*, accumulated mass of epidermis; *e*, pigment from blood-extravasation; *f*, abortive granulation-surface; *g*, divided fibrous tissues of the leg forming practically the floor of the ulcer; *h*, small artery. (× 40 diams.)

attributes of a hypertrophied part. Hypertrophy in the scientific sense of the term may be defined as *a condition of parts where the normal bulk of an organ or other tissue is augmented universally by an additional number or by increased dimensions of its tissue elements.*

In order that the overgrowth of an organ may come under the designation of "hypertrophy," the enlargement must be universal; a local increase of its tissue is known as a *neoplasm* (myoma, adenoma). When epidermis is overworked by having to withstand intermittent pressure, as in the use of tools in various avocations, it certainly hypertrophies. The pressure, as probably is the case in all overwork causing hypertrophy, must be intermittent; continuous pressure on any part induces atrophy. Glands, however, do not seem to suffer hypertrophy when overworked. On the contrary, they tend rather to degenerate. There is no evidence to show that the liver, the pancreas, or a salivary gland ever becomes hypertrophied from having increased strain put upon it; the first response of the liver to such strain is derangement of structure and function. The compensatory enlargement of the kidney, when that on the opposite side is removed experimentally or by disease, is often quoted as evidence of a gland becoming hypertrophied from overwork. The enlargement here, however, is something quite different from what occurs in muscle or epidermis: it is apparently unaccompanied by increase in true gland tissue, and is accounted for by distension of blood-vessels and lymphatics.

(4) *Continuous Over-pressure.*—The tissues of an animal or plant are all under a certain pressure, caused, in the one case, by the expulsive action of the heart and the restraint of the skin and other elastic tissues, and, in the other case, by the force of the rising sap and the restraint of the periderm or bark. Under this normal amount of pressure they can live and grow. But whenever, from any cause, the degree of pressure which they are naturally intended to withstand is surpassed, they fail to nourish themselves, become granular, die, and, falling to pieces, are absorbed. This is what we see in a typically atrophic part such as a cirrhotic kidney, a muscle withered by the pressure of a contracting cicatrix, or a tissue like that of the liver (Fig. 14, Plate V.) subjected to unduly great pressure from distension of its own capillaries (cyanotic atrophy).

Here again it is necessary to define in strict terms what is meant by "atrophy," for as mere enlargement of an organ does not necessarily signify that it is hypertrophied, so diminution in size does not necessarily imply that it is in a state of atrophy; atrophied organs, as previously remarked, are sometimes much enlarged. *Atrophy is the diminution in size or partial destruction of a part which results from direct and continuous over-pressure where the blood-supply is not deficient.* The pressure must be continuous, otherwise the part may become hypertrophied. Intermittent pressure exerted upon the epidermis causes it to hypertrophy, while continuous pressure, such as that of a badly-applied splint, will induce atrophy. The soft texture of an aneurysmal sac will cause atrophy of a hard texture, such as bone, so long as the pressure it exerts is continuous; and the over-pressure of the hepatic capillaries in regurgitant valvular disease of the heart will induce the most typical atrophy of the liver cells lying between them. Atrophic organs usually contain abundant blood-vessels; the arteries of a cirrhotic liver are relatively more abundant than in health, and in the case of the atrophy of the liver resulting from regurgitant valvular disease the compressing agent is the blood itself. Hence the degeneration from which the tissue suffers cannot be due to deficient blood-supply, but, apparently, is consequent upon failure in the tissue cells to assimilate the nourishment supplied to them on account of the over-pressure to which they are subjected. This is borne out by the actual degeneration from which the tissue suffers. We have seen that when a tissue is undernourished it begins to suffer from fatty degeneration. This is not the form of degeneration found in truly atrophic parts: the cell simply shrinks, falls to pieces, and is removed, without necessarily any fatty matter resulting from the breaking down of its protoplasm. Atrophy is a true and distinct form of degeneration, as distinct as any of the other forms of degeneration to which tissues are liable.

(5) *Deleterious Surroundings.*—There can be little doubt that all unnatural and artificial modes of life tend to deterioration of the powers of resistance of the organism to disease. We see it exemplified in plant life in circumstances which are unnatural to the life of the plant, and the prevalence of certain constitutional tendencies among the inhabitants of crowded cities bears evidence to the same law. Man, like other animals, was naturally intended to lead an outdoor life. He was originally a hunter and a tiller of the ground, breathing a pure atmosphere, living on a frugal diet, and exercising his muscles. Whenever these conditions are infringed, his powers of resistance to disease are lessened, and certain tendencies begin to show themselves, which are generally termed constitutional. Thus the liability to tubercular infection is far commoner in the midst of a depraved population than in one fulfilling the primary laws of Nature; rickets is a disease of great cities rather than of rural districts; and syphilis is more disastrous and protracted in its course in the depraved in health than in the robust. Cattle kept within-doors are in a large proportion of cases tubercular, while those leading an outdoor life are much less liable to infection. The improvement which has taken place in the general health of the inhabitants of cities during recent years, concurrent with hygienic legislation, is ample proof of the above assertions. The diminution in the number of deaths from tuberculosis during the last forty to fifty years of the 19th century of itself points in this direction. Every living organism, animal and vegetable, tends to maintain a normal state of health; it is when the natural laws of health are violated that the liability to disease begins to assert itself. If, in these circumstances, the food supply be also insufficient, the combination of influences is sure, in course of time, to bring about a physical deterioration of the race. Certain avocations have a direct and immediate influence in causing diseased states of body. Thus workers in lead suffer from the effects of this substance as a poison, those who work in phosphorus are liable to necrosis of bone and fatty degeneration of the blood-vessels and organs, and the many occupations in which dust is inhaled (coal-mining, stone-dressing, steel-polishing, &c.; Figs. 15 and 16, Plate V.) are fraught with the greatest danger, owing to the destructive influence exerted upon the lungs by the inhaled particles. Among the most dangerous of the last class (the pneumokonioses) is perhaps that in which the dust particles take the form of finely-divided freestone, as in stone-dressing and the dry-polishing on the grindstone of steel. The particles in this case set up a form of fibrosis of the lung, which, either of itself or by rendering the organ liable to tubercular infection, is extremely fatal. The abuse of alcohol may also be mentioned here as a factor in the production of disease.

(6) *Parasitism.*—Of all external agents acting for evil, however, probably vegetable and animal micro-organisms with a pathological bent are most to be feared. The subject is considered *in extenso* under PARASITIC DISEASES, and the reader is referred to that section of this subject for specific information. When we consider that tuberculosis, diphtheria, cholera, tetanus, typhoid fever, anthrax, malaria, and a host of other contagious diseases have each been proved to be of parasitical origin, an idea may be conveyed of the range of the subject. The living organism may be regarded as constantly engaged in a warfare with these silent and apparently insignificant messengers of destruction and death, with the result that too often the battle ends in favour of the attacking enemy.

(7) *Heredity.*—The *tendencies* to disease are in great part hereditary. They probably express a variation which may have occurred in a far-back ancestor, or in one more recent, and render the individual vulnerable to the attacks of parasitic fungi, or, it may be, become manifest as errors of metabolism. The psychopathic, the tubercular, the rickety, and the gouty constitution may all be transmitted through a line of ascendants, and only require the necessary exciting agents to render them apparent. A distinction must be drawn between the above and diseases, like syphilis and small-pox, in which the contagion of, not the tendency to, the disease is transmitted directly to the fœtus *in utero* (see HEREDITY).

THE CELLULAR DOCTRINE IN PATHOLOGY.

The cellular pathology is the pathology of to-day; indeed, protoplasm—its vital characteristics under abnormal influences and its decay—will be regarded most likely as the basis of pathology in all time. Its history dates back to Virchow's great discovery. When Virchow wrote, in 1850, "every animal presents itself as a sum of vital unities, every one of which manifests all the characteristics of life," he expressed a doctrine whose sway since then has practically been uninterrupted. The somatic cells represent communities or republics, as it were, which we name organs and tissues, but each cell possesses a certain autonomy and independence of action, and exhibits phenomena which are indicative of vitality.

Still, it must be borne in mind that this alleged autonomy of action is said to be founded upon an erroneous supposition, on the supposition that each cell is structurally, and, it may be said, functionally, separated from those in its neighbourhood. It is well known that in the vegetable kingdom the protoplasm of one cell frequently overflows into that of cells adjacent—that there is, as it were, a continuous network of protoplasm (idioplasm of Nägeli) prevailing throughout vegetable tissues, rather than an aggregation of isolated units. The same intercommunication prevails between adjacent cells in some animal tissues, and more particularly in those which are pathological, as in the case of the epithelial cells of cancer. Assuming, with Sedgwick and others, this amassed and bound condition of the tissues to be true, it would be necessary to reject the cell-doctrine in pathology altogether, and to regard the living basis of the organism as a continuous substance whose parts are incapable of living independently of the whole. Until, however, further evidence is forthcoming in support of this syncytial theory of structure, it would be unwise to regard it as established sufficiently to constitute a serviceable working hypothesis; hence, for the time being, we must accept the assertion that the cell represents the ultimate tissue-unit.

The only definition of a cell permissible at the present day is that of *a nucleated mass of protoplasm*. The cells met with in morbid parts which are in a state of active vitality are built up of the same components as those found in normal tissues (Plate I.[1]). Thus they are provided with a nucleus in the midst of which are chromosomes, true nucleoli (plasmosomes), and netknots (karyosomes). Inside the nucleolus there may be a second body known as the nucleoluolus (Auerbach). Within the cytoplasm are the granular bodies known as microsomes, and, either lying within the nucleus or at one side of it, is the centrosome, which, during mitotic division, splits into two, each half becoming surrounded by an attraction-sphere (astrosphere) defining the polar limits of the achromatic amphiaster.

Structure of pathological cells.

Some pathological cells, such as the giant-cells of tumours, of bone, and those of tubercle, are polynucleated; in some instances they may contain as many as thirty or more nuclei. The only evidence we have in pathology of living structures in which apparently a differentiation into cell-body and nucleus does not exist, is in the case of bacteria, but then there comes the question whether they may not possess chromatin distributed through their substance, in the form of metachromatic points, as is the case in some infusoria (Trachelocerca, Gruber).

The nucleoli of pathological growths (*e.g.*, sarcomata) sometimes vary in shape. They are mostly round, but elliptical, elongated, and nail-shaped forms may be met with. They usually stain with acid aniline dyes, but occasionally lose this property and become sensitive to those which are basic, a transformation which probably indicates a retrograde or degenerate state (Trambusti). They may be located either at the centre or at the periphery of the nucleus. As a rule they vanish during indirect division. Under the title of "Slumber cells," Grawitz drew attention to certain cells which he supposes to exist in connective tissues, and which are invisible even with refined methods of histological demonstration. They come into view only when the connective tissue is stimulated, and he affirms that the cell-material found in the regeneration of tendons, &c., is derived partly from this source. Ehrlich described certain cells of the leucocyte type which are found in normal, and particularly in pathological, circumstances in the blood and connective tissues, and which he names "Mastzellen." The granules within them are large and are basophil in reaction. They are present in considerable numbers in the blood of leucocythæmia. They have also been found by Westphal in chronic inflammatory conditions of connective tissue, and in cancers, and he supposes that they are simply connective-tissue cells altered by abnormal conditions of nutrition. Under the title of "Plasma-cells" Unna drew attention to certain peculiar bodies found in lupus, in various skin affections, and in granulations. They are cells of round, oval, polygonal, or elongated shape, whose protoplasm is usually free from granules, and stains intensely with methylene-blue. The nucleus is placed excentrically, contains several large chromatin granules, and is surrounded by a clear area. Krompecher traces the most of them to lymphocytes, some to polymorphous-nucleated leucocytes, but states that they may become transformed into connective-tissue cells.

Although the methods of cell-division prevailing in normal structures are maintained generally in those which are pathological, yet certain modifications of these methods are more noticeable in the latter than in the former. Thus in the neoplasmata direct cell-division is more the rule than in healthy parts. In actively-growing neoplasmata, certainly, the indirect method prevails largely, but seems to go on side by side with the direct.

A curious and interesting modification of the indirect method, known as "asymmetrical division," occurs frequently in epitheliomata, sarcomata, &c. (Hansemann). It consists in an unequal number of chromosomes passing over to each of the daughter nuclei, so that one may become hypochromatic, the other hyperchromatic. When this happens, the resulting cleavage of the cytoplasm and nucleus is also unequal. Several explanations have been given of the meaning of these irregularly chromatic cells, but that which most lends itself to the facts of the case seems to be that they represent a condition of abnormal karyorhexis.

In many pathological cells undergoing indirect segmentation, centrosomes appear to be absent, or at any rate do not manifest themselves at the poles of the achromatic spindle. When they are present, that at one end of the spindle may be unusually large, the other of natural size, and they may vary in shape. In pathological cell-division it happens occasionally that the segmentation of the cytoplasm is delayed beyond that of the mitotic network. The daughter nuclei may have arrived at the anaphase stage, and have even gone the length of forming a nuclear membrane, without any equatorial depression having shown itself in the cell-body. Sometimes the equatorial depression fails entirely, and the separation, as in some vegetable cells, takes place through the construction of a cell-plate. Intranuclear plexuses are not usually found in giant-cells, but have been described in the giant-cells of sarcomata by Klebs and Hansemann, and in those of tubercle by Baumgarten. Some of the nuclei within multinucleated cells may occasionally be engaged in mitotic division, the others being in the resting state.

In the earlier accepted notion of direct segmentation, usually known as the schema of Remak, division was described as commencing in the nucleolus, as thereafter spreading to the nucleus, and as ultimately implicating the cell-substance. Trambusti,

[1] DESCRIPTION OF PLATE I.

SERIES OF FIGURES ILLUSTRATIVE OF IRREGULAR DIVISION OF CELLS.

Figs. A to F are from the epithelial cells of a cancer of the mamma. (After Galeotti.)

,, *G to W are from a sarcoma. (After Trambusti.)*

FIG. A.—Resting epithelial cell.
,, B.—Asymmetrical dyaster.
,, C.—Tripolar division in which the splitting of the loops has commenced.
,, D.—Tetrapolar karyokinesis.
,, E.—Another form of tetrapolar division.
,, F.—Cell in a state of degeneration and chromatolysis; the large rounded body in the cell is a cancer parasite.
,, G.—Polynucleated cell with nuclei of normal size arising from multiple karyokinetic division.
,, H.—Pigmented cell with resting nucleus. The attraction-sphere and centrosome lie in the cytoplasma in the neighbourhood of the nucleus.
,, I.—Hypertrophic nucleolus.
,, K.—Large cell with a single nucleus; nucleoli in a state of degeneration.
,, L.—Multinucleated giant-cell, the nuclei small and produced amitotically.
,, M.—Karyokinetic figure, the one centrosome much larger than the other.
,, N.—Cell in process of karyokinetic division with retention of the nucleolus during division.
,, O.—Division of the nucleolus and formation of nuclear plate. The nucleolus is elongated, and its longest measurement lies in the direction of the equatorial plane of the nucleus.
,, P.—Division of the nucleolus by elongation, constriction, and equilateral division of the nucleus.
,, Q.—Division of the nucleolus without any evidence of division of the nucleus.
,, R.—Nucleus with many nucleoli.
,, S.—Direct division of nucleus.
,, T.—Multiple direct division of the nucleus.
,, V.—Nail-like nucleolus.
,, W.—Fragmentation of the nucleus.

curiously, finds confirmatory evidence of this in the division of cells in sarcoma. Contrary, however, to the experience of others, he has never found that the attraction-spheres play an important part in direct cell-division, or, indeed, that they exert any influence whatever upon the mechanism of the process. Where pigment was present within the cells (sarcoma), the attraction-spheres were represented by quite clear unpigmented areas, sometimes with a centrosome in their midst.

Repair of Injuries.

Healing by First Intention.—After a linear incision has been made with a sharp knife into the young stem of a plant, and the severed edges of the wound brought together by the application of pressure, the few cells which are actually cut through by the instrument in making the incision die and are removed, a number of cells just sufficient to fill the gap is generated from cells of a like nature on each surface of the wound, and the wound heals by their coalescence among themselves and with those on the immediate surface of the severed tissues (Shattock). After a like incision has been made into an animal tissue, if the wound be kept free from organismal contamination and the surfaces placed in accurate contact by pressure, without blood-clot or excess of lymph intervening, exactly the same method of healing is pursued in closing the breach of continuity. Those cells which have been injured by the knife die and are absorbed, and a few new cells, springing from the adjacent white fibrous tissues, organize and become interwoven with the parts on each side. New epidermic cells thrown off from the old soon cover the young cicatrix, and in course of time develop a horny layer (Fig. 17, Plate V.). In each of these instances of healing, the one from the animal, the other from the vegetable kingdom, it is only the tissues lying in the immediate proximity of the wound which are stimulated to growth; those at even a short distance from the wound remain uninfluenced, and consequently in each case the cicatrix is extremely fine—so fine, indeed, as to be scarcely visible even with the aid of the microscope. The above is the simplest means of healing, and is the type upon which all repair of wounded parts is effected; it is, as will be observed, simply a method of growth, in which, as in all natural growth, each new tissue element of the cicatrix is reproduced from its like in the pre-existing parts. Any other appearances met with in the healing of an injury are epiphenomena, and bear witness to an interruption in the natural course of events. In the case of the vegetable organism, it is mainly the deep cambium layer from which the reparative parenchyma is derived for the closure of the vacuity, while the cork cambium on the surface renews the protective covering; in that of the animal organism, it is chiefly the white fibrous tissue which furnishes the bond of union, while the epidermis generated from pre-existing epidermis grows over this as its natural investment.

White fibrous tissue and epidermis have more power of regenerating than any other tissues in the adult body. Separately, or conjointly, they represent the materials out of which all cicatrices and all fibrous new formations are constructed. In like manner, the cambium layer in plants is the tissue of reaction. The wood of the tree has little power of regeneration, being composed mostly of cells which are dead or whose segmental capacity is exhausted. The few living cells it contains may be stimulated to activity, say, in grafting, where the cut surfaces of scion and stock are brought into intimate contact, and its exposed vessels may become occluded by the ingrowth of tyloses, but otherwise it shows little evidence of reaction under the influence of a stimulus.

Healing by Second Intention.—Should the wound of the plant be larger than in the case we have supposed, and should the margins of the cambium layer remain widely apart, as where, for instance, a branch of a tree has been lopped off, numbers of complications arise, for here the floor of the wound is composed mainly of wood and pith—tissues, as we have just seen, having a low power of reaction. The cambium margins are thus separated by a space whose floor is composed of material in great part useless in the effort at repair, while the absence of any lasting protective covering exposes the wound to excessive damp and the ravages of parasites.

Nature, so far, tends to protect such a surface artificially by the exudation of gum, resin, turpentine, &c., but this can be of only temporary efficacy, seeing that many of these large wounds of trees take years to heal. The healing is accomplished by the gradual encroachment of new tissue derived from the cambium at the margin. A cushion-like pad of callus, composed of cells traceable to those of the cambium, rises up at the circumference and gradually invests the exposed wood. If the exposed wood be surmounted by dead tissue, this may become encapsuled by the encroaching callus, very much as a piece of dead bone may become encysted in the tissues of a living animal. The wound, after a time, comes to resemble very closely an indolent ulcer in man. The floor is covered by dead or dying unorganizable materials, without any layer of regenerative cells, and over this naturally the reparative callus at the margin runs with difficulty, so that it tends to accumulate in a pad-like ring around the gap. In the case of the indolent ulcer this pad of callus is represented by the indurated and elevated edge (Fig. 19, Plate V.). The floor of such a wound is devoid of any layer of young growing cicatrix elements; the tendons and fasciæ of underlying parts may be exposed on it, and the surfaces of these may be dead or dying. Over such a surface the epithelium will not spread, and as a result accumulates with other (connective tissue) reparative material at the margin, thus giving rise to the pad-like indurated edge. It is not until, under appropriate treatment, such a surface becomes invested with embryonic connective tissue, and is provided with just sufficient vascularity to aid in repair, that the wound will close. When this happens, the epidermis spreads over the young connective tissue layer covering the floor, and reassumes its original vocation as a protective investment. The elevation and induration of the margin of the wound, which, as just said, are caused in great part by accumulated epidermis, vanish as a consequence, and the wound assumes a more uniform level (Fig. 18, Plate V.).

Where a large gap is made in an animal tissue, as, say, by an injury, and where the skin and subcutaneous areolar tissue have been removed, the exposed surface is liable to the same vicissitudes as in the like case in a plant. The floor may be constituted, in great measure, of tissues of low vital reaction, such as muscle; the epithelial margins are widely apart; and now that the surface is broken and the underlying vulnerable tissues and liquids are exposed, these become a prey to destructive vegetable parasites. The wound may be covered with lymph or blood-clot, but neither of these has much power of resisting germ invasion, and both are evanescent substances, incapable of generating cicatrix. Hence they can serve only a temporary and ephemeral purpose in protecting the exposed surface, and when they lie in any quantity within a wound they rather hinder than aid its healing. They must be removed before the true cicatrix-forming elements of the tissues can come into play.

Like all porous substances (sponge, elder-pith, &c.; Fig. 21, Plate VI.), the clot may act as a framework or mould in which the future cicatrix is cast (Fig. 20, Plate VI.), that is to say, its porosities may be penetrated by connective tissue and blood-vessels, and it may thus aid in the healing of the part; but of itself it has absolutely no more power of generating tissue than coagulated white-of-egg, which it closely resembles in composition. When blood-clot or other extraneous substance has complicated and retarded the natural course of events, the resulting cicatrix is unnecessarily abundant: what ensues is an avowal on Nature's part of a certain clumsiness of procedure; it is not instinct of her best effort.

Granulations.

Such gaping wounds tend to granulate, and the granulations are often regarded as a provision for aiding in organization (Fig. 18, Plate V.). This notion is diametrically opposed to all the facts of pathology bearing upon the matter. A certain amount of vascularity is of course necessary for organization, but anything in excess of what is absolutely necessary in all circumstances tends to favour disorganization rather than to aid organization. The parts which heal quickest in the animal body are those in which blood-vessels are either absent (cornea), or in which they are sparsely distributed (linea alba of abdomen). Indeed, the advent of granulation loops, as Hamilton has sought to demonstrate, is probably an accident of the part, conditional upon its surface restraint having been removed, and usually, when at all exuberant, such granulations are the chief means of retarding organization. In the healing of exposed wounds in plants, there is nothing exactly corresponding to the granulating surface in animals. The vessels are not driven out on the surface, possibly because they are more rigidly bound to their surroundings than the animal vessels are. Still the means by which vegetable callus is formed presents certain analogies. It begins in the soft bast and in the embryonic tissue lying along the edge of the wound, namely, the cambium. According to Hartig, the initiation of this callus-production is at first purely mechanical, and is consequent upon the pressure exerted naturally on the subjacent parts being reduced. In normal circumstances there is always a certain amount of tension in the cortical mantle, whereby a considerable pressure is exerted upon the cambium. Should this pressure be lessened by a wound reaching to the wood, cell-division within the cambium is accelerated not only along the edges of the wound, but for some distance around. This cell-division proceeds most energetically in the direction of the surface of the wound, where, of course, the restraining counter-pressure is least. Masses of new callus can be seen protruding from between cortex and wood, in these circumstances, quite comparable to the luxuriant cell-tissue of granulations. The plan of healing by granulation, or, rather, in spite of granulation, is essentially alike with that known as healing by first intention, and both are really extensions of natural growth.

Fibrosis.—Where a chronic inflammatory process has taken possession of an organ, or, let us say, has been located in periosteum or other fibrous part, there is a great tendency to the production of cicatricial fibrous tissue in mass. Thus it is laid down in large quantity in cirrhosis of the liver (Fig. 22, Plate VI.), kidney, or lung, and reacts upon these organs by contracting and inducing atrophy. The term "cirrhosis" or "fibrosis" is usually applied to such a condition of organs; that of "sclerosis" is used when such a deposition of fibrous tissue occurs within the central nervous system (Fig. 23, Plate VI.). Gull and Sutton asserted that in particular states of body, and more especially in the condition associated with cirrhotic kidney, such a fibrosis becomes general, running, as they alleged it does, along the adventitia of arteries and spreading to their capillaries. They supposed that it was accompanied by a peculiar hyaline thickening of the arterial wall, usually of the tunica intima, and hence they termed the supposed diseased state "arterio-capillary fibrosis," and gave the fibrous substance the name "hyaline-fibroid." They held that the cirrhotic kidney is simply a local manifestation of a general fibrous disease. Their theory, however, has fallen into disfavour of late years.

Ætiology of Malignant Neoplasms.

Cancer. For long it has been suspected that malignant tumours are contagious, and that the contagion depends upon a micro-parasite. Cases of the supposed transference of cancer from one individual to another have been put on record from time to time, and it has been alleged that sarcoma has been successfully transplanted into the tissues of animals of the same species. Most of the cancer experiments, however, in this direction have proved negative. Still, the parasitical theory has gained a strong hold on the minds of pathologists, and has been reinforced by the discovery of bodies in cancer tumours which are not only alleged to be parasitical, but, it is asserted, are capable of communicating cancer afresh to suitable hosts. The bodies in question (Fig. F, Plate I.) for the most part inhabit the cytoplasm of the epithelial cells, but are also found in the nucleus. They are discovered in greatest abundance in the actively-growing parts of the tumour, and in these regions are present sometimes in almost every individual cell, and occasionally in great numbers in a single cell. In their youngest state they appear to be rounded bodies which are refractile and stain differentially with certain reagents such as Biondi's fluid. Later, they develop a double-contoured capsule with clear contents and a body which is generally called a nucleus. A peculiar radiate arrangement of their substance is noticed occasionally in hardened preparations. Plimmer stated that he had cultivated them artificially, and that on inoculation he produced an eruption of tumours having an endothelial structure. They have been referred to the protozoa (Metchnikoff), but Plimmer looks upon them rather as being related to the saccharomycetes.

Russell's fuchsin-bodies are peculiar structures—round, homogeneous, and refractile—which occur in various kinds of neoplasm. They range in size from about that of a coloured blood-corpuscle up to six, eight, or more times as large. They probably have no ætiologial relationship to the tumours in which they occur, although Russell supposed that they were the infective agents in cancer. They have variously been supposed to be protozoa, degenerated blood-corpuscles, yeast-cells, &c. None of these theories has been conclusively established.

Secondary cancer tumours present the same variety of epithelium as that which prevails in the primary tumour. Hence it is in a manner proved that, whatever the actual agency at work in their production, a transportation of the epithelial element of the tumour must take place, and that it is from this as a nucleus that the secondary tumour springs. That cells and actual fragments of an organ can be transported by the blood-vessels into the lung, has been demonstrated by Turner, Jürgens, Lubarsch, Maximoff, and others; and there is every reason to believe, from collateral observations on the production of metastatic tumours by Zahn and Ernst, that, in the case of the neoplasms, individual cells and small portions of the primary tumour are carried along in the blood-current and give rise to an auto-infection of distant parts. It is curious, in view of this, that there should be such difficulty in reproducing the tumour by transplantation into a fresh host.

Pathological Tissue Products.

Colloid.—This term is usually applied to a semi-solid substance of homogeneous and gelatinous consistence formed in certain pathological circumstances. It results from a degeneration of cellular structures, and more particularly of those of an epithelial type. Hence cancer tumours, especially those of the stomach and intestine, are liable to give rise to it, and the cysts in ovarian adenomata usually contain a ropy gelatinous substance which falls under this designation. In various diseases of the kidney there is often found within the urinary tubules a hyaline structureless substance in the form of a tube-cast, which, in certain instances at least, is to be reckoned as a degeneration of the epithelium, and as of the nature of colloid. The catarrhal cells in certain varieties of tubercular pneumonia are sometimes destroyed by colloid degeneration. Colloid degeneration of cancerous tumours appears to implicate exclusively the epithelial cells of the tumour (Fig. 24, Plate VI.). The stroma of the tumour remains unaffected, and lies dissected out in the surrounding homogeneous glassy substance.

Within the thyroid vesicles there accumulates a homogeneous and gelatinous product which often goes by the name of "colloid." The usual idea of its origin is that it is secreted by the thyroid. Notkin, however, takes a different view of the matter. He names the substance in question thyro-proteid, and looks upon it as an excrementitious substance formed in the tissues and merely removed from the blood by the thyroid. When the thyroid is destroyed in myxœdema, or when it is removed artificially in a healthy animal, this substance, thyro-proteid, accumulates in the soft tissues and occasions a characteristic swelling. He looks upon the substance as quite different from mucoid. As regards the composition of colloid found in other situations, it appears to vary—to be, in fact, a mixture of albuminoid substances. Scherer found a peculiar albumen-like constituent in the ropy viscid fluid from an ovarian cyst, to which he gave the name of *paralbumin*.

Mucoid.—By this is understood a gelatinous substance something like the foregoing in its physical characters, but differing from it in the fact of its being a substance of connective tissue origin, and in containing a large

percentage of mucin. Mucin is either absent from true colloid, or is present only in small quantity. Mucoid is met with in pathology chiefly as a constituent of connective tissue tumours—myxo-sarcomata (Fig. 25, Plate VI.), myxo-lipomata, fibromata, enchondromata, &c. The substance is either quite homogeneous and structureless, or is faintly stringy. The cells of the tumour lie embedded in it, and begin to throw out processes in all directions, which by anastomosing constitute a network. The processes are said by Kickhefel to constitute a system of plasma canals. The mucoid appears to result from a partial liquefaction of the fibrous stroma of the tumour, such as that contained in the adventitia of blood-vessels, partly also from a mucoid transformation of the bodies of the cells of the growth (Kickhefel). It may be mentioned that some holothurians have the remarkable property of converting their tough, brown, leather-like skin into mucoid within a few hours, on their being brought into air. The whole skin may undergo this viscous transformation.

Hyaloid.—The hyaloid degeneration seems to be closely related to the mucoid, and affects chiefly lymphatic glands (Wieger and Schüppel), the vessels and neuroglia of the brain (Arndt), and the stroma of epithelial tumours (Malassez). The part becomes infiltrated with a transparent homogeneous substance—particularly within and around blood-vessels—which does not give the reactions of amyloid, and does not exhibit the histological characters of the mucoid degeneration. It differs from the colloid in being a degeneration chiefly of fibrous tissues. In the brain-cortex it sometimes gives rise to deposits of a cartilage-like lustre and consistence.

Amyloid.—The wax-like or amyloid substance has a certain resemblance to the colloid, mucoid, and hyaloid. It has a firm gelatinous consistence and wax-like lustre, and microscopically is found to be homogeneous and structureless, with a translucency like that of ground-glass. The name "amyloid" was applied to it by Virchow on account of the blue reaction which it gives occasionally with iodine and sulphuric acid, resembling that given with vegetable cellulose. It is now known to have nothing in common with vegetable cellulose, but is regarded as one of the many albuminoid substances existing in the body under pathological conditions. Its percentage composition, according to Friedreich and Kekule, is C53–6, H7·0, N15·0, and O and S24·4. It is quite insoluble in water, resists putrefaction, and is not acted upon by pepsin- or trypsin-ferment in solution at a body-temperature. This last circumstance has been taken advantage of in the isolation of the substance in a pure condition. Unlike the colloid, it appears always to take on the character of a true infiltrate. The albumen (possibly serum-albumen), of which it is a derivative, is most likely poured into the affected organ in a soluble form, and subsequently becomes insoluble. There appears, however, to be a preamyloid stage, or several of them, leading up to the construction of the completely developed amyloid, in which the substance does not give the diagnostic colour reactions. These colour reactions are forthcoming only in the fully formed amyloid, and are as follows: (1) Watery solution of iodine imparts to it a deep mahogany brown colour; (2) iodine and sulphuric acid give occasionally, but not always, an azure-blue colour; (3) methyl-violet imparts to it a brilliant rose-pink; (4) methyl-green gives a reaction very much like that of methyl-violet, but not so vivid. The reaction with iodine is seen best with direct light, the reactions with the other substances are visible only with transmitted light. Chitin gives a brown reaction with iodine, and a violet, or blue, with iodine and sulphuric acid; methyl-violet stains it violet-red, but methyl-green has no effect upon it. In view of these positive staining reactions, Krawkow supposed that amyloid is chitinous in its nature, a combination of an albuminous body with chitin, and might be known consequently as "chitinoid." Oddi has isolated from the amyloid liver a substance which Schmiedeberg had previously obtained from cartilage and named "chondroitinic-sulphuric acid" (Chondroïtinschwefelsaure). It also occurs in bones and elastic tissue, but is not present in the normal human liver. Oddi does not regard it as the essential constituent of amyloid, chiefly because the colour reactions are forthcoming in the residuum after the substance has been removed, while the substance itself does not give these reactions. Quite likely the amyloid may be a combination of the substance with a proteid. The soda combination of the acid as obtained from the nasal cartilage of pigs had the composition $C_{18}H_{25}Na_2NSO_{17}$.

Amyloid develops, in various organs and tissues in connexion with simple chronic abscess, tubercular abscess and other suppurative states of body, and a number of interesting experiments, designed to test the relationship between the condition of suppuration and the production of amyloid, have been made of late years. The animal most suitable for experimenting upon is the fowl, but other animals have been found to react. Thus Krawkow and Nowak, employing the continuous injection subcutaneously of the usual organisms of suppuration, have induced in the fowl the deposition within the tissues of a homogeneous substance giving the colour reactions of true amyloid. When hardened in spirit, however, the greater part of this experimental amyloid in the fowl vanishes, and the reactions are not forthcoming. They were unable to verify any direct connexion between its production and the organism of tubercle. These observations have been verified in the rabbit, mouse, fowl, guinea-pig, and cat by Davidsohn, occasionally in the dog by Lubarsch; and confirmatory observations have also been made made by Czerny and Maximoff. Lubarsch succeeded in inducing it merely by the subcutaneous injection of turpentine, a result which it has been asserted is due to the turpentine exciting an abscess. Nowak, however, found later that he could generate it where the turpentine failed to induce suppuration, and he believes that it may arise quite apart from the influence of the organisms of suppuration, that it is not a biological product of the micro-organisms of disease, and also that it has nothing to do with emaciation.

Amyloid Bodies.—These are peculiar bodies which are found in the prostate, in the central nervous system, in the lung, and in other localities, and which get their name from being very like starch-corpuscles, and from giving certain colour reactions closely resembling those of vegetable cellulose, or even starch itself. They are minute structures having a round or oval shape, concentrically striated, and frequently showing a small nucleus-like body or cavity in their centre. Iodine gives usually a dark brown reaction, sometimes a deep blue; iodine and sulphuric acid almost always call forth an intense deep blue reaction; and methyl-violet usually a brilliant pink, quite resembling that of true amyloid. They are probably a degeneration-product of cells.

Spurious Amyloid.—If a healthy spinal cord be hung up in spirit for a matter of six months or more, a glassy substance develops within it quite like true amyloid. It further resembles true amyloid in giving all its colour reactions. The reaction with methyl-violet, however, differs from that with true amyloid in being evanescent.

Response of Tissues to Stimulation.

A stimulus may be defined as every change of the external agencies acting upon an organism; and if a stimulus come in contact with a body possessing the property of irritability, *i.e.* the capability of reacting to stimuli, the result is stimulation (Verworn). Stimuli comprise chemical, mechanical, thermal, photic, and electrical changes in the environment of the organism. A stimulus may act on all sides and induce a general effect without direction of movement, but in the production of movement in a definite direction the stimulus must be applied unilaterally. Stimuli applied generally, not unilaterally, in most cases induce increased divisibility of the cells of the part.

Thus the poison of various insects induces in plants the cellular new formation known as a gall-nut; a foreign body implanted in a limb may become encysted in a capsule of fibrous tissue; septic matter introduced into the abdomen will cause proliferation of the lining endo(epi)thelium; and placing an animal (salamander, Galeotti) in an ambient medium at a higher temperature than that to which it is accustomed naturally, increases the rapidity of cell-division of its epithelium with augmentation of the number of karyokinetic figures. Hair and some other like structures grow luxuriantly on a part to which there is an excessive flux of blood. Bone (*e.g.*, drill-bones) may develop in a soft tissue with no natural bone-forming tendencies, as a result of interrupted pressure, or a fatty tumour may arise in the midst of the natural subcutaneous fat in the same circumstances.

Among stimuli acting unilaterally, perhaps none has proved more interesting, in late times, than what is known as *Chemotaxis.* By it is meant the property an organism endowed with the power of movement has to move towards or away from a chemical stimulus applied unilaterally, or, at any rate, where it is applied in a more concentrated state on the one side than on the others, and more particularly where the concentration increases gradually in one direction away from the living organism acted upon. Observed originally by Engelmann in bacteria, by Stahl in myxomycetes, and by Pfeffer in ferns, mosses, &c., it has now become recognized as a widespread phenomenon. The influence of the chemical substance is either that of attraction or repulsion, the one being known as positive, the other as negative chemotaxis.

The female organs of certain cryptogams, for instance, exert a positive chemotactic action upon the spermatozoids, and probably, as Pfeffer suggests, the chemical agent which exerts the influence is malic acid. No other substance, at least, with which he experimented had a like effect, and it is possible that in the archegonium which contains the ovum malic acid is present. Massart and Bordet, Leber, Metchnikoff, and others have studied the phenomenon in leucocytes, with the result that while there is evidence of their being positively chemotactic to the toxines of many pathogenic microbes, it is also apparent that they are negatively influenced by such substances as lactic acid.

From a pathological point of view the subject of chemotaxis must be considered along with that of *phagocytosis.* Certain free mobile cells within the body, such as blood-leucocytes, as well as others which are fixed, as for instance the endothelium of the hepatic capillaries, have the property of seizing upon some kinds of particulate matter brought within their reach. Within a quarter of an hour after a quantity of cinnabar has been injected into the blood of the frog, nearly every particle will be found engulfed by the protoplasm of the leucocytes of the circulating blood. Some bacteria, such as those of anthrax (Fig. 26, Plate VI.), are seized upon in the same manner, indeed, very much as small algæ and other particles are incorporated and devoured by amœba. Melanine particles formed in the spleen in malaria, which pass along with the blood through the liver, are appropriated by the endothelial cells of the hepatic capillaries, and are found embedded within their substance. If the particle enveloped by the protoplasm be of an organic nature, such as a bacterium, it undergoes digestion, and ultimately becomes destroyed, and accordingly the term "phagocyte" is now in common use to indicate cells having the above properties. This phagocytal action of certain cells of the body is held by Metchnikoff and his followers to have an important bearing on the pathology of immunity. Phagocytes act as scavengers in ridding the body of noxious particles, and more especially of harmful bacteria.

A further application of the facts of chemotaxis and phagocytosis has been made by Metchnikoff to the case of *Inflammation.* It is well known that many attempts to define the process of inflammation have been made from time to time, all of them more or less unsatisfactory. Among the latest is that of Metchnikoff: "Inflammation generally," he says, "must be regarded as a phagocytic reaction on the part of the organism against irritants. This reaction is carried out by the mobile phagocytes sometimes alone, sometimes with the aid of the vascular phagocytes, or of the nervous system." Given a noxious agent in a tissue, such, let us say, as a localized deposit of certain bacteria, the phagocytes swarm towards the locality where the bacteria have taken up their residence. They surround individual bacteria, absorb them into their substance, and ultimately destroy them by digestion. The phagocytes are attracted from the blood-vessels and elsewhere towards the noxious focus by the chemotaxis exerted upon them by the toxines secreted by the bacteria contained within it. The chemotaxis in this instance is positive, but the toxines from certain other bacteria may act negatively; and such bacteria are fraught with particular danger from the fact that they can spread through the body unopposed by the phagocytes, which may be looked upon as their natural enemies.

Natural Protection against Parasitism.

The living organism is a rich storehouse of the very materials from which parasites, both animal and vegetable, can best derive their nourishment. Some means is necessary, therefore, to protect the one from the encroachments of the other. A plant or animal in perfect health is more resistant to parasitical invasion than one which is ill-nourished and weakly. Of a number of plants growing side by side, those which become infected with moulds are the most weakly, and an animal in low health is more subject to contagious disease than one which is robust. Each organism possesses within itself the means of protection against its parasitical enemies, and these properties are more in evidence when the organism is in perfect health than when it is debilitated.

One chief means employed by Nature in accomplishing this object is the investment of those parts of the organism liable to be attacked with an armour-like covering of epidermis, periderm, bark, &c. The grape is proof against the inroads of the yeast-plant so long as the husk is intact, but on the husk being injured, the yeast-plant finds its way into the interior and sets up vinous fermentation of its sugar. The root of the French vine is attacked by the Phylloxera, but that of the American vine, whose epidermis is thicker, is protected from it. The larch remains free from parasitism so long as its covering is intact, but as soon as this is punctured by insects, or its continuity interfered with by cracks or fissures, the Peziza penetrates, and before long brings about the destruction of the branch. So long as the epidermis of animals remains sound, disease germs may come in contact with it almost with impunity, but immediately on its being fissured, or a larger wound made through it, the underlying parts, the blood and soft tissues, are attacked by them. A very remarkable instance of an acquired means of protecting a wound against parasitical invasion is to be found in *granulations.* Should these remain unbroken, they constitute a natural barrier to the penetration of most pathogenic and other forms of germ-life into the parts beneath. Bacteria of various kinds which alight upon their surfaces begin to fructify in abundance, but are rapidly destroyed as they burrow deeply. This is accomplished by a twofold agency, for while numbers of them are seized upon by the granulation phagocytes, others are broken up and dissolved by the liquid filling the granulation interspaces (Afanassieff). This latter, or histolytic, property is not confined to the liquid of granulations; normal blood-serum possesses it to a certain extent, and under bacterial influence it may become very much exalted. Jürgelünas makes out that when an animal is rendered immune to a particular micro-organism this histolytic property becomes exalted.

Dropsy.

During conditions of health a certain quantity of lymphy liquid is constantly being effused into the tissues and serous cavities of the body, but in the case of the tissues it never accumulates to excess, and in that of the serous cavities it is never more than sufficient to keep them moist. When any excessive accumulation takes place, the condition is known as "hydrops" or "dropsy." A "transudate" is a liquid having a composition resembling that of blood-serum, while the term "exudate" is applied to an effused liquid whose composition approaches that of the blood-plasma in the relationship of its solid and liquid parts, besides in most cases containing numbers of colourless blood-corpuscles. Exudates are poured out under inflammatory conditions, while none of the truly dropsical effusions are of inflammatory origin; and hence the class of exudates, as above defined, may be rejected from the category of liquids we are at present considering. Where the dropsical condition is more or less general, the term "anasarca" is applied to it; if the tissues are infiltrated locally, the term "œdema" is employed; and various names are applied, with a local significance, to dropsies of individual parts or cavities, such as "hydrothorax," "hydroperitoneum" or "ascites," "hydrocephalus," and so on. In "anasarca" the tissues which suffer most are those which are peculiarly lax, such as the lower eyelids, the scrotum, and the backs of the hands and feet. It is invariably the result of some cause acting generally, such as renal disease, valvular defect of the heart, or an impoverished state of the blood; while a mere œdema is usually dependent upon some local obstruction to the return of blood or lymph, or of both, the presence of parasites within the tissue, such as the filaria sanguinis hominis or trichina spiralis, or the poisonous bites of insects. Dropsy of the serous cavities is very commonly merely part of a general anasarca, although occasionally it may be, as in the case of ascites, the sequel to an obstruction in the venous return. Dropsical liquids are usually pale yellow or greenish, limpid, with a saltish taste and alkaline reaction, and a specific gravity ranging from 1005 to 1024. They all contain albumen and throw down a precipitate with heat and nitric acid. None of them, in man, coagulates spontaneously, although they contain fibrinogen. The addition of some of the liquid squeezed out from a blood-clot, of the squeezed blood-clot itself, or of a little blood-serum, is sufficient to throw down a fibrinous coagulum (Buchanan), evidently by these substances supplying the fibrin-ferment. The proteid constituents are very much like those of blood-serum, although they never come up to them in amount (Runeberg). The quantity of proteid matter in a purely dropsical effusion never amounts to that of an inflammatory exudation (Lassar). Certain peculiar substances, probably degenerative products, some of them reducing copper, are occasionally met with. The liquid of ascites sometimes contains chyle in abundance (hydrops lacteus), the escape having taken place from a ruptured receptaculum chyli.

In a given case of anasarca due to a cause acting generally, it will be found that the liquid of the pleural cavity always contains the highest percentage of proteid, that of the peritoneal cavity comes next, that of the cerebral ventricles follows this, and the liquid of the subcutaneous areolar tissue contains the lowest. The reason of this is apparently that the negative pressure of the pleural, and partly of the peritoneal, cavity tends to aspirate a liquid relatively thicker, so to speak, than that effused where no such extraneous mechanism is at work (James).

The subject of the conditions under which dropsical liquids are poured out opens up a very wide question, and one about which there is the greatest diversity of opinion. It turns in part, but in part only, upon the laws regulating the effusion of lymph, and physiologists are by no means at one in their conclusions on this subject. Thus Ludwig was of opinion that the lymph-flow is dependent upon two factors, first, difference in pressure of the blood in the capillaries and the liquid in the plasma spaces outside; and, secondly, chemical interchanges setting up osmotic currents through the vessel-walls. His results, so far, have been confirmed by Starling, who finds that the amount of lymph-flow from the thoracic duct is dependent upon difference in pressure. It varies with the increase of the intracapillary or decrease of the extracapillary pressure, and is also in part regulated by the greater or lesser permeability of the vessel-walls. Heidenhain, on the other hand, rejected entirely the filtration view of lymph-formation, believing that the passage of lymph across the capillary wall is a true secretion brought about by the secretory function of the endothelial plates. Starling does not accept this view, and cannot regard as an article of faith Heidenhain's dictum that normally filtration plays no part in the formation of lymph. Lazarus-Barlow, again, looks upon the pouring out of lymph as evidence of the demands of the tissue-elements for nutrition. An impulse is communicated to the blood-vessels in accordance with this demand, and a greater or smaller outflow is the result. He traces various local dropsies to the starvation from which the tissues are suffering, the liquid accumulating in excess in accordance with the demand for more nourishment. It may be asked, however, whether a dropsical tissue is being held in a high state of nutrition, and whether, on the contrary, the presence of lymph in excess in its interstices does not tend to impair its vitality rather than to lend it support. According to Rogowicz and Heidenhain, certain substances increase the quantity of lymph given off from a part by acting upon the cells of the capillary wall; they hold, in fact, that these substances are true lymphagogues. Heidenhain recognizes two classes, first, such substances as peptone, leech extract, and cray-fish extract; and, secondly, crystalloids such as sugar, salt, &c. Starling sees no reason to believe that members of either class act otherwise than by increasing the pressure in the capillaries or by injuring the endothelial wall. The members of the first class influence the endothelial plates of the capillaries injuriously, inducing thereby increased permeability; those of the second class (sugar, &c.), on injection into the blood, attract water from the tissues and cause a condition of hydræmic plethora with increased capillary pressure. The increased flow of lymph is due to the increased pressure in the abdominal capillaries.

Increased flow of lymph, however, is one thing, the production of dropsy is another. For, even granted that the amount of lymph poured into a part varies with circumstances, there is not the slightest evidence to show, so long as the paths by which it is naturally removed, namely, the lymph, and blood-vessels, remain open and unimpaired, and so long as the composition of the blood remains normal, that the increased liquid tends to accumulate in the part. In fact, even where these paths are partially obstructed, there is great difficulty in rendering the part œdematous. The obstruction in the veins or lymphatics of a limb requires to be widespread in order to call forth any amount of local dropsy. Obstruction of the veins and lymphatics simultaneously is, however, more potent in occasioning such dropsy than any other measure. Feeble or obstructed action of the heart, combined with malcomposition of the blood, probably explains the tendency to dropsy in conditions of anæmia, the poor quality of the blood tending to bring about malnutrition of the capillary endothelium, and the feeble heart being insufficient to drive the lymph onwards. It is a question whether the malcomposition of the blood, in certain forms of renal diseases, may not be one of the main factors in the production of dropsy accompanying these diseases.

Practical Applications.

Medicine and Surgery have never been slow to appropriate and apply the biological facts of Pathology, and at no period have they followed more closely in its wake than during the last quarter of the 19th century. When, for instance, the cause of septic infection had been revealed, the prophylaxis of the disease became a possibility. Seldom has it happened, since the discovery of the law of gravity, that so profound an impression has been made upon the scientific world at large as by the revelation of the part played by germ-life in nature; seldom has any discovery been fraught with such momentous issues in so many spheres of science and industry.

The names of Pasteur and Lister will descend to posterity as those of two of the greatest figures in the annals of medical science, and indeed of science in general, during the 19th century. The whole system of treatment of tubercular disease has been altered by the discovery of the tubercle microphyte. Previously consumptive individuals were carefully excluded from contact with fresh air, and were advised to live in rooms almost hermetically sealed and kept at a high temperature. The treatment of the disease has now gone off in the opposite direction. Sanatoria have started up all over Europe and elsewhere for its treatment on the open-air principle. Individuals suffering from pulmonary phthisis are encouraged to live night and day in the open, and with the best results. The rapid diagnosis of diphtheria, by recognizing its bacillus, has enabled the practitioner of medicine to commence the treatment early, and it has also enabled the medical officer of health to step in and insist on the isolation of affected persons before the disease has had time to spread. The discovery of the parasite of malaria by Laveran, and of the method by which it gains entrance to the human body, through the bite of a particular variety of mosquito, by Manson and Ross, promises much in the way of eradication of the disease in the future. One of the most remarkable practical outcomes of germ-pathology, however, has been the production of the immunized sera now employed so extensively in the treatment of diphtheria and other contagious diseases. By the continuous injections under the skin, in increasing doses, of the toxines of certain pathogenic micro-organisms, such as that of diphtheria, an animal—usually the horse—may be rendered completely refractory to the disease. Its serum in course of time is found to contain something (antitoxine) which has the power of neutralizing the toxine secreted by the organism when parasitical upon the body. This immunity can be transferred to a fresh host (*e.g.*, man) by injecting such serum subcutaneously. In the general summary of the progress of pathology given in the commencement of this article, it was stated that myxœdema is to be traced to destruction of the thyroid gland. The continuous administration of extract of the gland, or of the gland itself *per os*, has been found to remove the symptoms of the disease. The modern system of hygiene is in great part founded upon recent pathology. The recognition of the dangers accompanying the drinking of polluted water or milk, or of those attached to the breathing of a germ-polluted atmosphere, has been the natural sequence of an improved knowledge of pathology in its bacteriological relationships. Skin-grafting and regeneration of bone are among not the least remarkable applications of pathological principles to the combat with disease in recent times; and in this connexion may also be mentioned the daring acts of surgery for the relief of tumours of the brain, rendered practicable by improved methods of localization, as well as operations upon the serous cavities for diseased conditions within them or in their vicinity.

II. PARASITIC DISEASES.

It has long been recognized that various specific pathological conditions are due to the presence and action of parasites in the human body, but since the publication of the ninth edition of this work the part played in the causation of the so-called infective diseases by various members of the Schizomycetes—fission fungi—has been more widely and more thoroughly investigated, and the knowledge gained has not only modified our conception of the pathology of these diseases, but has had a most important influence upon our methods of treatment of sufferers, both as individuals and as members of communities. The present article deals chiefly with these infective diseases, and with them only so far as new light has been thrown on their ætiology and pathology; and several diseases mentioned in the following classification are not further referred to in the text, because little or nothing, beyond what has already appeared, can be given. For example, Boil and Carbuncle, and Anthrax or Splenic Fever, had been as fully studied when the articles for the ninth edition were written as they are at the present time; it is therefore unnecessary to write what could only be of the nature of repetition. In certain conditions, such as Rheumatism, Vaccinia, Mumps, Dengue, Epidemic Dropsy, Oriental Sore, Verruga, Framboesia or Yaws, Beriberi,

and Syphilis, the disease is probably the result of the action of specific micro-organisms, though as yet it has not been possible to *demonstrate* any ætiological relationship between any micro-organisms found and the special disease. Recent work on Rheumatism and Scarlet Fever may render it necessary to revise this statement, but for the present it is advisable to allow it to stand. In addition to the above, one or two conditions in which the presence of animal parasites in the blood as causative factors of disease has been demonstrated are briefly described, but those which have for long been known to be due to the presence and action of the higher vegetable and animal parasites, and which have been adequately dealt with in the ninth edition, are not here considered. Such diseases as Hæmoglobinuric Fever or Black-Water Fever and Kala-Azar, which are also presumbably parasitic diseases, are not included, as they are probably associated directly with Malaria; this supposition is the more probable in that both of them are recognized as occurring specially in those patients who have been weakened by malaria, intestinal hæmorrhage, and similar conditions.

The following classification is based partly upon the biological relations of the parasites and partly on the pathological phenomena of individual diseases:—

A. Diseases due to Vegetable Parasites:
- I. To Schizomycetes, Bacteria or Fission Fungi:
  - 1. *Caused by the Pyogenetic Micrococci:*
    - Suppuration and Septicæmia.
    - Infective Endocarditis.
    - Erysipelas.
    - Gonorrhœa.
  - 2. *Caused by Specific Bacilli:*
    - ***(a) Acute Infective Diseases:***
      - Cholera.
      - Typhoid Group. Typhoid, Malta Fever, &c.
      - Relapsing Fever.
      - Plague.
      - Pneumonia.
      - Infective Meningitis.
      - Influenza.
      - Yellow Fever and Weil's Disease.
      - Diphtheria.
      - Tetanus.
    - ***(b) More Chronic Infective Diseases (tissue parasites):***
      - Tuberculosis.
      - Leprosy.
      - Glanders.
    - ***(c) Infective Diseases in which organisms have not yet been discovered:***
      - Hydrophobia.
      - Typhus Fever, Scarlet Fever, Measles, Mumps, Whooping-Cough, &c., &c.
- II. To Higher Vegetable Parasites:
  - Actinomycosis.
  - Madura Foot, Aspergillosis, and other Mycoses.

B. Diseases due to Animal Parasites:
- I. To Protozoa:
  - Malaria.
  - Dysentery.
  - Hæmoglobinuric Fever.
  - Kala-Azar.
- II. To other Animal Parasites:
  - Filariasis, &c.

A. Diseases due to Vegetable Parasites.

I. To Schizomycetes, Bacteria or Fission Fungi.

1. *Caused by the Pyogenetic Micrococci.*

Suppuration and Septicæmia.—It is now recognized that although nitrate of silver, turpentine, castor oil, perchloride of mercury, and certain other chemical substances are capable of producing suppuration, the most common causes of this condition are undoubtedly the so-called pus-producing bacteria. Of these perhaps the most important are the staphylococci (Fig. 1, Plate VII.) (cocci arranged like bunches of grapes), streptococci (Fig. 2, Plate VIII.) (cocci arranged in chains), and pneumococci, though certain other organisms not usually associated with pus-formation are undoubtedly capable of setting up this condition, *e.g.*, bacillus pyocyaneus, bacillus coli communis, and the typhoid bacillus. These organisms (the products of which, by chemical irritation, stimulate the leucocytes to emigration) bring about the death and digestion of the tissues and fluids (which no longer "clot") with which they come in contact, pus (matter) being thus formed: this accumulates in the tissues, in the serous cavities, or even on mucous surfaces; septicæmia or blood-poisoning, secondary infection of tissues and organs at a distance from the original site of infection, or pyæmia, with the formation of secondary abscesses, may thus be set up.

In septicæmia the pus-forming organisms grow at the seat of introduction, and produce special poisons or toxins, which, absorbed into the blood, give rise to symptoms of fever. From the point of introduction, however, the organisms may be swept away either by the lymph or by the blood, and carried to positions in which they set up further inflammatory or suppurative changes. In the streptococcal inflammations, spreading by the lymph channels appears to be more common. In the blood the organisms are usually destroyed by the powerful bactericidal action of the plasma; but should they escape, they are carried without multiplication into the systemic capillaries of the general circulation, of the lung, or the liver, where, being stopped, they may give rise to a second focus of infection, especially if at the point of impaction the vitality of the tissues is in any way lowered. Unless the blood is very much impoverished, its bactericidal action is usually sufficiently powerful to bring about the destruction of anything but comparatively large masses of pyogenetic organisms. This bactericidal power, however, may be lost, when the pus-forming organisms may actually multiply, a general hæmic infection resulting. Should micro-organisms be conveyed by the veins to the heart, and there be deposited on an injured valve, an *infective endocarditis* is the result; from such a deposit numerous organisms may be continuously poured into the circulation. Simple thrombi or clots may also become infected with micro-organisms. Fragments of these, washed away, may form septic plugs in the vessels and give rise to abscesses at the point of impaction. A distinction must be drawn between sapræmia and septicæmia. In sapræmia the toxic products of saprophytic organisms are absorbed from a gangrenous or necrotic mass, from an ulcerating surface, or from a large surface on which saprophytic organisms are living and feeding on dead tissues: for example, in the clots that sometimes remain after child-birth on the inner surface of the wall of the womb. So long as no micro-organisms follow the toxins, the condition is purely sapræmic, but should any organisms make their way into and multiply in the blood, the condition becomes one of septicæmia. The term pyæmia is usually associated with the formation of fresh secondary foci of suppuration in distant parts of the body. If the primary abscess occurs in the lungs, the secondary or metastatic abscesses usually occur in the vessels of the general or systemic circulation, and less frequently in other vessels of the lung. When the primary abscess occurs in the systemic area, the secondary abscesses occur first in the lung, and less frequently in the systemic vessels; whilst if the primary abscess be in the portal area (the veins of the digestive tract), the secondary abscesses are usually distributed over the same area, the lungs and systemic vessels being more rarely affected.

Infective Endocarditis.—Acute malignant or ulcerative endocarditis occurs in certain forms of septicæmia or pyæmia. It is brought about by the streptococcus pyogenes, the pneumococcus, or the staphylococcus pyogenes aureus, or, more rarely, by the gonococcus, the typhoid bacillus or the tubercle bacillus, as they gain access to acute or chronic valvular lesions of the heart. The aortic and mitral valves are usually affected, the pulmonary and tricuspid valves much more rarely, though Washbourn states that the infective form occurs on the right side more frequently than does simple endocarditis. A rapid necrosis of the surface of the valve is early followed by a deposition of fibrin and leucocytes on the necrosed tissue; the bacteria, though not present in the circulating blood during life, are found in these vegetations which break down very rapidly; ulcerative lesions are thus formed, and fragments of the septic clot (*i.e.* the fibrinous vegetations with their enclosed bacteria) are carried in the circulating blood to different parts of the body, and, becoming impacted in the smaller vessels, give rise to septic infarcts and abscesses. The ulceration of the valves, or in the first part of the aorta, may be so extensive that aneurysm, or even perforation, may ensue. In certain cases of streptococcic endocarditis the use of anti-streptococcic serum appears to have been attended with good results.

Suppurative Meningitis (see *Infective Meningitis*).

Erysipelas.—In 1883, Fehleisen demonstrated that in all cases of active erysipelatous inflammation a streptococcus or chain of micrococci (similar to those met with in certain forms of suppuration) may be found in the lymph spaces in the skin. The multiplying streptococci found in the lymph spaces form an active poison, which, acting on the blood-vessels, causes them to dilate; it also "attracts" leucocytes, and usually induces proliferation of the endothelial cells lining the lymphatics. These cells—perhaps by using up all available oxygen — interfere with the growth of the streptococcus and act as phagocytes, taking up or devouring the dead or weakened micro-organisms. Both mild and severe phlegmonous cases of erysipelas are the result of the action of this special coccus, alone, or in combination with other organisms. It has been observed that cancerous and other malignant tumours appear to recede under an attack of erysipelas, and certain cases have been recorded in which complete cessation of growth and degeneration of the tumour have followed such an attack. As the streptococcus of erysipelas can be isolated and grown in pure culture in broth, it was thought that a subcutaneous injection of such a cultivation might be of value in the treatment of cancerous tumours. No difficulty was experienced in setting up erysipelas by inoculation, but in some cases the process was so acute that the remedy was more fatal than the disease. The virulence of the streptococcus of erysipelas is greatly exalted when the coccus is grown alongside the bacillus prodigiosus and certain other saprophytic organisms which flourish at the body-temperature. It is an easier matter to control the action of a non-multiplying poison, even though exceedingly virulent, than of one capable, under favourable conditions, of producing an indefinite amount of even a weaker poison. The erysipelatous virus having been raised to as high a degree of activity as possible by cultivating it along with the bacillus prodigiosus—the bacillus of bleeding bread—in broth, it is killed by heat, and the resulting fluid, which contains a quantity of the toxic substances that set up the characteristic erysipelatous changes, is utilized for the production of an inflammatory process—which can now be accurately controlled, and which is said to be very beneficial in the treatment of certain malignant tumours. The accurate determination of the ætiology of erysipelas has led to the adoption of a scientific method of treatment of the disease. The streptococcus erysipelatis is found, not specially in the zone in which inflammation has become evident, but in the tissues outside this zone: in fact, the streptococci appear to be most numerous in the lymphatics of the tissues in which there is least change. Before the appearance of any redness there is a dilatation of the lymph spaces with fluid, and the tissues become slightly œdematous. As soon, however, as the distension of vessels and the emigration of leucocytes, with the accompanying swelling and redness, become marked, the streptococci disappear or are imperfectly stained — they are undergoing degenerative changes—the inflammatory "reaction" apparently being sufficient to bring about this result.

If it were possible to set up the same reaction outside the advancing streptococci, might not a barrier be raised against their advance? This theory was tested on animals, and it was found that the application of iodine, oil of mustard, cantharides, and similar rubefacients, would prevent the advance of certain micro-organisms. This treatment was applied to erysipelas patients with the most satisfactory result, the spread of the disease being prevented whenever the zone of inflammation was extended over a sufficiently wide area. The mere "ringing" of the red patch by nitrate of silver or some other similar irritant, as was at one time recommended, was not sufficient: it is necessary that the reaction should extend for some little distance beyond the zone to which the streptococci have already advanced.

Gonorrhœa.—A micro-organism, the gonococcus, is the cause of gonorrhœa. It is found in the pus of the urethra and in the conjunctiva lying between the epithelial cells, where it sets up considerable irritation and exudation; it occurs in the fluid of joints of patients affected with gonorrhœal arthritis; also in the pleuritic effusion and in the vegetations of gonorrhœal endocarditis. It is a small diplococcus, the elements of which are flattened or slightly concave discs apposed to one another; these, dividing transversely, sometimes form tetrads. They are found in large numbers, usually in the leucocytes, adherent to the epithelial cells or lying free. They stain readily with the basic aniline dyes, but lose this stain when treated by Gram's method. The gonococcus is best grown on human blood-serum mixed with agar (Wertheim), though it grows on ordinary solidified blood-serum or on blood-agar. Like the pneumococcus, it soon dies out, usually before the eighth or ninth day, unless reinoculations are made. It forms a semi-transparent disc-like growth, with somewhat irregular margins, or with small processes running out beyond the main colony. It acts by means of toxins, which have been found to set up irritative changes when injected, without the gonococci, into the anterior chamber of the eye of the rabbit.

2. *Caused by Specific Bacilli.*

(a) Acute Infective Fevers.

Cholera.—In 1884, Koch, in the report of the German Cholera Commission in Egypt and India, brought forward overwhelming evidence in proof of his thesis that a special bacterium is the causal agent of cholera; subsequent observers in all countries in which cholera has been met with have confirmed Koch's observation. The organism described is the "comma" bacillus, one of the spirilla, which usually occurs as a slightly-curved rod 1 to 2μ in length and 0·5 to $0{\cdot}6\mu$ in thickness. These comma-shaped rods occur singly or in pairs; they may be joined together to form circles, half-circles, or "S"-shaped curves (Fig. 3, Plate VIII.).

In cultivations in specially-prepared media they may be so grouped as to form long wavy or spiral threads, each of which may be made up of ten, twenty, or even thirty of the short curved rods; in the stools of cholera patients, especially during the earlier stages of the disease, they are found in considerable numbers; they may also be found in the contents of the lower bowel and in the substance of the mucous membrane of the lower part of the small intestine, especially in the crypts and in and around the epithelium lining the follicles. It is sometimes difficult, in the later stages of the disease, to obtain these organisms in sufficiently large numbers to be able to distinguish them by direct microscopic examination, but by using the Dunbar–Schottelius method they can be detected even when present in small numbers. A quantity of faintly-alkaline meat broth, with 2 per cent. of peptone and 1 per cent. common salt, is inoculated with some of the contents of the intestine, and is placed in an incubator at a temperature of 35° C. for about twelve hours, when, if any cholera bacilli are present, a delicate pellicle, consisting almost entirely of short "comma" bacilli, appears on the surface. If the growth be allowed to go on, the bacilli increase in length, but after a time the pellicle is gradually lost, the cholera organisms being overgrown, as it were, by the other organisms. In order to obtain a pure culture of the cholera bacillus, remove a small fragment of the young film, shake it up thoroughly in a little broth, and then make gelatin-plate cultivations, when most characteristic colonies appear as small greyish or white points. Each of these, when examined under a low-power lens, has a yellow tinge; the margins are wavy or crenated; the surface is granular and has a peculiar ground-glass appearance; around the growing colony liquefaction takes place, and the colony gradually sinks to the bottom of the liquefying area, which now appears as a clear ring. The organism grows very luxuriantly in milk, in which, however, it gives rise to no very noticeable alteration; its presence can only be recognized by a faint aromatic and sweetish smell, which can scarcely be distinguished from the aromatic smell of the milk itself, except by the most practised nose.

The cholera bacillus may remain alive in water for some time, but it appears to be less resistant than many of the putrefactive and saprophytic organisms. It grows better in a saline solution (brackish water) than in perfectly fresh water; it flourishes in serum and other albuminous fluids, especially when peptones are present. Its power of forming poisonous substances appears to vary directly with the amount and nature of the albumen present in the nutrient medium; and though it grows most readily in the presence of peptone, it appears to form the most virulent poison when grown in some form or other of crude albumen to which there is not too free access of oxygen. From the experiments carried out by Koch, Nicati and Rietsch, and Macleod, there appears to be no doubt that the healthy stomach and intestine are not favourable breeding-grounds for the cholera bacillus. In the first place, it requires an alkaline medium for its full and active development, and the acid found in a healthy stomach seems to exert an exceedingly deleterious influence upon it. Secondly, it appears to be incapable of developing except when left at rest, so that the active peristaltic movement of the intestine interferes with its development. Moreover, it forms its poison most easily in the presence of crude albumen. It is interesting to note what an important bearing these facts have on the personal and general spread of cholera. Large quantities of the cholera bacillus may be injected into the stomach of a guinea-pig without any intoxicative or other symptoms of cholera making their appearance. Further, several healthy individuals have swallowed, without any ill effect, pills containing the dejecta from cholera cases. If, however, previous to the injection of the cholera bacillus, the acidity of the stomach be neutralized by an alkaline fluid, especially if at the same time the peristaltic action of the intestine be paralysed by an injection of morphia, a characteristic attack of cholera is developed, the animal is poisoned, and in the large intestine a considerable quantity of fluid fæces containing numerous cholera bacilli may be found. There appear to be slight differences in the cholera organisms found in connexion with different outbreaks, but the main characteristics are preserved throughout, and are sufficiently distinctive to mark out the organisms as belonging to the cholera group. Amongst the known predisposing causes of cholera are the incautious use of purgative medicines, the use of unripe fruit, insufficient food, and intemperance. These may all be looked upon as playing the part of the alkaline solution in altering the composition of the gastric juices, and especially as setting up alkaline fermentation in the stomach and small intestine; beyond this, however, the irritation set up may bring about an accumulation of inflammatory serous fluid, from the albumens of which, as we have seen, the cholera organism has the power of producing very active toxins.

The part played by want of personal cleanliness, overcrowding, and unfavourable hygienic conditions, may be readily understood if it be remembered that the cholera bacillus may grow outside the body. The number of cases in which epidemics of cholera have been traced to the use of drinking-water contaminated with the discharges from cholera patients is now considerable. The more organic matter present, the greater is the virulence of water so contaminated; and the addition of such water to milk has, in one instance at least, led to an outbreak. If cholera dejecta be sprinkled on moist soil or damp linen, and kept at blood-heat, the bacillus multiplies at an enormous rate in the first twenty-four or thirty-six hours; but, as seen in the Dunbar-Schottelius method, at the end of three or four days it is gradually overcome by the other bacteria present, which, growing strongly and asserting themselves, cause it to die out. The importance of this saprophytic growth in the propagation of the disease can scarcely be over-estimated. Water which contains an ordinary amount of organic and inorganic matter in solution does not allow of the multiplication of this organism, which may soon die out; but when organic matter is present in excess, as at the margin of stagnant pools and tanks, development occurs, especially on the floating solid particles. This bacillus grows at a temperature of 30° C. on meat, eggs, vegetables, and moistened bread; also on cheese, coffee, chocolate, and dilute sugar solutions. In some experiments carried out by Cartwright Wood and the writer in connexion with the passage of the cholera organism through filters, it remained alive in the charcoal filtering medium for a period of at least forty-two days, and probably for a couple of months. It must be remembered that cholera bacilli are gradually overcome by other organisms, as only in this way can the immunity enjoyed by certain regions, even after the water and soil have been contaminated, provided that no fresh supply is brought in "to relight the torch," be explained. In most of the regions in which cholera remains endemic the wells are merely dug-out pits beneath the slightly-raised houses, and are open for the reception of sewage and excreta at all times. These dejecta contain organic material which serves as a nutriment on which infective organisms, derived from the soil and ground-water, may flourish. Not only dejecta, but also the rinsings from soiled linen and utensils used by cholera patients, should be removed as soon as possible, "without allowing them to come into contact with the surface of the soil, with wells," or with vegetables and the like. The discovery of Koch's comma bacillus has so altered our conceptions of the ætiology of this disease, that we now study the conditions under which the bacillus can multiply and be disseminated, instead of concerning ourselves with the cholera itself as some definite entity. Telluric agencies merely become secondary factors, the dissemination of the disease by winds from country to country is no longer regarded as being possible, whilst the spread of cholera epidemics along the lines of human intercourse and travel is now recognized. The virulent bacillus requires the human organism to carry it from those localities in which it is endemic to those in which epidemics occur. The epidemiologist has come to look upon the study of the cholera organism and the conditions under which it exists as of more importance than mere local conditions, which are only important in so far as they contribute to the propagation and distribution of the cholera bacillus, and he knows that the only means of preventing its spread is the careful inspection of everything coming from cholera-stricken regions. He also recognizes that the herding together of people of depressed vitality, under unhygienic and often filthy conditions, in quarantine stations or ships, is one of the surest means of promoting an epidemic of the disease; that attention should be confined to the careful isolation of all patients, and to the disinfection of articles of clothing, feeding utensils, and the like; that the comma bacillus can only be driven out of rooms by means of light and fresh air; that thorough personal, culinary, and household cleanliness is necessary; that all water except that known to be pure should be carefully boiled; and that all excess, both in eating and drinking, should be avoided. The object of the physician in such cases must be, first, to isolate as completely as possible all his cholera patients, and then to get rid of all predisposing causes in the patients themselves, causes which have already been indicated in connexion with the ætiology of the disease.

Attention has frequently been drawn to the fact that patients who have lived for some time in a cholera region, or who have already suffered from an attack of cholera, appear to enjoy a partial immunity against the disease. Haffkine, working on the assumption that the symptoms of cholera are produced by a toxin formed by the cholera organism, came to the conclusion that, by introducing first a modified and then a more virulent poison directly into the tissues under the skin, and not into the alimentary canal, it would be possible to obtain a certain insusceptibility to the action of this poison. He found that for this purpose the cholera bacillus, as ordinarily obtained in pure culture from the intestinal canal, is too potent for the preliminary inoculation, but is not sufficiently active for the second, if any marked protection is to be obtained. By allowing the organism to grow in a well-aërated culture the virulence is gradually diminished, and this virulence, once abolished, does not return even when numerous successive cultures are made on agar or other nutrient media. On the other hand, by passing the cholera bacillus successively through the peritoneal cavities of a series of about thirty guinea-pigs, he obtains a virus of great activity; this activity is soon lost on agar cultivations, and it is necessary from time to time again to pass the bacillus through guinea-pigs, three or four passages now being sufficient to reinforce the activity.

From these two cultures the vaccines are prepared as follows:—The surface of a slant agar tube is smeared with the modified cholera organism. After this has been allowed to grow for twenty-four hours, a small quantity of sterile water is poured into the tube, and the surface-growth is carefully scraped off and made into an emulsion in the water; this is then poured off, and the process is repeated until the whole of the growth has been removed. The mixture is made up with water to a bulk of 8 c.c., so that if 1 c.c. is injected the patient receives $\frac{1}{8}$ of a surface-growth; it is found that this quantity, when injected subcutaneously into a guinea-pig, gives a distinct reaction, but does not cause necrosis of the tissues. If the vaccine is to be kept for any length of time, the emulsion is made with 0·5 per cent. carbolic acid solution, prepared with carefully sterilized water, and the mixture is made up to 6 c.c. instead of 8 c.c., since the carbolic acid appears to interfere slightly with the activity of the virus. The stronger virus is prepared in exactly the same way. The preliminary injection, which is made in the left flank, is followed by a rise in temperature and by local reaction. After three or four hours there is noticeable swelling and some pain; and after ten hours a rise in temperature, usually not very marked, occurs. These signs soon disappear, and at the end of three or four days the second injection is made, usually on the opposite side. This is also followed by a rise of temperature, by swelling, pain and local redness: these, however, as before, soon pass off, and leave no ill effects behind. A guinea-pig treated in this fashion is now immune against some eight or ten times the lethal dose of cholera poison, and, from all statistics that can be obtained, a similar protection is conferred upon the human being.

Evidence has been collected that spirilla, almost identical in appearance with the cholera bacillus, may be present in water and in healthy stools, and that it is in many cases almost impossible to diagnose between these and the cholera bacillus; but although these spirilla may interfere with the diagnosis, they do not invalidate Koch's main contention, that a special form of the comma bacillus, which gives a *complete group* of reactions, is the cause of this disease, especially when these reactions are met with in an organism *that comes from the human intestine.*

Typhoid Fever. — Our information concerning the ætiology of typhoid fever was largely increased during the last twenty years of the 19th century. In 1880 Eberth and Klebs independently, and in 1882 Coats, described a bacillus which has since been found to be intimately associated with typhoid fever. This organism (Fig. 4, Plate VIII.) usually appears in the form of a short bacillus from 2 to 3μ in length and 0·3 to $0{\cdot}5\mu$ in breadth; it has slightly rounded ends and is stained at the poles; it may also occur as a somewhat longer rod more equally stained throughout. Surrounding the young organism are numerous long and well-formed flagella, which give it a very characteristic appearance under the microscope. At present there is no evidence that the typhoid bacillus forms spores. These bacilli are found in the adenoid follicles or lymphatic tissues of the intestine, in the mesenteric glands, in the spleen, liver, and kidneys, and may also be detected even in the small lymphoid masses in the lung, and in the post-typhoid abscesses formed in the bones, kidneys, or other parts of the body; indeed, it is probable that they were first seen by von Recklinghausen in 1871 in such abscesses. They undoubtedly occur in the dejecta of patients suffering from typhoid fever, whilst in recent years it has been demonstrated that they may also be found in the urine. It is evident, therefore, that the urine, as well as the fæces, may be the vehicle by means of which the disease has been unwittingly spread in certain otherwise inexplicable outbreaks of typhoid fever, especially as the bacillus may be present in the urine when the acute stage of the disease has gone by, and when it has been assumed that, as the patient is convalescent, he is no longer a focus from which the infection may be spread. There can be little doubt that typhoid bacilli are not, as is very frequently assumed, present merely in the lymphatic glands and in the spleen (Fig. 5, Plate VIII.): they may be found in almost any part of the lymphatic system, in lymph spaces, in the connective tissues, where they appear to give rise to marked proliferation of the endothelial cells, and especially in the various secreting organs. It is probable that the proliferation often noticed in the minute portal spaces in the liver, in cases of typhoid fever, is simply a type of a similar proliferation going on in other parts and tissues of the body. It was for long assumed that the typhoid bacillus could multiply freely in water, but recent experiments appear to indicate that this is not the case, unless a much larger quantity of soluble organic matter is present than is usually met with in water. The fact, however, that the organism may remain alive in water is of great importance; and, as in the case of cholera, it must be recognized that certain of the great epidemics of typhoid or enteric fever have been the result of "water-borne infection." The bacillus, a facultative parasite, grows outside the body, with somewhat characteristic appearances and reactions: it flourishes specially well on a slightly acid medium; in the presence of putrefactive organisms which develop strongly alkaline products it may gradually die out, but it appears to retain its vitality longer in the presence of acid-forming organisms. It may, however, be stated generally, that after a time the typhoid bacillus becomes weakened, and may even die out, in the presence of rapidly-growing putrefactive organisms. In distilled water it may remain alive for a considerable period—five or six weeks, or even longer. It grows on all the ordinary nutrient media.

It does not coagulate milk; hence it may grow luxuriantly in that medium without giving rise to any alteration in that fluid: milk, therefore, is a specially dangerous vehicle for its dissemination. When inoculated on potato, careful examination will reveal the fact that certain almost invisible moist patches are present; these are made up of rapidly-multiplying typhoid bacilli. The typhoid bacillus grows in gelatin, especially on the surface, somewhat like the bacillus coli communis, but with a less luxuriant growth. This organism, when taken from young broth cultures twelve to twenty-four hours old —during the period at which flagella are best seen— and examined microscopically, exhibits very lively movements. When, as pointed out by Gruber and Durham, blood-serum, in certain dilutions, from a case of typhoid fever is added to such a culture, the broth, at first turbid, owing to the suspended and moving micro-organisms, gradually becomes clear, and a deposit is formed which is found to be made up of masses or clumps of typhoid bacilli which have lost their motility. This reaction is so characteristic and definite, that when the mixture is kept under examination under the microscope, it is quite possible to follow the slowing-down and massing together of the organisms. It is found, moreover, that normal diluted blood-serum has no such effect on the bacilli. This property of the blood-serum is acquired at such an early date of the disease—sometimes even at the end of the first week—and occurs with such regularity, that typhoid fever may now actually be diagnosed by the presence or absence of this "agglutinating" property in the blood. If serum taken from a patient supposed to be suffering from typhoid fever, and diluted with saline solution to 1 in 10, to 1 in 50, or in still greater dilution, causes the bacilli to lose their motility and to become aggregated into clumps within an hour, it may be concluded that the patient is suffering from typhoid fever; if this agglutination be not obtained with a dilution of 1 in 10, in from 15 to 30 minutes, experience has shown that the patient is not suffering from this disease. Certain other diseases, such as cholera, give a similar specific serum reaction with their specific organisms. These sera have, in addition, a slight common action—a general agglutinating power— which, however, is not manifested except in concentrated solutions, the higher dilutions failing to give any clumping action at all, except with the specific bacillus associated with the disease from which the patient from whom the serum is taken is suffering.

Mediterranean or Malta Fever.—Until recently, Mediterranean Fever was looked upon as a form of typhoid fever, which in certain respects it resembles; the temperature curve, however, has a more undulatory character, except in the malignant type, where the temperature remains high throughout the course of the attack. According to Hughes, this disease is widely distributed in the countries bordering upon the Mediterranean south of latitude 46° N., and along the Red Sea littoral. Analogous forms of fever giving a "specific" serum reaction with the micrococcus of this disease are also met with in parts of India, China, Africa, and America.

The *Micrococcus melitensis vel Brucei*, which is found most abundantly in the enlarged spleen of the patient suffering from Malta fever, is a very minute organism ($0 \cdot 33\mu$ in diameter), ovoid or nearly round, arranged in pairs or in very short chains (Fig. 6, Plate VII.). If a drop of the blood taken directly from the spleen be smeared over the surface of agar nutrient medium, minute transparent colourless colonies appear; in thirty-six hours these have a slight amber tinge, and in four or five days from their first appearance they become opaque. These colonies, which flourish at the temperature of the human blood, cease to grow at the room-temperature except in summer; and if kept moist, soon die at anything below 60° F., though when dried they retain their vitality for some time. They cause opacity of broth at the end of five or six days, forming a precipitate with a comparatively clear supernatant fluid. They grow best on media slightly less alkaline than human blood.

This organism is distinctly pathogenetic to monkeys, and its virulence may be so increased that other animals may be affected by it. Though unable to live in clean or virgin soil, it may lead a saprophytic existence in soil polluted with fæcal matter. Hughes maintains that the "virus" usually enters the body with inspired air, and leaves it with the fæces and urine; it seldom appears to be carried for any considerable distance. He divides this fever into three types. In the malignant form the onset is sudden, there are headache, racking pain over the whole body, nausea, and sometimes vomiting; the tongue is foul, coated, and swollen, and the breath very offensive; the temperature may continue for some time at 103° to 105° F. The stools in the diarrhœa which is sometimes present may be most offensive. At the end of a few days the lungs become congested and pneumonic, the pulse weak, hyperpyrexia appears, and death ensues. A second type, by far the most common, is the "undulatory" type, in which there is remittent pyrexia, separated by periods in which the patient appears to be improving. These pyrexial curves, from one to seven in number, average about ten days each, the first being the longest, eighteen to twenty-three days. In an intermittent type, in which the temperature-curve closely resembles the hectic pyrexial curve of phthisis or suppuration, the "undulatory" character is also marked. A considerable number of toxic symptoms make their appearance — localized neuritis, synovitis, anæmia, emaciation, bronchial catarrh, weakness of the heart, neuralgia, profuse night sweats, and similar conditions. Patients otherwise healthy usually recover, even after prolonged attacks of the disease, but the mortality amongst patients suffering from organic mischief of any kind may be comparatively high. The diagnosis from malaria, phthisis, rheumatic affections, and pneumonia may in most cases be made fairly easily, but the serum reaction with cultures of the micrococcus melitensis, corresponding to the typhoid reaction with the typhoid bacillus, is sometimes the only trustworthy diagnostic feature between this fever and the above-mentioned diseases. The best preventive measures are: the avoidance of chills, good drainage, and disinfection of stools and urine from the patients affected, so as to stop pollution of the soil.

Relapsing Fever.—The specific cause of relapsing fever (famine fever) appears to be the Spirillum Obermeieri, an organism which occurs in the blood of patients suffering from this disease (during the febrile stages). Between the febrile stages are periods of intermission, during which the spirillum disappears from the blood and apparently retires to the spleen. This disease, in epidemic form, follows in the footsteps of famine and destitution, specially affecting young people between the ages of fifteen and twenty; it seldom attacks children under five years of age, but in patients over thirty it assumes a more virulent form. In monkeys inoculated with blood containing the Spirillum Obermeieri the first symptoms appear between the second and sixth days. In the human subject this incubation period may last as long as three weeks; then comes an attack of fever, which continues for about a week, and is followed by a similar period of apparent convalescence, on which ensues a pyrexial relapse, continuing about half as long as the first. The spirilla, the cause of this disease, are fine spirals with pointed ends, three or four times as long as the diameter of a red blood corpuscle. Although it has as yet been found impossible to cultivate these spirilla outside the body, human beings, and monkeys injected with blood containing them, contract the disease; and in monkeys it has been found that during the period before the relapse the spirilla have made their way into the cells of the spleen. As yet little is known as to the mode of development of these organisms, and of the method of their transmission from one patient to another, but it is thought that, as in the case of malaria and the tsetse-fly disease, they may be carried by bloodsucking insects. Relapsing fever is distinguished from typhoid by its sudden onset, and by the distinct intermissions; and from influenza by the enlargement of the spleen and liver. The most satisfactory method of diagnosis is the examination of the blood for the presence of the spirillum during the febrile period. The *post-mortem* appearances are those of a toxic (bacterial) poisoning. Curious infarction-like masses, in which are numerous spirilla, are found in the spleen; in the liver there is evidence of acute interstitial hepatitis, with cloudy swelling of the liver cells; and similar changes occur in the kidney. Fatty degeneration of the heart and voluntary muscles may also be met with.

Plague.—During recent years opportunities for the study of plague have unfortunately been only too numerous. In patients suffering from this disease, a micro-organism, capable of leading either a saprophytic life or a parasitic existence in the human body, and in some of the lower animals, was described independently by Kitasato and by Yersin, in 1894, in Hong Kong. It is a short, moderately thick bacillus, with rounded ends, which stain deeply, leaving a clear band in the centre (Fig. 7, Plate VIII.). It thus resembles the short diphtheria bacillus and the influenza bacillus. Certain other forms are met with, but the above is the most characteristic. It grows readily on most media at the temperature of the body, but, like the glanders bacillus, soon loses its virulence in cultivations. It may be obtained in pure cultures from the lymph glands, and from the abscesses that are formed in the groin or other positions in which the glands become enlarged and softened. It may also be found in the spleen and in the blood, and, in the case of patients suffering from the pneumonic form of the disease, even in the lungs and in the sputum. It has also been found in the fæces and urine. (It is very important that these excretions from plague patients should always be most carefully disinfected.) This organism, when obtained in pure culture and inoculated into rats, mice, guinea-pigs, or rabbits, produces exactly the same symptoms as does material taken fresh from the softened glands. The symptoms are local swelling, enlargement and softening of the lymphatic glands, and high fever. The fact that rats are susceptible to the disease is one of peculiar significance, as these animals by their habits have special facilities for carrying the plague bacillus from point to point, and thus of spreading the infection very rapidly. It has been noticed that large numbers of rats succumb to plague before the disease assumes the epidemic form; and in Bombay, at an early period of the last outbreak, it was almost impossible to obtain a rat on which to carry out experiments for the purpose of determining whether the organism was really the plague bacillus or not. In India, where the notions of cleanliness are somewhat different from those recognized in Great Britain, most of the conditions favourable to the spread of the plague bacillus are of the most perfect character. This organism may pass into the soil with fæces; it may there remain for some time, and then be taken into the body of one of the lower animals, or of man, and give rise to a fresh outbreak. Kitasato and Yersin were both able to prove that soil and dust from infected houses contain the bacillus, that such bacillus is capable of inducing an attack of plague in the lower animals, and that flies fed on the dejecta or other bacillus-containing material, die, and in turn contain bacilli which are capable of setting up infection. Hankin claims that ants, and Simonds that fleas, may carry the plague to and from rats, and so to the human being. It has already been mentioned that the organism rapidly loses its virulence when cultivated outside the body; on the other hand, on being passed through a series of animals its virulence gradually increases. Thus may be explained the fact that in most outbreaks of plague there is an early period during which the death-rate is very low; after a time the percentage mortality is enormously increased, the virulence of the disease being very great and its course rapid. There seem to be notable differences in the degree of susceptibility of different races and different individuals, and those who have passed safely through an attack appear to have acquired a marked degree of immunity. Two methods of treatment, both of which seem to have been attended with a certain degree of success, are now being tried. Haffkine, applying his inoculation method (first used with cholera) to plague, appears to have produced a certain active immunity, inoculated patients becoming less susceptible to the action of the plague bacillus. This method of treatment, however, is of no use in the case of patients already attacked; for such cases Yersin has used a serum taken from horses into which graduated and systematic injections of the plague bacillus and its products have been made. This "antipest" serum, it is claimed, has induced a favourable turn in the disease in cases which otherwise must inevitably have succumbed.

Pneumonia.—The case in favour of acute lobar pneumonia being an infective disease was a very strong one, even before it was possible to show that a special organism bore any ætiological relation to it. In 1880, Friedländer claimed that he had isolated such an organism, but the pneumobacillus then described appears to be inactive as compared with the pneumococcus isolated by Fraenkel and Talamon. This latter organism, which is usually found in the sputum, is an encapsuled diplococcus (Fig. 8, Plate VII.). Grown on serum or agar over which sterile blood has been smeared, it occurs as minute, glistening, rather prominent points, almost like a fine spray of water or dew. When the organism is cultivated in broth the capsule disappears, and chains of diplococci are seen. It resembles the influenza bacillus in a most remarkable manner. It may be found, in almost every case of pneumonia, in the "rusty" or "prune-juice" sputum. Injected into rabbits, it produces death with very great certainty; and by passing the organism through these animals its virulence may be markedly increased. Like the influenza bacillus and even the diphtheria bacillus, this organism may be present in the mouth and lungs of perfectly healthy individuals, and it is only when the vitality of the system is lowered by cold or other depressing influences that pneumonia is induced; two factors, the presence of the bacillus and the lowered vitality, being both necessary for the production of this disease in the human subject. It is quite possible, however, that, as in the case of cholera, a slight inflammatory exudation may supply a nutrient medium in which the bacillus rapidly acquires greatly increased virulence, and so becomes a much more active agent of infection.

It is claimed by the brothers Klemperer, by Washbourn, and by others, that they have been able to produce an anti-pneumococcic serum, by means of which they are able to treat successfully severe cases of pneumonia. The catarrhal pneumonia so frequently met with during the course of whooping-cough, measles, and other specific infective fevers, is also in all probability due to the action of some organism of which the influenza bacillus and the diplococcus pneumoniæ are types.

Infective meningitis is, in most of the recent works on medicine, divided into four forms: (1) the acute epidemic cerebro-spinal form; (2) a posterior basic form, which, however, is closely allied to the first; (3) suppurative meningitis, usually associated with pneumonia, erysipelas, and pyæmia; and (4) tubercular meningitis, due to the specific tubercle bacillus.

(1) The first form is usually associated with Weichselbaum's *diplococcus intracellularis meningitidis* (two closely-apposed discs), which is found in the purulent exudate, especially in the leucocytes, of the meninges of the brain and cord. It grows, as transparent colonies, on blood-agar at the temperature of the body, but dies out very rapidly unless reinoculated, and has little pathogenetic effect on the lower animals, though under certain conditions it has been found to produce meningitis when injected under the dura mater. (2) *Posterior-basic meningitis*, according to Dr Still, "is frequently seen during the first six months of life, a period at which tuberculous and epidemic cerebro-spinal meningitis are quite uncommon." The organism found in this disease resembles very closely the *diplococcus intracellularis meningitidis*, but differs from it in that it remains alive without recultivation for a considerably longer period. It is less pathogenetic than that organism, of which possibly it is simply a more highly saprophytic form. This is a somewhat important point, as it would account for the great resemblance that exists between the sporadic and the epidemic forms of meningitis. (3) In *suppurative meningitis* these two organisms may still be found in a certain proportion of the cases, but their place may be taken by the pneumococcus or diplococcus pneumoniæ or Fraenkel's pneumococcus—diplococcus lanceolatus—which appears to grow in two forms. In the first it is an encapsulated organism, consisting of small oval cocci arranged in pairs or in short chains; the capsule is unstained. When the pneumococcus grows in chains—the second form—as when cultivated outside the body, on blood-serum or on agar over the surface of which a small quantity of sterile blood has been smeared, it produces very minute translucent colonies. Like Weichselbaum's bacillus, it must be recultivated every three or four days, otherwise it soon dies out. Unlike the other forms previously described, it may, when passed through animals, become extremely virulent, very small quantities being sufficient to kill a rabbit. Although the pneumococcus is found in the majority of these cases, especially in children, suppurative meningitis may also accompany or follow the various diseases that are set up by the streptococcus pyogenes and streptococcus erysipelatis; whilst along with it staphylococci and the bacillus coli communis have sometimes been found. In other cases, again, there is a mixed infection of the pneumococcus and the streptococcus pyogenes, especially in cases of disease of the middle ear. As might be expected in meningitis occurring in connexion with the specific infective diseases, *e.g.*, influenza and typhoid fever, the presence of the specific bacilli of these diseases may usually be demonstrated in the meningeal pus or fluid. (4) The fourth form, *tubercular meningitis* (acute hydrocephalus), is met with most frequently in young children. It is now generally accepted that this condition is the result of the introduction of the tubercle bacillus into the blood-vessels and lymph spaces of the meninges at the base of the brain, and along the fissures of Sylvius.

Influenza.—From 1889 up to the present time, influenza has every year with unfailing regularity broken out in epidemic form in some part of the United Kingdom, and often has swept over the whole country. The fact that the period of incubation is short, and that the infective agent is extremely active at a very early stage of the disease, renders it one of the most rapidly-spreading maladies with which we have to deal. The infective agent, first observed by Pfeiffer and Canon, is a minute bacillus or diplococcus less than 1μ in length and $0{\cdot}5\mu$ in thickness; it is found in little groups or in pairs. Each diplococcus is stained at the poles, a clear band remaining in the middle; in this respect it resembles the plague bacillus. It is found in the blood—though here it seems to be comparatively inactive—and in enormous numbers in the bronchial mucus. It is not easily stained in a solution of carbol-fuchsin, but in some cases such numbers are present that a cover-glass preparation may show practically no other organisms. Agar, smeared with blood and inoculated, gives an almost pure cultivation of very minute transparent colonies, similar to those of the diplococcus pneumoniæ, but as a rule somewhat smaller. This organism, found only in cases of influenza, appears to have the power of forming toxins which continue to act for some time after recovery seems to have taken place; it appears to exert such a general devitalizing effect on the tissues, that micro-organisms which ordinarily are held in check are allowed to become active, with the result that catarrh, pneumonia, and similar conditions are developed, especially when cold and other lowering conditions co-operate with the poison. This toxin produces special results in those organs which, through over-use, impaired nutrition, or disease, are already only just able to carry on their work. Hence in cases of influenza the cause of death is usually associated with the failure of some organ that had already been working up to its full capacity, and in which the margin of reserve power had been reduced to a minimum. It is for this reason that rest, nutrition, warmth, and tonics are such important and successful factors in treatment.

Yellow Fever, endemic in the West Indies and the north-eastern coasts of South America, may become epidemic wherever the temperature and humidity are high, especially along the seashore in the tropical Atlantic coast of North America. It appears to be one of the specific infective fevers in which the liver, kidney, and gastro-intestinal systems, and especially their blood-vessels, are affected. In 1897, Sanarelli reported, in the *Annales de l'Institut Pasteur*, that he had found a bacillus in the blood-vessels of the liver and kidneys, and in the cells of the peritoneal fluid, but never in the alimentary tract, of yellow fever patients. These, he maintained, were perfectly distinct from the putrefactive microbes occurring in the tissues in the later stages, their colonies not growing like those of the bacillus coli communis. They grow readily on all the ordinary artificial nutrient media, as short rods with rounded ends, usually about 2 to 4μ in length and about half as broad as they are long. They are stained by Gram's method and readily by most of the aniline dyes, are ciliated, and do not liquefy gelatin. They flourish specially well alongside moulds, in the dark, in badly-ventilated, warm, moist places, and remain alive for some time in sea-water: these facts, as Sanarelli points out, afford an explanation of the special persistence of yellow fever in old, badly-ventilated ships, and in dark, dirty, and insanitary seacoast towns. Once the organism, whatever it may be, finds its way into the system, it soon makes its presence felt, and toxic symptoms are developed. The temperature rises; the pulse, at first rapid, gradually slows down; and after some time persistent vomiting of bile comes on. At the end of three or four days the temperature and pulse fall, and there is a period during which the patient appears comparatively well; this is followed in a few hours by icterus and scanty secretion of urine. There may be actual anuria, or the small quantity of urine passed may be loaded with casts and albumen; delirium, convulsions, and hæmorrhages from all the mucous surfaces may now set in, or secondary infections of various kinds, boils, abscesses, suppurations, and septicæmia, may result. These often prove fatal when the patient appears to be almost convalescent from the original disease. As regards prognosis, it has been found that the "lower the initial temperature the milder will the case be" (Macpherson). An initial temperature of 106° F. is an exceedingly unfavourable sign. Patients addicted to the use of alcohol are, as a rule, much more severely affected than are others. The treatment is principally directed towards prevention and towards the alleviation of symptoms, though Sanarelli has hopes that an "anti"-serum may be useful. More recently Flexner, working with the American Commission, has isolated another organism, which, he maintains, is the pathogenetic agent in the production of yellow fever; whilst Durham and Myers maintain that a small bacillus previously observed by Sternberg and others is the true cause of this disease.

Weil's disease, a disease which may be considered along with acute yellow atrophy and yellow fever, is one in which there is an acute febrile condition, associated with jaundice, inflammation of the kidney, and enlargement of the spleen. It appears to be a toxic condition of a less acute character, however, than the other two, in which the functions and structure of the liver and kidney are specially interfered with. There is a marked affection of the gastro-intestinal system, and the nervous system is also in some cases profoundly involved. Hæmorrhage into the mucous and serous membranes is a marked feature. The liver cells and kidney epithelium undergo fatty changes, though in the earlier stages there is a cloudy swelling, probably also toxic in its origin. Certain organisms of the Proteus group, which appear to have the power in certain circumstances of forming toxic substances in larger quantities than can be readily destroyed by the liver, and which then make their appearance in the kidney and spleen, are supposed to be the cause of this condition.

Diphtheria.—In regard to no disease has medical opinion undergone greater modification than it has in respect of diphtheria. Accurately applied, bacteriology has here gained one of its greatest triumphs. Not only have the ætiology and diagnosis of this disease been made clear, but knowledge acquired in connexion with the production of the disease has been applied to a most successful method of its treatment. In 1875, Klebs described a small bacillus with rounded ends, and with here and there small clear unstained spaces in its substance. He, however, also described streptococci as present in certain cases of diphtheria, and concluded that there must be two kinds of diphtheria, one associated with each of these organisms. In 1883 he again took up the question; and in the following year Loeffler gave a systematic description of what is now known as the Klebs-Loeffler bacillus, which was afterwards proved by Roux and Yersin and many other observers to be the *causa causans* of diphtheria. This bacillus is a slightly-curved rod with rounded, pointed, or club-shaped end or ends (Fig. 9, Plate VIII.[1]). It is usually from 1·2 to 5μ or more in length and from 0·3 to 0·5μ in breadth; rarely it may be considerably larger in both dimensions. It is non-motile, and may exhibit great variety of form, according to the age of the culture and the nature of the medium upon which it is growing. It is stained by Gram's method if the decolorizing process be not too prolonged, and also by Loeffler's methylene-blue method. Except in the very young forms, it is readily recognizable by a series of transverse alternate stained and unstained bands. The bacillus may be wedge-shaped, spindle-shaped, comma-shaped, or ovoid. In the shorter forms the polar staining is usually well marked; in the longer bacilli, the transverse striation. Very characteristic club-shaped forms or branching filaments are met with in old cultures, or where there is a superabundance of nutritive material. In what may be called the handle of the club the banded appearance is specially well marked. These specific bacilli are found in large numbers on the surface of the diphtheritic membrane (Fig. 10, Plate VIII.[1]), and may easily be detached for bacteriological examination. In certain cases they may be found by direct microscopic examination, especially when they are stained by Gram's method, but it is far more easy to demonstrate their presence by the culture method. On Loeffler's special medium the bacilli flourish so well at body-temperature—about 37° C.—that, like the cholera bacillus, they outgrow the other organisms present, and may be obtained in comparatively pure culture. Distinct colonies may often be found as early as the eighth or twelfth hour of incubation; in from eighteen to twenty-four hours they appear as rounded, elevated, moderately translucent, greyish white colonies, with a yellow tinge, the surface moist, and the margins slightly irregular or scalloped. They are thicker and somewhat more opaque in the centre. When the colonies are few and widely separated, each may grow to a considerable size, 4 to 5 mm.; but when more numerous and closer together, they remain small and almost invariably discrete, with distinct intervals between them. In older growths the central opacity becomes more marked and the crenation more distinct, the moist, shiny appearance being lost. When the surface of the serum is dry, the growth, as a rule, does not attain any very large size.

These "pure" colonies, when sown in slightly alkaline broth, grow with great vigour; and if a small amount of such a forty-eight hours' culture be injected under the skin of a guinea-pig, the animal succumbs, with a marked local reaction and distinct symptoms of toxic poisoning very similar to those met with in cases of diphtheria of the human subject. Roux and Yersin demonstrated that the poison was not contained in the bodies of the bacilli, but that it was formed and thrown out by them from and into the nutrient medium. Moreover, they could produce all the toxic symptoms, the local reactions, and even the paralysis which often follows the disease in the human subject, by injecting the culture from which they had previously removed the whole of the diphtheria bacilli by filtration. This cultivation, then, contains a poisonous material, which, incapable of multiplying in the tissues, may be given in carefully graduated doses. If, therefore, there is anything in the theory that tissues may be gradually "acclimatized" to the poisons of these toxic substances, they saw that it should be possible to prove it in connexion with this disease. Behring, going still farther, found that the tissues so acclimatized have the power of producing a substance capable of neutralizing the toxin, a substance which, at first confined to the cells, when formed in large quantities overflows into the fluids of the blood,

with which it is distributed throughout the body. The bulk of this toxin-neutralizing substance remains in the blood-serum after separation of the clot. In proof of this he showed that (1) if this serum be injected into an animal before it is inoculated with even more than a lethal dose of the diphtheria bacillus or its products, the animal remains perfectly well; (2) a certain quantity of this serum, mixed with diphtheria toxin and injected into a guinea-pig, gives rise to no ill effects; and (3) that even when injected some hours after the bacillus or its toxins, the serum is still capable of neutralizing the action of these substances. In these experiments we have the germ of the present antitoxic treatment which has so materially diminished the percentage mortality in diphtheria. This serum may also be used as a prophylactic agent.

The antitoxic serum as now used is prepared by injecting into the subcutaneous tissues of a horse the products of the diphtheria bacillus. The bacillus, grown in broth containing peptone and blood-serum or blood-plasma, is filtered and heated to a temperature of 68° or 70° C. for one hour. It then contains only a small amount of active toxin, but it renders the horse highly insusceptible to the action of strong diphtheria toxins, and even induces the production of a considerable amount of antitoxin. This production of antitoxin, however, may be accelerated by repeated and increasing injections of strong diphtheria toxin, which may be so powerful that $\frac{1}{4}$ to $\frac{1}{5}$ of a drop, or even less, is a fatal dose for a medium-sized guinea-pig. The antitoxic serum so prepared may contain 200, 400, 600, or even more "units" of antitoxin per c.c.—the unit being that quantity of antitoxin that will so far neutralize 100 lethal doses (a lethal dose is the smallest quantity that will kill a 250-gramme guinea-pig on the fifth day) of toxin for a 250-gramme guinea-pig, that the animal continues alive on the fifth day from the injection. This, however, is a purely arbitrary standard of neutralizing power, as it is found that, owing to the complicated structure of the toxin, the neutralizing and the lethal powers do not always go hand in hand; but as the toxin used in testing the antitoxin is always compared with the original standard, accurate results are easily obtained.

Diphtheria, though still prevalent in cities, has now lost many of its terrors. In large hospitals the death-rate has fallen from nearly 40 per cent. to under 14 per cent.; and if antitoxin could be given as soon as the disease manifests itself, the mortality might be brought down to a very insignificant figure. It has been maintained that as soon as antitoxin came into use the number of cases of paralysis increased rather than diminished. This may be readily understood when it is borne in mind that many patients recover under the use of antitoxin who would undoubtedly have succumbed in the pre-antitoxin days; and it cannot be too strongly insisted, that although the antitoxin introduced neutralizes the free toxin and prevents its further action on the tissues, it cannot entirely neutralize that which is already acting on the cells, nor can it make good damage already done before it is injected. Even allowing that antitoxin is not accountable for the whole of the improvement in the percentage mortality statistics since 1896 or so, it has undoubtedly accounted for a very large proportion of recoveries. Antitoxin often cuts short functional albuminuria, but it cannot repair damage already done to the renal epithelium before the antitoxin was given. The clinical evidence of the value of antitoxin in the relief that it affords to the patient is even greater than that derived from the consideration of statistics.

The diphtheria bacillus or its poison acts locally as a caustic and irritant, and generally or constitutionally as a protoplasmic poison, the most evident lesions produced by it being degeneration of nerves and muscles, and in acute cases changes in the walls of the blood-vessels. Other organisms, streptococci or staphylococci, when present, may undoubtedly increase the mortality by producing secondary complications, which end in suppuration. Diphtheria bacilli may also be found in pus, as in the discharges from cases of otorrhœa.

Tetanus (*Lockjaw*).—Although tetanus was one of the last of the diseases to which a definite micro-organismal origin could be assigned, it has long been looked upon as a disease typical of the "septic" group. Nicolaier described in 1885 an organism multiplying outside the body and capable of setting up tetanus, but this was only obtained in pure culture by Kitasato, a Japanese, and by the Italians in 1889. It has a very characteristic series of appearances at different stages of its development. It grows first of all as long, very slender threads, which rapidly break up into shorter sections from 4 to 5μ in length (Fig. 12, Plate VIII.). In these shorter rods spores may appear on the second or up to the seventh day, according to the temperature at which the growth goes on. The rods then assume a very characteristic pin or drum-stick form; they are non-motile, are somewhat rounded at the ends, and at one end the spore, which is of considerably greater diameter than the rod, causes a very considerable expansion. Before sporulation the organisms are distinctly motile, occurring in rods of different lengths, in most cases surrounded by bundles of beautiful flagella, which at a later stage are thrown off, the presence of flagella corresponding very closely with the "motile" period (Fig. 11, Plate VIII.). The bacillus grows best at the temperature of the body; it becomes inactive at 14° C. at the one extreme, and at from 42° to 43° C. at the other; in the latter case involution forms, clubs and branching and degenerated forms, often make their appearance. It is killed by exposure for an hour to a temperature of from 60° to 65° C.; but the spores are very resistent to the action of heat, as they withstand the temperature of boiling water for several minutes. The organism has been found in garden earth, in the excrement of animals—especially horses—and in dust taken from the streets or from living-rooms, especially when it has been allowed to remain at rest for a considerable period. It has also been demonstrated in, and separated from, the pus of wounds (Fig. 12, Plate VIII.) in patients suffering from lockjaw, though it is then invariably found associated with the micro-organisms that give rise to suppuration.

It is important to remember that this bacillus is a strict anaërobe, and can only grow when free oxygen has been removed from the cultivation medium. It may be cultivated in gelatin to which has been added from 2 to 3 per cent. of grape-sugar, when, along the line of the stab culture, it forms a delicate growth, almost like a fir-tree, the tip of which never comes quite to the surface of the gelatin. The most luxuriant growth—evidenced by the longest branches—occurs in the depth of the gelatin away from free oxygen. After a time the gelatin becomes sticky, and then undergoes slow liquefaction, the growth sinking and leaving the upper layers comparatively clear. This organism is not an obligate, but a facultative, parasite; it may grow outside the body and remain alive for long periods.

Lockjaw is most common amongst agricultural labourers, gardeners, soldiers on campaign, in those who go about with bare feet, or who, like young children, are liable to get their knees or hands accidentally wounded by contact with the ground. Anything which devitalizes the tissues—such as cold, bruising, malnutrition, the action of other organisms and their products—may all be predisposing factors, in so far as they place the tissue at a disadvantage and allow of the full development of the specific bacillus of tetanus. In order to produce the disease, it is not sufficient merely to inoculate tetanus bacilli, especially where resistent animals are concerned: they must be injected along with some of their toxins or with other organisms, the presence of which seems to increase the power of, or assist, the tetanus organism, by diverting the activity of the cells and so allowing the bacillus to develop. The poison formed by this organism resembles the enzymes and diphtheria poison, in that it is destroyed at a temperature of 65° C. in about five minutes, and even at the temperature of the body soon loses its strength, although, when kept on ice and protected from the action of light, it retains its special properties for months. Though slowly formed, it is tremendously potent, $\frac{1}{2500000}$ part of a drop (the five-millionth part of a c.c.) of the broth in which an active culture has been allowed to grow for three weeks or a month, being sufficient to kill a mouse in twenty-four hours, $\frac{1}{250}$ of a drop killing a rabbit, $\frac{1}{25}$ a dog, or $\frac{1}{10}$ of a drop a fowl or a pigeon; it is from 100 to 400 times as active as strychnine, and 400 times as poisonous as atropine. It has been observed that, quite apart from size, animals exhibit a varying degree of susceptibility. Frogs kept at their ordinary temperature are exceedingly insusceptible, but when they are kept warm it is possible to tetanize them, though only after a somewhat prolonged incubation period, such as is met with in very chronic cases of tetanus in the human subject. In experimentally-produced tetanus the spasms usually commence and are most pronounced in the muscles near the site of inoculation. It was at one time supposed that this was because the poison acted directly upon the nerve terminations, or possibly upon the muscles; but as it is now known that it acts directly on the cells of the central nervous system, it may, as in the case of rabies, find its way along the lymphatic channels of the nerves to those points of the central nervous system with which these nerves are directly connected, spasms occurring in the course of the muscular distribution of the nerves that receive their impulses from the cells of that area. As the amount of toxin introduced may be contained in a very small quantity of fluid and still be very dilute, the local reaction of the connective-tissue cells may be exceedingly slight; consequently a very small wound may allow of the introduction of a strong poisonous dose. Many of the cases of so-called idiopathic tetanus are only idiopathic because the wound is trifling in character, and, unless suppuration has taken place, has healed rapidly after the poison has been introduced. In tetanus, as in diphtheria, the organisms producing the poison, if found in the body at all, are developed only at the seat of inoculation; they do not make their way into the surrounding tissues. In this we have an explanation of the fact that all the earlier experiments with the blood from tetanus patients gave absolutely negative results. It is sometimes stated that the production of tetanus toxin in a wound soon ceases, owing to the arrest of the development of the bacillus, even in cases that ultimately succumb to the disease. Roux and Vaillard, however, maintain that no case of tetanus can be treated with any prospect of success, unless the focus into which the bacilli have been introduced is freely removed. The antitetanic serum was the first antitoxic serum produced. It is found, however, that though the antitetanic serum is capable of acting as a prophylactic, and of preventing the appearance of tetanic symptoms in animals that are afterwards, or simultaneously, injected with tetanus toxin, it does not give very satisfactory results when it is injected after tetanic symptoms have made their appearance. It would appear that in such cases the tetanus poison has become too firmly bound up with the protoplasm of the nerve cells, and has already done a considerable amount of damage.

(b) More Chronic Infective Diseases (tissue parasites).

Tuberculosis.—In no quarter of the field of preventive medicine have more important results accrued from the discovery of a specific infective organism than in the case of Koch's demonstration and separation in pure culture of the tubercle bacillus and the association of this bacillus with the transmission of tuberculosis. In connexion with diagnosis—both directly from observation of the organism in the sputum and urine of tuberculous patients, and indirectly through the tuberculin test, especially on animals—this discovery has been of very great importance; and through a study of the life-history of the bacillus and its relation to animal tissues much has been learned as to the prevention of tuberculosis, and something even as to methods of treatment. One of the great difficulties met with in the earlier periods of study of this organism was its slow, though persistent, growth. At first cultivations in fluid media were not kept sufficiently long under observation to allow of its growth; it was exceedingly difficult to obtain pure cultures, and then to keep them, and in impure cultures the tubercle bacilli were rapidly overgrown. Taken directly from the body, they do not grow on most of the ordinary media, and it was only when Koch used solidified blood-serum that he obtained pure cultures. Though they may now be demonstrated by what appear to be very simple methods, before these methods were devised it was practically impossible to obtain any satisfactory results.

The principle involved in the staining of the tubercle bacillus is that when once it has taken up fuchsin, or gentian violet, it retains the stain much more firmly than do most organisms and tissues, so that if a specimen be thoroughly stained with fuchsin and then decolorized in a mineral acid—25 per cent. of sulphuric acid, say—although the colour is washed out of the tissues and most other organisms, the tubercle bacilli retain it; and even after the section has been stained with methylene-blue, to bring the other tissues and organisms into view, these bacilli still remain bright red, and stand out prominently on a blue background. If a small fragment of tuberculous tissue be pounded in a sterile mortar and smeared over the surface of inspissated blood-serum solidified at a comparatively low temperature, and if evaporation be prevented, dry scaly growths make their appearance at the end of some fourteen days. If these be reinoculated through several generations, they ultimately assume a more saprophytic character, and will grow in broth containing 5 per cent. of glycerin, or on a peptone beef-agar to which a similar quantity of glycerin has been added. On these media the tubercle bacillus grows more luxuriantly, though after a time its virulence appears to be diminished. On blood-serum its virulence is preserved for long periods if successive cultivations are made. It occurs in the tissues or in cultivations as a delicate rod or thread 1·5 to 3·5μ in length and about 0·2 to 0·5μ in thickness (Fig. 15, Plate VIII.). It is usually slightly curved, and two rods may be arranged end to end at an open angle. There is some doubt as to whether tubercle bacilli contain spores, but little masses of deeply-stained protoplasm can be seen, alternating with clear spaces within the sheath; these clear spaces have been held to be spores. This organism is found in the lungs and sputum in various forms of consumption, in tubercular ulcers of the intestine, in the lymph spaces around the vessels in tubercular meningitis, in tubercular nodules in all parts of the body, and in tubercular disease of the skin—lupus. It is found also in the tubercular lesions of animals; in the throat-glands, tonsils, spleen, and bones of the pig; in the spleen of the horse; and in the lungs and pleura of the cow. Tuberculosis may be produced artificially by injecting the tubercle bacillus into animals, some being much more susceptible than others. Milk drawn from an udder in which there are breaking-down tubercular foci, may contain an enormous number of active tubercle bacilli; and pigs fed upon this milk develop a typical tuberculosis, which can be traced from point to point, commencing in the glands of the throat, with the utmost precision. It

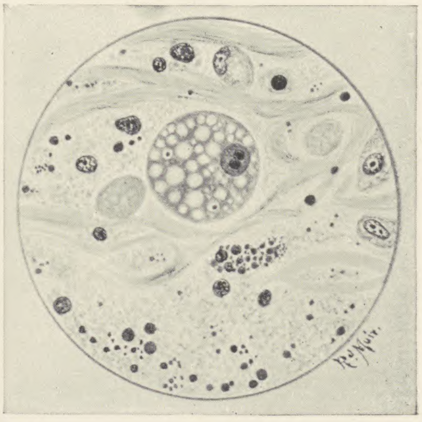

Fig. 19.

must be assumed that what takes place in the pig may also take place in the human subject; and a sufficient number of cases are now on record to show that the swallowing of tuberculous material is a cause of tuberculosis, especially amongst children and adolescents. Inhaled tubercle bacilli from the recently-dried sputum of phthisical patients, like milk derived from tuberculous udders, may set up tuberculosis of the lungs or of the alimentary tract, especially when the epithelial layer is unhealthy or imperfect. The two main causes of the prevalence of tuberculosis in the human subject are: (1) tubercle bacilli may become so modified that they can flourish saprophytically; as yet it has not been possible to trace the exact conditions under which they live, but we are gradually coming to recognize that although when they come from the body they are almost obligate parasites, they may gradually acquire saprophytic characters. (2) Many of the domestic animals are readily infected with tuberculosis, and in turn may become additional centres from which infection may radiate.

Although Koch's tuberculin, from which at one time so much was expected therapeutically, has not entirely fulfilled its promise, it is of great use in early diagnosis, and therefore should prove invaluable in the eradication of tuberculosis.

Tuberculin, from which the tuberculin test derives its name, consists of the products of the tubercle bacillus when grown for a month or six weeks in peptone meat-broth to which a small proportion, say 5 or 6 per cent., of glycerin has been added. The tubercle bacilli are then killed at boiling-temperature, and are partially removed by sedimentation, and completely by filtration through a Berkfeld or Pasteur-Chamberland filter. If a large dose of this filtered fluid be injected under the skin of a healthy man or brute, it is possible to produce some local swelling and to induce a rise of temperature; but in a similar patient suffering from tuberculosis a very much smaller dose (one which does not affect the healthy individual in the slightest degree) is sufficient to bring about the characteristic swelling and rise of temperature. To obtain trustworthy results the dosage must always be carefully attended to. The reaction is only obtained under certain well-defined conditions. Driven animals seldom, if ever, react properly. Cattle to be tested should be allowed to remain at rest for some time; they should be well fed, and be carefully protected from cold or draughts. After an injection of tuberculin into the subcutaneous tissues (usually in front of the shoulder or on the chest-wall) they should be kept under the same conditions and should be watered very carefully; the temperature should be taken at the sixth hour, and every three hours afterwards up to the twenty-first or even twenty-fourth hour. If during this time the temperature rises to 104° F., there can be little doubt that the animal is tuberculous; but if it remains under 103°, the animal must be considered free from disease: if the temperature remains between these points, the case is a doubtful one, and, according to Principal M'Fadyean, should be retested at the end of a month. It is interesting to note that the test is not trustworthy in the case of animals in which tuberculosis is far advanced, especially when the temperature is already high—103° F. In such cases, however, it is an easy matter to diagnose the disease by the ordinary clinical methods. At first objections were raised to this test on two grounds: (1) that mistakes in diagnosis are sometimes made; (2) that tuberculin may affect the milk of healthy animals into which it is injected. As the methods of using the tuberculin have been perfected, and as the conditions under which the reaction is obtained have become better known, mistakes have rapidly become fewer; further, it has been amply proved that tuberculin has not the slightest deteriorating effect on the quality of the milk.

Leprosy.—Armauer Hansen in 1871, and Neisser in 1881, described a "leprosy bacillus" corresponding in size and in certain points of staining reaction to the tubercle bacillus, and it is now generally accepted that this bacillus is the direct and specific causal agent of leprosy. The discovery of this organism paved the way for the proof that the tubercular and anæsthetic forms of leprosy are essentially the same disease, or rather are the manifestations of the action of a common organism attacking different series of tissues.

To demonstrate the presence of the leprosy bacillus, tie an indiarubber ring firmly around the base of one of the leprosy tubercles. As soon as the blood is driven out, leaving the nodule pale, make a puncture with the point of a sharp knife. From this puncture a clear fluid exudes; this, dried on a cover-glass, stained with carbol-fuchsin, and rapidly decolorized with a weak mineral acid, shows bacilli stained red and very like tubercle bacilli; they differ from that organism, however, in that they are somewhat shorter, and that if the acid be too strong, or be allowed to act on them for too long a time, the colour is discharged from them much more readily. These organisms, which are from 4 to 6μ in length and 0·3μ in breadth, are as a rule more rigid and more pointed than are the tubercle bacilli (Fig. 16, Plate VIII.). It is doubtful whether they form spores. They are found in large numbers lying embedded in a kind of gelatinous substance in the lymphatics of the skin, in certain cells of which they appear to be taken up.

It is curious that these bacilli affect specially the skin and nerves, and rarely the lungs and serous membranes, thus being in sharp contrast to the tubercle bacillus, which affects the latter very frequently and the former rarely. They are seldom found in the blood, though they have been described as occurring there in the later stages of the disease. It is stated that leprosy has been inoculated directly into the human subject, the patient dying some five or six years after the inoculation had been made; but up to the present no pure culture of the leprosy bacillus has been obtained; it has therefore been impossible to produce the disease by the inoculation of the bacillus only. What evidence we have at our disposal, however, is all in favour of the transmissibility of the disease from patient to patient and through the agency of the leprosy bacillus. None of the numerous non-bacillary theories of leprosy account at all satisfactorily for this transmissibility of the disease, for its progressive nature, and for the peculiar series of histological changes that are met with in various parts and organs of the leprous body. Leprosy occurs in all climates. It is found where no fish diet can be obtained, and where pork and rice are never used, though to these substances has been assigned the power of giving rise to the disease. Locality appears to influence it but little, and with improved sanitation and increased cleanliness it is being gradually eradicated. The only factor that is common in all forms of leprosy, and is met with in every case, is the specific bacillus; and in spite of the fact that it has yet been found impossible to trace the method of transmission, we must, from what is known of the presence and action of bacilli in other diseases, especially in tuberculosis, assign to the leprosy bacillus the rôle of leprosy-producer, until much stronger evidence than has yet been obtained can be brought forward in favour of any of the other numerous causes that have been assigned. Two cases are recorded in which people have contracted leprosy from pricking their fingers with needles whilst sewing a leper's clothes; and a man who had never been out of Dublin is said to have contracted the disease by sleeping with his brother, a soldier who had returned from India suffering from leprosy.

Glanders.—Farcy in the human subject resembles the same disease experimentally produced in animals with material from a glandered animal, and as there is no pathological distinction between the two, from the ætiological standpoint, they may be considered together. If the pus from a glanders abscess be mixed with a little sterile saline solution and spread over the cut surface of a boiled potato kept at the body-temperature, bright yellow or honey-coloured, thick, moist-looking colonies grow very rapidly and luxuriantly. These colonies gradually become darker in colour, until they assume a *café-au-lait*, or even a chocolate, tint. On examining one of them microscopically, it is found to be made up of bacilli 2 to 5 μ long and $\frac{1}{5}$ to $\frac{1}{8}$ of their own length broad (Figs. 13 and 14, Plate VII.). The bacillus is usually straight or slightly curved and rounded at one end; it appears to be non-motile. As first pointed out by Loeffler and Schütz, when a portion of a culture is inoculated subcutaneously, typical farcy, with the acute septicæmia or blood-poisoning so characteristic of certain cases of glanders and farcy, is the result. The human subject is usually inoculated through wounds or scratches, or through the application of the nasal discharge of a glandered animal to the mucous membrane of the nose or mouth. Man is not specially susceptible to the glanders virus; cattle never take it in the usual way, and even when inoculated exhibit nothing more than localized ulceration. The goat appears to occupy an intermediate position between cattle and the horse in this respect; in sheep, which are fairly susceptible, the disease runs its course slowly, and appears to resemble chronic farcy in man. In rabbits and the dog the disease runs a very slow and modified course. Although field-mice are extraordinarily susceptible, white mice and house mice, unless previously fed on sugar or with phloridzin, are unaffected. The pigeon is the only bird in which glanders has been produced. Lions and tigers are said to contract the disease, and to take it in a very severe and rapidly fatal form. The glanders organism rapidly loses its virulence and even its vitality. Dry, it dies in about ten days; placed in distilled water, in about five days; but kept moist, or when grown on culture media, it retains its vitality for about a month, although its activity soon becomes considerably lessened. These bacilli are readily killed at a temperature of 55° C.; they can pass through the kidneys even when there is no lesion to be made out either with the naked eye or under the microscope (Sherrington and Bonome).

The glanders bacillus grows best in the presence of oxygen, but it may grow anaërobically; it then appears to have the power of forming toxin, either more in quantity or of greater activity than when it has access to a free supply of oxygen. This poison (mallein) is used for the purpose of diagnosing the presence of glanders. A cultivation is made in peptonized bouillon to which a small portion of glycerine has been added. This is allowed to grow at the temperature of the body for a month or six weeks; the bacilli are killed by heat, and 0·5 per cent. carbolic acid is added. The cultivation is then filtered through a porcelain filter in order to remove the bodies of the bacilli, and the resulting fluid, clear and amber-coloured, should have the power, when injected in quantities of 1 c.c., of giving the glanders reaction in an animal suffering from that disease; in a healthy animal 6 c.c. should give no reaction. The suspected animal should be kept at rest and in a warm stable for twenty-four to forty-eight hours before the test is applied. The temperature should be normal, as no proper reaction is obtained in an animal in which the temperature is high. This reaction, which is a very definite one, consists in a rise of temperature of from 2° to 4° F., and the appearance of a swelling, of from 3 to 4 inches in diameter and from 1 to $1\frac{1}{2}$ inches in height, before the sixteenth or eighteenth hour; this swelling should continue to increase for some hours. It has been suggested that the injection of $\frac{1}{20}$ to $\frac{1}{15}$ c.c. of mallein, at intervals of two or three days, may be used with advantage in the treatment of glanders. Glandered horses seem to improve under this treatment, and certainly do not react even to much larger doses of mallein. The mallein test has revealed the fact that glanders is a far more common and more widespread disease than was at one time supposed.

(c) Infective Diseases in which Organisms have not yet been discovered.

Hydrophobia is usually contracted by man through inoculation of an abraded surface with the saliva of an animal affected with rabies—through the bite of a dog, the animal in which the so-called rabies of the streets occurs. The other animals that may be affected "naturally" are wolves, cats, foxes, horses, cows, and deer; but all warm-blooded animals may be inoculated with the disease. The principal changes are in the nervous system, and include distension of perivascular lymphatic sheaths; dilatation of blood-vessels and hæmorrhages, especially in the floor of the fourth ventricle of the brain, and in the various mucous and serous membranes; hyaline changes in and around the walls of blood-vessels; proliferation of the endothelium; swelling and vacuolation of nerve cells; pericellular infiltration with leucocytes, and also infiltration of the salivary glands with leucocytes (Coats). An increased number of leucocytes and microcytes in the blood has also been made out. As yet the definite form of the virus is unknown, but, whatever it may be, it has a power of multiplying in the tissues and of producing a toxic substance which, as in the case of tetanus toxin, appears to act specially on the central nervous system. At present two organisms are being studied in connexion with this disease—one a yeast described by Dr G. Memmo, the other an organism something like Fraenkel's diplococcus, by Bruschettini—but neither of them has as yet been satisfactorily worked out. The nature of the disease produced by the inoculation of saliva from a rabid animal appears to depend upon (1) the quantity of the rabic virus introduced; (2) the point of its introduction; (3) the activity of the virus. Thus by diluting the poison with distilled water or saline solution and injecting small quantities, the period of incubation may be prolonged. Slight wounds of the skin, of the limbs, and of the back are followed by a long incubation period; but when the inoculation takes place in the tips of the fingers or in the skin of the face, where nerves are numerous, and especially where the wound is lacerated or deep, the incubation period is much shorter and the attack usually more severe. This, as in tetanus, is accounted for by the fact that the lymphatics of the nerves are much more directly continuous with the central nervous system than are any other set of lymphatics. The poison appears to act directly upon the cells of the central nervous system.

Arising out of recent researches on hydrophobia, two methods of treatment—one of which, at any rate, has been attended by conspicuous success—have been put into practice. The first of these, Pasteur's, is based upon the fact that rabic virus may be intensified or attenuated at will. Pasteur found that although the virus taken from the cerebrospinal fluid of the dog always produces death in the same period when inoculated into the same animal, virus taken from other animals has not the same activity. If passed through a succession of monkeys it may become so attenuated that it is no longer lethal. If either the "monkey virus," which is not fatal to the rabbit, or the "dog virus," which kills in twelve to fourteen days, be passed through a series of rabbits, the virulence may be so exalted that it may kill in about six days, though its activity cannot be increased beyond this point by any means at present at our disposal. This intensified virus was therefore named by Pasteur the *virus fixe*, and it forms a standard from which to work. He found, too, that under certain conditions of temperature the virus may be readily attenuated, one hour at 50° C. or half an hour at 60° completely destroying it. A 5 per cent. solution of carbolic acid acting for half an hour, or a 1 per 1000 solution of bichloride of mercury or acetic acid or permanganate of potash, brings about the same result as do also exposure to air and sunlight. The poison contained in the spinal cords of rabbits exposed to dry air and not allowed to undergo putrefactive changes, gradually loses its activity, and at the end of fourteen to fifteen days is incapable of setting up rabid symptoms. A series of cords from rabbits inoculated with the *virus fixe* are cut into short segments, which, held in series by the dura mater, are suspended in sterile glass flasks plugged with cotton-wool and containing a quantity of potassium hydrate—a powerful absorbent of water. At the end of twenty-four hours the activity of the virus is found to have fallen but slightly; at the end of forty-eight hours there is a still further falling off, until on the fourteenth or fifteenth day the virus is no longer lethal. With material so obtained Pasteur treated patients who had been bitten by mad dogs. On the first day of treatment small quantities of an emulsion of the cord exposed for thirteen or fourteen days in saline solution are injected subcutaneously, and the treatment is continued for from fifteen to twenty-one days, according to the severity of the bite, a stronger emulsion—*i.e.* an emulsion made of a cord that has been desiccated for a shorter period—being used for each succeeding injection, until at last the patient is injected with an emulsion which has been exposed to the air for only three days. In the human subject the period of incubation of the disease is comparatively prolonged, owing to the insusceptibility of the tissues to the action of this poison; there is therefore some chance of obtaining a complete protection or acclimatization of the tissues before the incubation period is completed. The virus introduced at the bite has then no more chance of affecting the nerve centres than has the strong virus injected in the late stages of the protective inoculation: the nerve centres, having become gradually acclimatized to the poisons of the rabic virus, are able to carry on their proper functions in its presence, until in time, as in the case of microbial poisons, the virus is gradually neutralized and eliminated from the body. Various modifications and improvements of this method have from time to time been devised, but all are based on, and are merely extensions of, Pasteur's original work and method. As soon as it was found that antitoxins were formed in the tissues in the case of an attack of tetanus, attention was drawn to the necessity of determining whether something similar might not be done in the production of an antirabic serum for the treatment of rabies. Babes and Lepp, and then Tizzoni and his colleagues Schwarz and Centanni, starting from *virus fixe*, obtained a series of weaker inoculating materials by submitting it for different periods to the action of gastric juice. Beginning with a weak virus so prepared, and from time to time injecting successively stronger emulsions (seventeen injections in twenty days) into a sheep, they succeeded in obtaining a serum of such antirabic power that if injected in the proportion of 1 to 25,000 of body-weight, an animal is protected against a lethal dose of *virus fixe*. The activity of this serum is still further reinforced if a fresh series of injections is made at intervals varying from two to five months, according to the condition of the animal, each series occupying twelve days. This antirabic substance stored in the blood has not only the power of anticipating (neutralizing?) the action of the poison, but also of acting as a direct curative agent; as a prophylactic agent, readily kept in stock and easily and rapidly exhibited, it possesses very great advantages. It must be borne in mind that the longer the period after the inoculation, the greater must be the amount of serum used to obtain a successful result.

There can be little doubt that hydrophobia is a specific disease due to a multiplication of virus in the nervous system, in the elements of which it is ultimately fixed; that it passes from the wound to the central nervous system by the lymphatics; and that, as in tetanus, the muscular spasms are the result of the action of some special poison on the central nervous system.

Small-pox.—There have been few recent additions to our knowledge of the ætiology of small-pox, though Dr Monckton Copeman now holds that the small-pox organism, like that of vaccine, is probably a very minute bacillus, which, from its behaviour in the presence of glycerin, is possessed of the power of forming spores. If vaccine lymph, taken from the calf, be protected from all extraneous spore-bearing organisms and treated with 50 per cent. solution of glycerin, it in time becomes absolutely sterile as regards ordinary non-spore-bearing organisms. Even the staphylococci and streptococci, usually found in calf lymph, cannot withstand the prolonged action of this substance, but spore-bearing organisms still remain alive and active. Moreover, the lymph still retains its power of producing vaccine vesicles, so that the vaccine organism, in its powers of resistance, resembles the spore-bearing, and not the non-spore-bearing, organisms with which we are acquainted. This vaccine organism is very minute; it is stated that it can be cultivated only on special media, though it multiplies freely in the superficial cutaneous tissues of the calf, the monkey, and the human subject. Perhaps the most important outcome of Dr Copeman's work on this subject is that he has obtained a vaccine lymph from which are eliminated all streptococci and staphylococci, and, if the lymph be taken with reasonable care, any other organisms which could possibly give rise to untoward results.

Typhus Fever.—Up to the present time, although it is fully recognized that typhus must be one of the specific infective fevers brought about by the action of a special micro-organism, no definite information as to the bacterial ætiology of this condition has been obtained. It is always looked upon as a "filth" disease; and from the frequency of minute hæmorrhages, and from the resemblance to the hæmorrhagic septicæmias in other respects, it appears probable that the bacillus of typhus is the organism described by Mott in 1883 as an actively motile dumb-bell coccus, and ten years later by Dubieff and Bruhl as the diplococcus typhosus exanthematicus; the polar staining and general resemblance to the diplococcus of fowl cholera, the plague bacillus, the diplococcus of "Wildseuche," certain forms of swine fever and hog cholera, and others of the hæmorrhagic septicæmias, are sufficient to suggest the generic affinity of this organism to this septicæmic group. We have as yet, however, no absolute proof of the ætiological relation of the bacillus to this disease, such as has been obtained in connexion with other diseases, and it is impossible to add anything beyond this to the article contributed by Dr Affleck to the ninth edition.

Scarlet Fever.—In scarlet fever recent observations have been comparatively few and unimportant. Crooke, and later Klein, and others have, however, shown that in the glands and throats of scarlet fever patients a streptococcus, to which is assigned the chief ætiological rôle in connexion with this disease, is present. On the other hand, it is maintained by many observers that these streptococci are nothing more than the streptococci found in puerperal fever, erysipelas, and similar infective conditions, and certainly the organisms described closely resemble streptococcus pyogenes.

Measles.—In measles, as in scarlet fever, micrococci have had ascribed to them the power of setting up the specific disease. Canon and Pielicke have, however, described minute bacilli somewhat resembling those described as occurring in vaccine lymph. These are found in the blood in the early stages of the disease, and also in the profuse catarrhal secretions so characteristic of this condition. There are no records of the successful inoculation of this minute bacillus, and until such evidence is forthcoming this organism must be looked upon as being an accessory, possibly, but not the prime cause, of measles.

Mumps.—It is generally accepted that mumps is probably caused by a specific micro-organism, the infective material making its way in the first instance through the ducts to the parotid and other salivary glands. It appears to bring about a peculiar œdematous inflammation of the interstitial tissue of the glands, but slight parenchymatous changes may also be observed. The virus is present in the tissues for some days before there is any manifestation of parotid swelling, but during this period it is extremely active, and the disease may be readily transmitted from patient to patient. The infectivity continues for some time, probably for nearly a week after naked-eye manifestations of the diseased condition have disappeared. The specific organism has not yet been isolated.

Whooping-Cough.—Within the last few years there has been little addition to our knowledge either of the ætiology, course, or treatment of whooping-cough, although a diplococcus, a streptococcus, and various higher fungi have in turn been put down as the cause of this disease. It must, from its resemblance to the other specific infective fevers, be considered as an infective disease of microbic origin, which goes through a regular period of incubation and invasion, and in which true nervous lesions, especially of the pneumogastric and superior laryngeal nerves, are somewhat common.

Affanassieff, and later Koplick, have described a minute bacillus, with rounded ends and bi-polar staining, which occurs in the mucus discharged at the end of a paroxysm of whooping-cough. Koplick examined sixteen cases, and found this organism in thirteen of them. There can be little doubt that the infective material is contained in the expectoration. It may remain active for a considerable period, but is then usually attached to solid particles. It is not readily carried by the breath, and multiplies specially in the mucous membranes, setting up inflammation, probably through its toxic products, which appear to be absorbed, and, as in the case of the tetanus poison, to travel specially along the lymphatics of the local nerves. Affections of the lung—bronchitis and broncho-pneumonia—may be directly associated with the disease, but it is much more likely that these affections are the result of secondary infection of tissues already in a weakened condition.

II. To Higher Vegetable Parasites.

Actinomycosis.—A disease very prevalent in certain low-lying districts, especially amongst cattle, giving rise to the condition known as "sarcoma," "wooden tongue," "wens," "bony growths on the jaw," &c. It is characterized by the presence of a fungus, which, at first growing in the form of long slender threads that may be broken up into short rods and cocci, ultimately, as the result of a degenerative process, assumes the form of a "ray-fungus," in which a series of club-like rays are arranged around a common centre. It is probably a streptothrix—streptothrix Försteri (Fig. 17, Plate VII.). Numerous cases have been observed in the human subject. Suppuration and the formation of fistulous openings, surrounded by exuberant granulations, "proud flesh," usually supervene, and in the pus discharged are found yellowish green or reddish brown points, each made up of a central irregular mycelium composed of short rods and spores, along with the clubs already described. The mycelial threads may reach a considerable length (20 to 100μ); some of them become thicker, and are thus differentiated from the rest; the peripheral club is the result of swelling of the sheath; the filaments nearer the centre contain the spores, which measure from 1 to 2μ in diameter. This fungus appears to lead a saprophytic existence, but it has the power of living in the tissues of the animal body, to which it makes its way through or around carious or loose teeth, or through abrasions of the tongue or tonsils. After the above positions, the abdomen, especially near the vermiform appendix, is a special seat of election, or in some cases the thorax, the lesions being traceable downwards from the neck. Any of the abdominal or thoracic organs may thus be affected. The process spreads somewhat slowly, but once started may extend in any direction, its track being marked by the formation of a large quantity of fibrous tissue, often around a long fistula. In the more recent growths, and in solid organs, cavities of some size, containing a soft semi-purulent cheesy-looking material, may be found, this mass in some cases being surrounded by dense fibrous tissue. When once a sinus is formed the diagnosis is easy, but before this the disease, where tumours of considerable size are rapidly formed, may readily be mistaken for sarcoma, or, when the lungs are affected, for tuberculosis, especially as bronchitis and pleuritic effusion are frequently associated with both actinomycosis and tuberculosis.

Mycetoma, the Madura foot of India, is a disease very similar to actinomycosis, and, like that disease, is produced by a somewhat characteristic streptothrix. It usually attacks the feet and legs, however, and appears to be the result of infection through injured tissues. Under certain conditions and in long-standing cases the fungus appears to become pigmented (black) and degenerated.

Other forms of fungus disease or *Mycoses* are described. Aspergillosis, or pigeon-breeders' disease, is the result of the infection with the Aspergillus fumigatus. Certain tumours appear to be the result of the action of a yeast, Blastomycosis or Saccharomycosis. The spores of the Penicillium glaucum, and of some of the Mucors, are also said to have the power of setting up irritation, which may end in the formation of a so-called granuloma or granulation tissue tumour. These, however, are comparatively rare.

B. Diseases due to Animal Parasites.

I. To Protozoa.

Malaria.—Following Laveran's discovery, in 1880, of a parasite in the blood of patients suffering from malaria, our knowledge of the disease has increased by leaps and bounds, and one of the most important questions concerning tropical diseases has now been cleared up. Numerous observations have been carried out to determine the different parasites found in different forms of malaria—the tertian, quartan, and æstivo-autumnal fever—in each of which, in the red blood corpuscles, a series of developmental stages of a parasite from a small pale translucent amœbiform body may be followed. This small body first becomes lobulated, nucleated, and pigmented; it then, after assuming a more or less marked rosette-shape with a deeply pigmented centre, breaks up into a series of small rounded hyaline masses of protoplasm, each of which has a central bright point. The number of these, contained in a kind of capsule, varies from 12 to 20 in the tertian and æstivo-autumnal forms, and from 8 to 10 in the quartan form. There are certain differences in the arrangement of the pigment, which is present in larger quantities and over a wider area in the somewhat larger parasites that are found in the tertian and quartan fevers. In the parasite of the æstivo-autumnal fever the pigment is usually found in minute dots, dividing near the pole at the point of division of the organism, along with it in the earlier stages (Fig. 18, Plate VII.). Here, too, the rosette form is not so distinct as in the parasite of tertian fever, and in that not so distinct as in the quartan parasites. These dividing forms make their appearance immediately before the onset of a malarial paroxysm, and their presence is diagnostic. The process of division takes place especially in the blood-forming organs, and is therefore found more frequently in the spleen and in bone-marrow than in any other situations. The parasites, at certain stages of their development, may escape from the red blood corpuscles, in which case (especially when exposed to the air for a few minutes) they send out long processes of protoplasm and become very active, moving about in the plasma and between the corpuscles, sometimes losing their processes, which, however, continue in active movement. In the æstivo-autumnal fever curious crescent-shaped or ovoid bodies were amongst the first of the parasitic organisms described as occurring in the blood, in the red corpuscles of which they develop. Manson maintains that from these arise the flagellate forms, all of which, he thinks, are developed in order that the life of the malarial parasite may be continued outside the human body. It is probable that most of the pigment found in the organs taken from malarial patients is derived from red blood corpuscles broken down by the malarial parasites; many of these, in turn, are devoured by leucocytes, which in malarial blood are usually greatly increased in number, and frequently contain much pigment, which they have obtained either directly from the fluid plasma or from the pigmented parasitic organism. The work recently carried out by Bruce on the tsetse-fly parasite, by Smith on Texas fever, and by Thayer and Hewitson on the blood parasites of birds, has opened up the way for the further study of the malarial parasites outside the human body. There can be no doubt as to the close relation of the multiplication and sporulation of the malarial parasite with the ague paroxysm: the anæmia results from the breaking down of blood corpuscles. Toxic substances are present in the blood during the setting free of the spores; of this we have proof in the increased toxicity of the urine during the paroxysmal phases of the disease; necrotic areas, similar to those found in acute toxic fevers produced by other micro-organisms, are also met with. It is well to bear in mind that the accumulation of débris of parasites and corpuscles in the capillaries may be an additional factor in this necrosis, especially when to this is added the impairment of nutrition necessarily involved by the impoverished condition of the malarial blood. It is interesting to note that, although, as pointed out by Nuttall, the Italian and Tyrolese peasantry have long been firmly of the opinion that malaria is transmitted through the mosquito, and although Nott of New Orleans as early as 1848 "refers to malaria as if the mosquito theory had already been advanced," little attention has been given to this question by most observers. Still earlier, Rasori (in 1846) had stated that "for many years I have held the opinion that intermittent fevers are produced by parasites, which renew the paroxysm by the act of their reproduction, which recurs more or less rapidly according to the variety of the species"; and this appears to be the first well-authenticated reference to this subject. Nuttall, who gives an excellent summary of the literature on the mosquito theory of malaria, assigns to King the honour of again drawing attention to this question. Laveran in 1891, Koch in 1892, Manson in 1894, Bignami and Mendini in 1896, and Grassi in 1898, all turned their attention to the mosquito theory. Manson, basing his theory upon what he had observed as regards the transmission of Filaria by the mosquito, suggested a series of experiments to Major Ronald Ross. These were carried out in 1895, when it was found that in mosquitoes that had taken up blood containing amœboid parasites, crescents, which were first described as cells, appeared in the stomach-wall after four or five days; these contained a number of stationary vacuoles and pigment granules, ten to twenty in number, bunched together or distributed in lines. Grassi, Bignami, and Bastianelli have confirmed and added to Ross's observations; they find that *anopheles claviger*, taking the blood from a patient suffering from malaria, soon develops hæmosporidia in the intestine. These parasites are then found between the muscular fibres of the stomach; they increase in size, become pigmented, and more and more vacuolated, until they project into the body-cavity. On the sixth day these large spheres contain an enormous number of minute bodies, refractive droplets like fat, and a diminishing amount of pigment. On the seventh day numerous filaments, arranged in rows around several foci, are seen. They are very delicate, are stained with difficulty, and appear to be perfectly independent of each other, though grouped within a capsule. After the capsule has ruptured, these thread-like "sporozooites," escaping into the body-cavity, gradually make their way to, and accumulate in, the cells or tubules of the salivary glands, whence their passage through the proboscis into the human blood is easily understood.

Development of the malarial parasite.

Two phases or cycles of existence have then been demonstrated—one within the human body, the second in the mosquito. That within the human body appears to be capable of going on almost indefinitely as long as the patient lives, but that in the mosquito appears to be, as it were, an intermediate stage. The minute specks of protoplasm, the amœbulæ, which have already been described as occurring in the red blood corpuscles of the higher animals, increase in size, take up blood pigment, probably from the red corpuscles, and then become developed into sporocytes or gametocytes. The sporocyte is the form which, remaining in the body, ultimately breaks up, as already seen, into a series of minute spores or amœbulæ, which in turn go through the same cycle again, increasing in size and forming spores, and so on indefinitely. Gametocytes (the true sexual form) are in certain species, to outward appearance, very similar to the sporocyte, but in others they assume the crescentic shape, and can thus be recognized. The male cell resembles the female cell very closely, except that the protoplasm is hyaline and homogeneous-looking, whilst that of the female cell is granular. It has already been noted that when the blood is withdrawn from the body certain of the malarial parasites become flagellated. These flagella may be looked upon as sperm elements, which, forming in the male gametocyte, are extruded from that cell, and, once set free, seek out the granular female gametocytes. A single flagellum becomes attached to a small projection that appears on the female cell; it then makes its way into the protoplasm of the female cell, in which rapid streaming movements are then developed. In certain species the female cell is somewhat elongated, and may be peculiarly constricted. It becomes motile, and appears to have the power of piercing the tissues. In this way the first stages of development in the mosquito are passed. The gametocytes, taken along with the blood into the stomach of this insect, pass through the various phases above mentioned, though the zygote form has not yet been traced in the human malarial parasite. In the blood of a patient bitten by an infected mosquito, the ordinary malarial parasite may be demonstrated without any difficulty at the end of a week or ten days, and the cycle recommences. This theory, in which the mosquito acts as an intermediary host for one stage of the parasite and transmits the parasite to man, affords an explanation of many apparently anomalous conditions associated with the transmission of malaria, whilst it harmonizes with many facts which, though frequently observed, were very difficult of explanation. Malaria was supposed to be associated with watery exhalations and with the fall of dew, but a wall or a row of trees was seemingly quite sufficient to prevent the passage of infection. It was met with on wet soils, on broken ground, in marshes, swamps, and jungles; on the other hand, it was supposed to be due to the poisonous exhalations from rocks. All this is now explained by the fact that these are the positions in which mosquitoes occur: wherever there are stagnant pools, even of a temporary nature, mosquitoes may breed. It has been observed that although the malarial "miasma" never produces any ill effects in patients living at more than a few feet from the surface of the ground, malaria may be found at a height of from 7000 to 9000 feet above the sea-level; and the fact that a belt of trees or a wall will stop the passage of the poison is readily explicable on the mosquito theory. These insects are incapable, owing to their limited power of flight, of rising more than a few feet from the ground, and cannot make their way through a belt of trees of even moderate thickness. The fact that broken ground, such as is found in connexion with railway cuttings and canals, may be a focus from which malaria may spread, is further support of this theory, from the fact that in such broken ground pools are of common occurrence, and afford the conditions for the development of the mosquito, whilst the infected tools used in one area may easily convey the germs to another. The conditions of climate under which malaria is most rife are those which are most suitable for the development of the mosquito. The protection afforded by fires, the recognized value of mosquito curtains, the simultaneous disappearance of anopheles and malaria on the complete draining of a neighbourhood, the coincidence of malaria and mosquitoes, and the protection afforded by large expanses of water near walls and trees, are all important in this connexion.

Mosquitoes, malarial parasites, and malaria have the same geographical distribution.

The mosquitoes specially associated with the transmission of malaria in the human subject belong apparently to the genus Anopheles, *Anopheles claviger* (*maculipennis*) and *Anopheles bifurcatus*, both species found in Great Britain, and *Anopheles pictus*, another species found in Europe, but so far not in Great Britain. The important member of the genus Culex is the grey mosquito or *Culex fatigans*, the intermediate host of the proteosoma of birds, on which many of the intermediate phases of the life-history of these malarial parasites has been studied. Ross describes a dappled-wing mosquito as the one with which he performed his experiments on birds in India. *Anopheles claviger* is a British species, an interesting fact in association with the former prevalence of malaria in Great Britain. The remedy for malaria appears to be thorough drainage of pools and puddles, or, where this cannot be easily effected, the throwing of a certain amount "of kerosene on the surface of these pools" (Nuttall).

Species of mosquito concerned.

Amœbic Dysentery.—In addition to the dysentery set up by bacteria, a form has been described which is said to be due to an animal parasite—amœbic dysentery or amœbic enteritis—and it has been proposed to separate the various types of dysentery according to their ætiology, in which case the amœbic group is probably more specific than any other. The amœba supposed to give rise to this condition was first described by Lösch in 1875. Since then it has been described either as a harmless parasite or as a cause of dysentery in Europe, Africa, the United States, and in Brazil, and more recently in India. This organism, which is usually placed amongst the rhizopods, consists of a small globule of protoplasm, varying in size from 6 to 35μ, though, as Lafleur points out, these limits are seldom reached, the organism being usually from one and a half to three times the diameter of a leucocyte—from 12 to 26μ (Fig. 19, Plate VIII.). Its margins are well defined, and the body appears to consist of a granular inner portion and a homogeneous outer portion, the latter being somewhat lighter in colour than the inner; in the resting stage this division cannot be made out. The organism appears to pass through at least two phases, one corresponding to a cystic, the other to an amœboid, stage. In the latter stage, if the organism be examined on a warm stage, it is seen to send out processes, and, as in other amœbæ, vacuoles may be seen as clear spaces lying in the granular and darker-coloured inner protoplasm. In some cases these vacuoles are so numerous that they occupy the whole of the spaces usually occupied by the granular protoplasm, and are merely surrounded by a zone of variable thickness, which "has the appearance of finely granular glass of a distinctly pale green tint" (Lafleur). In the cystic stage it is often easy to make out the presence of a nucleus which appears amongst the vacuoles, usually towards one side of the amœba. This nucleus is of considerable size, *i.e.* nearly as large as a red blood corpuscle, and is readily distinguishable from the surrounding protoplasm. When stained by the Benda method (safranin and light green) a nucleolus may be seen in the nucleus. The nucleus is perhaps best seen when stained by this method, but it is always difficult to obtain well-stained specimens of this organism. Red blood corpuscles are often englobed by this amœba, as are also micrococci and bacilli. The movements of the amœbæ are most active at a temperature of about 90° to 98° F. From the fact that pigment is contained in these organisms, it is supposed that they take in the red blood corpuscles as nutritive material, and that other substances may be taken in to serve a similar purpose. Nothing is known of the method of multiplication of the amœba, but it is supposed that it may be both by fission and by spore formation. These organisms are present in the early stage of the acute disease, and disappear at the later stages. A similar organism, however, may be found even in the normal intestine. Perhaps of some importance is the fact that the abscesses found in the liver and lung, which occur so frequently in cases of dysentery, usually contain, especially in the portions immediately adjoining the suppurating mass, a considerable number of these amœbæ. In the very small abscesses the amœbæ are numerous and active, and occupy the capillaries in the tissues. It is quite possible that this plugging of the capillaries with amœbæ is the cause both of the hæmorrhages and of the small areas of necrosed tissue, the supply of nutriment being cut off from the liver cells and from the lung tissues, and that suppuration only occurs as a secondary process, though Councilman and Lafleur maintain that the amœba itself is the primary cause of suppuration. It is possible, of course, that the suppuration is due to the action of pus-forming organisms conveyed along with, or following, the amœba, as we know that the growth of suppurating organisms can go on in dead tissues when these organisms have no chance of surviving in the healthy tissues and fluids of the body. Lafleur holds that the amœba forms a toxic substance which exerts a direct devitalizing effect on the liver cells, and that the amœba itself causes suppuration. The abscesses in the lung, which invariably extend directly from the liver and occur at the base of the right lung, also contain these amœbæ. It is for these reasons that this organism is looked upon as the cause of dysentery and of certain forms of dysenteric abscess.

Tsetse-Fly Disease.—The interesting observations carried out by Surgeon-Major Bruce have invested the tsetse-fly with an entirely new significance and importance. In 1895, Bruce first observed that in the tsetse disease—*nagana*—there may be found a flagellated hæmatozoon closely resembling the Trypanosoma Evansii found in Surra. This, like the Surra organism, is very similar in appearance to, but considerably smaller than, the hæmatozoon often found in the blood of the healthy rat. It has, however, as a rule a single flagellum only. A small quantity of blood, taken from an affected buffalo, wildebeest, koodoo, bushbuck, or hyæna—in all of which animals it was found by Bruce—when inoculated into a horse, mule, donkey, cow, dog, cat, rabbit, guinea-pig, or rat, produces a similar disease, the organisms sometimes being found in enormous numbers in the blood of the inoculated animal, especially in the dog and in the rat. He then found that the tsetse-fly can only produce the disease in a healthy animal when it has first charged itself with blood from a diseased animal, and he produced evidence that *Glossina morsitans* is not capable of producing the disease, except by carrying the parasites from one animal to another in the blood that it takes through its proboscis into its stomach. The parasites taken in along with such blood may remain in the stomach and alive for a period of 118 hours, but shortly after that the stomach is found to be empty, and the parasites contained in the excrement no longer retain their vitality. The mode of multiplication of these organisms has been studied by Rose-Bradford and Plimmer, who maintain that the multiplication takes place principally in the spleen and lymphatic glands. The tsetse-fly parasite, however, is still imperfectly understood, though much attention is now being paid to its life-history and development.

Surra.—In Surra, Evans described a hæmatozoon—Trypanosoma Evansii—which in many points resembles the Trypanosoma of tsetse disease. This disease, which specially affects horses, mules, and camels in India, and, according to Steel, the dog and the monkey, was at one time supposed to correspond to relapsing fever, but careful comparison of the spirillum or spirochæte with the organism found in the tsetse disease and the hæmatozoon of the rat, has led to the conclusion that the two parasites are perfectly distinct, and these latter are now recognized as an animal parasite—Trichomonas. When this parasite is found in the blood of an animal, especially in advanced forms of the disease, there is marked fever, often jaundice and minute hæmorrhages—especially in the mucous membranes, and sometimes the serous membranes—marked general malaise, muscular weakness, and great wasting. The disease does not appear to be infectious or contagious in the ordinary sense of the term; but when blood from an infected animal is introduced into the stomach or subcutaneous tissues of an animal, the latter is rapidly attacked, the Trypanosoma making its way into the blood and multiplying with extraordinary rapidity. The exact site and method of multiplication have not yet been fully worked out. There is sufficient resemblance between this organism and the tsetse-fly parasite to render a comparison between the two unavoidable, but the general opinion of those who have worked at these parasites is that not only are the species distinct, but that they give rise to somewhat different lesions and symptoms in the animals in which they multiply.

II. To other Animal Parasites.

Filariasis.—Since Bancroft and Manson first described *Filaria nocturna* and its relation to the common form of filariasis, the most important contribution to our knowledge has been made, at the suggestion of the younger Bancroft, by Dr G. C. Low, who has demonstrated that the embryos of the filaria may be found in the proboscis of the mosquito (*Culex ciliaris*), whence they probably find their way into the circulating blood of the human subject. It appears that the filaria embryo, after being taken with the blood of the patient into the stomach of the mosquito, loses its sheath; after which, leaving the stomach, it passes into the thoracic muscles of its intermediate host, and becomes more fully developed, increasing considerably in size and attaining a mouth, an alimentary canal, and the characteristic trilobed caudal appendage. It now leaves the thoracic muscles, and, passing towards the head, makes its way "into the loose cellular tissue which abounds in the prothorax in the neighbourhood of the salivary glands." Most of them then "pass along the neck, enter the lower part of the head," whence they may pass into the proboscis. Although it has never been demonstrated that the filaria is directly inoculated into the human subject from the proboscis of the mosquito, it seems impossible to doubt that when the mosquito "strikes," the filaria makes its way into the circulation directly from the proboscis. It is important to note that the mosquito, when fed on banana pulp, does not get rid of the filaria from its proboscis. This, however, is not to be wondered at, as the filaria is apparently unable to live on the juices of the banana, whilst the consistence of the banana is very different from that of the human skin. The importance of this observation, as affording an additional reason for taking measures to get rid of the mosquito in districts in which filariasis is rife, can scarcely be over-estimated.

(G. S. W.)

III. NEUROPATHOLOGY.

The morbid processes affecting the nervous system are numerous and varied, but usually they are clinically divided into two great groups of (1) organic disease, (2) functional disturbance. Such a classification depends upon whether or not symptoms observed during life can be associated with recognizable changes of the nervous system, gross or microscopical, after death. Sometimes this is the morbid process itself, sometimes only the ultimate result of the process. It must be remarked, however, that many diseases which we now look upon as functional may be found due to recognizable changes when suitable methods of investigation shall have been discovered. The paroxysmal neuroses and psychoses may be considered *a priori* to be due to temporary morbid functional conditions. Our knowledge of the first group is naturally much more advanced than of the latter, for, given certain symptoms during life, we are able, as a rule, to predict not only the nature of the morbid process, but its particular locality.

The histological elements which make up the nervous system may also be divided into two groups: (1) the nervous units or neurones, (2) the supporting, protecting, and nutrient tissues. Organic diseases may start primarily in the nervous units or neurones and cause their degeneration; such are true diseases of the nervous system. But the nervous units may be affected secondarily by diseases starting in the supporting, protecting, and nutrient tissues of the nervous system; such are essentially diseases *within* the nervous system, and include diseases of the blood-vessels, lymphatics, membranes, and the special nervous connective tissue, neuroglia (a residue of the embryonal structure from which the nervous system was developed). Tumours and new growths must also be included.

The modern conception of the "neurone" as an independent complex cell with branching processes, in physiological rather than anatomical association with other neurones, has modified our ideas of the morbid processes affecting the nervous system, especially as regards degenerations of systems, communities, or collections of neurones subserving special functions. It was formerly believed, and generally taught, that the primary systemic degenerations were due to a sclerosis; thus locomotor ataxy was believed to be caused by an overgrowth of the supporting glia tissue of the posterior columns of the spinal cord, which caused a secondary atrophy of the nervous tissue. We now know that this overgrowth of glia tissue is secondary to the atrophy of the nervous elements, and the only true primary overgrowth of glia tissue is really of the nature of the new growth (gliosis). But even in this case it is doubtful if the mere proliferation of the glia tissue elements could destroy the nervous elements, if it were not for the fact that it leads to changes in the vessel walls and to hæmorrhages.

The symptoms manifested during life depend upon the nature of the morbid process and the portion of the nervous system affected. A correct understanding of neuropathology involves the study of (1) the causes which give rise to morbid conditions, which are often complex and due to various combinations of factors arising from without and within the body, and (2) the changes in the structure and functions of the nervous system brought about by intrinsic and extrinsic causes. It will be assumed that the reader has already acquired a knowledge of the anatomy and physiology of the nervous system.

The *causes of pathological processes* occurring in the nervous units (neurones) may be divided into *internal* and *external*, and it may be remarked that in all cases except direct injury the two groups are generally more or less combined.

A. *Internal Causes.*—Of all the causes of nervous disease, *hereditary predisposition* stands pre-eminently first; it may be convergent, paternal, maternal; from grandparents or even more remote ancestors. Especially does this statement apply to functional neuroses, *e.g.*, epilepsy, migraine, hysteria, and neurasthenia; and to psychoses, *e.g.*, delusional insanity, mania, and melancholia. In 70 per cent. of 150 cases of idiocy or imbecility in the London county asylums, Dr Tredgold found a family history of insanity in some form or another. Strictly speaking, it is the tendency to nervous disease rather than the disease itself that is inherited, and this is frequently spoken of as a neuropathic or psychopathic taint. There are, besides, a number of inherited diseases, which, although somewhat rare, are of interest inasmuch as they affect members of a family, the same disease frequently commencing in each individual at about the same age. These are termed *family diseases*, and include hereditary ataxia (Friedreich's disease), myotonia (Thomsen's disease), hereditary (Huntingdon's) chorea, amaurotic idiocy, and various forms of idiopathic muscular atrophy. Alcoholism, tuberculosis, and syphilis in the parents, especially if one or both come from a neuropathic or psychopathic stock, frequently engender idiocy, imbecility, epilepsy, and general paralysis in the offspring, by the production of defects in the vitality of the germinal plasm, causing arrest, imperfect development, or premature decay of groups, communities, or systems of neurones, especially those which are latest developed—the symptoms manifested depending upon the portions of the nervous system affected. To explain the hereditary neuropathic tendency morphologically, we may suppose that there is an inherited defect in the germinal plasm which is concerned in the formation of the neurones. We may regard the neurone as a complex cell, and the nervous system as a community of neurones arranged in systems and groups having special functions. Like all cells, the neurone nourishes itself and is not nourished; certainly it depends for its development, life, and functional activity upon a suitable environment, but it must also possess an inherent vital energy by which it can assimilate and store up nutrient material which may be regarded as *potential* (latent nerve energy), to be converted into nerve force as required. A constant constructive and destructive bio-chemical process occurs in the neurones of a healthy nervous system, latent nervous energy is high, and the sense of fatigue is the natural indication for sleep and repose, whereby it is constantly recuperated. In the neuropathic or psychopathic individual it may be conceived that in some portion of the nervous system, especially the brain, there may exist communities, systems, or groups of neurones with inherited low potential, readily becoming exhausted, and, under the influence of altered blood states or stress, especially liable to functional depression, from which arise function-paralysis and melancholia. Again, the bio-chemical substance which represents potential in the nervous system may be in a chemically unstable condition, so as readily to fulminate when excited by abnormal conditions (*e.g.*, toxic conditions of the blood), thus acting as a centre of discharge of nervous energy, which may be manifested by mental or bodily symptoms. We know that in strychnia and tetanus poisoning the most localized peripheral excitation will cause general muscular spasm; in both toxic conditions the spread is probably due to a bio-chemical change in the protoplasm of the spinal neurones, whereby the excitability is greatly increased and a slight stimulus is sufficient to fulminate the whole system of motor neurones. In epilepsy and other paroxysmal neuroses and psychoses it is possible that some altered condition of the blood, when associated with an inherited bio-chemical instability of certain groups, systems, or communities of neurones, may act as a *fulminating agent*. In neuralgia and local hyperæsthesia the slightest general or distant local irritation suffices to produce pain; thus coughing, the vibration of a passing train, or the slamming of a door, may produce pain by the stimulation of the hyper-excitable neurones. Moreover, it must be borne in mind that the symptoms of nervous disease are due as much to normal physiological functional activity improperly applied, as to actual loss of function occasioned by disease. Thus squint, caused by paralysis of one of the muscles of the eyeball, causes less trouble to the patient than the double vision occasioned by the physiological activity of the two retinæ, upon the corresponding points of which the images are prevented by the paralysis from falling.

B. The *external causes* producing morbid changes in the nervous elements are:—

I. Abnormal conditions of the blood and lymph, by which the neurones are poisoned and their metabolism morbidly affected.

II. Excess or deficiency of normal stimulation, or existence of abnormal stimulation.

III. Injury or diseases of supporting, enclosing, or vascular tissues.

I. *Abnormal Conditions of the Blood and Lymph.*—The immediate environment of all the cellular elements of the body is lymph, and in the central nervous system there is a special form of lymph, the cerebro-spinal fluid. The neurones, like other cellular elements, are bathed in the lymph, and extract from it the materials necessary for their growth and vital activities, casting out the waste products incidental to the bio-chemical changes which are continually taking place. The lymph, therefore, serves as a medium of exchange between the blood and the tissues, consequently the essential causes of change in environment of the nervous elements (neurones) are: (1) Deficiency or absence of blood-supply to the nervous system in general (as after severe hæmorrhage), or to some particular portion, owing to local vascular disturbance or occlusion. (2) Alterations in the normal condition of the blood, due to (*a*) deficiency or absence of certain essential constituents, (*b*) excess of certain normal constituents, (*c*) the presence of certain abnormal constituents produced within the body, or entering it from without.

(1) *Quantity of Blood Supply.*—Syncope or fainting occurs when the blood supply suddenly fails to reach the higher centres of the brain; this usually arises from sudden reflex arrest of the heart's action. If a portion of the central nervous system is cut off from its arterial blood-supply by embolic plugging or by clotting of the blood in a vessel with diseased walls, the portion of the brain substance thus deprived of blood undergoes softening, the nervous elements are destroyed, and the systems of nerve fibres, which have had their trophic and genetic centres in the area destroyed, undergo *secondary degeneration.* Clotting of the blood in the veins may also give rise to destructive softening of the brain, and similar secondary degeneration.

(2) *Quality of Blood Supply.*—(*a*) *Insufficiency of oxygen*, due to poverty of the colouring matter or of the number of the red corpuscles, which constitutes the various forms of anæmia, leads to functional depression, lassitude, and mental fatigue. Impoverishment of the blood in women by frequent pregnancies and excessive lactation causes neuralgia, nervous exhaustion, and, in the neuropath, hysteria, neurasthenia, melancholia, and mania. The mental depression, and the tendency that the various neuroses and psychoses have to occur and recur at the time of the menstrual and climacteric periods in women, suggests the possibility of an alteration in the composition of the blood, either in the nature of an auto-intoxication or "sub-minimal deficiency," as the probable

contributory factor of the mental disturbance. It may be remarked that eclampsia, puerperal and lactational mania, are relatively common forms of insanity in women; although sometimes of septic origin, they more frequently are occasioned by some morbid metabolism as yet little understood. The most striking examples we have, however, of the effect of absence or "sub-minimal" deficiency of a normal constituent of the blood upon the development and functions of the nervous system, are afforded by cretinous idiots, who are born without thyroid glands, and whose brains never develop in consequence; and by those people who suffer from the disease known as *myxœdema*, occasioned by the absence of iodothyrin, a product of the internal secretion of the thyroid gland. The proof of this is shown by the disappearance of the nervous phenomena, slowness of thought, slowness of speech, &c., after a preparation of the gland has been continuously administered by the mouth. Even cretinous idiots, when subjected in early life to thyroid treatment, improve considerably. The removal of the testicles in the male may produce a profound effect upon the nervous temperament; for probably there is an internal secretion of this gland in the male, as of the ovary in the female, which has some subtle influence upon the functional activity of the nervous system. The seminal fluid contains a large amount of complex phosphorus-containing substances, which, lost to the body by sexual excess or onanism, have to be replaced by the blood; the nervous system, which also needs these complex organic phosphorus compounds, is thereby robbed, and neurasthenia ensues. Brown-Séquard's testicular injection treatment for many nervous complaints, based upon this idea, has not, however, met with much success.

(*b*) *Excess of certain Normal Constituents in the Blood.*—Excess of carbonic acid causes drowsiness, and probably in asphyxia is one of the causes of the convulsions. All the series of the nitrogenous waste products—the most highly oxidized, most soluble, and least harmful of which is urea—are normal constituents of the blood; but should the oxidation process be incomplete, owing to functional or organic disease of the liver, or should these substances accumulate in the blood, owing to inadequate function of the kidneys, a toxic condition, called uræmia, may supervene, the nervous manifestations of which are headache, drowsiness, unconsciousness or coma, epileptiform convulsions, and sometimes symptoms of polyneuritis. Again, in Graves's disease, nervous phenomena, in the form of exophthalmos, fine tremors, palpitation, and mental excitement, have by some authorities been explained by the excess of thyroid internal secretion, due to the enlargement and increased functional activity of the gland.

(*c*) The presence of *abnormal constituents in the blood* is a most important cause of disease of the nervous elements. We may consider the subject under the following headings: Poisons produced within the body (α) by perverted function of organs or tissues, auto-intoxication; (β) by the action of micro-organisms upon the living fluids and tissues of the body; (γ) poisons introduced into the body from without, in the food and drink, or by inhalation.

(α) *Poisons resulting from perverted Function of the Organs.*—In the process of digestion a number of poisonous substances, *e.g.*, albumoses, &c., are produced, which, although absorbed in the alimentary canal, are prevented by the living epithelium, and possibly by the liver, from entering the systemic circulation. Fatigue products, *e.g.*, sarcolactic acid in prolonged muscular spasms, may lead to auto-intoxication. Excess of uric acid in the blood is associated with high arterial pressure, deposits of lithates in the urine, headache and nervous irritability; it is an indication of imperfect metabolism and auto-intoxication, as shown by the fact that marked improvement occurs by suitable diet and treatment. Phosphoruria, oxaluria, and glycosuria, tokens of deranged metabolism, may be associated with various nervous phenomena. Bile in the blood, cholæmia, resulting from obstructive jaundice, may be attended by stupor and psychical depression; and the term melancholia, signifying "black bile," indicates the importance which has long been attached to the liver as an organ the derangement of which causes nervous depression. The rapidly fatal results attending acute yellow atrophy of the liver, namely, the profound changes in the urine, the jaundice, and the nervous phenomena of delirium, motor irritation, delusions, stupor, and coma, demonstrate the important part this organ plays in preserving the normal quality of the blood. The delirium and coma which sometimes supervene in diabetes, heralded by acetonæmia, is another instance of auto-intoxication. The coma is very possibly due to the saturation of the sodium salts of the blood by aceto-acetic and oxybutyric acids, products of imperfect proteid metabolism. The effect of this would be an interference with the elimination of carbonic acid in the processes of tissue and pulmonary respiration. Again, in pernicious and certain grave anæmias, the degenerative changes in the spinal cord found in some cases is due, not so much to the defect in the red corpuscles, as to some neuro-toxin, which probably arises from imperfect metabolism or absorption from the alimentary canal. In this question of auto-intoxication, it must be remarked that all the tissues of the body are mutually interdependent. If one suffers, all suffer, and a disease of one organ or tissue is thereby apt to establish a vicious circle which is constantly enlarging; therefore nervous symptoms manifesting themselves in the course of a disease add much to the gravity of the complaint.

(β) *Poisons produced by Infective Micro-organisms.*—Some of these poisons have a general devitalizing influence, by an alteration of the blood and the production of fever. In the course of the acute infectious diseases, typhoid, typhus, small-pox, scarlet fever, measles, influenza, also tuberculosis and septicæmia, delirium is a frequent complication; it may be the result of high fever or prolonged fever, or directly due to the poison, or the two combined. In severe cases stupor and coma may occur, and it has been shown that in this extreme stage the nerve cells undergo an acute morbid bio-chemical change. These particular poisons have no selective toxic action upon a particular part of the nervous system, and symptoms not only during, but after, the acute illness are liable to supervene, especially in a neuropathic individual. Thus many cases of neurasthenia, insanity, neurosis, also neuritis, date their origin from an acute specific fever. In cerebro-spinal meningitis, tubercular meningitis, acute delirious mania, and leprous neuritis, the inflammation of the membranes of the brain and spinal cord, is due to the growth of the specific organism in the lymph and interstitial tissue elements.

Poisons may have a *selective influence* upon some part of the nervous system. The syphilitic poison is the most important factor in the production of two progressive degenerations of the nervous system—one affecting especially the afferent conducting tracts of the spinal cord, namely, locomotor ataxy, and the other affecting especially the frontal and central convolutions of the cerebral hemispheres, namely, general paralysis of the insane. A striking instance of the selective action of the syphilitic poison is shown in the fact that only in persons affected with acquired or inherited syphilis is a symptom known as Argyll-Robertson pupil found; this is the absence of the pupil reflex contraction to light, while that for accommodation persists. Seeing that this is the most common objective phenomenon in the two diseases mentioned, it strengthens the presumption, based on experience, that the syphilitic poison is the cause of these diseases in the majority of instances. Again, syphilis, when it attacks the supporting, enclosing, and nutrient vascular tissues, shows a predilection to affect structures about the base of the brain, and paralyses of the third nerve are almost pathognomonic of this disease. In rabies, although the whole nervous system is charged with the poison, the medulla oblongata (as shown by the symptoms) is especially affected. Again, in tetanus the bacilli are only found in the wound; they must therefore be comparatively few in number, but they elaborate a virulent poison, which affects particular groups of neurones. The fact that lockjaw nearly always occurs first, shows that the poison selects the motor nucleus of the fifth nerve; but it is remarkable that experiment has shown that the tetanus toxin, if mixed with an emulsion of nervous matter before injection into an animal, loses its toxicity. This fact indicates its affinity for nervous matter, and also a power of absorption of the poison by some chemical substance in the nervous matter. Another example is offered by diphtheria. A neuro-toxin is produced by the local action of the bacilli, for they do not become freely generalized in the blood and tissues. Whether the poison is a direct production of the bacilli themselves, or is an auto-toxin created in the body itself, by an influence exerted on the living fluids and tissues by a ferment-like product of the bacilli, is not determined. But whatever may be the source of the toxin, its effects upon the neurones are constant, as shown by the sufferings of the patients—paralysis of the soft palate, with nasal speech and regurgitation of fluids through the nose when swallowing is attempted; inability to read, owing to the paralysis of the muscle of accommodation; weakness and incoordination of the limbs, which may amount to paralysis; absence of the knee-jerks; and often skin anæsthesia.

(γ) *Poisons introduced into the Body.*—The most widespread and potent cause of nervous and mental disease is the abuse of alcoholic stimulants. At least 20 per cent. of the inmates of the asylums of London are suffering from the effects of the abuse of alcohol. Most of these patients, however, inherit the neuropathic tendency, and it is a rare thing, among such, to find cirrhosis of the liver with ascites, a condition which indicates long persistent spirit-drinking. The writer, from a very large experience as pathologist to the asylums of London, only remembers one such case, and that was in a notorious woman who was convicted nearly four hundred times for drunkenness before she could be certified as of unsound mind, a fact which indicates that she inherited a very stable nervous constitution. To people with unstable nervous systems a relatively small quantity of alcohol may act as a poison. Alcohol may produce acute delirium, with fine tremors, and, generally, visual hallucinations of a horrible nature, indicating acute toxic influence upon the brain. This acute form of alcohol poisoning is much commoner in men than in women, and it is remarkable how a severe injury or illness, such as pneumonia, will bring out *delirium tremens* in a drunkard. Alcohol acts especially upon the higher centres of the brain, and a drunken man may exhibit "the abstract and brief chronicle of insanity, going through its successive phases in a short period of time" (Maudsley). The effect on the nervous system of chronic tippling is dementia, a very characteristic manifestation of the mental degradation being absence of knowledge of time and place, personal illusions, and loss of memory of recent events, indicating a failure of receptivity and of the formation of memory-pictures in the higher centres. A certain amount of improvement may occur when total abstinence is enforced, which shows the poison has damaged but not destroyed the nervous elements. Besides mental symptoms of alcoholic poisoning, there is frequently paralysis, affecting especially the lower limbs (structures suffer most where vitality is least), although the upper limbs, and even the respiratory muscles, may be affected in severe cases. The patient becomes helpless and bedridden, and death frequently occurs from heart failure. Characteristic features of this affection are great tenderness on pressure of the muscles, especially of the calves, absence of reflexes, a variable degree of skin anæsthesia, wasting of muscles and alteration of the normal electrical reactions, and frequently pyrexia. There is no loss of control over the bladder and bowels, unless there is very marked dementia. This "complex of symptoms" points to a *peripheral polyneuritis*, although frequently changes occur also in the ganglion cells, from which the axis cylinders of the nerves have their origin (*vide* Plate X., Nos. 6, 7, 8, and 9). Many other poisons, notably lead and arsenic, the specific fevers before mentioned, syphilis, and alterations of the blood due to imperfect metabolism, such as occur in diabetes and gout, may produce, or become important factors in producing, peripheral neuritis. The outbreak of arsenical neuritis from beer containing this poison in Manchester in 1900 is of interest, from the fact that the symptoms closely resemble acute alcoholic neuritis. A distinctive feature, however, was the pigmentation of the skin and the severity of the nervous symptoms. A disease which is common in the East, termed *Beriberi*, is a form of neuritis, the cause of which is not exactly known, although it is possibly infective, and due to elaboration by micro-organisms of some chemical poison which escapes into the blood. Still, the fact that it has almost disappeared from the Japanese navy with improved diet and better hygiene would suggest that it is due to auto-intoxication from defective metabolism. Anæsthetic leprosy is an interstitial inflammation of the nerves due to the *Lepra bacillus*. Among the nervous diseases due to occupation may be cited lead-poisoning. This is peculiar in selecting the nerve which supplies the extensor muscles of the wrist and fingers, so that dropped wrist is almost characteristic of this form of toxic neuritis. Lead also produces a chronic inflammation of the cerebral cortex, *Encephalitis saturnina*, causing a complex of symptoms, namely, dementia, loss of memory, weakened intellect, paresis and epileptiform seizures, hallucinations of sight and hearing, and mental exaltation or depression. Mirror-makers suffer with characteristic fine tremors, from the slow absorption of mercury into the system. Workmen at indiarubber factories may suffer from severe mental symptoms, owing to the inhalation of the fumes of bisulphide of carbon.

There are a certain number of poisons, besides alcohol, which act upon the nervous system when continually entering the body as the result of a *habit*, namely, absinthe, ether, cocaine, opium, morphia, haschish, and tobacco. Each of these poisons produces a train of symptoms denoting a selective influence upon certain parts of the nervous system. In illustration thereof may be mentioned impairment of central vision in tobacco amblyopia.

Unsound Food.—In northern Italy and Egypt numbers of people suffer with *Pellagra*, an affection of the skin associated with degenerative changes in the brain and spinal cord. The symptoms of the disease are generally a fatuous melancholy with suicidal impulses, sometimes mania associated with paresis. It is supposed that this disease is due to the bad maize upon which the people at times have to subsist. Another disease, *ergotism*, in an epidemic form, has affected poor people in Russia and North Germany when obliged to subsist upon bread made of rye which has been attacked by the ergot fungus. The poison thus introduced into the system produces progressive degenerative changes in the brain and spinal cord, which are manifested by psychical disturbances, such as slowness of thought, weakness of memory, dulness of perception, sometimes delirium and incoherence; other symptoms are blunted sensibility, dilated pupils, muscular spasms, perhaps even epileptiform seizures and ataxy, and, lastly, stupor deepening into coma. Sausage disease, due to eating decayed meat and fish infected with *Bacillus botulinus*, is associated with symptoms which frequently terminate fatally, and it has been shown that the symptoms are due to a poison which has a very destructive effect upon the nerve cells (Plate X., No. 10).

II. *Normal and Abnormal Stimulation.*—The nervous system, in order to develop and manifest functional activity, requires suitable stimulation from without. Structure and function are mutually reciprocal and interdependent; for a structure which is not used will gradually lose its function, while its nutrition will also suffer, and in time atrophy may occur. Consciously and unconsciously, a continuous stream of impulses is pouring into the nervous system from without by the sensory channels, which are the avenues of experience and intelligence, and our somatic and psychical life depends upon the existence of such stimuli. The nervous system in the form of systems, groups and communities of neurones, each with special functions, yet all woven together in one harmonious whole, develops in a particular way in consequence of the awakening influence of these stimuli from without. Consequently nervous structures which are not used are liable to undergo regressive metamorphosis and atrophy; thus amputation of a limb in early life causes atrophy of the nervous structures which presided over the sensation and movement of the part. This is seen both in the grey and white matter of the spinal cord. A healthy physical, intellectual, and moral environment of the individual is an essential factor in the prevention and cure of psychoses and neuroses, because it tends to develop and strengthen body and mind, deliberation, judgment, and the higher controlling functions of the brain. A function not used will gradually disappear, and become more and more difficult to evoke. This fact is of importance in functional neuroses and psychoses, *e.g.*, hysterical paralysis, melancholia, and delusional insanity, because the longer mental or bodily function is left in abeyance, the more likely is the defect to become permanently installed. The converse is also true: the longer a perverted function exists, the more unlikely it is to disappear. Thus auditory hallucinations, a very important and frequent symptom in the insane, commence with indistinct noises; these are followed by "voices," which eventually become so distinct and real that the greater part of the patient's psychical existence is concentrated upon, and determined by, this abnormal stimulus from within, indicating progressive strengthening and fixation of the perverted functions of the mind, and progressive weakening and dissolution of the normal functions.

Mental pain in the form of grief, worry, anxiety, fright, shock, violent emotions (pleasurable or painful), disappointed love, sexual excesses or perversions, and excessive brain work, frequently precede and determine, in persons with the insane or neuropathic taint, various forms (*a*) of psychoses, *e.g.*, mania, melancholia, delusional insanity; (*b*) of neuroses, *e.g.*, chorea, hysteria, epilepsy, hystero-epilepsy; (*c*) of organic brain disease, *e.g.*, apoplexy, thrombosis, general paralysis.

Visceral reflex irritation affords many examples of neuroses and psychoses, the symptoms of which are set up by irritation of the viscera, *e.g.*, intestinal worms. Teething and indigestible food are often the exciting cause in infants and young children of convulsions, spasms of the glottis, and tetany. Various functional and organic diseases of the female reproductive organs act as exciting causes in the production of hysteria, hystero-epilepsy, melancholia, and mania; moreover, paroxysmal attacks in these diseases are more liable to occur at the menstrual period or menopause. The irritation of a carious tooth may produce spasmodic tic and trigeminal neuralgia. Wax in the ear may occasion vertigo and tinnitus; and errors of refraction in the eyes may be the cause of attacks of migraine, and even tend to excite epileptic fits in a person suffering from epilepsy. Numerous other examples of peripheral disturbance could be mentioned as exciting causes of nervous affection in neurotic individuals. Irritation of the terminals of the vagus in almost any part of its widespread visceral distribution may lead to vomiting. The characteristic pain of angina pectoris, which radiates down the inner side of the left arm, is explained by the fact that the cardiac branches of the sympathetic arise from the same segments of the spinal cord as the sensory branches of the ulnar nerve; consequently the pain is referred to the corresponding skin area supplied by this nerve. This is one example of a great number of *referred pains*.

III. *Injury or disease of enclosing or supporting structures* may lead to paralytic or irritative lesions of the nervous system, or the two may be combined. Blows or wounds of the head and spine may damage or destroy the nervous structures by shock or direct injury. Concussion of the brain or spinal cord may occur, as a result of injury, without any recognizable serious damage of the enclosing structures or even the central nervous system. Shock, due to concussion, can only be explained by a molecular or bio-chemical change in the nervous structures.

Direct injury or a fall fracturing the skull, driving the fragments into the brain, will cause direct destruction of the nervous tissue; but wounds and diseases of the enclosing and supporting structures, if producing simple non-infective inflammation, give rise only to such symptoms as accord with the nerve structure irritated or destroyed. Should, however, the wound or diseased structure become infected with micro-organisms, the disease spreads and becomes generalized, likewise the symptoms. Of all the causes of infective inflammation, middle-ear disease, on account of its frequency and insidious onset, is the most important. It is very liable, when neglected, to be followed by a septic meningitis, encephalitis, and brain abscess, the most frequent seat of which is in the adjacent temporal lobe, but it may be in other parts of the brain, *e.g.*, the cerebellum and frontal lobe (Fig. 2, Plate IX.). The peripheral nerves may be destroyed or irritated by direct injury, disease, or new growth in adjacent tissues, or they may be involved in the callus thrown out round the seat of a fracture.

Diseases of the blood-vessels are among the most frequent causes of organic brain disease. Arteries or veins—more frequently the former—may become blocked or ruptured from various causes, the result being destruction of some portion or portions of the nervous tissue, with corresponding loss and disturbance of function. The cerebral arteries may be occluded by embolism; a portion of a clot or vegetation from a diseased valve of the left side of the heart may be detached, and escape into the circulation; and this is carried into one of the arteries of the brain, usually the middle cerebral, more often of the left side than the right. The area of brain tissue supplied by that artery is deprived of blood, and undergoes softening in consequence, resulting in paralysis of the opposite half of the body (hemiplegia), associated with aphasia when the paralysis affects the right side in a right-handed person. Softening may also arise from coagulation of the blood (thrombosis) in an artery the walls of which are diseased. This is a very common cause of paralysis and dementia in people who have passed middle life. General disease of the arteries of the body, associated especially with chronic Bright's disease and high arterial pressure, is frequently attended with the formation of minute miliary aneurysms upon the cerebral arteries, which may rupture and cause apoplexy. Hæmorrhage into the brain from this cause is especially liable to occur in certain situations; one vessel in particular, supplying the basal ganglia, most frequently gives way, the effused blood tearing through the motor efferent fibres, which, proceeding from the cerebral cortex in the shape of a funnel, become aggregated together to form the neck between the two masses of grey matter—the optic thalamus and the corpus striatum (Fig. 4, Plate IX.). The result is hemiplegia of the opposite side of the body. Disease of the arteries of the central nervous system, occurring in a person under forty, is generally due to syphilis, the poison of which produces an inflammation of the coats of the vessel, especially the inner. Occlusion and softening may arise; and seeing that any or all the arteries of the brain may be affected successively, simultaneously, or at random, the symptoms may be manifold. They may be general or local, and not uncommonly are associated with inflammation of the membranes. The disease, under treatment, may abate, and the paralytic or mental phenomena partially or completely disappear, indicating the restoration, or partial restoration, of the circulation in the diseased arteries; sometimes with the lapse of treatment and sometimes without, new symptoms, such as paralysis of a fresh group of muscles or of the opposite side of the body, may manifest themselves, showing that the disease has attacked a fresh set of arteries. *Disseminated sclerosis* (*insular*) is another random morbid process, affecting especially the white matter, with certain characteristic symptoms of a progressive character, the pathology of which is not understood fully. Islands of nervous tissue undergo a morbid change, commencing in the myelin sheath and ending in an increase of the supporting neuroglia tissue at the expense of the true nervous tissue.

Tumours and new growths in the central and peripheral nervous systems may be primary or secondary: the former arise in the supporting, enclosing, or nutrient tissue elements; the latter are metastatic deposits from tumours originating elsewhere. Tumours may be single or multiple, the special symptoms occasioned depending upon the seat of the tumour and whether it destroys or only irritates the adjacent nervous tissue. Tumours situated within the cranial cavity cause general symptoms, namely, optic neuritis, severe headache and vomiting; these symptoms, which are caused by increased intracranial pressure, are more severe in rapidly-growing vascular tumours, even though small, than in large slow-growing tumours. If the growth is situated in a portion of the cortex having some special localizing function, *e.g.*, the motor area (*vide* Fig. 1), it may give rise to epileptiform convulsions, starting in a limb or definite group of muscles; but the irritation usually spreads to the whole motor area of the same side, and even extends to the opposite hemisphere, by an overflow of the discharge through the corpus callosum. In such case there is loss of consciousness. If, however, the tumour destroys the cerebral cortex of a particular region, it may give rise to a paralytic lesion, *e.g.*, paralysis of the arm (*vide* Fig. 3, Plate IX.).

Organic diseases of the blood-vessels, or of supporting and enclosing tissues, produce secondary degenerations of the nervous system. The symptoms, like the lesion, are obvious, coarse, and obtrusive; frequently arising suddenly, they may in a short time terminate fatally, or tend towards

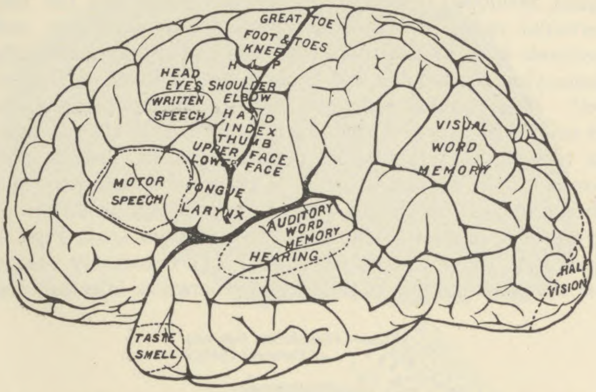

FIG. 1.—Diagram of left cerebral hemisphere, showing localization of function. The motor region is situated in front of the central sulcus, and is arranged in a series from "toe to larynx" downwards, corresponding in an inverse manner to the spinal series. Irritation of any part of this area will cause localized convulsive spasms, which may spread in a definite march to the whole motor area, as in Jacksonian epilepsy. Destructive lesions will cause paralysis. The centre for "taste and smell" is represented at the tip of the uncinate convolution. The centre for "half-vision" is only in small part represented, for the larger part is on the mesial surface. "Hearing" is represented occupying the posterior half of the first temporal convolution. Included in this area, but in the *left* hemisphere only, is the centre for "auditory word memory"; destruction of this causes inability to understand the meaning of words uttered, although the patient is able to read aloud. Behind this, in the angular gyrus, is the centre for "visual word memory"; destruction of this causes loss of power of understanding of written or printed words—therefore inability to read. In front of the motor area is Broca's convolution, the centre of "motor speech"; destruction of this produces motor aphasia, or inability to articulate words. Above this is a centre which is connected with written speech. These four centres concerned with verbal and written language are connected by commissural fibres, and destruction of these connexions leads to various defects in verbal and written language. It will be understood from this diagram that diseases of the left hemisphere in right-handed persons are associated with results of more significance than similar affections of the right hemisphere.

partial or complete recovery. Various forms of motor and sensory loss and disturbance of function may arise, indicating destruction or disturbance of particular regions of the central nervous system; and degenerations in certain tracts and systems of fibres arise, corresponding in histological character with those observed when a nerve fibre

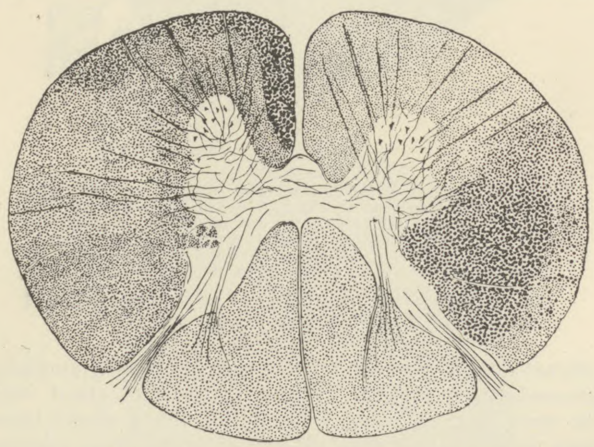

FIG. 2.—Diagram of section of the spinal cord in the upper cervical region, showing recent degeneration of the crossed pyramidal tract of the right side and direct pyramidal tract of the left side. The black dots indicate the degenerated fibres stained by the Marchi method. This degeneration is secondary to hæmorrhage into the internal capsule of the left hemisphere, and it will be observed by the number of degenerated fibres that the greater bulk have crossed over to the right side of the spinal cord, thus agreeing with the fact that the paralysis is of the right half of the body.

is separated from its cell of origin by section (secondary degeneration of Waller and Türck) (*vide* Fig. 2, with explanation). This form of degeneration must be distinguished from primary degeneration, which is due to an inherent nutritional defect of the nerve cell and all its processes (the neurone), in which a regressive metamorphosis occurs; it starts in the structures of the neurones latest developed (namely, the myelin sheath and the fine terminal twigs of the axis cylinder and dendrons), and proceeds back to the main branches and trunk, eventually destroying the trophic and genetic centre itself, the nerve cell. These *primary* degeneration processes are insidious in origin, progressive in character, and nearly always fatal in termination; they affect definite systems, groups, and communities of neurones in a progressive manner, and therefore are associated with a progressive evolution of symptoms, related to the structures affected (*vide* Figs. 3 and 4). To cite some examples: (1) Locomotor ataxy, on the one hand, is a primary degeneration affecting the

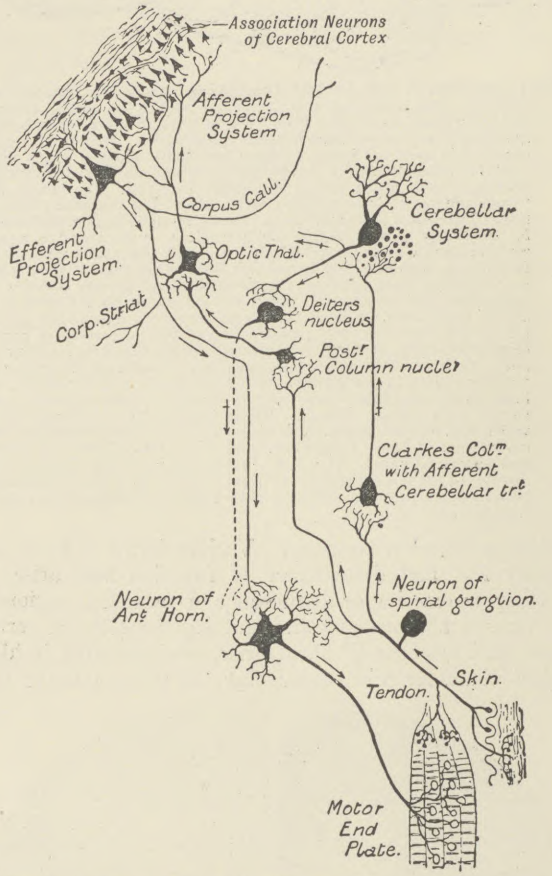

FIG. 3.—A diagram to indicate afferent, efferent, and association systems of neurones. It will be observed that there are three nervous circles indicated by the arrows—spinal, cerebellar, and cerebral. In every perfect co-ordinate movement impulses properly adjusted are flowing along these three systems of neurones. In systemic degenerations one or more of these systems may be affected, and the symptoms will depend partly upon the function which is lost or disturbed, and partly upon the disturbance of equilibrium of the three co-ordinated systems.

afferent system of neurones; it is characterized by muscular inco-ordination without wasting, inability to stand with the eyes shut, lightning pains in the limbs, absent knee-jerks, Argyll-Robertson pupils, and other symptoms pointing to a morbid process affecting especially the afferent sensory system of neurones. (2) Progressive muscular atrophy, on the other hand, is a disease of the *efferent* motor system of neurones of the brain and spinal cord, characterized by progressive wasting of groups of muscles innervated by groups of neurones which are undergoing degeneration. A fatal termination to this disease frequently arises from affection of the medulla oblongata, causing what is known as bulbar paralysis. Infantile paralysis is an acute inflammation of the anterior horns of the spinal cord, causing destruction of the spinal motor neurones of the anterior horn. It differs from the above chronic disease in its sudden onset and non-progressive character; it resembles

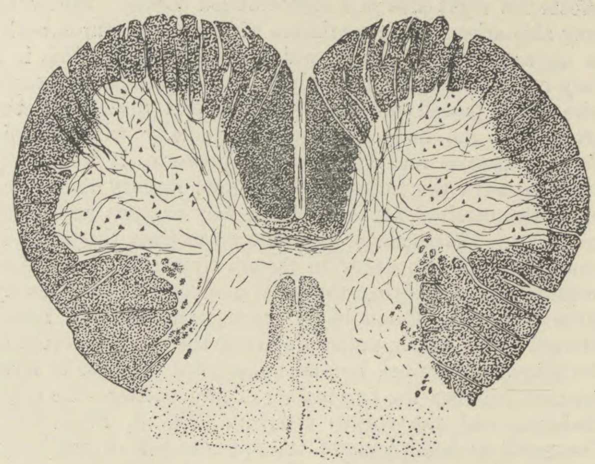

FIG. 4.—Diagram of spinal cord, fifth lumbar segment, from a case of advanced *tabes dorsalis*. The posterior column is shrunken, and but faintly stained, except in the anterior part; the shrinkage and the loss of stainability are due to the absence of fibres of the posterior roots, which normally form the greater part of this region of the cord. The fibres which are seen in the anterior part of the posterior column are derived from cells within the spinal cord, and belong to spinal association neurones.

it in producing paralysis of muscles without sensory disturbance. (3) General paralysis of the insane is a degeneration which begins in the association system of neurones of the cerebral cortex, but which may be, and frequently is, associated with degeneration of the afferent or efferent systems (Fig. 3).

It is not attempted in this article to explain neuroses and psychoses by morphological changes in the brain (Fig. 1, Plate IX.). We know little or nothing accurately about the morbid histology of insanity, except as regards the morphological changes met with in cases of amentia and dementia. The conditions of amentia, namely, idiocy and imbecility, are associated with arrest of development of the brain, as a whole or in part, the naked-eye evidence of which may be afforded by small size and simplicity of convolutions of the brain as a whole or in part (Figs. 7, 8, and 9, Plate IX.); and the microscopical evidence by arrest of development, or imperfect development, of structures connected with the higher functions of the mind, namely, the association neurones in the superficial layers of the cerebral cortex (Fig. 5). Conditions of dementia, primary or secondary, are associated with progressive decay and atrophy of the superficial layers of the grey matter of the cortex, and naked-eye evidence thereof is afforded by partial or general wasting of the cerebral hemispheres, accompanied with thickening of the pia-arachnoid membrane, atrophy of the convolutions, and with deepening and widening of the intervening sulci (Figs. 5 and 6, Plate IX.). This wasting is especially due to atrophy of the cells and fibres of the superficial grey matter of the cortex, sections of which, examined microscopically, after suitable methods of staining have been employed, show great poverty, or complete loss, of three sets of delicate myelinated fibres, namely, tangential, super-radial, and the inter-radial corresponding to the line of Baillarger. This degeneration of the superficial association fibres of the cerebral cortex affects especially the frontal and central convolutions, and is the earliest and most constant microscopical change in progressive dementia; it is accompanied usually by vascular changes, atrophy of the nerve cells, and proliferation of the neuroglia (Fig. 5). Possibly new methods may enable us to show changes of structure in diseases such as epilepsy and delusional insanity, in which hitherto

PLATE X.

Varions Motor Cells, drawn from microphotographs of preparations stained by Nissl method to show microchemical changes produced by various diseases. 1. Normal motor cell from cerebral cortex, showing a mosaic pattern of the cytoplasm due to a substance stainable by basic aniline dyes; this stainable substance exists also on the dendrons. By comparing the appearances of this cell with the other figures a just idea can be obtained of the morbid changes which result in various pathological conditions. 2. Cell from a case of hyper-pyrexia—disappearance of the mosaic pattern, substance uniformly stained; absence of the chromatic elements on the dendrons, due to a precipitation of cell-globulin by the heat. 3. Cell in an advanced stage of coagulation necrosis, complete absence of mosaic pattern; diffuse fine dust-like stain; breaking off of the processes; all caused by softening of the brain from vascular obstruction. 4. Another specimen from the same brain in a still more advanced stage of destruction, and showing a phagocyte attached to the cell and devouring the decayed structure. 5. A cell with enormously swollen nucleus, the result of hydration due to absorption of fluid after ligature of cerebral vessels. Such a cell will probably recover. 6, 7, 8, and 9. Spinal motor cells in various stages of destruction, from a case of acute alcoholic poly-neuritis, illustrating, 6, chromatolysis; 7, ditto with eccentric nucleus; 8, extrusion of nucleus; 9, vacuolation. 10. Cell illustrating swelling of nucleus and chromatolysis in acute toxæmia produced by poison of bacillus botulinus.

no naked-eye or microscopical structural defects accounting for the symptoms have been certainly demonstrated.

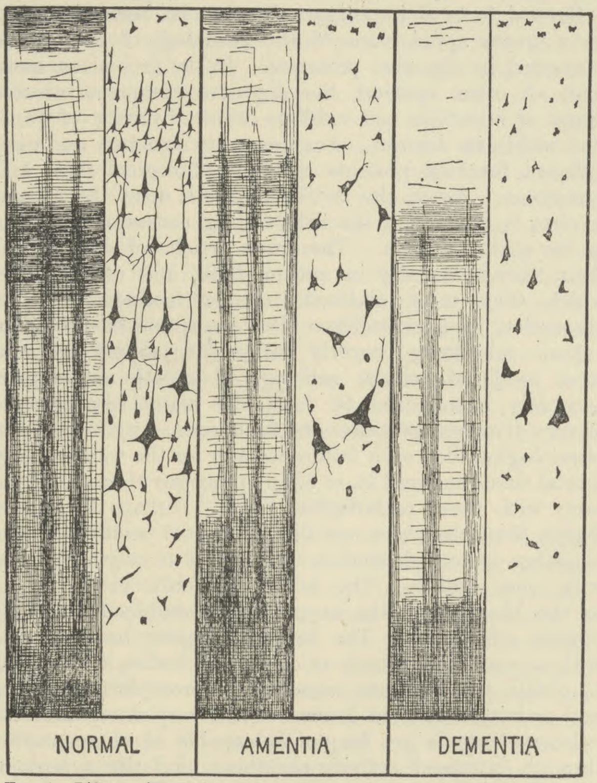

FIG 5.—Diagram illustrating the relative number and wealth of cells and fibres in the cerebral cortex in the normal brain, in amentia and dementia. The horizontal systems of fibres are association systems, and it will be observed that these are especially diminished in amentia, and still more in dementia, whereas the radial fibres are less affected. In the normal, there are five layers of cells arranged in columns (Meynert's); in the pathological conditions it will be observed that the pyramidal-shaped cells no longer have their apical processes pointing vertically upwards. The processes are broken off, the cells are distorted in shape and diminished in numbers, and the degree of dementia in a wasted brain is proportional to the atrophy and destruction of the small and medium-sized pyramids of the whole cerebral cortex, and the disappearance of the superficial layers of fibres. This is especially manifested in paralytic dementia and the dementia of chronic insanity.

In conditions of acute mania there is usually considerable vascular engorgement.

Microscopical changes in degeneration of the neurone.—About 1850, Waller demonstrated that a nerve fibre underwent degeneration to its termination when separated from its cell of origin; hence the term "Wallerian degeneration." Embryological researches by Professor His showed that the axis-cylinder process (the essential conducting portion of the nerve fibre) is an outgrowth of the nerve cell. The cell, therefore, is the trophic and genetic centre of the nerve fibre. Acute alterations and death of the nerve cells may occur from toxic conditions of the blood; from high fever (107–110° F.); arrest of the blood supply, as in thrombosis and embolism; or actual destruction by injury, hæmorrhage, or inflammation. These morbid processes produce, as a rule, bio-chemical as well as morphological changes in the nerve cell and its processes. Space will not allow of a full description, but some of these changes are indicated in Plate X. When a nerve cell dies, the nerve fibre undergoes secondary degeneration and death; that is to say, the whole neurone dies, and regeneration, at any rate in the higher vertebrates, does not take place. Restoration, or partial restoration, of function is due to other structures taking on the function, and the more specialized that function is, the less likely is restoration to take place. If, however, a peripheral nerve is divided, its component fibres are merely severed from their cells of origin. All that portion of the nerve which is in connexion with the nerve cells of origin practically undergoes no change. The peripheral portion undergoes degeneration, but from the central end of the nerve new axis cylinders again grow out and a new nerve is formed. With this regeneration comes restoration of function, which may be hastened by suturing the ends of the cut nerve. A similar regeneration, however, does not occur after section of fibres of the white matter of the central nervous system, and this may be due to the fact that the nerve fibres of the white matter of the cerebro-spinal axis possess no nucleated sheath of Schwann, which, by the light of recent investigations, is shown to play an important part in regeneration; in the writer's opinion, the neurilemmal sheath of the old fibre forms a new protoplasmic basis, into which the axis-cylinder from above grows, the passage of stimulus determining its function. The accompanying Fig. 6, Nos. 1–8, with explanatory text, shows the changes which occur in degeneration and regeneration of a peripheral nerve after section, with loss of function; and subsequent union, with restoration of function. The writer, in conjunction with Professor Halliburton, has shown that the characteristic microscopical changes in the myelin sheath which occur in the process of degeneration are due to a splitting up of the complex phosphoretted substance "protagon" into glycero-phosphoric acid, choline, and oleic acid by a process of hydration. The Marchi reaction, which has been found so useful for demonstrating degeneration of the central and peripheral nervous systems, is dependent upon the

FIG. 6.—Diagram to illustrate various stages in degeneration and regeneration of medullated nerve fibres. 1. Normal medullated nerve with node of Ranvier. 2. Degenerated nerve, ten days after section, showing degenerated myelin stained black; disappearance of axis-cylinder. 3. Central end of cut nerve, showing at the top an axis-cylinder budding out, proliferated neurilemmal cells, and still some degenerated myelin in sheath. 4. Peripheral cut end of same, showing proliferated neurilemmal cells, still some degenerated myelin. 5. Complete absorption of degenerated myelin, protoplasmic basis of new fibre formed out of neurilemmal cells. 6. A new fibre, with axis-cylinder. 7. Central end of cut nerve at junction, showing an axis-cylinder sprouting and forming a number of axis-cylinder processes, which grow into the peripheral end to form new channels of conduction. 8. is a new regenerated fibre resembling a sympathetic fibre in having as yet no myelin sheath; as the nerve becomes excitable and stimulus passes, a myelin sheath is formed.

fact that the myelin sheath, after hardening in a solution of bichromate of potash, does not turn black when acted upon by osmic acid, whereas the simpler non-phosphoretted fatty product of degeneration is stained black. When the Marchi reaction of degeneration is fully developed, it has been ascertained that the nerve yields no phosphorus. The degeneration resulting from section of a nerve is termed *secondary*, to distinguish it from another, *primary*, due to slow and progressive decay of the whole neurone, beginning usually at the terminal twigs and proceeding back towards the cell body with its contained nucleus. These primary degenerations involve systems of neurones, correlated by function rather than by anatomical situation. Examples are afforded by locomotor ataxy and progressive muscular atrophy, the former being a degeneration of the afferent sensory system of neurones, the latter of the motor efferent system. The cause of primary degenerations is probably a defect inherited or acquired in the "vita propria" of the neurones affected. They slowly atrophy and disappear, and their place is filled up by an overgrowth of the supporting neuroglia tissue (Figs. 4 and 7). This overgrowth of dense tissue is termed sclerosis, and was erroneously considered to be the cause, instead of the effect, of the atrophy of the nervous tissue.

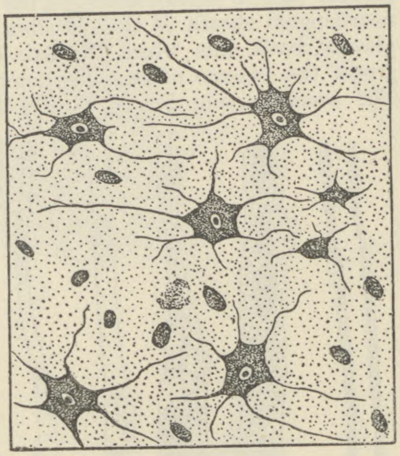

FIG. 7.—Diagram drawn from micro-photograph to show different forms of neuroglia cells in a patch of sclerosis secondary to degeneration and disappearance of the neurones. Observe the large branched cells of Deiters.

For further information the reader may consult the Croonian Lectures on the Degeneration of the Neurone, by the writer of this article, published in the *Lancet*, 1900; also Gower's *Handbook of the Nervous System*, Von Monakow's *Gehirn Pathologie*, and Ford-Robertson's *Pathology of Mental Diseases*. (F. W. MO.)

EXPLANATIONS OF PLATE IX.

PHOTOGRAPHS OF THE BRAIN (ABOUT ⅓ THEIR NATURAL SIZE) ILLUSTRATING VARIOUS PATHOLOGICAL CONDITIONS.

1. Left hemisphere, case of delusional insanity; this in all respects might pass for a normal brain.
2. Left hemisphere, case of abscess of the frontal lobe: the convolutions and sulci are obliterated and the membranes thickened, so that the fore part of the brain presents the appearance of a membranous bag; this contained a large amount of pus.
3. Right hemisphere seen from above instead of laterally: a hole corresponding to the middle of the central convolutions is seen, out of which a tumour is displaced towards the middle line. This tumour was situated over the region of the arm area, and gave rise at first to fits commencing in the left arm and hand, and eventually to paralysis.
4. Brain from a case of apoplexy: the tops of the hemispheres have been sliced off to show the hæmorrhage (dark patch) in the right centrum ovale, which has ruptured the fibres proceeding from the motor area of the brain, situated between the basal ganglia.
5. Case of paralytic dementia with thickened membranes, which have been stripped off the frontal lobe and thrown back.
6. Left hemisphere: a case of advanced dementia, showing atrophy of the convolutions, with deep and wide sulci intervening.
7. Left hemisphere of low-grade imbecile, with simple convolutional pattern, and small in size.
8. Brain of extreme case of microcephalic idiocy. The convolutional pattern is simpler than that of an embryo of eight months.
9. Left hemisphere and cerebellum of a case of porencephaly. A local atrophy of the convolutions, owing to a vascular lesion before birth, is seen in the parietal lobe.

IV. DIGESTIVE SYSTEM.

Several facts of importance have to be borne in mind for a proper appreciation of the pathology of the organs concerned in digestive processes. In the first place, more than all other systems, the digestive comprises greater range of structure and exhibits wider diversity of function within its domain. Each separate structure and each different function presents special pathological signs and symptoms. Again, the duties imposed upon the system have to be performed notwithstanding constant variations in the work set them. The crude articles of diet offered them vary immensely in nature, bulk, and utility, from which they must elaborate simple food-elements for absorption, incorporate them after absorption into complex organic substances properly designed to supply the constant needs of cellular activity, of growth and repair, and fitly harmonized to fulfil the many requirements of very divergent processes and functions. Any form of unphysiological diet, each failure to cater for the wants of any special tissue engaged in, or of any processes of, metabolism, carry with them pathological signs. Perhaps in greater degree than elsewhere are the individual sections of the digestive system dependent upon, and closely correlated with, one another. The lungs can only yield oxygen to the blood when the oxygen is uncombined; no compounds are of use. The digestive organs have to deal with an enormous variety of compound bodies, from which to obtain the elements necessary for protoplasmic upkeep and activity. Morbid lesions of the respiratory and circulatory systems are frequently capable of compensation through increased activity elsewhere, and the symptoms they give rise to follow chiefly along one line; diseases of the digestive organs are more liable to occasion disorders elsewhere than to excite compensatory actions. The digestive system includes every organ, function, and process concerned with the utilization of food-stuffs, from the moment of their entrance into the mouth, their preparation in the canal, assimilation with the tissues, their employment therein, up to their excretion or expulsion in the form of waste. Each portion resembles a link of a continuous chain; each link depends upon the integrity of the others, the weakening or breaking of one straining or making impotent the chain as a whole.

Descriptions of the different organs of the digestive system are given elsewhere. (See ANATOMY.) The mucous membrane lining the alimentary tract is the part most subject to pathological alterations, and in this connexion it should be remembered that this membrane differs both in structure and functions throughout the tract. Chiefly protective from the mouth to the cardia, it is secretory and absorbent in the stomach and bowel; while the glandular cells forming part of it secrete both acid and alkaline fluids, several ferments, or mucus. Over the dorsum of the tongue its modified cells subserve the sense of taste. Without, connected with it by the submucous connective tissue, is placed the muscular coat, and externally over the greater portion of its length the peritoneal serous membrane. All parts are supplied with blood-vessels, lymph-ducts, and nerves, the last belonging either to local or to central circuits. Associated with the tract are the salivary glands, the liver, and the pancreas; while, in addition, lymphoid tissue is met with diffusely scattered throughout the lining membranes in the tonsils, appendix, solitary glands and Peyer's patches, and the mesenteric glands. The functions of the various parts of the system in whose lesions we are here interested are many in number. It would take up too much space to enumerate all their proved and suggested functions. Broadly, they may be given as: (1) Ingestion and swallowing of food, transmission of it through the tract, and expulsion of the waste material; (2) secretion of acids and alkalies for the performance of digestive processes, aided by (3) elaboration and addition of complex bodies, termed enzymes or ferments; (4) secretion of mucus; (5) protection of the body against organismal infection, and against toxic products; (6) absorption of food elements and reconstitution of them into complex substances fitted for metabolic application; and (7) excretion of the waste products of protoplasmic action. These functions may be altered by disease, singly or in conjunction; it is rare, however, to find but one affected, while an apparently identical disturbance of function may often arise from totally different organic lesions. Another point of importance is seen in the close interdependence which exists between the secretions of acid and those of alkaline reaction. The difference in reaction seems to act *mutatis mutandis* as a stimulant in each instance.

General Diseases.

Vascular lesions.

In all sections of the alimentary canal actively engaged in the digestion of food, a well-marked local engorgement of the blood-vessels supplying the walls occurs. The hyperæmia abates soon after completion of the special duties of the individual sections. This normal condition may be abnormally exaggerated by over-stimulation from irritant poisons introduced into the canal; from too rich, too copious, or indigestible articles of diet; or from too prolonged an experience of some unvaried kind of food-stuff, especially if large quantities of it are necessary for metabolic needs; entering into the first stage of inflammation, acute hyperæmia. More important, because productive of less tractable lesions, is passive congestion of the digestive organs. Whenever the flow of blood into the right side of the heart is hindered, whether it arise from disease of the heart itself, or of the lungs, or proceed from obstruction in some part of the portal system, the damming-back of the venous circulation speedily produces a more or less pronounced stasis of the blood in the walls of the alimentary canal and in the associated abdominal glands. The lack of a sufficiently vigorous flow of blood is followed by deficient secretion of digestive agents from the glandular elements involved, by decreased motility of the muscular coats of the stomach and bowel, and lessened adaptability throughout for dealing with even slight irregular demands on their powers. The mucous membrane of the stomach and bowel, less able to withstand the effects of irritation, even of a minor character, readily passes into a condition of chronic catarrh, while it frequently is the seat of small abrasions, hæmorrhagic erosions, which may cause vomiting of blood and the appearance of blood in the stools. Obstruction to the flow of blood from the liver leads to dilatation of its blood-vessels, consequent pressure upon the hepatic cells adjoining them, and their gradual loss of function, or even atrophy and degeneration. In addition to the results of such passive congestion exhibited by the stomach and bowel as noted above, passive congestion of the liver is often accompanied by varicose enlargement of the abdominal veins, in particular of those which surround the lower end of the œsophagus, the lowest part of the rectum and anus. In the latter position these dilated veins constitute what are known as hæmorrhoids or piles, internal or external as their site lies within or outside the anal aperture.

The mucous and serous membranes of the canal and the glandular elements of the associated organs are the parts most subject to inflammatory affections. Among the several sections of the digestive tract itself, the œsophagus and jejunum are singularly exempt from inflammatory processes; the fauces, stomach, cæcum and appendix, ileum, mouth and duodenum (including the opening of the common bile duct), are more commonly involved.

Inflammatory lesions.

Carious teeth, accumulations of sordes, and attacks of acute fevers frequently are the causal agents in stomatitis or inflammation of the mouth; while a more local form of the ailment over the dorsum of the tongue is commonly a sympathetic condition accompanying gastric or hepatic derangements. An ordinary "sore throat" usually signifies acute catarrh of the fauces, and is in all likelihood of purely organismal origin, "catching cold" being only a secondary and minor cause. In "relaxed throats" there is a chronic catarrhal state of the lining membrane, with some passive congestion. The tonsils are peculiarly liable to catarrhal attacks, as might *a priori* be expected by reason of their Cerberus-like function with regard to bacterial intruders. Still, acute attacks of tonsillitis appear on good evidence to be more common among individuals predisposed constitutionally to rheumatic manifestations. Cases of acute tonsillitis may or may not go on to suppuration or quinsy; in all there is great congestion of the glands, increased mucus secretion, and often secondary involvement of the lymphatic glands of the neck. Repeated acute attacks often lead to chronic inflammation, in which the glands are enlarged, and often hypertrophied in the true sense of the term. In children, however, hypertrophy of the tonsils seems to occur *sui generis.* The œsophagus is the seat of catarrh but seldom; too hot food and strong solutions of corrosive or irritant substances, if swallowed, may cause the symptoms common to inflamed tissues. The physical changes presented by the coats of the stomach and the intestine, the subjects of catarrhal attacks, closely resemble one another, but differ symptomatically. Acute catarrh of the stomach is associated with intense hyperæmia of its lining coats, with visible engorgement and swelling of the mucous membrane, and an excessive secretion of mucus. The formation of active gastric juice is arrested, digestion ceases, peristaltic movements are sluggish or absent, unless so over-stimulated that they act in a direction the reverse of the normal, and induce expulsion of the gastric contents by vomiting. The gastric contents, in whatever degree of dilution or concentration they may have been ingested, when ejected are of porridge-thick consistency, and often but slightly digested. Such conditions may succeed a severe alcoholic bout, be caused by irritant substances taken in by the mouth, or arise from fermentative processes in the stomach contents themselves. Should the irritating material succeed in passing from the stomach into the bowel, similar physical signs are present; but as the quickest path offered for the expulsion of the offending substances from the body is downwards, peristalsis is increased, the flow of fluid from the intestinal glands is larger in bulk, though of less potency as regards its normal actions, than in health, and diarrhœa, with removal of the irritant, follows. As a general rule, the more marked the involvement of the large bowel, the severer and more fluid is the resultant diarrhœa.

Catarrhal affections of the cæcum and its attached appendix vermiformis are very common, and give rise to several special symptoms and signs. Acute inflammatory appendicitis appears to be increasing in frequency, and is caused without doubt, in the great majority of instances, by fæcal accumulation, with the entrance of a small fæcal mass into the lumen of the organ, or by the occurrence of bacterial fermentation of a malign type, along with, it may be, and because of, fæcal stasis. Occasionally the entrance of some foreign body, a cherry-stone, a fish-bone, or a pin, sets up an attack; but exciting agents of this type are less commonly met with than popular ideas would suggest. Very similar symptomatically is the condition termed perityphlitis, doubtless in former days frequently due to the appendix, an acute or chronic inflammation of the walls of the cæcum often leading to abscess formation outside the gut, with or without direct communication with the canal. The colon and sigmoid flexure are more subject to chronic inflammatory attacks than to acute, save in cases of acute gastro-enteritis and diarrhœa, or of special infections. Prolonged constipation, with fæcal accumulation in the large bowel, may lead to a secondary diarrhœa, from the severe irritation of the mucous membrane of the gut occasioned by the scybalous masses. Acute simple hepatitis is a rare disease; acute pancreatitis is usually of septic origin.

Chronic catarrhal affections of the stomach are very common, and often follow upon repeated acute attacks. In them the connective tissue increases at the expense of the glandular elements; the mucous membrane becomes thickened and less active in function. Should the muscular coat be involved, the elasticity and contractility of the organ suffer; peristaltic movement is weakened; expulsion of the contents through the pylorus hindered; and, aggravated by these effects, the condition becomes worse, atonic dyspepsia in its most pronounced form results, with or without dilatation. Chronic vascular congestion may occasion in process of time similar signs and symptoms.

Duodenal catarrh is constantly associated with jaundice, indeed is most probably the commonest cause of catarrhal jaundice; often it is accompanied by catarrh of the common bile duct. Chronic inflammation of the small intestine gives rise to less prominent symptoms than in the stomach. It generally arises from more than one cause; or rather secondary causes rapidly become as important as the primary in its incidence. Chronic congestion and prolonged irritation lead to deficient secretion and sluggish peristalsis; these effects encourage intestinal putrefaction and auto-intoxication; and these latter, in turn, increase the local unrest. Chronic catarrh of the colon is frequently characterized by secretion of an excessive amount of mucus from the goblet cells and its appearance in the stools—mucous colitis; or, again, by the passage of membranous shreds and casts of the bowel—membranous colitis—the casts really consisting of a mucus skin from the surface of the gut, including some of the epithelial cells. The rectum may suffer in the same way—proctitis. Membranous colitis is stated to be closely associated with disordered nervous control. Simple chronic peritonitis is not of frequent occurrence, nor are the views held as to its causation very clear. In common with the acute form, it may be localized or general. A hyperplastic variety is met with in which the peritoneal membrane is greatly thickened. Undoubtedly some cases arise from pelvic disease in women. Distinct localized forms occur over the liver and spleen—perihepatitis and perisplenitis—in which an external chronic fibroid change coincides with similar conditions within the organs.

Infective lesions.

The intestinal mucous membrane, the peritoneum, and the mesenteric glands are the chief sites of tubercular infection in the digestive organs. Rarely met with in the gullet and stomach, and comparatively seldom in the mouth and lips, tubercular inflammation of the small intestine and peritoneum is common. Tubercular enteritis is a frequent accompaniment of phthisis pulmonum, but may occur apart from tubercle of other organs. Children are especially subject to the primary form. Tubercular peritonitis often is present also. The inflammatory process readily tends towards ulcer formation, with hæmorrhage and sometimes perforation. If in the large bowel, the symptoms are usually less acute than those characterizing tubercular inflammation of the small intestine. The appendix has been found to be the seat of tubercular processes; in the rectum they form the general cause of the fistulæ and abscesses so commonly met with here. Tubercular peritonitis may be primary or secondary, acute or chronic; occasionally very acute cases are seen running a rapid course; the majority are chronic in type. The tubercles spread over the surface of the serous membrane, and if small and not very numerous, may give rise in chronic cases to few symptoms; if larger, and especially when they involve and obstruct the lymph- and blood-vessels, ascites follows. It is hardly possible that tubercular invasion of the mesenteric glands can ever occur unaccompanied by peritoneal infection; but when the infection of the glands constitutes the most prominent sign, the term *tabes mesenterica* is sometimes employed. Here the glands, enlarged, form a doughy mass in the abdomen, leading to marked protrusion of the abdominal walls, with wasting elsewhere, and diarrhœa.

The liver is seldom attacked by tubercle, unless in cases of general miliary tuberculosis. Now and then it contains large caseous tubercular masses in its substance.

An important fact with regard to the tubercular processes in the digestive organs lies in the ready response to treatment shown by many cases of peritoneal or mesenteric invasion, particularly in the young.

The later sequelæ of syphilis display a predilection for the rectum and the liver, usually leading to the development of a stricture in the former, to a diffuse hepatitis or the formation of gummata in the second. The upper incisor teeth in cases of congenital syphilis are often stunted and peg-shaped. As the result both of syphilis and of tubercle, the tissues of the liver and bowel may present a peculiar alteration; they become amyloid, or lardaceous, a condition in which they appear "waxy," are coloured dark mahogany brown with dilute iodine solutions, and show degenerative changes in the connective tissue.

Malarial cirrhosis of the liver is described, but the connexion between it and abuse of alcohol requires further study.

The bacillus of Eberth, which appears to be the invariable associate and probable causal agent of typhoid fever, has its chief seat of activity in the small intestine, more especially in the lower half of the ileum. Attacking the lymphoid follicles in the mucous membrane, it causes first inflammatory enlargement, then necrosis and ulceration. The adjacent portions of the mucous membrane show acute catarrhal changes. Diarrhœa, of a special "pea-soup" type, may or may not be present; while hæmorrhage from the bowel, if ulcers have formed, is common. As the ulcers frequently extend down to the peritoneal coat of the bowel, perforation of this membrane and extravasation into the peritoneal cavity is easily induced by irritants introduced into or elaborated in the bowel, acting physically or by the excitation of hyper-peristalsis.

True Asiatic cholera has been shown to be due to the presence of a spirillum in the contents of the bowel, and to its growth therein; more rarely, and only in chronic types, to its development in the tissues of the intestinal wall. The spirillum of cholera produces an intense irritation of the bowel, seldom of the stomach, without giving rise locally to any marked physical change; it causes violent diarrhœa and copious discharges of "rice-water" stools, consisting largely of serum swarming with the organism.

The lesions in dysentery are almost entirely confined to the large bowel; at first inflammatory, later ulcerative. The stools are chiefly composed of gelatinous mucus and blood. Two forms are distinguished—the non-amœbic, ascribed to famine and close confinement, and the amœbic, from the *amœba coli* (Lösch) constantly found with it; the disease is common to the warmer climates.

Acute parotitis, or mumps, is an infectious disease of the parotid glands, chiefly interesting because of the association between it and the testes in males, inflammation of these glands occasionally following or replacing the affection of the parotids. The causal agent is probably organismal, but has as yet escaped detection.

New growths.

The relative frequency with which malignant growths occur in the different organs of the digestive system may be gathered from the following tabular analysis of 1768 cases recorded in the books of the Edinburgh Royal Infirmary as having been treated in the medical and surgical wards between the years 1892 to 1899 inclusive. Of these, 1263, or 71·44 per cent., were males; 505, or 28·56 per cent., females:—

Males.		Females.		Both Sexes.	
Organ or Tissue in Order of Frequency.	Percentage.	Organ or Tissue in Order of Frequency.	Percentage.	Organ or Tissue in Order of Frequency.	Percentage.
1 Stomach	22·56	1 Stomach	22·37	1 Stomach	22·49

Note.—The figures where several organs are bracketed apply to each organ separately.

If the figures given above be classified upon broader lines, the results are as follows, and speak for themselves:—

Males.	Percentage.	Females.	Percentage.	Total.	Percentage.
1 Mouth and pharynx	37·85	1 Intestines	28·9	1 Œsophagus and stomach	31·78
2 Œsophagus and stomach	33·46	2 Œsophagus and stomach	27·7	2 Mouth and pharynx	30·27
3 Intestines	17·04	3 Liver	15·5	3 Intestines	20·42
4 Liver	7·8	4 Peritoneum	13·1	4 Liver	10·02
5 Peritoneum	2·75	5 Mouth and pharynx	11·3	5 Peritoneum	5·71
6 Pancreas	1·1	6 Pancreas	3·5	6 Pancreas	1·80

The digestive organs are peculiarly subject to malignant disease, a result of the incessant changes from passive to active conditions, and *vice versâ*, called for by repeated introduction of food; while the comparative frequency with which different parts are attacked depends, in part, upon the degree of irritation or changes of function imposed upon them. Scirrhous, encephaloid, and colloid forms of carcinoma occur. In the stomach and œsophagus the scirrhous form is most common, the soft encephaloid form coming next. The most common situation for cancerous growth in the stomach is the pyloric region. Walsh out of 1300 cases found 60·8 per cent. near the pylorus, 11·4 per cent. over the lesser curvature, and 4·7 per cent. more or less over the whole organ. The small intestine is rarely attacked by cancer; the large intestine frequently. The rectum, sigmoid flexure, cæcum, and colon are affected, and in this order, the cylindrical-celled form being the most common. Carcinoma of the peritoneum is generally colloid in character, and is often secondary to growths in other organs. Cancer of the liver follows cancer of the stomach and rectum in frequency of occurrence, and is relatively more common in females than males. Secondary invasion of the liver is a frequent sequel to gastric cancer. The pancreas occasionally is the seat of cancerous growth.

Sarcomata are not so often met with in the digestive organs. When present, they generally involve the peritoneum or the mesenteric glands. The liver is sometimes attacked, the stomach rarely.

Benign tumours are not of common occurrence in the digestive organs. Simple growths of the salivary glands, cysts of the pancreas, and polypoid tumours of the rectum are the most frequent.

Animal parasites.

The intestinal canal is the habitat of the majority of animal parasites found in man. Frequently their presence leads to no morbid symptoms, local or general; nor are the symptoms, when they do arise, always characteristic of the presence of parasites alone. Discovery of their bodies, or of their eggs, in the stools is in most instances the only satisfactory proof of their presence. The parasites found in the bowel belong principally to two natural groups, Protozoa and Metazoa. The great class of the Protozoa furnish amœbæ, members of Sporozoa, and Infusoria. The amœbæ are almost invariably found in the large intestine; one species, indeed, is termed *amœba coli*. The frequently-observed relation between attacks of dysentery and the presence of amœbæ in the stools has led to the proposition that an *amœba dysenterica* exists, causing the disease,—a theory supported by the detection of amœbæ in the contents of dysenteric abscesses of the liver. No symptoms of injury to health appear to accompany the presence of Sporozoa in the bowel, while the species of Infusoria found in it, the *Cercomonas*, and *Trichomonas intestinalis*, and the *Balantidium coli*, may or may not be guilty of prolonging conditions within the bowel such as have previously set up diarrhœa.

The Metazoa supply examples of intestinal parasites from the classes Annuloida and Nematoidea. To the former class belong the various tapeworms found in the small intestine of man. They, like other intestinal parasites, are destitute of any power of active digestion, simply absorbing the nutritious proceeds of the digestive processes of their hosts. Nematode worms infest both the small and large intestine; *Ascaris lumbricoides*, the common round worm, and the male *Oxyuris vermicularis* are found in the small bowel, the adult female *Oxyuris vermicularis* and the *Tricocephalus dispar* in the large.

The eggs of the *Trichina spiralis*, when introduced with the food, develop in the bowel into larval forms which invade the tissues of the body, to find in the muscles congenial spots wherein to reach maturity. Similarly, the eggs of the *Echinococcus* are hatched in the bowel, and the embryos proceed to take up their abode in the tissues of the body, developing into cysts capable of growth into mature worms after their ingestion by dogs.

Table showing the more important Vegetable Organisms and Animal Parasites.

Vegetable Organisms.

Mouth and Fauces.	Stomach.	Small Intestine.	Large Intestine.
A. Simple. Spirochæta buccalis. Leptothrix buccalis. Micrococcus tetragenus. Various fission bacilli.	Bacillus acidi lactici. Bacterium lactis aërogenes. Bacillus coli communis. Sarcina ventriculi. Vegetable parasites.

Numbers of bacterial forms habitually infest the alimentary canal. The names of the more common species are given in the foregoing table. Many of them are non-pathogenic; some develop pathogenic characters only under provocation or when a suitable environment induces them to act in such a manner; others may form the *materies morbi* of special lesions, or be casual visitors capable of originating disease if opportunity occurs. Apart from those organisms associated with acute infective diseases, disturbances of function and physical lesions may be the result of abnormal bacterial activity in the canal; and these disturbances may be both local and general. Many of the bacteria commonly present produce putrefactive changes in the contents of the tract by their metabolic processes. They render the medium they grow in alkaline, produce different gases, and elaborate more or less virulent toxins. Other species set up an acid fermentation, seldom accompanied by gas or toxin formation. The products of either class are inimical to the free growth of members of the other. The species which produce acids are more resistant to the action of acids. Thus, when the contents of the stomach possess a normal or excessive proportion of free hydrochloric acid, a much larger number of putrefactive and pathogenic organisms in the food are destroyed or inhibited than of the bacteria of acid fermentation. Diminished gastric acidity allows of the entry of a greater number of putrefactive (and pathogenic) types, with, as a consequence, increased facilities for their growth and activity, and the appearance of intestinal derangements.

It is still a moot question if bacteria can penetrate the coats of the bowel and enter surrounding tissues when no solution of continuity exists. The frequent septic conditions of abscesses adjoining but not communicating with the bowel seem to favour the possibility of bacterial penetration; and the occurrence of acute peritonitis without any appreciable peritoneal lesion supports it. Bacterial forms are said to be able to pass through the mucous membrane of the canal and reach the blood-stream, where, unless they are of excessive number, they are killed. Passage of bacteria from the blood through the peritoneal membrane into the abdominal cavity has been recorded.

Whenever putrefactive processes are excessive in the bowel, and in prolonged constipation, symptoms of auto-intoxication may occur, caused by absorption of poisonous bacterial products in larger amount than can be dealt with by the defensive power of the liver.

The fæces have been shown to be composed in large part of various species of bacteria.

Physical abnormalities.

Hare-lip, cleft palate, hernia, and imperforate anus belong to the subject of Surgery. The œsophagus may be the seat of a diverticulum, or blind pouch, usually situated in its lower half, which in most instances is probably partly acquired and partly congenital; a local weakness succumbing to pressure. Hypertrophy of the muscular coat of the pyloric region is an infrequent congenital gastric anomaly in infants, preventing the passage of food into the bowel, and causing death in a short time. Incomplete closure of the vitelline duct results in the presence of a diverticulum—Meckel's—generally connected with the ileum, mainly important by reason of the readiness with which it occasions intestinal obstruction. Idiopathic congenital dilatation of the colon has been described.

Traction diverticula of the œsophagus not uncommonly occur as sequels to suppurative inflammation of cervical lymphatic glands. More frequently dilatation of a section is met with, due as a rule to the presence of a stricture. The stomach often diverges from the normal in size, shape, and position. Normally capable in the adult of containing from fifty to sixty ounces, either by reason of organic disease, or as the result of functional disturbance, its capacity may vary enormously. The writer has seen post mortem a stomach which held a gallon (160 ounces), and again, one holding only two ounces. Cancer spread over a large area and cirrhosis of the stomach wall cause diminution in capacity; pyloric obstruction, weakness of the muscular coat, and nervous influences are associated with dilatation. A peculiar distortion of the shape of the stomach follows cicatrization of ulcers of greater or lesser curvature; the gastric cavity becomes "hour-glass" in shape. In addition, the stomach may be displaced downwards as a whole, a condition known as gastroptosis: if the pyloric portion only be displaced, the lesion is termed pyloroptosis. Ptoses of other abdominal organs are described; the liver, transverse colon, spleen, and kidneys may be involved. Displacements downwards of the stomach and transverse colon, along with a movable right kidney and associated with dyspepsia and neurasthenia, form the malady termed by Glénard enteroptosis. Displacements of the abdominal viscera are almost invariably accompanied by symptoms of dyspepsia of a neurotic type. The rectum is liable to prolapse, consequent upon constipation and straining at stool, or following local injuries of the perineal floor.

Every pathological lesion shown by digestive organs is closely associated with the state of the nervous system, general or local; so stoppage of active gastric digestive processes after profound nervous shock, and occurrence of nervous diarrhœa from the same cause. Gastric dyspepsia of nervous origin presents most varied and contradictory symptoms: diminished acidity of the gastric juice; hyperacidity; over-production; arrest of secretion; lessened or increased movements; greater sensitiveness to the presence of contents; dilatation; or spasm. Often the nervous cause can be traced back farther. In females, frequently to the pelvic organs; in both sexes, to the condition of the blood, the brain, or the bowel. Unhealthy conditions related to evacuation of the bowel-contents commonly induce reflex nervous manifestations of abnormal character referred to the stomach and liver. Gastric disturbances similarly react upon the proper conduct of intestinal functions.

Influence of the nervous system.

Local Diseases.

The Mouth.—The lining membrane of the cheeks inside the mouth, of the gums and the under-surface and edges of the tongue, is often the seat of small irritable ulcers, usually associated with some digestive derangement. A crop of minute vesicles over these parts has been lately stated by Koplik to be an early symptom of measles. Xerostomia, or dry mouth, is a rare condition, connected with lack of salivary secretion. Gangrenous stomatitis, cancrum oris, or noma, occasionally attacks debilitated children, or patients convalescing from acute fevers, more especially after measles. It commences in the gums or cheeks, and causes widespread sloughing of the adjacent soft parts; it may be of the bones.

The Stomach.—It were futile to attempt to enumerate all the protean manifestations of disturbance which proceed from a disordered stomach. The possible permutations and combinations of the causes of gastric vagaries almost reach infinity. Idiosyncrasy, past and present gastric education, penury or plethora, actual digestive power, motility, bodily requirements and conditions, environment, mental influences, local or adjacent organic lesions, and, not least, reflex impressions from other organs, all contribute to the variance.

Ulcer of the stomach, however—the perforating gastric ulcer—occupies a unique position among diseases of this organ. Gastric ulcers are circumscribed, punched out, rarely larger than a sixpenny-bit, funnel-shaped, the narrower end towards the peritoneal coat, and distributed in those regions of the stomach wall which are most exposed to the action of the gastric contents. They occur most frequently in females, especially if anæmic, and are usually accompanied by excess of acid, actual or relative to the state of the blood, in the stomach contents. Local pain, dorsal pain, generally to the left of the eighth or ninth dorsal spinous process, and hæmatemesis or melæna, are symptomatic of it. The amount of blood lost varies with the rapidity of ulcer formation and the size of vessel opened into. Fatal results arise from ulceration into large blood-vessels, followed by copious hæmorrhage, or by perforation of the ulcer into the peritoneal cavity. Scars of such ulcers may be found post mortem, although no symptoms of gastric disease have been exhibited during life; gastric ulcers, therefore, may be latent.

Irritation of the sensory nerve-endings in the stomach wall from the presence of an increased proportion of acid, organic or mineral, in the stomach contents is accountable for the well-known symptom, heartburn. Water-brash is a term applied to eructation of a colourless, almost tasteless fluid, probably saliva which has collected in the lower part of the œsophagus from failure of the cardiac sphincter of the stomach to relax; reversed œsophageal peristalsis causing regurgitation. A similar reversed action serves in merycism, or rumination, occasionally found in man, to raise part of the food, lately ingested, from the stomach to the mouth. Vomiting also is aided by reversed peristaltic action, both of the stomach and the œsophagus, with the help of the diaphragm and the muscles of the anterior abdominal wall. Emesis may be caused both by local nervous influence, and through the central nervous mechanism either reflexly or from the direct action of substances circulating in the blood. Further, the causal agent acting on the central nervous apparatus may be organic or functional, as well as medicinal. Vomiting without any apparent cause suggests nervous lesions, organic or reflex. The obstinate vomiting of pregnancy is a case in point. Here the primary cause proceeds reflexly from the pelvis. In females the pelvic organs are often the true source of emesis. Hæmatemesis accompanies gastric ulcer, cancer, chronic congestion with hæmorrhagic erosion, congestion of the liver, or may follow violent acts of vomiting. In cases of ulcer the blood is usually bright and in considerable amount; in cancer, darker, like coffee-grounds; and in cases of erosion, in smaller quantity and of bright colour. The reaction of the stomach contents, if the cause be doubtful, yields valuable aid towards a diagnosis. Of normal or increased acidity in gastric ulcer, normal in hepatic congestion, it is diminished in cancer; but as the acid present in cancer is largely lactic, analysis of the gastric contents must often be a *sine quâ non*, because hyperacidity from lactic may obscure hypoacidity of hydrochloric acid.

Flatulence usually results from fermentative processes in the stomach and bowel, as the outcome of bacterial activity. The gases evolved are various and complex in nature. Proteid decomposition sometimes leads to the formation of sulphuretted hydrogen; while inflammable marsh gas, formed by the same in the stomach, has been accidentally set alight at the mouth in a few instances. A different form of flatulence is common in neurotic individuals; in such the gas evolved consists simply in carbonic acid liberated from the blood, and its evolution is generally characterized by rapid development and by lack of all fermentative signs.

The Liver.—The liver is an organ frequently libelled for the delinquencies of other organs, and regarded as a common source of ill. In catarrhal jaundice it is in most cases the bowel that is at fault, the liver acting properly, but unable to get rid of all the bile produced. The liver suffers, however, from several diseases of its own. Its fibrous or connective tissue is very apt to increase at the expense of the cellular elements, destroying their functions. This cirrhotic process usually follows long-continued irritation, such as is produced by too much alcohol absorbed from the bowel habitually, the organ gradually becoming harder in texture and smaller in bulk. Hypertrophic cirrhosis of the liver is not uncommonly met with, in which the liver is much increased in size, the "unilobular" form, also of alcoholic origin. In still-born children and in some infants a form of hypertrophic cirrhosis is occasionally seen, probably of hereditary syphilitic origin. Acute congestion of the liver forms an important symptom of malarial fever, and often leads in time to establishment of cirrhotic changes; here the liver is generally enlarged, but not invariably so, and the part played by alcohol in its causation has still to be investigated. Acute yellow atrophy of the liver is a disease *sui generis*. Of rare occurrence, possibly of toxic origin, it is marked by jaundice, at first of usual type, later becoming most intense; by vomiting; hæmorrhages widely distributed; rapid diminution in the size of the liver; the appearance of leucin and tyrosin in the urine, with lessened urea; and in two or three days, death. The liver after death is soft, of a reddish colour dotted with yellow patches, and weighs only about a third part of the normal—about $1\frac{1}{2}$ lb in place of $3\frac{3}{4}$ lb. A closely analogous affection of the liver, known as Weil's disease, is of infectious type, and has been noted in epidemic form. Hepatic abscess is another condition not infrequent among dwellers in tropical climates, especially should they have suffered previously from dysentery. There is strong reason to believe that the *amœba coli* has a direct connexion with its causation. Injuries of the liver are sometimes followed by abscess formation, while septic abscesses in this organ are common in blood-poisoning.

The Gall-Bladder.—The formation of biliary calculi in the gall-bladder is the chief point of interest here. At least 75 per cent. of such cases occur in women, especially in those who have borne children. Tight-lacing has been stated to act as an exciting cause, owing to the consequent retardation of the flow of bile. Gall-stones may number from one to many thousands. They are largely composed of cholesterin, combined with small amounts of bile-pigments and acids, lime and magnesium salts. Their presence may give rise to no symptoms, or may cause violent biliary colic, and if the bile-stream be obstructed, to jaundice. Inflammatory processes may be initiated in the gall-bladder or the bile-ducts, catarrhal or suppurative in character.

The Pancreas.—Hæmorrhages into the body of the pancreas, acute and chronic inflammation, calculi, cysts, and tumours, among which cancer is by far the most common, are recognized as occurring in this organ; the point of greatest interest regarding them lies in the relations established between pancreatic disease and diabetes mellitus, affections of the gland frequently being complicated by, and probably causing, the appearance of sugar in the urine.

The Small Intestine.—Little remains to be added to the account of inflammatory lesions in connexion with the small intestine. It offers but few conditions peculiar to itself, save in typhoid fever, and the ease with which it contrives to become kinked, or intussuscepted, producing obstruction, or to take part in hernial protrusions, for which the article on SURGERY should be consulted. The first section, the duodenum, is subject to development of ulcers very similar to those of the gastric mucous membrane. For long duodenal ulceration has been regarded as a common complication of extensive burns of the skin, but the relationship between them still lacks evidence sufficiently trustworthy to disprove the possibility of coincidence in lieu of effect. The condition of colic in the bowel usually arises from over-distension of some part of the small gut with gas, the frequent sharp turns of the gut facilitating temporary closure of its lumen by pressure of the dilated gut near a curve against the part beyond. In the large bowel accumulations of gas seldom cause such acute symptoms, having a readier exit.

The Large Intestine.—The colon, especially the ascending portion, may become immensely dilated, usually after prolonged constipation and paralysis of the gut; occasionally the condition is congenital. Straining efforts made in defæcation may often account for prolapse of the lower end of the rectum through the anus. Hæmorrhage from the bowel is usually a sign of disease situated in the large intestine: if bright in colour, the source is probably low down; if dark, from the cæcum or from above the ileocæcal valve. Blood after a short stay in any section of the alimentary canal darkens, and eventually becomes almost black in colour. (A. L. G.)

V. RESPIRATORY SYSTEM.

The term respiratory system comprises the nose, part of the pharynx, the larynx, trachea, bronchial tubes, lungs and pleura, together with the framework of the chest, the muscles of respiration, and that part of the nervous and circulatory systems concerned in the aëration of the blood. It is proposed, however, in the present article not to consider in detail the morbid changes affecting all these parts, but to give an account of the more important pathological processes which affect the lungs, pleuræ, and bronchial tubes. In the ætiology of pulmonary affections, the relations between the lungs and the external air, and also between them and the circulatory system, are important. The lungs are, so to speak, placed between the right and left cavities of the heart, and the only way for the blood to pass from the right ventricle to the left side of the heart, except in cases of a patent foramen ovale or other congenital defect forming a communication between the two sides of the organ, is by passing through them. The result is that not only may they become diseased by foreign material carried into them by the blood, but any obstruction to the flow of blood through the left side of the heart tends sooner or later to engorge or congest them, and lead to further changes. Through the nose and mouth they are in direct connexion with the external atmosphere. Hence the variable condition of the air as regards temperature, degree of moisture, and density, is liable to produce directly various changes in the lungs, or to predispose them to disease; and the contamination of the air with various pathogenic germs and irritating particles in the shape of dust, is a direct source of many lung affections.

Bronchitis. Bronchitis, or inflammation of the bronchial tubes, is one of those affections generally attributed to exposure to inclement atmospheric conditions, although we are quite unaware what is the essential condition that gives rise to it. We know, however, that it is much more common in the winter than the summer months in the United Kingdom, and that exposure to inclement weather is apt to be followed by the disease, especially when the nasal and laryngeal passages are themselves in a state of catarrh, the catarrhal inflammation apparently then spreading directly from the upper respiratory passages to the bronchi. Although it is possible that micro-organisms play a part in the production of bronchitis, we know of no specific organism which is its cause. Bronchitis may affect the whole bronchial tract, or more especially the larger or the smaller tubes. It may occur as an acute or as a chronic affection. In the acute form the inflammation may remain limited to the bronchial tubes and gradually subside, or it may lead to inflammation of the surrounding lung tissue, giving rise to disseminated foci of inflammation of greater or less extent throughout the lungs (catarrhal or broncho-pneumonia). This is a common complication of bronchitis, especially where the smaller tubes are affected, and is more frequently seen in children than adults. In cases of chronic bronchitis the affection as a rule begins as a slight ailment during the winter, and recurs in succeeding winters. The intervals of freedom from the trouble get shorter, and in the course of a few years it persists during the summer as well as the winter months. A condition of chronic bronchitis is thus established. The persistent cough which this occasions is one of the chief causes of the development of the condition of *emphysema*, where there is a permanent enlargement of the air cells of the lungs with an atrophy of the walls of the air vesicles. The emphysema occasions an increase in the shortness of breath from which the person had previously suffered, and later, in consequence of the greater difficulty with which the blood circulates through the emphysematous lungs, the right side of the heart becomes dilated, and from that we have the development of a general dropsy of the subcutaneous tissues, and less and less perfect aëration of the blood.

Diseases of Occupations.—We all inhale a considerable amount of carbonaceous and other foreign particles, which in health are partly got rid of by the action of the ciliated cells lining the bronchial tubes, and are partly absorbed by cells in the wall of the tubes, and carried in the lymph channels to the bronchial lymphatic glands, where they are deposited, and cause a more or less marked pigmentation of the tissues. Part of such pigment is also deposited in the walls of the bronchial tubes and the interstitial tissue of the lungs, giving rise to the grey appearance presented by the lungs of all adults who live in large cities. The ordinary occupations of life are, however, not associated with the presence of such an amount of foreign particles in the atmosphere as to cause any serious inconvenience, the foreign particles being either got rid of or stored up in the tissues in the manner above described without causing the individual any great discomfort. In certain dusty occupations, however, such as those of stonemasons, knife-grinders, colliers, &c., the foreign particles inhaled do cause trouble. The most common affection so produced is chronic bronchitis, to which becomes added emphysema. In some cases not only is bronchitis developed, but the foreign particles lead to an increase of the fibrous tissue round the bronchi and in the interstitial tissue of the lungs, and so to a greater or lesser extent of fibroid consolidation. As this fibrous tissue may later undergo softening and cavities be formed, a form of consumption is produced, which is named according to the particular occupation giving rise to it; *e.g.*, stonemasons' phthisis, knife-grinders' phthisis, colliers' phthisis. It should, however, be pointed out that these dusty occupations are probably not so frequently the cause as was at one time taught of these simple inflammatory fibroid changes in the lungs with their subsequent cavity formation; individuals engaged in such occupations are apt to suffer from a chronic tuberculosis of the lung associated with the formation of much fibrous tissue, and the occupation simply predisposes the lung to the attacks of the tubercular virus.

Pneumonia.

The term pneumonia is frequently used of different forms of inflammation of the lungs, and includes affections which run different clinical courses, present diverse appearances after death, and probably have different exciting causes. It would be better if the term *acute pneumonia* were reserved for that form of acute inflammation of the lungs which is usually characterized by sudden onset, and runs an acute course, which terminates generally by crisis from the fifth to the tenth day, the inflammation leading to the consolidation by fibrinous effusion of the greater part or whole of one lobe of a lung. Acute pneumonia usually occurs in a sporadic form, and is most prevalent in the United Kingdom from November to March. Occasionally, however, it is epidemic, and there is evidence to show that sometimes it is an infective disease, a healthy individual contracting it directly from an affected one. There is great difficulty, however, in being quite certain that the occurrence of the disease in those who have been attending upon or brought into intimate connexion with sufferers from pneumonia is the result of infection, for such cases may be due to an epidemic of the disease, or to the various individuals attacked having been exposed to the same cause. Still, after allowing for this fallacy, it seems probable that some cases of pneumonia are infective, presenting a virulence and danger to the attendants not associated with the ordinary run of cases. Formerly acute pneumonia was considered to be a disease occasioned by what was termed "catching cold," and by some it is still so regarded. The tendency, however, at the present time is to look upon it as caused by the invasion of a specific virus, a micro-organism, and to relegate the exposure to inclement weather to the less important position of a predisposing cause, by which the conditions are rendered favourable for the development and growth of the germ. It cannot, however, be said that we are at present certain of the particular micro-organism which is the cause of pneumonia, or that all cases of acute pneumonia as above defined are due to one and the same germ. The various forms of pneumonia do not appear to have been sufficiently differentiated by the observers who have considered the relationship of the micro-organisms found in the inflamed lung to the ætiology of the disease, and it is probable that they are not all excited by one and the same micro-organism. Fraenkel's pneumococcus is an organism which is found in the inflamed lung in the large majority of cases, though not in all, and it has further been shown to be capable of producing pneumonia when inoculated into mice and guinea-pigs. But in other cases different forms of micro-organisms have been detected, and it is a debatable point what relation these bear to the causation of the disease. Fraenkel's pneumococcus is the organism most commonly present, and has the largest amount of evidence in its favour as the exciting cause of the disease. It must, however, be remembered that an organism which is apparently identical with that bearing Fraenkel's name frequently occurs in the saliva of healthy individuals. If, therefore, it is the most common exciting factor, some other element must be necessary before it can exert its action and produce pneumonia. This other element is commonly supposed to be the resisting power of the individual, by virtue of which the tissues of healthy persons, in whose saliva the pneumococcus is present, are able to offer a resistance to the multiplication of the germ and to the production of the inflammatory process in the lungs. Many conditions appear to lessen this resisting power. Exposure to inclement weather has already been referred to in this connexion, but even in idiopathic pneumonia it is frequently impossible to satisfy one's self that the patient has been exposed to unsuitable atmospheric conditions immediately before the attack. In other words, the effects of a so-called chill as a frequent cause of acute pneumonia have probably been exaggerated. A lowered state of general health usually precedes the onset of the disease, and anything producing a depressed nervous condition would appear to be important as a predisposing cause. Chronic alcoholism is one of the most important of such causes, and pneumonia frequently comes on in the course of Bright's disease and acute rheumatism, or as a sequela of influenza. Unlike many acute diseases, pneumonia does not render a person less liable to future attacks; on the contrary, those who have been once attacked must be looked upon as more prone to be affected again. Acute pneumonia usually attacks the whole or greater part of one lobe of one lung, but more than one lobe may be affected, or both lungs may be involved. The disease produces a solid and airless condition of the affected part owing to a fibrinous exudation taking place into the air cells and smaller bronchial passages. In favourable cases the exudation is partly absorbed and partly expectorated, and the lung returns to its normal healthy condition; in others, death may ensue from the extent of lung affected, or from the spread of the inflammation to other parts, as for instance the pericardium or meninges of the brain. In such cases it is interesting to note that the same micro-organism has been found in the inflammatory exudation in the pericardium or on the meninges as in the pneumonic lung; probably the organism had been absorbed from the lung, and was the cause of the secondary inflammations. In cases of death from uncomplicated pneumonia a very variable extent of lung is involved. Sometimes it is comparatively small, and we are surprised that it has been sufficient to lead to a fatal termination. In some such cases this result may be ascribed to the weakness of the individual and especially of the heart, but in others the virulence of the micro-organisms and the toxins which they have produced is probably the more correct explanation. The improvement in a patient suffering from pneumonia usually commences suddenly, with a rapid fall in the temperature. The day on which this "crisis" takes place varies, but most commonly it appears to be the seventh from the initial rigor (22 per cent. of the cases, Jürgensen). It may, however, occur a few days earlier or later, being observed in about 74 per cent. between the fifth and the ninth day of the disease (Jürgensen). The disease occasionally ends in the formation of an abscess, in gangrene, or in fibroid induration of the lung, but these terminations are rare.

Broncho-pneumonia.—It is usual to recognize a form of inflammation of the lungs which differs from the above lobar pneumonia, and in which small patches of consolidation are usually scattered throughout the lower lobes of both lungs. This broncho or catarrhal [1] pneumonia is usually preceded by an attack of bronchitis, to which it bears an intimate relation. In some cases the small foci of inflammation may run together so as to affect the greater part of a lobe of a lung, and the distinction between such a form of broncho-pneumonia and lobar pneumonia presents such difficulties in the view of some observers, that they have refused to recognize any essential difference between the two. Usually, however, it is not difficult to distinguish the two affections both clinically and anatomically. Broncho-pneumonia is especially seen as a complication of bronchitis, and while it more frequently attacks children than young adults, it is not uncommon in old people, especially secondary to bronchitis. It is frequent in children after acute infectious fevers, especially measles and diphtheria, and in cases of whooping-cough. It differs from the above-mentioned pneumonia in that it does not usually attack the whole of a lobe of a lung, but occurs in small disseminated patches more especially throughout the lower lobe of both lungs. The accompanying fever is more irregular than in the preceding form, and the disease usually runs a more prolonged course. It is an extremely fatal affection in both the very young and old. Young persons who have suffered from it are not unfrequently attacked by pulmonary tuberculosis subsequently. It must be admitted that we are even less certain of its bacteriology than we are of that of lobar pneumonia. In some cases Fraenkel's pneumococcus is found, and in others various other micro-organisms. Many of the latter are doubtless saprophytic, and are not the essential cause of the disease, but it is not probable that any one particular form of organism accounts for all forms of broncho-pneumonia.

Tubercle. The tubercular virus, the tubercle bacilli, may gain entrance to the lungs through the inspired air or by means of the blood or lymph currents. In the latter cases an acute eruption of tubercle takes place throughout the lungs in the form of small scattered foci forming the so-called miliary tubercles. Such miliary tuberculosis of the lungs is frequently only a part of a general tuberculosis, a similar tubercular affection being found in other organs of the body. In other cases the lungs may be the only or the principal seat of the affection. The source whence the tubercular virus is derived varies in different cases. Old tubercular glands in the abdomen, neck, and elsewhere, and tubercular disease of bones or joints, are common sources whence tubercular bacilli may become absorbed, and occasion a general dissemination of miliary tubercles in which the lungs participate. Where the source of infection is an old tubercular bronchial gland or a focus of old tubercle in the lung, the pulmonary organs may be the only seat of the development of miliary tuberculosis for a time; but even then, if life is sufficiently prolonged, other parts of the body become involved. Acute miliary tuberculosis of the lungs is not unfrequently a final stage in the more chronic tubercular lesions of the different forms of pulmonary phthisis.

[1] The term catarrhal pneumonia has been usually regarded as synonymous with the term broncho-pneumonia, and this usual nomenclature has been maintained in the present article. We must, however, recognize that all simple acute broncho-pneumonias are not purely catarrhal in the strict pathological sense. For instance, a considerable amount of fibrinous exudation is not unfrequently present in the patches of broncho-pneumonia, and some of the cases of septic broncho-pneumonia can scarcely be accurately termed *catarrhal.*

Phthisis. Pulmonary phthisis, or consumption, arises from the action of tubercle bacilli which have usually gained entrance with the inspired air. The disease usually commences at the apex of one lung, but runs a very variable course. In a large majority of cases it remains confined to one small focus, and not only does not spread, but undergoes retrograde changes and becomes arrested. In such cases fibrous tissue develops round the focus of disease and the tubercular patch dries up, often becoming the seat of the deposit of calcareous salts. This arrest of small tubercular foci in the lung is doubtless of very frequent occurrence, and in post-mortem examinations of persons who have died from injuries or various diseases other than tubercle it is common to find in the lungs arrested foci of tubercle, which in the majority of instances have never been suspected during life, and probably have occasioned few, if any, symptoms. It has been shown that in more than 37 per cent. of persons, over 21 years of age, dying in a general hospital of various diseases, there is evidence of arrested tubercle in the lungs. As such persons are chiefly drawn from the poorer classes, among whom tubercle is more common than among the well-to-do, this high percentage may not be an accurate indication of the frequency with which pulmonary tubercle does become arrested among the members of the community in general. It does, however, show that the arrest and the healing of tuberculosis of the lungs is by no means infrequent, and that it occurs among those who from their position in life are not only very prone to become infected, but whose circumstances commonly preclude them from putting themselves in the most favourable circumstances to promote the arrest of the disease. These facts indicate that the human organism does offer a resistance to the growth of the tubercle bacilli, and that the tissues of man, although so frequently attacked by the disease, do not afford the best conditions for the spread of tubercular disease. The knowledge of the frequency with which early cases of pulmonary tubercle become arrested must also be of the greatest comfort to those who are attacked, and one of the most encouraging factors for treatment. Consumption is still too frequently regarded by the general public as an incurable disease. In the advanced cases that view is doubtless correct, but in the early stage of the disease the process may become arrested, and the individual restored to health and rendered capable of leading a useful life.

A focus of pulmonary tubercle may become arrested for a time and then resume activity. In many cases it is difficult to say why this is so, but often it is clearly associated with a lowering in the general health of the individual, so that we must assume his resisting power to have been lessened. Frequently this is due to his premature return to his occupation and previous habits of life. It cannot be too strongly insisted that the arrest of a tubercular focus in the lung is a slow process and requires a long time. Commonly a person in the early stage of phthisis goes away to a health resort, and in the course of a few weeks or months improves so much that he returns to a densely populated town and resumes his former employment. In a short time his symptoms return and the disease shows renewed activity, because the improved conditions under which he was placed were not maintained long enough to ensure the complete arrest of the disease.

Instead of the tubercular focus becoming arrested, it may continue to spread and to give rise to other separate foci in its immediate neighbourhood. The original focus and the secondary ones are at first patches of consolidated lung. Later, their central parts soften and burst into a bronchus; then the softened portion is coughed up, and a small cavity is left, which tends gradually to increase in size by peripheric extension and by merging with other cavities. This process is repeated again and again, and sooner or later the other lung becomes similarly affected. At any stage of the softening process the blood-vessels may become involved and give rise by rupture to a large or a small hæmorrhage (*hæmoptysis*). It not unfrequently happens that such hæmoptysis occurs at a very early stage of the disease, and it may be the first symptom that seriously attracts attention. At a later period hæmorrhage frequently takes place in large or small amounts from the rupture of vessels, which frequently are dilated and form small aneurysms in the walls of cavities. A fatal termination may be hastened by the absorption by means of the blood-vessels and lymphatics of the tubercular virus from some of the foci of disease, and the occurrence therefrom of a local miliary tuberculosis of the lungs or a general tuberculosis of other organs. The rapidity with which the destructive process spreads throughout the lung varies considerably. In some cases we have extensive destruction in the course of a few weeks, in others the disease progresses slowly and extends over many years. We therefore recognize acute phthisis or galloping consumption, and chronic phthisis. In the acute cases the softening progresses rapidly and is associated with the development of very little fibrous tissue; probably various forms of micro-organisms other than the tubercle bacilli assist in the rapid softening. In the more chronic cases there is development of much fibroid tissue, and the disease is associated with periods of temporary arrest of the tubercular process.

The expectoration from cases of phthisis contains tubercle bacilli, and under favourable conditions is a source of danger to healthy individuals, in whom it may produce the disease. There is very little danger of infection from the sputum when freshly expectorated, but when it becomes dry and pulverized it is undoubtedly dangerous; hence the prevention of this drying is an important sanitary precaution. Attendance on persons suffering from phthisis involves very little risk of infection if proper care is taken to prevent the expectoration becoming dry and disseminated as dust; but it has been conclusively shown that the dust taken from rooms inhabited by phthisical persons does contain the virus of tubercle, and is capable of producing the disease when inoculated into healthy animals. Perfect cleanliness is therefore to be insisted upon in the rooms inhabited by a phthisical person. The tubercle bacilli soon lose their virulence in the presence of fresh air and sunshine, and therefore these agents are not only desirable for the direct benefit of the phthisical patient, but also are agents in preventing the development of fresh disease in healthy individuals.

Although the tubercle bacilli are the essential agents in the development of pulmonary tuberculosis, there are other conditions which must be present before they will produce the disease. Were this not so, tuberculosis would certainly be a much more common malady in the human subject than it is at present. It is probable that large numbers of individuals are exposed to the action of tubercle bacilli which gain entrance to the pulmonary tract, and yet do not give rise to the disease because the conditions of their growth and multiplication do not exist. In such cases we may consider that the seed is present, but that the soil is unsuitable for its growth. We do not know all the conditions that are favourable or inimical to the growth of the tubercular virus, but we are aware of some. Certain families appear more predisposed to tuberculosis than others. In some instances there would appear to be a direct transmission from parent to offspring of a liability to the disease, but in others a large number of cases of tuberculosis occur in a family though neither parent is apparently affected. Age has an important influence on the development of phthisis, which is most frequent in early adult life. Insanitary conditions of all kinds, especially overcrowding and the absence of fresh air and sunlight from dwellings and workrooms, are important predisposing causes. Anything which impairs the general health is likewise of importance, such as insufficient and improper food, chronic alcoholism, frequent childbearing, and prolonged lactation. Occupations associated with deficient ventilation and the presence of much dust in the atmosphere also furnish a large number of cases of consumption. The deteriorated state of health brought about by diabetes is not uncommonly associated with the development of pulmonary phthisis, and previous disease of the lungs also renders them more liable to a tubercular affection.

The most important circulatory disturbances met with in the lungs are those seen in cases of dilated heart, with or without disease of the mitral valve, when engorgement of the pulmonary vessels sets up a condition of venous engorgement of the lungs. This may lead to various changes. After it has lasted a variable time, and if it is very intense, serous transudation occurs into the substance of the lung and the alveoli, and thus a condition of pulmonary dropsy or œdema is established. The venous engorgement also predisposes the subjects of such heart affections to bronchitis and pneumonia. In disease of the mitral valve, in cardiac dilatation, and in simple feebleness of the heart, such as is seen in old age and after debilitating fevers, especially typhoid, there is commonly developed a venous congestion of the bases of the lungs, forming the so-called hypostatic congestion of those organs, and to this is frequently added pneumonia. In long-standing cases of pulmonary congestion brought about by disease of the mitral valve and dilatation of the heart, a certain amount of fibrous tissue may be found in the interstitial tissue of the lungs, and from transudation of certain elements of the blood we get the formation in the newly-formed fibrous tissue of blood pigment. In these cases blood pigment is found in the cells, in the pulmonary alveoli, and such cells also carry the pigment into the interstitial tissue. This condition constitutes the state known as *brown induration of the lungs*. Acute congestion of the lungs occurs as part of the first stage of pneumonia. It also probably exists during violent exertion, and may possibly be brought about by excitement.

Congestion.

Embolism and Thrombosis.—Another circulatory disturbance of great importance is that arising from blocking of the pulmonary artery or its branches by an embolus or thrombus. Where the obstruction takes place in the main vessel, death rapidly ensues. Where, however, a small branch of the vessel is occluded, as frequently occurs from a coagulum forming in the right side of the heart, or in the pulmonary vessels in cases of disease of the mitral valve, or in dilatation of the heart, or from the detachment of a small vegetation from disease of the tricuspid or pulmonary valves, a hæmorrhagic exudation takes place, forming a patch of consolidation in the lung (*hæmorrhagic infarct*). As this hæmorrhagic exudation takes place not only into the substance of the lung, but also into the bronchial tubes, such lesions are usually associated with spitting of blood (*hæmoptysis*). The increased tension produced in the pulmonary vessels in cases of mitral disease may also probably lead to the formation of hæmorrhagic exudations into the lungs, apart from the occurrence of embolism or thrombosis. Usually the occurrence of pulmonary embolism and the formation of hæmorrhagic infarcts in the lungs mark an important epoch in the course of a case of heart disease. It usually occurs at a late stage of the affection, and not unfrequently contributes materially to a fatal termination. It is probable that many of the cases of pneumonia and pleuritic effusion, coming on in cases of valvular heart disease and of cardiac dilatation, owe their origin to an embolus and to the formation of a hæmorrhagic infarct.

Asthma.

The term asthma is commonly applied to a paroxysmal dyspnœa of a special type which is associated with a variety of conditions. In true spasmodic asthma there may be no detectable organic disease, and the paroxysms are generally believed to be due to a nervous influence which, acting upon the bronchial muscles, produces a spasm of the tubes, or, acting through the vasomotor branches of the sympathetic, produces a congestion of the bronchial mucous membrane. The exciting cause may not be at all apparent even on the most careful observation and examination of the sufferer, but in other cases the attacks may be brought about by some reflex irritation. Nasal polypi and other diseases of nasal mucous membrane have been shown in some cases to be a cause of asthma. Flatulence and constipation are other occasional exciting causes. Irritation of the bronchial mucous membrane appears to be one of the most common, but it is usually difficult to say exactly in what the irritation consists. It is known that a locality is sometimes responsible, and change of residence to a very short distance may make all the difference. The condition of the weather has a very variable influence. In some asthmatic subjects dust and fog in the atmosphere have a marked effect; in other cases, however, a foggy atmosphere has no influence, and an asthmatic individual may be actually better in foggy weather than in a clear dry atmosphere. Emotion and various nervous disturbances may occasionally produce the attacks. Allied to true asthma is the bronchial asthma frequently met with in the subjects of bronchitis and emphysema. In such cases the irritation evidently proceeds from the inflamed bronchial mucous membrane. Hay asthma is the variety in which the pollen of certain plants, especially grasses, is the exciting cause of the paroxysms. In cardiac feebleness, in valvular disease of the heart, and in cardiac dilatation, we may get dyspnœic attacks of a more or less paroxysmal nature, to which the term cardiac asthma has been applied. Similarly, to a form of dyspnœa met with occasionally as a manifestation of uræmia in chronic Bright's disease the term of renal asthma has been given. It is probable that in both these latter conditions the state of the central nervous system brought about by the cardiac and renal affections respectively is the important element producing the paroxysms of dyspnœa.

Pleurisy.

Pleurisy, or inflammation of the pleura, is a very common affection, and is met with under different forms. In many instances we have simply the pouring out, over a greater or less area of the surface of the pleura, of a fibrinous exudation which may become absorbed or undergo organization, a certain amount of thickening of the pleura, and adhesions of the two layers resulting. Such cases form the group known as cases of dry pleurisy. In other instances a greater or lesser amount of serous exudation takes place into one or other pleural cavity, forming the cases of serous pleuritic effusion. In others the exudation into the pleural cavity is purulent, giving rise to the condition known as empyema or purulent pleuritic effusion. The occurrence of dry pleurisy is probably very frequent, and leads to small pleural adhesions which cause little or no inconvenience. In post-mortem examinations of persons who have died from various diseases, it is common to find such pleural adhesions present, although they have never been suspected during life. Pleurisy in one or other of the above forms may come on in a person apparently in good health (idiopathic pleurisy), or it may follow a fracture of the ribs or other injury to the chest. It is not uncommonly secondary to some other disease; thus it is almost a constant accompaniment of acute lobar pneumonia. In such cases the effusion is most commonly a simple fibrinous one, which with the subsidence of the primary disease is in great part absorbed. In other cases of pneumonia we get a certain amount of serous effusion into the pleura; and sometimes, especially in children, the pneumonia is followed by the development of an empyema. Pleurisy with effusion is also frequently a complication of valvular heart disease and dilatation of the heart, and in such cases is often associated with the formation of superficial pulmonary infarcts. It is also seen in many other diseases of the lungs. For instance, in chronic phthisis pleuritic adhesions over various parts of the lungs are the rule; and we also frequently get serous effusion into the pleura as a complication of the various forms of pulmonary tuberculosis. Purulent effusion is less common in phthisis, but it is the rule where the pleura is perforated by the necrosis of a tubercular focus in the lung and the establishment of a communication between the pleura and a tubercular cavity and the bronchial tubes (*pyopneumonothorax*), a combination in which there is both air and pus in the pleural cavity. Secondary pleurisy is also seen in an extension of the disease from neighbouring parts, as from peritonitis, sub-diaphragmatic abscess, and suppuration in the liver or spleen. As a secondary disease pleurisy is also known in the course of various forms of nephritis, rheumatism, and the acute specific diseases.

The cases of so-called idiopathic pleurisy arising in apparently healthy individuals are very interesting and of great importance from an ætiological point of view. In them the pleurisy is commonly attributed to catching cold, but, as in pneumonia, such an occurrence is now generally regarded rather as a predisposing element, and as rendering the pleura a favourable seat for the action of various micro-organisms. It has long been known that persons who have been the subjects of apparently idiopathic serous pleuritic effusion become at a later date the subjects of pulmonary phthisis. More recently it has been shown that the effusion removed from the pleura in such cases is frequently capable of producing tuberculosis when inoculated into guinea-pigs, and hence it is probable that a large number of what are apparently cases of simple inflammation of the pleura are really cases of tuberculosis of the pleura. In many such cases, although at the time of the pleuritic effusion no sign of disease is manifest in the lungs, a tubercular focus does exist which remains for a time latent and subsequently assumes renewed activity. In other cases the pneumococcus appears to be the cause of a purulent or, in rarer instances, of a serous pleuritic effusion; and this may be in cases where pneumonia is, or previously has been present. It is probable also that the pneumococcus sometimes produces a pleurisy without the intervention of pneumonia. In other cases, again, of purulent effusion into the pleura, streptococci seem to be the essential agents of the disease, and account for the production of the pleurisy secondary to various lung affections, and for the spread of inflammation from the peritoneum and other parts, secondary to various general diseases, such as the acute specific diseases, scarlet fever, diphtheria, and erysipelas. (T. H*.)

VI. The Blood.

The changes in the blood in disease are probably as numerous and varied as the diseases which attack the body, for the blood is not only the medium of respiration, but also of nutrition, of defence against organisms, and of many other functions, none of which can be affected without corresponding alterations occurring in the circulating fluid. The immense majority of these changes are, however, so subtle that they escape detection by our present methods. We are beginning to recognize such reactions of infection as the agglutination of the typhoid bacillus by the blood of patients suffering from enteric fever; we are groping for the changes associated with immunity from various diseases; but, speaking generally, we know comparatively little about changes in the blood unless these betray themselves by somewhat coarse alterations in its morphological elements. The changes in the plasma are as yet very imperfectly known, and chemical methods of investigation are still only clinical curiosities. The methods at present employed in examining the blood are: the enumeration of the red and white corpuscles per cubic millimetre; the estimation of the percentage of hæmoglobin and of the specific gravity of the blood; the microscopic examination of freshly-drawn blood and of blood films made upon cover-glasses, fixed and stained. In special cases the alkalinity and the rapidity of coagulation may be ascertained, or the blood may be examined bacteriologically. We have no universally accepted means of estimating, during life, the total amount of blood in the body, though the method of Haldane and Lorrain Smith, in which the total oxygen capacity of the blood is estimated, and its total volume worked out from that datum, seems to promise important results (*Journ. of Physiol.*, vol. xxv., p. 331, 1900). After death the amount of blood sometimes seems to be increased, and sometimes, as in pernicious anæmia, it is certainly diminished. But the high counts of red corpuscles which are occasionally reported as evidence of plethora or increase of the total blood, are really only indications of concentration of the fluid. It is necessary, therefore, in examining blood diseases, to confine ourselves to the study of the blood-unit, which is always taken as the cubic millimetre, without reference to the number of units in the body.

Anæmia is often used as a generic term for all blood diseases, for in almost all of them the hæmoglobin is diminished, either as a result of diminution in the number of the red corpuscles in which it is contained, or because the individual red corpuscles contain a smaller amount of hæmoglobin than the normal. As hæmoglobin is the medium of respiratory interchange, its diminution causes obvious symptoms, which are much more easily appreciated by the patient than those caused by alterations in the plasma or the leucocytes. It is customary to divide anæmias into "primary" and "secondary": the primary are those for which no adequate cause has as yet been discovered; the secondary, those whose cause is known. Among the former are usually included chlorosis, pernicious anæmia, and sometimes the leucocythæmias; among the latter, the anæmias due to such agencies as malignant disease, malaria, chronic metallic poisoning, chronic hæmorrhage, tubercle, Bright's disease, infective processes, &c. As our knowledge advances, however, this distinction will probably be given up, for the causes of several of the primary anæmias have been discovered. For example, the anæmia due to *bothriocephalus*, an intestinal parasite, is clinically indistinguishable from the other forms of pernicious anæmia with which it used to be included, and leucocythæmia has been declared by Löwit, though probably erroneously, to be due to a blood parasite closely related to that of malaria. In all these conditions there is a considerable similarity in the symptoms produced and in the pathological anatomy. The general symptoms are pallor of the skin and mucous membranes, weakness and lassitude, shortness of breath, palpitation, a tendency to fainting, and usually also gastro-intestinal disturbance, headache, and neuralgia. The heart is often dilated, and on auscultation the systolic murmurs associated with that condition are heard. In fatal cases the internal organs are found to be pale, and very often their cells contain an excessive amount of fat. In many anæmias there is a special tendency to hæmorrhage. Most of the above symptoms and organic changes are directly due to diminished respiratory interchange from the loss of hæmoglobin, and to its effect on the various organs involved. The diagnosis depends ultimately in all cases upon the examination of the blood.

Though the relative proportions of the leucocytes are probably continually undergoing change even in health, especially as the result of taking food, the number of red corpuscles remains much more constant. Through the agency of some unknown mechanism, the supply of fresh red corpuscles from the bone-marrow keeps pace with the destruction of effete corpuscles, and in health each corpuscle contains a definite and constant amount of hæmoglobin. The disturbance of this arrangement in anæmia may be due to loss or to increased destruction of corpuscles, to the supply of a smaller number of new ones, to a diminution of the amount of hæmoglobin in the individual new corpuscles, or to a combination of these causes. It is most easy to illustrate this by describing what happens after a hæmorrhage. If this is small, the loss is replaced by the fully-formed corpuscles held in reserve in the marrow, and there is no disturbance. If it is larger, the amount of fluid lost is first made up by fluid drawn from the tissues, so that the number of corpuscles is apparently diminished by dilution of the blood; the erythroblasts, or formative red corpuscles, of the bone-marrow are stimulated to proliferation, and new corpuscles are quickly thrown into the circulation. These are apt, however, to be small and to contain a subnormal amount of hæmoglobin, and it is only after some time that they are destroyed and their place taken by normal corpuscles. If the loss has been very great, nucleated red corpuscles may even be carried into the blood-stream. The blood possesses a great power of recovery, if time be given it, because the organ (bone-marrow) which forms so many of its elements never, in health, works at high pressure. Only a part of the marrow, the so-called red marrow, is normally occupied by erythroblastic tissue, the rest of the medullary cavity of the bones being taken up by fat. If any long-continued demand for red corpuscles is made, the fat is absorbed, and its place gradually taken by red marrow. This compensatory change is found in all chronic anæmias, no matter what their cause may be.

It is often very difficult, especially in "secondary" anæmias, to say which of the above processes is mainly at work. In acute anæmias, such as those associated with septicæmia, there is no doubt that blood destruction plays the principal part. But if the cause of anæmia is a chronic one, a gastric cancer, for instance, though there may possibly be an increased amount of destruction of corpuscles in some cases, and though there is often loss by hæmorrhage, the cancer interferes with nutrition, the blood is impoverished and does not nourish the erythroblasts in the marrow sufficiently, and the new corpuscles which are turned out are few and poor in hæmoglobin. In chronic anæmias, regeneration always goes on side by side with destruction, and it is important to remember that the state of the blood in these conditions gives the measure, not of the amount of destruction which is taking place so much as of the amount of regeneration of which the organism is capable. The evidence of destruction has often to be sought for in other organs, or in secretions or excretions.

Of the so-called primary anæmias the most common is *chlorosis*, an anæmia which occurs only in the female sex, between the ages of fifteen and twenty-five as a rule. Its symptoms are those caused by a diminution of hæmoglobin, and though it is never directly fatal, and is extremely amenable to treatment with iron preparations, its subjects very frequently suffer from relapses at varying intervals after the first attack. Its causation is probably complex. Bad hygienic conditions, over-fatigue, want of proper food, especially of the iron-containing proteids of meat, the strain put upon the blood and blood-forming organs by the accession of puberty and the occurrence of menstruation, all probably play a part in it. It has also been suggested that internal secretions may be concerned in stimulating the bone-marrow, and that in the female sex in particular the genital organs may act in this way. Imperfect assumption of function by these organs at puberty, caused perhaps by some of the above-mentioned conditions, might lead to sluggishness in the bone-marrow, and to the supply to the blood of the poorly-formed corpuscles deficient in hæmoglobin which are characteristic of the disease. Chlorosis is the type of anæmias from imperfect blood-formation. Lorrain Smith has produced evidence to show that the total amount of hæmoglobin in the body is not diminished in this disease, but that the blood-plasma is greatly increased in amount, so that the hæmoglobin is diluted and the amount in each blood-unit greatly lessened.

Pernicious anæmia is a much rarer disease than chlorosis, occurs usually later in life, and is distributed nearly equally between the two sexes. But it is of great importance because of its almost uniformly fatal termination, though its downward course is generally broken by temporary improvement on one or more occasions. The symptoms are those of a progressive anæmia, in which gastro-intestinal disturbance usually plays a large part, and they become at last much more severe than those of any secondary anæmia. The patient may die in the first attack, but more usually, when things seem to be at their worst, improvement sets in, either spontaneously or as the result of treatment, and the patient slowly regains apparent health. This remission may be followed by a relapse, that again by a remission, and so on, but as a rule the disease is fatal within, at the outside, two or three years. The outstanding feature in its pathology is the occurrence of blood-destruction in some part of the portal system, as is proved by the storage in the liver of the iron from the broken-down red corpuscles, and by other facts. This blood-destruction is almost certainly caused by the absorption of toxic substances from the stomach and intestine, but the source of these substances is quite unknown, except in one set of cases, those in which the dead and decomposing *bothriocephalus* poisons its host. The statement of Hunter, that the disease is due to a chronic poisoning by streptococcal micro-organisms, is in direct contradiction to all our knowledge of the behaviour of the blood in streptococcous infections. The condition of the blood in this disease is sharply distinguished from that in any other anæmia. The red corpuscles are enormously diminished; it is usual to find 1,000,000 or less in the cubic millimetre, instead of the normal 5,000,000. The special characteristic of the disease is that though the hæmoglobin is of course absolutely diminished, it is often present in relatively higher percentage than the blood corpuscles. The meaning of this is that the individual corpuscles are on the average larger than usual, and this again occurs because the erythroblasts of the hypertrophied bone-marrow are not of the normal size (normoblasts), but are much larger than normal (megaloblasts). This is a reversion to the type of blood-formation in the fœtus, and the occurrence of megaloblasts in the circulating blood is practically pathognomonic of pernicious anæmia.

Other anæmias, such as those known as *lymphadenoma*, or Hodgkin's disease, *splenic anæmia*, and the *anæmia pseudo-leucæmica* of children, need not be described here, as they are either rare or their occurrence or nature is still too much under discussion.

The number and nature of the leucocytes in the blood bears no constant or necessary relation to the number or condition of the red corpuscles, and their variations depend on entirely different conditions. The number in the cubic millimetre is usually about 7000, but may vary in health from 5000 to 10,000. A diminution in their number is known as *leucopenia*, and is found in starvation, in some infective diseases, as for example in the later weeks of typhoid fever, and in pernicious anæmia. An increase is very much more frequent, and is known as *leucocytosis*, though in this term is usually connoted a relative increase in the proportion of the polymorphonuclear neutrophile leucocytes (see ANATOMY). Leucocytosis occurs under a great variety of conditions, normally to a slight extent during digestion and after violent exercise, and abnormally after hæmorrhage, in the course of inflammations and many infective diseases, in malignant disease, in such toxic states as uræmia, and after the ingestion of nuclein and other substances. It does not occur in some infective diseases, the most important of which are typhoid fever, malaria, influenza, measles, and uncomplicated tuberculosis. In all cases where it is sufficiently severe and long continued, the reserve space in the bone-marrow is filled up by the active proliferation of the leucocytes normally found there, and is used as a nursery for the leucocytes required in the blood. The nature and cause of leucocytosis are not yet determined for all cases, but in many it is known to be associated with the defence of the organism from injurious influences, and its amount depends on the relation between the severity of the attack and the power of resistance. There may be an increase in the proportions present in the blood of lymphocytes (*lymphocytosis*), and of eosinophile cells (*eosinophilia*), but these are of interest only to the clinician.

The disease in which the number of leucocytes in the blood is greatest is *leucocythæmia* or leucæmia. There are two main forms of this disease, in both of which there are anæmia, enlargement of the spleen and lymphatic glands, or of either of them, leucocytic hypertrophy of the bone-marrow, and deposits of leucocytes in the liver, kidney, and other organs. The difference lies in the kind of leucocytes present in excess in the blood, blood-forming organs, and deposits in the tissues. In the one form these are lymphocytes, which are found in health mainly in the lymph glands and in the lymphatic tissue round the alimentary canal; in the other they are the kinds of leucocytes normally found in the bone-marrow—myelocytes, neutrophile and eosinophile, and polymorphonuclear cells, also both neutrophile and eosinophile. The clinical course of the two forms may differ. The first, known as lymphatic leucæmia or *lymphæmia*, may be acute, and prove fatal in a few weeks or even days, or may be chronic and last for one or two years or longer. The second, known as spleno-myelogenous leucæmia or *myelæmia*, is almost always chronic, and may last for several years. Recovery does not take place, though remissions may occur. The most recent view of the pathology of the disease is that of Löwit, who believes, on grounds of pathological observation and experimental inoculation, that both forms are due to blood parasites, sporozoa not unlike the malarial plasmodium, which are found in myelæmia in the leucocytes of the peripheral blood, in lymphæmia in those of the blood-forming organs, and differ somewhat in appearance in the two forms. The former disease he regards as the expression of parasitism *in* the leucocytes; the latter as due to the poison produced by the parasites stimulating the lymphocytes to proliferation and to passage into the blood. It is right to say that Löwit's observations are as yet unconfirmed, and do not seem altogether conclusive.

VII. CIRCULATION.

On account of its intimate relations with every part of the body, the circulation is prone to disturbances arising from a great series of causes. Some of these produce effects which may be regarded as functional—mere changes in metabolism, whose disturbances react upon the rest of the body; others give rise to definite structural alterations. In considering the pathology of the circulation, it is useful to take up the subject under the headings of (1) *Causes*, (2) *Processes*, and (3) *Effects*.

1. *Causes.*—The factors leading to abnormal conditions of the circulation naturally fall into two groups. I. *Intrinsic*, *i.e.* belonging to the individual. Chief amongst these are: heredity—certain families inherit tendencies

to reactive processes in the cardiac serous membranes, or to degenerative changes in the heart and vessels; age—young persons are more prone to acute reaction changes in the serous membranes, while elderly people are more liable to chronic degenerative alterations in the walls of the heart and of the blood-vessels; sex—males are more subject to degenerative, and females to acute, diseases of the heart; occupation—those engaged in physical over-exertion are liable to sclerotic changes in the vessels and hypertrophy of the heart, while sufficient, but not excessive, muscular activity only serves to maintain a healthy condition of the circulation; habits—healthy modes of life preserve the integrity of the circulatory mechanism, while indolence and indulgence induce fatty changes. II. *Extrinsic, i.e.* arising from without. These causes may be classified under two heads. (1) *General.*—Infective agents, as in the different fevers, give rise to acute affections of the serous membranes of the heart, and to some extent also of the muscular walls; metabolic disturbances, as in gout and its allies, produce chronic fibrous changes, particularly in the vessels, but also to a certain degree in the heart itself; wasting diseases and blood impoverishment lead to retrograde processes, such as fatty degeneration of the heart muscle. (2) *Local.*—Certain diseases originally restricted in distribution produce considerable effects on the circulation. Thus some diseases of the kidneys involve alterations in the systemic arteries and in the left side of the heart, while many affections of the lungs cause analogous effects in the pulmonary blood-vessels and in the right side of the heart.

2. *Processes.*—The changes undergone by the heart and vessels in disease are similar to those which occur in other parts of the body, but are necessarily modified by the special conditions of the circulatory system. Arising in consequence of one or more of the factors just mentioned, the changes may be regarded, for convenience, as belonging to one or other of two great classes—*degenerative* or *retrograde*, and *inflammatory* or *reactive*.

Degenerative.—From the presence of toxic substances in the blood (whether introduced from without or arising within the body) the cells of the muscle fibres are apt to undergo what is termed *cloudy swelling*—the simplest form of degenerative process. The cells become larger and duller, with a granular appearance, and the nuclei are less distinct. As a result of interference with nutrition, whether by simple diminution or perverted processes, *fatty degeneration* ensues. It may be associated, but is not necessarily connected, with adipose accumulation and encroachment, commonly termed infiltration. In true fatty degeneration the muscle cells have part of their protoplasm converted into adipose tissue. The fibres become granular, and the cells lose their definition, while the nuclei are obscure. In some of the acute infective diseases *hyaline degeneration* of muscle fibre takes place, apparently as the effect of coagulative processes. The tissues assume a somewhat glassy appearance, with a distinct tendency towards segmentation. *Calcareous infiltration* is brought about by the deposition of lime salts in tissues which have previously undergone fatty or fibroid changes; it particularly affects the arteries in senile affections. In elderly persons, as well as in cachectic conditions at earlier periods of life, *pigmentary atrophy* takes place. The change consists in a diminution of the size of the muscle fibres, with a great increase of pigment around the nuclei of the cells. And, lastly, *simple atrophy* occurs, through a diminution in the number as well as in the size of the cells in cases of wasting disease.

Reactive.—The acute and chronic processes grouped together under this head form a series characterized by many points of resemblance, but differing widely, according to the tissues in which they are found. They are all due to the reaction of the tissues to irritation, but they vary as they occur in serous membranes, muscular textures, or connective tissues. As regards the serous membranes, their results are quite different in the case of the pericardium, which is highly vascular, and the endocardium upon the valves, which is not rich in blood-vessels. In the case of the pericardium, an exudation of a sero-fibrinous character, which may tend more towards either of these types—serous and fibrinous—is poured out, and to some extent coagulates in most instances, but little emigration or proliferation of cells is found. Analogous processes affecting the endocardium produce granulations or vegetations, sometimes attended by sclerotic changes, causing retraction and deformity of the cusps, at other times accompanied by destructive lesions leading to loss of tissue. The myocardium undergoes both acute and chronic reaction changes. In the former there is enlargement of the nuclei, with proliferation but without karyokinesis. The muscle cells become swollen and lose their striation, while they are softer in texture and altered in outline. The intermuscular tissues are swollen, and may be invaded by leucocytes; this may end in abscess formation, or in the production of newly-formed fibrous tissue. Chronic processes affecting the myocardium give rise to a large amount of fibrosis, and the newly-formed fibrous tissue separates and compresses the areas of muscle fibres, giving rise to what is commonly known as chronic interstitial myocarditis. The analogous changes occurring in connective tissues, such as enter so largely into the structure of the aorta and other large vessels, may be also acute or chronic. In the acute form there are considerable swelling and softening, attended both by exudation and proliferation, the latter of which may, but does not by any means frequently, go on to the formation of pus. The chronic type is characterized by the development of a large amount of newly-formed fibrous tissue, resulting in considerable thickening of the walls, and leading to fatty or calcareous changes.

As a sequel to what has been said regarding pathological processes, it may be added that there are certain efforts of nature by which some of their effects are obviated or lessened. Hypertrophy, when within physiological limits, is to be considered as a means of adaptation. When occurring in pathological circumstances, it must be regarded as a method of compensation. Every structure and every function in a healthy body has greater or lesser reserve of energy. In healthy conditions the ordinary demands made upon various organs are far below their possible responses, and if these be excessive in extent or duration, the organs adapt themselves to the conditions imposed on them. In abnormal circumstances the process of hypertrophy is brought about by the power which the structures have of responding to the demands made upon them, and so long as the process is adequate, all disturbances may be averted. As an example of such readjustment may be cited the fact that in chronic renal cirrhosis, with increased thickness of the middle tunic of the arteries, there is hypertrophy of the left ventricle.

Restitution or recovery may occur to a varying extent in almost all of the disease-processes which have been considered, but it has to be kept in view that in certain of the degenerative affections there is little if any possibility of getting rid of the results of the process, while in the reactive changes terminating in the formation of much fibrous tissue, or its conversion into adipose or calcareous material, the same holds true. Many of the changes, which are no doubt in their essence conservative, lead to far-reaching consequences, by their interference with nutritive possibilities.

3. *Effects.*—The disturbances of the circulation resulting from the processes which have been analysed can be conveniently arranged in a limited number of groups, according as their chief morbid effects are experienced by the heart, the vessels, or the blood. No doubt many factors operate by influencing two or all of these divisions, but it renders the subject clearer to classify the various agencies.

Disturbances connected with the heart may, in the first place, be mainly of *pericardial* origin. An effusion of serous fluid into the pericardial sac causes considerable embarrassment to the course of the blood, by rendering the negative pressure, normally present in the sac, positive. The reason for the interference with the circulation, brought about by this alteration of pressure, is that the auricles are by compression rendered incapable of accommodating the blood-return from the veins. Analogous effects are produced by pressure upon the heart from without, whether by aneurysm or tumour, and pleural effusion or pneumothorax, affecting the viscera from without. In pericarditis it has further to be remembered that the effect of the process itself upon the muscle fibres lying beneath the membrane is to cause a softening of texture and weakening of function, whereby the driving power of the heart is diminished. In obliteration of the pericardium, again, the presence of the adhesions between these two layers leads to interference with the contraction of the myocardium, whereby its functions are interfered with. Alterations in the *endocardial* tissues bring into play another group of causes. The affections of the orifices and valves, so largely produced by alterations of the endocardium, lead to much disturbance of the circulation, either by obstructing the orifices or by permitting regurgitation. In the case of obstruction there must be a lessened current through the orifice, unless the obstacle is in some way overcome; while in the case of regurgitation, unless it be in some way compensated, too little blood is present in the cardiac cavities for propulsion in the right direction. In both lesions, therefore, whether obstructive or regurgitant, the onward flow of the blood is lessened, either by an obstacle to the ongoing current, or a loss of part of it backwards. The action of the ventricles in drawing blood into them is also interfered with directly or indirectly, since obstruction interferes with the direct aspiratory action, while regurgitation, in consequence of the backward escape, causes some of the blood to be drawn towards the heart more than once.

The causes which operate by means of the *myocardium* are almost invariably of a secondary character. The various degenerations already detailed, and the different forms of myocarditis, as well as simple debility of the muscle, are all examples of changes due to general or local disturbance. All processes which directly or indirectly interfere with the energy of the walls of the heart produce twofold effects, by diminishing the aspiratory or suction-pump action during diastole, and by lessening its expulsive or force-pump action during systole. The immediate result upon the heart itself of such disturbances is dilatation of that cavity immediately affected. This may occur under perfectly healthy conditions. In these, however, the dilatation is evanescent, while in the circumstances now under consideration it is permanent, and, although compensated, it leads to persistent dilatation. Upon the blood-vessels the result, whether on account of diminished aspiratory or propulsive energy, is that the amount of blood in the arterial system is decreased, while it is increased in the venous. It is not a necessary consequence that because there is less blood in the arteries the arterial pressure will be diminished, or the venous pressure increased because the veins contain more than their normal amount of blood, seeing that the blood pressure depends upon many different factors. It is a fact, nevertheless, that in consequence of the alteration in the relative amount of blood in the arteries and veins there is a considerable disturbance of blood pressure. Gravitation may overcome the contractile and elastic factors, and several consequences arise from the resulting venous engorgement. From transudation, œdema of the dependent parts of the body and the serous membranes occurs. From the sluggish nature of the current, the blood absorbs too much carbonic acid and loses too much oxygen, hence cyanosis is the result. On account, also, of the slowness of the circulation, there is a longer period for radiation of heat, and the superficial parts of the body accordingly become cold.

The engorgement of internal organs leads to distinct changes in them. The solid viscera, such as the liver, the spleen, the kidney, and the lung, become enlarged and hyperæmic, and if the disturbance be continued, cyanotic atrophy ensues. Change in structure, with loss of function, takes place from blocking of the vessels by blood-clot, whether due to coagulation on the spot, or by the conveyance thither of clots formed elsewhere; a cirrhotic termination also is not infrequent, although there is still some doubt whether in this latter condition other concomitant causes have not at the same time been operative. The brain, although suffering less from hyperæmia, is subject to disturbance of the circulation through it, while it is a common seat of embolic and thrombotic processes. The heart itself, lastly, suffers in consequence of the disturbed circulation through it, and by undergoing venous stasis, with weakening of its walls and increase of its fibrous tissue, it completes the final link in a vicious circle. Effusion into the serous sacs, such as the pleura, the pericardium, and the peritoneum, leads to great disturbance of the viscera with which they are connected. The mucous membranes, both respiratory and digestive, become the seat of catarrhal changes in consequence of the backward pressure and impure blood.

The *blood-vessels* possess the properties of contractility and elasticity in different degrees. Their contractility is characterized by great tonicity, considerable rhythmic action, and little or no rapidity of contraction. Their elasticity stores up energy in a potential condition, and this may be liberated in kinetic form as required. The vessels are supported in various degrees by the different tissues in which they are found. In the more solid viscera they are strongly supported, as in the liver and kidney, while in those which are less dense, as in the case of the brain and the lungs, they are not so well sustained.

In many conditions the contractility and elasticity of the blood-vessels become diminished. As part of a senile change, in consequence of many toxic agencies and as the effect of long-continued stress, the blood-vessels undergo a loss of their normal properties. This is compensated by the growth of an excessive amount of fibrous tissue, leading to various forms of *arterial sclerosis.* As the result of these fibrous changes there is interference with the blood current, since the vessels become unyielding yet frangible, instead of distensile and elastic, tubes. The sclerotic changes lead, moreover, to dilatation of blood-vessels, as well as to the formation of definite aneurysms. They also pave the way for coagulation of blood within them, *i.e.* thrombosis, while in certain situations, more particularly in the brain and in the kidney, rupture is apt to take place. Upon the heart also these changes bring about far-reaching effects. Dilatation, accompanied by hypertrophy, is a certain result of generalized arterial degeneration, while changes in the coronary arteries lead to some of the definite results in the walls of the heart which have already been considered.

The condition of the *blood* is always in a state of fluctuation in consequence of the tissue changes throughout the entire system. It may be temporarily increased or diminished in quantity, and it undergoes great changes not merely as regards the proportion of its different elements, but in respect of many different substances which are apt to circulate through it. The result of such changes is to produce degenerative and reactive processes in the heart and blood-vessels such as have been fully referred to.

The various disturbances which have been considered are compensated by certain of the processes which have been detailed. Chief amongst the compensatory changes is cardiac hypertrophy. A considerable amount of disturbance may take place without the production of hypertrophy, seeing that there is so much reserve of energy in the healthy heart. If the disturbances are permanent, so that the organ labours under continuous stress, the changes summed up under the term hypertrophy ensue, whereby the circulation is sustained. In addition to an absolute increase in the size and number of the muscle fibres of the heart, there is very commonly some fibroid change, and not infrequently some fatty degeneration along with the hypertrophy. Hypertrophy is only possible when the nutrition of the heart is good—when the blood is healthy and the coronary arteries are adequate. It is, however, subject to individual possibilities.

The loss of the normal properties in the blood-vessels is followed by the fibroid changes which have been remarked upon, and these may be regarded as compensatory; but they lead, as has been seen, to further changes, and are to be regarded also as part of a vicious circle.

The alterations in the blood are probably compensated for by an increase in those elements which are of vital importance, such as the coloured and colourless corpuscles.

(G. A. G.)

VIII. Metabolic Diseases.

All disease is primarily due to alterations, quantitative or qualitative, in the chemical changes in the protoplasm of some or all of the tissues of the body. But while in some pathological states these modifications lead to structural changes, in others they do not produce gross lesions, and these latter conditions are commonly classified as Functional Diseases. When such functional disturbances affect the general nutrition of the body they have been termed Metabolic Diseases (*Stoffwechselkrankheiten*). It is impossible to draw a hard and fast line between functional and organic disease, since the one passes gradually into the other, as is well seen in gout. Nor is it always easy to decide how far the conditions are due merely to quantitative alterations in the metabolism and how far to actual qualitative changes, for, as is pointed out in the article Physiology, it is highly probable that many of the apparently qualitative alterations are really quantitative disturbances in one part of the protoplasmic mechanism, leading to an apparent qualitative change in the total result of the activity. The clinical features of such metabolic diseases have been fully treated in the ninth edition of this work, and in the present article the advances in our knowledge of their pathology are alone considered.

A. *Changes in Metabolism mainly Quantitative.*

Obesity.—It is as fat that the surplus food absorbed is stored in the body; but the power of storing fat varies enormously in different individuals, and in some it may be considered pathological. The reasons of this are very imperfectly understood. One undoubted cause of obesity is taking a supply of food in excess of the energy requirements of the individual. The amount of food may be *absolutely* large or large *relatively* to the muscular energy evolved in mechanical work or in heat-production; but in either case, when fat begins to be deposited, the muscular activity of the body tends to diminish and the loss of heat from the surface is reduced; and thus the energy requirements become less, and a smaller diet is sufficient to yield the surplus for further storage of fat. Fat is formed from carbohydrates, and either directly or indirectly from proteids (see Physiology: *Nutrition*). Individuals probably vary in their mode of dealing with these substances, some having the tendency to convert them to fat, some to burn them off at once. Von Noorden, however, who has studied the metabolism in cases of obesity, finds no marked departure from the normal. It may be that in some there is a very perfect absorption of food, but so far no scientific evidence for this view is forthcoming. In all cases the fat stored is available as a source of energy, and this circumstance is taken advantage of in the various fat "cures," which consist in giving a diet containing enough proteids to cover the requirements of the body, with a supply of fats and carbohydrates insufficient to meet the energy requirement of the individual. This is illustrated by the dietaries of some of the best known of these "cures":—

	In Grms. per Diem.			
	Proteid.	Fat.	Carbohydrates.	Calories.
Banting's cure	172	8	81	1112
Oertel's ,,	156–170	25–45	75–120	1180–1608
Ebstein's ,,	102	85	47	1401

In a normal individual in moderate muscular activity about 3000 to 3500 calories per diem are required (see Dietetics), and therefore under the diets of these "cures," especially when accompanied by a proper amount of muscular exercise, the fats stored in the body are rapidly used up.

Diabetes is produced by a diminution in the power of the tissues to use sugar, which thus accumulates in the blood and escapes in the urine. One great source of energy being unavailable, the tissues have to use more fats and more proteids to procure the necessary amount, and hence, unless these are supplied in very large amounts, there is a tendency to emaciation.

The power of using sugar in the tissues is strictly limited, and varies considerably in healthy individuals. Normally, when about 200 grms. of glucose is taken at one time, some of it appears in the urine within one hour. In some individuals the taking of even 100 grms. leads to a transient glycosuria, while others can take 250 grms. or more and use it all. But even in the same healthy individual the power of using sugar varies at different times and in different conditions, muscular exercise markedly increasing the combustion. Again, some sugars are more readily used than others, and therefore have a less tendency to appear in the urine when taken in the food. Milk-sugar and lævulose appear in the urine more readily than glucose. This power of using sugar possessed by an individual may depend to a small extent on the capacity of the liver to store as glycogen any excess of carbohydrates absorbed from the food, and some slight cases of transient glycosuria may be accounted for by a diminution of this capacity. But the typical form of diabetes cannot be thus explained. It has been maintained that increased production of sugar is a cause of some cases of the disease, and this view has been supported by Bernard's classical experiment of producing glycosuria by puncturing the floor of the fourth ventricle. But after such puncture the glycosuria occurs only when glycogen is present in the liver, and it is transient and has nothing to do with true diabetes. The fact that various toxic substances, *e.g.*, carbon monoxide, produce glycosuria has been used as an argument in support of this view, but they too seem to act by causing a conversion of glycogen to glucose, and are effective only when the liver is charged with the former substance. At one time it was thought that the occurrence of glycosuria under the administration of phloridzin proved that diabetes is due to a poison. But the fact that, while sugar appears abundantly in the urine under phloridzin, it is not increased in the blood, shows that the drug acts not by diminishing the power of the tissues to use sugar, but by increasing the excretion of sugar through the kidneys and thus causing its *loss* to the body. Hence the tissues have to fall back upon the proteids, and an increased excretion of nitrogen is produced. This, however, is a totally different condition from diabetes.

Anything which produces a marked diminution in the normally limited power of the tissues to use sugar will cause the disease in a lighter or graver form. As age advances the activity of the various metabolic processes may diminish irregularly in certain individuals, and it is possible that the loss of the power of using sugar may be sooner impaired in some than in others, and thus diabetes be produced. But Minkowski and von Mering have demonstrated, by experiments upon animals, that pathological changes in the pancreas have probably a causal relationship with the disease. They found that excision of that organ in dogs, &c., produced all the symptoms of diabetes—the appearances of sugar in the urine, its increased amount in the blood, the rapid breaking-down of proteids, and the resulting emaciation and azoturia. At the same time the absorption from the intestine of proteids, fats, and carbohydrates was diminished. How this pancreatic diabetes is produced has not been explained. It has been suggested that the pancreas forms an internal secretion which stimulates the utilization of sugar in the tissues. Though in a certain number of cases of diabetes disease of the pancreas has been found, other cases are recorded where grave disease of that organ has not produced this condition. But the apparent extent of a lesion is often no measure of the depth to which the functions of the structure in which it is situated are altered, and it is very possible that the functions of the pancreas may in many cases be profoundly modified without our methods of research being able to detect the change. The pancreas consists of two parts, the secreting structure and the epithelial islets, and one or other of these may be more specially involved, and thus alteration in digestion and absorption on the one hand, and changes in the utilization of carbohydrates on the other, may be separately produced. The subcutaneous injection of large doses of extracts of the supra-renal bodies causes glucosuria and an increase of sugar in the blood, but the relationship of this condition to diabetes has not yet been investigated.

The disease may be divided into two forms:—

1. *Slight cases.*—The individual can use small quantities of sugar, but the taking of larger amounts causes glycosuria. Supposing that the energy requirements of an individual are met by a diet of—

Proteid . .	100 grms.	410 calories.
Fat . .	100 ,,	930 ,,
Carbohydrate	400 ,,	1640 ,,
		2980 ,,

then if only 100 grms. of glucose can be used, the energy value of 300 grms., *i.e.*, 1230 calories, must be supplied from proteids and fats. To yield this, 300 grms. of proteids or 132 grms. of fats would be required. If these are not forthcoming in the diet, they must be supplied from the tissues, and the individual will become emaciated; hence a diabetic on an ordinary diet is badly nourished, and hence the huge appetite characteristic of the disease.

2. *Grave cases.*—From the products of the splitting of proteids sugar can be formed, probably in the liver, and in the more serious form of the disease, even where carbohydrates are excluded from the food, a greater or lesser quantity of the sugar thus formed escapes consumption and may be excreted. Theoretically, 100 grms. of proteid can yield 113·6 grms. of glucose, *i.e.*, 1 grm. of nitrogen will be set free for each 7·5 grms. of glucose formed. In the urine of grave cases of diabetes on a proteid diet, the proportion of nitrogen to sugar is about 1 to 2. This may mean that the theoretically possible amount of sugar is not yielded, or that some of the sugar formed is used in the economy. Both hypotheses may be correct, but the latter is supported by the fact that even in grave cases the decomposition of proteid may be diminished by giving sugar, and that in muscular exercise the proportion of sugar falls.

In the course of the disease the amount of sugar which the tissues can use varies from day to day. It is in the utilization of glucose—the normal sugar of the body—that the tissues chiefly fail. Many diabetics are able to use lævulose, or the inulin from which it is derived, and lactose (milk-sugar) to a very considerable extent. It has, however, been observed that under the administration of these sugars the excretion of glucose may be increased, the tissues, apparently by using the foreign sugar, allowing part of the glucose which they would have consumed to escape. The increased decomposition of proteid, rendered necessary to supply the energy not forthcoming in the sugar, leads to the appearance of a large quantity of nitrogen in the urine—*azoturia*—and it also leads to the formation of various acids. Sulphuric acid and phosphoric acid are formed by oxidation of the sulphur and phosphorus in the proteid molecule, and they are neutralized by the production of ammonia. Hence in the urine of diabetics the proportion of nitrogen as ammonia to the nitrogen as urea is always high. But in the breaking-down of proteids organic acids are also liberated, chiefly belonging to the lower fatty acid series—lactic acid, aceto-acetic acid, and β-oxybutyric acid—and these also are, in part at least, neutralized by ammonia. By the development of these various acids the alkalinity of the blood is diminished. These acids appear in the urine, and their presence in large quantities is indicative of extensive decomposition of proteid, and is sometimes associated with the onset of a comatose condition, which seems to be due rather to an acid intoxication than to the special toxic action of any particular acid.

Myxœdema.—The thyroid gland forms a material which has the power of increasing the metabolism of proteids and of fats; and when the thyroid is removed, a condition of sluggish metabolism, with low temperature and a return of the connective tissues to an embryonic condition, supervenes, accompanied by the appearance of depression of the mental functions and other nervous symptoms. The disease myxœdema, which was first described by Gull in 1873, was shown by Ord in 1878 to be due to degenerative changes in the thyroid gland. It affects both sexes, but chiefly females, and is characterized by a peculiar puffy appearance of the face and hands, shedding of the hair, a low temperature, and mental hebetude. The symptoms are similar to those produced by removal of the thyroid, and are indicative of a condition of diminished activity of metabolism. The nervous symptoms may be in part due to some alteration in the metabolism, leading to the formation of toxic substances. The administration of thyroid gland extract causes all the symptoms to disappear.

Cretinism, the symptoms of which are fully described in the ninth edition, may now be defined as myxœdema in the infant, and it has been definitely proved to be associated with non-development or degeneration of the thyroid gland. The characters of the disease are all due to diminished metabolism, leading to retarded development, and the treatment which has proved of service, at least in some sporadic cases, is the administration of various thyroid preparations.

Exophthalmic Goître—Graves's Disease or Basedow's Disease.—This disease chiefly affects young women, and is characterized by three main symptoms: increased rate and force of the heart's action, protrusion of the eyeballs, and enlargement of the thyroid gland. The patient is nervous, often sleepless, and generally becomes emaciated and suffers from slight febrile attacks. The increased action of the heart is the most constant symptom, and the enlargement of the thyroid gland may not be manifest. Various theories as to the pathology of the condition have been advanced, but in the light of our knowledge of the physiology of the thyroid the most probable explanation is an increased functional activity of that gland.

B. *Changes in Metabolism probably Qualitative.*

At one time the list of diseases ascribed to quantitative changes in the metabolism was considerable. Thus oxaluria was looked upon as a disease due to increased formation of oxalic acid, rheumatism as due to excessive formation of lactic acid, and gout as caused by the formation of uric acid in too large quantities. But oxaluria is now regarded as a form of acid dyspepsia, and rheumatism as an acute infective disease, while evidence against the causal relationship between uric acid and gout is accumulating. Primary qualitative alterations in the metabolism are doubtful. Possibly the production of such substances as glycuronic acid in apparently normal individuals is one of the best examples of such a condition, while probably acute gout is due to a change of this nature.

Gout has often been divided into the typical and atypical forms. The first is undoubtedly a clinical and pathological entity, but the second, though containing cases of less severe forms of true gout, is largely constituted of imperfectly diagnosed morbid conditions. The accumulation of urate of soda in the tissues in gout formerly led physicians to believe in a causal relationship between an increased formation of that substance and the onset of the disease. Garrod's investigations, however, seemed to indicate that diminished excretion rather than increased production is the cause of the condition. He found an accumulation of uric acid in the blood and a diminution in its amount in the urine during the attack. That uric acid is increased in the blood is undoubted, but the changes described by Garrod in the urine, and considered by him as indicative of diminished excretion and retention, are rendered of less value by the imperfections of the analytic method employed. More recent work with better methods has thrown still further doubt upon the existence of such a relationship, and points rather to the accumulation of uric acid being, like the other symptoms of the condition, a result of some unknown modification in the metabolism, and a purely secondary phenomenon. The important fact that in leucæmia (von Jaksch), in lead-poisoning (Garrod), and in other pathological conditions, uric acid may be increased in the blood and in the urine without any gouty symptoms supervening, is one of the strongest arguments against the older views. That the gouty inflammation is not caused by the deposit of urate of soda, seems to be indicated by the occurrence of cases in which there is no such deposition. The results of modern scientific investigation have overthrown the uric-acid theory of gout, but so far they offer no definite explanation of the ætiology of the disease. Nevertheless, while they have not confirmed the view as to the causal relationship of the uric acid to the inflammation and other symptoms of the gouty paroxysm, they have thrown interesting light upon the probable source of the uric acid which is so apt to be deposited, and they also offer a more or less intelligible explanation of the process of deposition. From the true nucleins, which form so important a constituent of living protoplasm, a series of bodies which were formerly classed as the xanthin bases, but which are now more generally known as the purin bases, are formed. Uric acid is a member of this series, and its excretion is increased when substances rich in nuclein, *e.g.*, sweetbreads, &c., are administered. While uric acid itself has not been demonstrated to have any injurious action, the closely allied adenin has been found to produce toxic symptoms. After the discovery of this source of uric acid, physiologists for a time inclined to regard it as the only mode of production. But it must be remembered that in birds uric acid is formed from the lactate of ammonia of the intestine and muscles, just as urea is formed from the same substance in mammals. Uric acid is a di-ureide—a body composed of two urea molecules linked by acrylic acid—an unsaturated propionic acid. Now sarolactic acid is a hydroxy-propionic acid, and hence uric acid is either upon the direct road, or very slightly off the direct road, of the transformation of lactate of ammonia to urea. It is therefore highly probable that in many conditions the conversion of lactate of ammonia to urea is not complete, and that a certain amount of uric acid is formed apart from the decomposition of nucleins.

Sir William Roberts has adduced evidence to show that uric acid circulates in the blood in a freely soluble combination or quadurate—that is, a compound in which one molecule of an acid salt $BH\bar{U}$ is linked to a molecule of the acid $BH\bar{U}.\ H_2\bar{U}$. These compounds are said to be readily decomposed and the bi-urates formed, which are at first gelatinous but become crystalline. The deposition of urate of soda in joints, &c., has been ascribed to this change. Tunnicliffe, however, has published the results of certain investigations which throw doubt upon this explanation.

Rheumatism.—Rheumatic fever was formerly regarded as due to some disturbance in the metabolism, but at the present time the trend of opinion is towards the view that it is a specific micro-organismal disease. The whole clinical picture is that of an infective fever, and it is closely related to gonorrhœal rheumatism and to certain types of pyæmia. A number of independent observers, among them Poynton and Paine in Great Britain, have succeeded in isolating from cases of rheumatic fever a diplococcus which produces similar symptoms in the rabbit to those which characterize the disease in man.

Excluding the peculiar changes in the joints which occur in *rheumatoid arthritis* and in *Charcot's disease*, and which are almost certainly primary affections of the nervous system, it is found that a large number of individuals suffer from pain in the joints, in the muscles, and in the fibrous tissues, chiefly on exposure to cold and damp or after indiscretions of diet. This so-called *chronic rheumatism* appears to be a totally distinct condition from rheumatic fever; and although its pathology is not investigated, it looks as if it were due either to a diminished elimination or an increased production of some toxic substance or substances, but so far we have no evidence as to their nature.

Rickets is undoubtedly a manifestation of a profound alteration of the metabolism in childhood, but how far it is an idiopathic condition and how far a result of the action of toxin introduced from without is not yet definitely known. Kassowitz long ago showed that the bone changes are similar to those which can be produced in animals by chronic phosphorus poisoning, and that they are really irritative in nature. Spillmann, in his work *Le Rachitisme*, discusses the evidence as regards the action of various conditions, and comes to the conclusion that there is no evidence that it is due to a mere primary disturbance of the metabolism, or to excessive production of lactic acid, or to any specific micro-organismal poisoning. But he adduces evidence, perhaps not very convincing, that in the disease there is a specific intoxication derived from the alimentary canal and provoking inflammatory lesions in the bones.

See Dr Carl von Noorden, *Lehrbuch der Pathologie des Stoffwechsels.* Berlin, 1893. (D. N. P.)

IX. Fever.

The term fever is generally used to include all conditions in which the normal temperature of the body is markedly exceeded for any length of time. Every rise of temperature is due to a disturbance in the heat-regulating mechanism, the chief variable in which is the action of the skin in eliminating heat (see Physiology: *Animal Heat*). Although for all practical purposes this mechanism works satisfactorily, it is not by any means perfect, and many physiological conditions cause a transient rise of temperature; *e.g.*, severe muscular exercise, in which the cutaneous eliminating mechanism is unable at once to dispose of the increased amount of heat produced in the muscles. Pathologically, the heat-regulating mechanism may be disturbed in three different ways: 1st, by mechanical interference with the nervous system; 2nd, by interference with heat elimination; 3rd, by the action of various poisons.

1. In the human subject, fever the result of *mechanical interference* with the nervous system rarely occurs, but it can readily be produced in the lower animals by stimulating certain parts of the great brain, *e.g.*, the anterior portion of the corpus striatum. This leads to a rise of temperature with increased heat production and increased excretion of carbonic acid and of urea. Possibly some of the cases of high temperature recorded after injuries to the nervous system may be caused in this way; but some may also be due to stimulation of vaso-constrictor fibres to the cutaneous vessels diminishing heat elimination. So far the pathology of this condition has not been studied with the same care that has been devoted to the investigation of the third type of fever.

2. Fever may readily be produced by *interference with heat elimination.* This has been done by submitting dogs to a temperature slightly below that of the rectum, and it is seen in man in *Sunstroke* (*Ency. Brit.*, 9th edition, vol. xxii. p. 666). The typical nervous symptoms of fever are thus produced, and the rate of chemical change in the tissues is accelerated, as is shown by the increased excretion of carbonic acid. The protoplasm is also injured and the proteids are broken down, and thus an increased excretion of nitrogen is produced and the cells undergo degenerative changes.

3. The products of various micro-organisms have a toxic action on the protoplasm of a large number of animals, and among the symptoms of this toxic action one of the most frequent is a rise in temperature. While this is by no means a necessary accompaniment, its occurrence is so general that the term *Fever* has been applied to the general reaction of the organism to the microbial poison. Toxins which cause a marked rise of temperature in men may cause a fall in other animals. It is not the alteration of temperature which is the great index of the severity of the struggle between the host and the parasite, but the death and removal to a greater or lesser extent of the protoplasm of the host. In this respect fever resembles poisoning with phosphorus and arsenic and other similar substances. The true measure of the intensity of a fever is the extent of disintegration of protoplasm, and this may be estimated by the amount of nitrogen excreted in the urine. The increased disintegration of protoplasm is also indicated by the rise in the excretion of sulphur and phosphorus and by the appearance in the urine of acetone, diacetic acid, and oxybutyric acids (see PHYSIOLOGY: *Nutrition*). Since the temperature is generally proportionate to the intensity of the toxic action, its height is usually proportionate to the excretion of nitrogen. But sometimes the rise of temperature is not marked, while the excretion of nitrogen is very decidedly increased. When the temperature is sufficiently elevated, the heat has of itself an injurious action on the protoplasm, and tends to increase disintegration just as when heat elimination is experimentally retarded. But the increase due to rise of temperature is small compared to that produced by the destructive action of the microbial products. In the beginning of a fever the *activity of the metabolism* is not increased to any marked extent, and any increase is probably due to the greater activity of the muscles of the heart and respiratory mechanism, and to the muscular contractions which produce the initial rigors. Thus the excretion of carbon dioxide—the great measure of the activity of metabolism—is not usually increased, and there is no evidence of an increased combustion. In the later stages the increased temperature may bring about an acceleration in the rate of chemical change; but this is comparatively slight, less in fact than the increase observed on taking muscular exercise after rest. The *rise of temperature* is really due to diminished heat elimination. This diminished giving off of heat was demonstrated by means of the calorimeter by Rosenthal, while Maragliano showed that the cutaneous vessels are contracted. Even in the later stages, until defervescence occurs, heat elimination is inadequate to get rid of the heat produced.

The toxic action is manifested not only by the increased disintegration of protoplasm, but also by disturbances in the functions of the various organs. The activity of the *digestive glands* is diminished and appetite is lost. Food is therefore not taken, although when taken it appears to be absorbed in undiminished quantities. As a result of this the patient suffers from inanition, and lives largely on his own fats and proteids, and for this reason rapidly emaciates. The functions of the *liver* are also diminished in activity. Glycogen is not stored in the cells, and the bile secretion is modified, the essential constituents disappearing almost entirely in some cases. The production of urea is also interfered with, and the proportion of nitrogen in the urine not in the urea increases. This is in part due to the increased disintegration of proteids setting free sulphur and phosphorus, which, oxidized into sulphuric and phosphoric acids, combine with the ammonia which would otherwise have been changed to urea. Thus the proportion of ammonia in the urine is increased. Concurrently with these alterations in the functions of the liver-cells, a condition of granular degeneration and probably a state of fatty degeneration makes its appearance. That the functional activity of the *kidneys* is modified, is shown by the frequent appearance of proteoses or of albumen and globulin in the urine. Frequently the toxin acts very markedly on the protoplasm of the kidney epithelium, and causes a shedding of the cells and sometimes inflammatory reaction. The *muscles* are weakened, but so far no satisfactory study has been made of the influence of microbial poisons on muscular contraction. A granular and fatty degeneration supervenes, and the fibres waste. The *nervous structures*, especially the nerve-cells, are acted upon, and not only is their functional activity modified, but they also undergo structural changes of a chromatolytic nature. The *blood* shows two important changes—first, a fall in the alkalinity due to the products of disintegration of protoplasm, and, secondly, an increase in the number of leucocytes, and chiefly in the polymorpho-nuclear variety This is best marked in pneumonia, when the normal number is often increased twofold and sometimes more than tenfold, while it is altogether absent in enteric fever.

An interesting general modification in the metabolism is the enormous fall in the excretion of chlorine, a fall far in excess of what could be accounted for by inanition, and out of all proportion to the fall in the sodium and potassium with which the chlorine is usually combined in the urine. The fevered animal in fact stores chlorine in its tissues, though in what manner and for what reason is not at present known.

(D. N. P.)

X. THE KIDNEYS.

The results of morbid processes in the kidney may be grouped under three heads: (1) the actual lesions produced in the kidneys, (2) the effects of these on the composition of the urine, and (3) the effects of the kidney lesion on the body at large.

(1) Lesions of the kidney are either congenital or acquired, and when acquired they may be either the sole result of a pathological process limited to the kidney, in which case they are spoken of as primary, or else the morbid process in the kidney may be an accompaniment or sequel of disease in other parts of the body, and they are then often spoken of as secondary.

Congenital Lesions.—The principal congenital lesions are—(1) anomalies in the number or position of the kidneys or of their ducts, (2) atrophy of one kidney, (3) cystic disease of the kidney, and (4) growths. The most common abnormality is the existence of a *single kidney*—very rarely a third or supernumerary kidney may be present—or both may be absent; the last, however, is only of embryological interest, and is found most frequently in acephalous monsters. The presence of a single kidney may be due to the absence of development of one, or to the atrophy of one, in fœtal life; it may also be dependent on the fusion of originally separate kidneys, and this fusion commonly occurs in such a way as to lead to the formation of a horse-shoe kidney, the two organs being connected at their lower extremities by a mass of renal tissue. In some cases the apparently single horse-shoe kidney is really double, the organs being united by fibrous tissue. Occasionally the two kidneys are fused end to end, producing an apparently single organ with two ureters opening in their normal situations. A third variety is that where the fusion is more complete, producing a disc-like mass from which the ureters issue and follow their normal course. The kidneys may be situated in *abnormal positions;* thus they may be found in front of the sacro-iliac articulation, or they may sink into the pelvis or the iliac fossa. The main importance of such displacements lies in the fact that the organs may be mistaken clinically for tumours. Congenital displacements of one or other kidney are sometimes associated with malformation of the large intestine. The causes of *atrophy* during fœtal life are obscure. In some cases it is associated with maldevelopment, so that only the medullary portion of the kidney is developed; in others it is apparently associated with arterial obstruction, and sometimes it may be dependent upon obstruction of the ureter, as this has been found experimentally to be capable of causing very complete atrophy. *Congenital cystic disease* is not uncommon, the organ being transformed into a mass of cysts, and the enlargement of the kidneys may be so great as to produce difficulties in birth. The cystic degeneration is generally looked upon as dependent upon either obstruction of the uriniferous tubules or else upon anomalies in development, with persistence of portions of the Wolffian body. In some cases cystic degeneration of the kidneys is accompanied by anomalies in the ureters and in the arterial supply; in others these are normal. *Growths of the kidney* are sometimes found in infants. They are not uncommonly malignant, and may consist of a peculiar form of sarcoma, which has been spoken of as rhabdo-sarcoma owing to the presence in the tumour mass of involuntary muscular fibre. The existence of these peculiar tumours is thought to be dependent on anomalies of development, inasmuch as the tissue which forms the primitive kidney belongs to the same layer as that which gives rise to the muscular system (mesoblast). *Anomalies of the excretory ducts* of the kidneys are of no great importance. Sometimes the ureter is double, in others it is greatly dilated; in others the pelvis of the kidney may be greatly dilated, with or without dilatation of the ureter.

Acquired Diseases.

One or both kidneys in the adult may be preternaturally mobile (nephroptosis). This condition is more common in women than in men; and although sometimes dependent on congenital anomalies, it is more usually acquired as a result of injury, or owing to the abdominal walls becoming lax as a sequel to abdominal distension or to the effects of tight-lacing. The more extreme forms of movable kidney are dependent, generally, on congenital anomalies in the arrangement of the peritoneum, so that the organ has a partial mesentery; and to this condition, where the kidney can be moved more or less freely from one part of the abdomen to another, the term *floating kidney* is applied. More usually the organ is loose under the peritoneum, and is not efficiently supported in its fatty bed by peritoneal bands. It is possible that, in addition to the causes just enumerated, emaciation may produce mobility of the kidney. Movable kidney produces a variety of symptoms—pain in the loin and back, nausea, and vomiting—and the function of the organ may be seriously interfered with owing to the structures in the hilum becoming kinked. In this way hydronephrosis, or distension of the kidney with urine, may be produced. The return of blood through the renal vein may also be hindered, and in this way temporary vascular engorgement of the kidney, with hæmaturia, may be produced.

1. *Embolism.*—The anatomical arrangement of the kidney vessels is one which is peculiarly favourable to the production of wedge-shaped areas of necrosis dependent on blocking of the renal arterioles by emboli, and renal infarcts are commonly seen in all conditions in which embolism is liable to occur. Sometimes the embolus is a blood-clot detached from the interior of the heart, or even a calcareous plate from the interior of the aorta, and the effects produced are simply mechanical, from the arrest of the circulation in the part of the kidney supplied by the blocked artery. In other cases, the embolus, in addition, is infective owing to the presence of a variety of micro-organisms; and in these circumstances the necrotic area undergoes other changes dependent on the presence of these organisms, leading not uncommonly to abscess in the kidney. The small vessels are sometimes blocked by masses of organisms only, producing minute embolisms. It is exceptional for the larger branches of the renal artery to be blocked by emboli, so that the symptoms produced in the ordinary cases are only temporary derangements of the secretion, *e.g.*, the sudden appearance of hæmaturia, albuminuria, and pain in the back.

2. *Thrombosis*, or blocking of the renal vessels as a result of disease of the walls of the vessels, is also not uncommon, and in exceptional cases it may lead to complete disorganization of one or both kidneys. Thrombosis of the veins, leading to extreme congestion of the kidney, also occurs, either limited to the renal vein or extending into it from the vena cava. It is most frequently seen in cachectic conditions produced by general diseases causing extreme weakness and wasting, sometimes in septic conditions, as in puerperal pyæmia, where a clot, formed first in one of the pelvic veins, may spread up the vena cava and secondarily block the renal veins. Thrombosis of the renal vein also occurs in malignant disease of the kidney, and in certain forms of chronic Bright's disease.

3. *Passive congestion* of the kidneys is seen more especially in heart diseases and lung diseases, where the return of venous blood to the heart is seriously interfered with. It may also be produced by tumours and other lesions pressing on or involving the vena cava. The passively engorged kidneys become brownish red in colour, considerably enlarged and fibroid, and they secrete a scanty high-coloured dense urine.

4. *Active congestion* is difficult to separate from the earlier stages of inflammation or nephritis, and these two conditions are often produced by the excretion in the urine of irritating bodies, *e.g.*, turpentine and cantharides, and the toxins of various diseases. These irritants produce engorgement and inflammation of the kidney, much in the same way as they would that of other structures with which they come in contact. It is probable that a great many varieties of active congestion of the kidney and of nephritis in general diseases are produced by the excretion of microbic poisons. Further, it is thought that extreme congestion of the kidneys may be produced by exposure to cold, owing to some intimate relationship existing between the skin vessels and the kidney vessels, the constriction of the one being accompanied by the dilatation of the other. There is at present no experimental evidence to justify this view. Infective diseases, such as typhoid fever, pneumonia, scarlet fever, and, in fact, most acute specific diseases, produce during their height a transitory or temporary nephritis, which is not usually followed by any permanent or serious alteration in the kidney; but some acute specifics tend, in addition, to cause a more severe nephritis, which may lay the foundation of fatal or permanent renal disease. This is much more frequent as a result of scarlet fever than as a sequel to pneumonia, typhoid, or other febrile diseases. It is probable that the lesions in so-called transitory nephritis are often partial, involving only some portion of the kidney.

5. *Bright's disease* is the term applied to certain varieties of acute and chronic nephritis. Three forms are usually recognized—acute, chronic, and the granular or cirrhotic kidney. The position of this third lesion, however, is a little doubtful, as one form of cirrhotic or contracted kidney is sometimes the sequel to acute or chronic Bright's disease, and in these cases it is a purely kidney lesion and a variety of Bright's disease. In the other and more common form of granular kidney the kidney lesion is only part of a widespread affection involving the whole arterial system, and is not in any way related to Bright's disease. Chronic Bright's disease is sometimes the sequel to acute Bright's disease, but in a great number of cases the malady is chronic from the beginning. The lesions of the kidney are probably produced in the majority of cases by the irritation of the kidney structures owing to the excretion of toxic substances which have either been ingested or formed in the body; it is thought by some that the malady may sometimes arise simply as a result of exposure to cold. The principal causes of Bright's disease are alcoholism, pregnancy, the action of certain poisons, *e.g.*, lead, gout, &c.; it may also occur as

a sequel to acute diseases, more especially acute specifics such as scarlet fever. Persons following certain occupations are peculiarly liable to certain forms of Bright's disease, *e.g.*, engineers who work in hot shops and pass out into the cold air scantily clothed; and painters, in whom the malady is apparently dependent on the action of lead on the kidney. In the case of alcohol and lead the poison is ingested; in the case of scarlet fever, pneumonia, and perhaps pregnancy, the toxic agent causing the renal lesion is formed in the body and probably excreted by the urine. In Bright's disease all the elements of the kidney, the glomeruli, the tubular epithelium, and the interstitial tissue, are affected. In the different varieties of the disease these structures are affected to different degrees. Thus in Bright's disease following scarlet fever, the glomerular structures are mostly affected, the capsules being greatly thickened by the formation of fibrous tissue, and the glomerular tuft compressed, atrophied, and degenerated. The epithelium of the convoluted tubules undergoes degeneration, and considerable quantities of it are shed, and form the well-known casts that are found in the urine. The tubules, too, become blocked by the shed epithelium, and become distended above with the pent-up urine; this is one of the causes of the very considerable increase in size that the kidneys undergo in certain forms of Bright's disease. The lesions in the tubules and in the glomeruli are not usually uniform, certain portions being more affected than others. The interstitial tissue is always affected to a certain extent, and exudation, proliferation, and formation of fibrous tissue all occur. In the granular and contracted kidney the lesion in the interstitial tissue reaches a high degree of development, so that in advanced cases but little renal secreting tissue is left in many places. Such renal tubules as remain are often dilated, and the epithelium lining them is greatly altered, the cells becoming hyaline and losing their characteristic structure. The vessels also undergo changes, becoming greatly narrowed owing to thickening of the sub-endothelial layer of the inner coat; and the muscular coat undergoes hypertrophy and fibroid changes, so that the vessels are abnormally rigid as well as narrow. When the overgrowth of fibrous tissue is considerable, the surface of the organ loses its smooth character and becomes uneven, owing to the irregular development of fibrous tissue, and it is for this reason that the term granular kidney has been applied to this condition. In acute Bright's disease the kidney is considerably increased in size, engorged with blood, and the changes described above are in active progress. In the chronic form the kidney may be large or small, and is usually white or mottled in colour. If large, the cortex is thickened, pale and waxy-looking on section, and the pyramids are congested; if small, the fibrotic change has advanced to a greater extent, and the cortex is greatly diminished in width. Bright's disease, both in its acute and chronic forms, is essentially a disease of the cortical secreting portion of the kidney. The true granular kidney, classified by some as a third variety of Bright's disease, is usually part of a general arterial degeneration, and the overgrowth of fibrous tissue in the kidney and the lesions in the arteries are well marked.

6. *Degenerations.* — The principal degenerations affecting the kidney are the fatty and the albuminoid. Fatty degeneration of the kidney often reaches a high degree in alcoholics, where fatty degeneration of the heart and liver are also present. Albuminoid disease of the kidney is frequently associated with some varieties of Bright's disease, and is also seen as a result of chronic bone disease, suppuration, and syphilis, involving other parts of the body; it is not so common as it was formerly, owing to the progress in the surgical treatment of the diseases causing it.

7. *Growths of the Kidney.*—The principal growths affecting the kidney are tubercle, adenoma, sarcoma, and carcinoma. In addition to these, lipomata and fibromata, the nodules of glanders and the gummata of syphilis, are sometimes found. Tuberculous disease of the kidney is sometimes primary; more frequently it is secondary to tubercle in other portions of the genito-urinary apparatus. The genito-urinary tract may be infected by tubercle in two ways, one ascending, the other descending. By ascending tuberculosis is meant a condition in which the primary lesion is in the testicle, epididymis, or urinary bladder, and the kidney becomes secondarily involved by the lesion travelling up the ureter or lymphatics to the kidney. A descending infection, on the other hand, is usually a result of a blood infection, where the tubercle bacillus reaches the kidney through the blood-vessels. In these circumstances, miliary tubercle, the condition in which scattered tuberculous granules are seen, more especially in the cortex of the kidney, is usually produced. With descending infection of the kidney the lesion is necessarily generally bilateral; in primary tuberculosis of the kidney and in ascending tuberculosis the lesion is at first unilateral. Malignant disease of the kidney generally takes the form of sarcoma or carcinoma. Sometimes it is dependent on the malignant growths starting in what are spoken of as adrenal rests in the cortex of the kidney. Sarcoma of the kidney is a condition most often seen in the young, carcinoma in the middle-aged and elderly. Carcinoma may be primary or secondary, but the kidney is an organ of the body that is not so prone to malignant disease as other organs, such as the stomach, bowel, &c.

8. *Cystic Kidneys.*—Several different varieties of cysts are found in the kidney. Thus single cysts occur, sometimes of large size, while scattered small cysts are more especially seen in cases of chronic Bright's disease and in the granular contracted kidney, where the dilatation of certain tubules reaches a high degree of development, ultimately forming cysts. Certain growths of the kidney, again, such as adenomata, are liable to undergo cystic degeneration, and in some cases of malignant disease cysts are found. Finally, there is a rare condition of general cystic disease somewhat similar to that seen congenitally. In this form the kidneys are greatly enlarged, and consist of a congeries of cysts separated by the remains of renal tissue.

9. *Parasitic Affections.*—The more common parasites affecting the kidney, or some other portion of the urinary tract, and causing disease, are filaria, bilharzia, and the cysticercus form of the tænia echinococcus. The presence of *filaria* in the thoracic duct and other lymph channels may cause the presence of chyle in the urine, together with the ova and young forms of the filaria, owing to the distension and rupture of a lymphatic vessel into some portion of the urinary tract. This is the common cause of chyluria in hot climates, but chyluria is occasionally seen in the United Kingdom without the presence of filaria. *Bilharzia*, especially in Egypt and South Africa, causes hæmaturia. The cysticercus form of the *tænia echinococcus* leads to the production of hydatid cysts in the kidney. This organ, however, is not so often affected in this manner as the liver.

10. *Nephrolithiasis.*—Calculi are frequently found in the kidney, consisting usually of uric acid, sometimes of oxalates, more rarely of phosphates. Calculous disease of the bladder is generally the sequel to the formation of a stone in the kidney, which passing down into the bladder, and owing to secondary changes produced by its presence in the bladder, is followed by the deposition of the salts in the urine round it as a nucleus. Calculi are usually formed in the pelvis of the kidney, and their formation is dependent either on the excessive amounts of uric acid, oxalic acid, &c., in the urine, or on an alteration in the composition of the urine, such as increased acidity, or on the crystals of the uric acid or of the oxalate of lime being present in an abnormal and large form. The formation of abnormal crystals is often dependent on the presence of some colloid, such as blood, mucus, or albumen, in the secretion, modifying the crystalline form. Once a minute calculus has been formed, its subsequent growth, owing to the deposition on it of the urinary constituent forming it, is easily understood. Calculi formed in the pelvis may be single and may reach a very large size, forming, indeed, an actual cast of the pelvis and calyces of the kidney. At other times they are multiple and of very varying size. When formed, they may give rise to no symptoms, or, on the other hand, they may give rise to renal colic of varying degrees of severity, especially when they are passed or attempted to be passed. A great variety of complications may result from the presence of a stone, such as hydronephrosis, from the urinary secretion being pent up behind the obstruction, or complete suppression, which is apparently produced reflexly through the nervous system, the presence of the stone in the pelvis or ureter leading to complete arrest of the function of the kidney. In such cases the surgical removal of the stone is often followed by the restoration of the renal secretion. Pyonephrosis, distension of the pelvis of the kidney with pus, abscesses of the kidney, and perinephritic abscess, are not uncommon complications of renal calculus. Finally, cancer of the kidney is thought by many to be associated with the long-continued irritation produced by the presence of stones.

11. *Pyelitis.*—Inflammation of the pelvis of the kidney is generally produced by the extension of inflammation upwards from the bladder and lower urinary tract, or by the presence of stones or of tubercle in the pelvis of the kidney. Pyonephrosis, distension of the kidney with pus, may result as a sequel to pyelitis or as a complication of hydronephrosis, and in many such cases the inflammation spreads to the capsule of the kidney, leading to the formation of what is described as a perinephritic abscess. In some cases a peri nephritic abscess results from a septic infarct of kidney, or may occur primarily, as the result of traumatism or of other causes, in the loose cellular tissue surrounding the kidney, without any lesion of the kidney or pelvis of the kidney.

12. *Hydronephrosis*, or distension of the kidney with pent-up urine, results from obstruction of the ureter, although all obstructions of the ureter are not followed by it, *e.g.*, calculous obstruction often causing complete suppression. Obstruction of the ureter, causing hydronephrosis, is most frequently dependent on the presence of a stone, or on pressure on the ureter from a tumour in the pelvis—as, for instance, cancer of the uterus—or on some abnormality of the ureter, more especially an abnormality in its attachment to the pelvis of the kidney, as, for instance, when attached at an angle, or when preternaturally narrow. Sometimes the ureter is obstructed sufficiently to cause hydronephrosis by

unnatural mobility of the kidney. The hydronephrosis produced by obstruction of the ureter is sometimes intermittent; and when a certain degree of distension is produced, either as a result of the shifting of the calculus or of some other cause, the obstruction is temporarily relieved and the urinary flow re-established. When the hydronephrosis has existed for any considerable length of time, the kidney is converted into a sac, the remains of the renal tissues being spread out as a thin layer.

(2) *Effects on the Urine.*—Diseases of the kidney produce alterations of two kinds in the composition of the urine: either the proportion of the normal constituents is altered, or substances not normally present are excreted in greater or less abundance. In most diseases the quantity of urinary water is diminished, especially in those in which the activity of the circulation is impaired. There are certain diseases, however, more especially the granular kidney and certain forms of chronic Bright's disease, in which the quantity of urinary water is considerably increased, notwithstanding the profound anatomical changes that have occurred in the kidney. When the quantity is diminished there may be actual suppression, and two forms of this are recognized—(1) obstructive suppression, seen where the ureter is blocked by stone or other morbid process, and (2) non-obstructive suppression, a condition which is more especially seen as a terminal phenomenon in advanced diseases of the kidney of inflammatory or other nature. In some cases complete suppression may occur as the result of injuries to other parts of the body. In some diseases in which the quantity of urinary water excreted is normal, or even greater than normal, the efficiency of the renal activity is really diminished, inasmuch as the urine secreted is very dilute and contains but few solids. In estimating the efficiency of the kidneys, it is necessary to take into consideration the so-called "solid urine," that is to say, the quantity of solid matter excreted per diem. The nitrogenous constituents—urea, uric acid, creatinin, &c.—vary greatly in amount in different diseases. In most renal diseases the quantities of these substances are diminished. The most important abnormal constituents of the urine present in disease are serum albumen, serum globulin, albumoses (albuminuria), blood (hæmaturia), blood pigment (hæmoglobinuria), pus (pyuria), chyle (chyluria), and abnormal pigments (melanuria, urobilinuria, &c.).

(3) *Effects on the Body at large.*—Diseases of the kidney tend to produce certain effects on the body at large, all of which are not usually seen to accompany any single disease of the kidney, nor are they equally developed in different cases of the same disease. These effects may be divided into the persistent and the intermittent or transitory. The most important persistent remote effects produced by disease of the kidney are, first, nutritional changes leading to wasting, cachexia, &c.; and, secondly, certain cardio-vascular phenomena, such as enlargement (hypertrophy) of the heart, and thickening of the inner and degeneration of the middle coats of the smaller arteries. The intermittent or transitory effects liable to be produced by kidney disease are: (1) dropsy, (2) secondary inflammations of certain organs and serous cavities, and (3) uræmia. Some of these effects are seen in every form of severe kidney disease; thus uræmia may occur in any kidney disease which progresses to an extent sufficient to inflict serious damage on the kidneys. On the other hand, renal dropsy is more especially seen in certain forms of Bright's disease, and the cardiac and arterial changes are particularly common in the granular or contracted kidney, but may be conspicuous by their absence in other diseases which destroy the kidney tissue, such as hydronephrosis. *Uræmia* is a toxic condition, and clinically three varieties are usually recognized: the acute, the chronic, and the latent, according to the severity and character of the symptoms. Many of these effects are dependent upon the action of poisons retained in the body owing to the deficient action of the kidneys as excretory organs. It is also probable that abnormal substances having a toxic action are produced as a result of a perverted metabolism. All observers are agreed that uræmia is of toxic origin, and it is probable that the dropsy of renal disease is due to effects produced in the capillaries by the presence of abnormal substances in the blood. Some pathologists consider that high arterial tension, cardiac hypertrophy, and arterial degeneration are also of toxic origin, whilst others regard these results as produced by an attempt on the part of the body to maintain an active circulation through the greatly diminished amount of kidney tissue available. The exact manner in which high tension and all its results are produced is not thoroughly understood.

(J. R. B.)

XI. Skin.

The diseases of the skin do not essentially differ from those of the other organs of the body. Like these, the skin is composed of cells resting on a connective tissue framework, in which run the vessels which nourish it and the nerves which keep up its communications with the rest of the body. But it has certain differences from other organs, some dependent on its structure and some on its exposed position. Thus, instead of, like the kidney, to which it may best be compared, having its epithelium faced by epithelium, all lies open, and the various processes are all "one-sided." There are no depths to be attacked, and any diseases, if they spread, must do so superficially: spreading as they often do equally in all directions, the diseases of the skin have a tendency to assume a circular form, independently of any parasitic cause, though when such cause is present the patches are of a more perfectly circular shape. Further, from the extent of its superficial area and its exposed position, the skin is liable to be attacked by more forms of irritation, parasitic or other, than any other organ of the body. Every stage and variety of disease is open to view; minute differences, minor or important, are at once noted; and thus it is that the recognized distinct maladies of the skin are so numerous. In no other organ, with the partial exception of the eye, can the changes be watched from day to day; in none can so many stages of the same disease be simultaneously observed; and in no other is it so simple a matter to remove and instantly fix for microscopic examination the living tissue. It is possible to distinguish on the skin between the effects of organisms which it is hardly possible to tell from each other by any other method, cultural or tinctorial; and the relative harmlessness of inoculation makes confirmatory experiments easy.

The multitude of its affections renders the difficulties of arranging the diseases of the skin very great, and the absence of any generally accepted scheme of classification has always been and still remains one of the main obstacles to their intelligent study. The older systems, constructed before the days of bacteriology, were commonly based on the form which the eruption assumed (scaly, moist, purulent), but they usually contained in addition a certain number of diseases under the heading of *Parasitic.* Though obviously illogical, such systems served well enough while the recognized parasitic diseases were few, such as those caused by such gross parasites as the *Acarus scabiei* (the itch mite), the *pediculi* (lice), and the hyphomycetic fungi such as the *Achorion Schönleinii.* The discoveries of bacteriology have enormously enlarged this class, but the difficulty is that one and the same disease is regarded as parasitic by one authority, as dependent on nerve influence by another, while a third sasumes an agnostic position. Dermatologists may perhaps be divided into three schools, though it must be understood that these merely represent the general trend of the countries referred to, and that members of each are found in all. The German school, most of its leaders being pupils of the great Hebra, tend to look to external irritants as the cause of the great majority of diseases, and they are often described as "externalists." The discoveries of bacteriology have greatly strengthened their position, for it seems a reasonable assumption that if a disease closely resembles in its course another which can be proved to be due to some micro-organism, it probably owns a similar origin, though the actual *causa causans* may have escaped detection. There are few who do not admit this argument in the case of small-pox, measles, and scarlatina. It is, however, incorrect to conclude that the German school regards all diseases as of external origin: some are manifestly due to internal causes, and it is in regard to the disputed cases that the term "externalist" is applied. The French school inclines to the theory of internal causes, and lays great stress on the influence of the nervous system and on diatheses (*e.g.*, rheumatic, lymphatic, and dartrous) as the cause or modifying factor in many diseases. The Anglo-Saxon school (Great Britain and America) endeavours to take the best from both. Of the disputed diseases it puts some in the one class and some in the other, while it confesses its inability to decide with regard to the remainder. The following is a useful working classification, based mainly on the lines laid down by Unna in his great work on the *Histo-Pathology of the Skin*:—

- I. Anomalies of Sensation: *Pruritus, Anæsthesia, Dermatalgia.*
- II. Anomalies of Secretion: *Hyperidrosis, Chromidrosis, Anidrosis.*
- III. Anomalies of Circulation: *Urticaria, Purpura.*
- IV. Inflammations:—
  - **Traumatic**: *Dermatitis venenata, Trade dermatitis, Dermatitis medicamentosa, Dermatitis artefacta.*
  - **Neurotic**: *Erythema, Prurigo, Hydroa, Pemphigus, Herpes.*
  - **Infective**: Inflammations of the surface epidermis (cutaneous catarrh)—*Scabies, Cheiropompholyx, Miliaria, Impetigo, Ecthyma, Eczema, Seborrhœa, Psoriasis, Pityriasis rosea, Pityriasis rubra, Pityriasis rubra pilaris, Ichthyosis.* Inflammations of the deep or submerged epidermis (glands and follicles)—*Acne, Sycosis, Favus, Ringworm, Alopecia areata.* Diseases of the nails. Inflammations of the corium—*Erysipelas, Furuncle, Anthrax, Glanders, Actinomycosis, Rhinoscleroma, Yaws, Mycosis fungoides, Lichen, Syphilis, Tuberculosis* (lupus), *Leprosy.*
- V. New Growths: Benignant and malignant.
- VI. Retrogressive Changes (Atrophies): *Lupus erythematosus, Scleroderma, Sclerema neonatorum.*
- VII. Malformations: *Hyperkeratosis congenitalis, Hypertrichosis.*
- VIII. Saprophytes: *Pityriasis versicolor, Erythrasma.*
- IX. Anomales of Pigmentation: *Ephelis, Chloasma, Vitiligo.*

The diseases grouped under the first two headings do not lend themselves to pathological description. They are usually dependent on some systemic disease the discussion of which would here be out of place. In the diseases placed under the heading "Anomalies of Circulation" many phenomena suggest a dependence on irritants brought to the skin by the blood. Thus in the group of diseases known as *purpura*, where hæmorrhages of varying size make their appearance on widely-separated parts of the skin, we know that in some cases the cause is a poison, either inorganic (phosphorus, mercury) or organic (small-pox, measles, typhus), and it does not seem too much to assume that in other cases, such as those associated with Bright's disease, a similar cause is at work, and that in all these cases the poisons, by weakening the vessels' walls, predispose them to rupture, for a lesion is found in all carefully examined specimens. In the disease known as *urticaria* or nettle-rash we meet with many cases of unknown origin. Reasoning from our knowledge of what happens where the disease is produced by some irritant poison introduced into the stomach, we may conjecture that in such cases some unknown irritant is circulating in the blood. The pathology of the lesions in this disease is as follows: reacting to some irritant, the blood-vessels dilate, serum is poured out from them into the tissues around, and compressing the vessels from without empties them of blood. This explains the white centre of the urticarial wheal, the red margin of which is the clinical expression of the dilated and uncompressed vessels at the border. In those diseases grouped together under the name of *erythema*, although the majority of authors place them under the heading of inflammation, there is a good deal suggestive of a close relation to *urticaria*. Some cases are caused by the ingestion of certain drugs, a good many are directly associated with the rheumatic poison, while others are apparently connected with fermentative changes in the gastro-intestinal tract. Thus all those examples of the disease with the cause of which we are approximately acquainted are readily enough attributed to some circulating irritant. This disease differs histologically from urticaria in the persistent dilatation of the vessels. Although serum is poured out from them as freely as in urticaria, the dilatation of the vessels is so active that they are not compressed as in that disease, while the presence of numerous cells around the vessels seems to suggest a more severe irritant, and the fact that the lesions are clinically more persistent further confirms that suggestion.

The inflammations of the skin are divided by Unna into *traumatic* (due to the application of some mechanical, chemical, or physical irritant), *neurotic* (a somewhat doubtful class, from which we have already suggested the removal of the diseases grouped as erythema), and *infective* (a group which includes the majority of the commoner skin diseases). With reference to this last class, it has already been pointed out that a large amount of assumption in regard to many of the diseases is necessary, for only in some of them has the actual infective agent been demonstrated. The inflammatory reaction takes many different forms, each no doubt due to some subtle variant in the irritant or in the surface to which it is applied, for the same irritant will produce different results on different subjects; but as yet we are only on the threshold of a knowledge by which we shall be able to recognize the irritant from the effects which it produces. If *scabies* be excluded, probably half the rest of the diseases of the skin are written down as *eczema*. A discussion of the pathological changes found in that and allied diseases will probably be the best method of explaining the pathology of the skin.

When certain irritants are applied to the skin we know beforehand what effects they will produce. Thus croton oil produces a vesicular and pustular eruption, that of cantharides is vesicular or bulbous, while other drugs are followed by results dependent on their concentration, ranging from a mere redness produced by dilute applications to actual death of the skin from concentrated ones. With the milder irritants which produce the results clinically known as *eczema* we have invariably more or less pronounced certain definite phenomena. The blood-vessels dilate; serum is exuded from them—it may be merely into the deeper layers of the skin, or it may reach into and among the epidermic cells, or burst its way through these and appear in drops on the surface. The epithelial cells are, immediately if the irritation be slight, later if it be more severe, stimulated to increased activity of growth and production; and this activity, often misdirected, is so great that the normal process of hardening in the cells is interfered with, and we have what is known as *parakeratosis* (irregular cornification) and the consequent production of scales. Should this be the prominent pathological change, the exudation spends itself among the cells of the scales, and a condition pathologically moist appears to the clinical observer as a dry eruption. Thus according to the reaction—which is presumably largely dependent on the irritant to which it is due—we have various degrees and forms of inflammation of the skin, all of them covered clinically by the term *eczema*. When such a dermatitis is produced experimentally by the application of such an irritant as croton oil we can more or less accurately predict the duration of the inflammation, which gradually becomes less and less and usually terminates in dry scaling. So in *eczema*, as long as the irritant continues to act so long will its results be evident on the skin. Unfortunately the irritant which is the cause of *eczema* still remains to be discovered.

In studying other inflammations we have the advantage of definitely knowing their cause. Thus in *Impetigo contagiosa* all of Koch's postulates have been fulfilled, and we now know, mainly owing to the work of Saboraud, that the cause of the disease is the streptococcus pyogenes. The first result of inoculation is a minute red spot (dilatation of the vessels), which is rapidly followed by the appearance on the surface of a vesicle or bleb (exudation of serum), which is soon converted into a pustule (exudation of leucocytes). The leucocytes apparently have a restraining influence on the activity of the organisms, for the whole dries up into a scab, which when thrown off discloses a healthy or slightly reddened skin. The organisms are not destroyed by the leucocytes, for if the case be not properly treated fresh areas are constantly attacked, and the disease lasts indefinitely.

In *ringworm*, where the cause of the disease is the growth in the superficial layers of the skin of one or other of the different varieties of fungus grouped together under the common name of ringworm, a reaction more resembling that of *eczema* is produced. There is the same dilatation of the vessel with exudation of fluid, sometimes reaching the surface in the form of vesicles, sometimes spending itself through and among the epidermic cells and only evidenced clinically by the presence of more or less scaling. In other cases the exudation early becomes purulent (this is said to occur regularly when the disease is contracted from the horse), a change which, though occasionally noted, is by no means frequent in *eczema*.

The inflammations of the corium or deeper layer of the skin are due, with very few exceptions, to the growth of well-known organisms, and where none have yet been discovered their existence is generally accepted. *Erysipelas*, *furuncle*, *anthrax*, and *glanders* are diseases which run an acute course and rapidly terminate, the two former usually in recovery, the two latter often fatally. The other more chronic affections all follow one course; in their earlier stages there is a new growth of connective tissue cells in their lowest forms (granuloma), and this later breaks down, either rapidly, as in *syphilis*, or slowly, as in *tuberculosis* and *leprosy*. Most of these diseases leave behind them a well-defined scar.

The new growths of the skin are the same as those found elsewhere. Only two present special characters requiring notice here. *Keloid* is a peculiar form of fibroma which, although benignant as regards any general infection, invariably recurs locally after removal. *Rodent ulcer* is a form of cancer which occurs usually on the face, and whose malignancy is almost entirely local. The class of atrophies of the skin comprises those diseases where the atrophy is primary, and those where it succeeds to previous hypertrophic or inflammatory changes. Under saprophytes are included those fungi which vegetate on the skin but produce very slight if any symptoms. Anomalies of pigmentation are those of excess and lack. *Chloasma*, in which dark patches appear, most frequently on the face, is usually associated with disease of some internal organ, such as the liver or uterus, being frequently observed in pregnancy. The cause of *vitiligo*, in which the pigment normally present disappears from certain areas, a phenomenon more striking in coloured than in white races, is unknown. (N. W.)

XII. Eye.

The specially important diseases of the eye are those which temporarily or permanently interfere with sight. In considering the pathology of the eye it may in the first place be remembered that it is a double organ.

A. The two eyes act together, under normal conditions, for all practical purposes exactly as if there were but one eye placed in the middle of the face. All impressions made upon either retina, to the one side of a vertical line through the *fovea centralis*, before giving rise to conscious perception cause a stimulation of the same area in the brain. Impressions formed simultaneously, for instance, on the right side of the right retina and on corresponding areas of the right side of the left retina, are conveyed to the same spots on the right occipital lobe of the brain. Pathological processes, therefore, which are localized in the right or left occipital lobes, or along any part of the course of the fibres which pass from the right or left optic tracts to these "visual centres," cause defects in function of the right or left halves of the two retinæ. *Hemianopia*, or half-blindness, arising from these pathological changes, is of very varying degrees of severity, according to the nature and extent of the particular lesion. The blind areas in the two fields of vision, corresponding to the outward projection of the paralysed retinal areas, are always symmetrical both in shape and degree. The central lesion may for instance be very small, but at the same time destructive to the nerve tissue. This will be revealed as a sector-shaped or insular symmetrical complete blindness in the fields of vision to the opposite side. Or a large central area, or an area comprising many or all of the nerve fibres which pass to the visual centre on one side, may be involved in a lesion which causes impairment of function but no actual destruction of the nerve tissue. There is thus caused a symmetrical weakening of vision (*amblyopia*) in the opposite fields. In such cases the colour vision is so much more evidently affected than the sense of form that the condition has been called *hemiachromatopsia*, or half-colour-blindness. Hemianopia may be caused by hæmorrhage, by embolism, by tumour growth which either directly involves the visual nerve elements or affects them by compression, and by inflammation.

The two eyes also act as if they were one in accommodating. It is impossible for the two eyes to accommodate simultaneously to different extents, so that where there is, as occasionally happens, a difference in focus between them, this difference remains the same for all distances for which they are adapted. In such cases, therefore, both eyes cannot ever be accurately adapted at the same time, though either may be alone. It often happens as a consequence that the one eye is used to receive the sharpest images of distant, and the other of near objects. Any pathological change which leads to an interference in the accommodating power of one eye alone must have its origin in a lesion which lies peripherally to the nucleus of the third cranial nerve. Such a lesion is usually one of the third nerve itself. Consequently, a unilateral accommodation paresis is almost invariably associated with pareses of some of the oculo-motor muscles. A bilateral accommodation paresis is not uncommon. It is due to a nuclear or more central cerebral disturbance. Unlike a hemianopia, which is practically always permanent, a double accommodation paresis is frequently transitory. It is often a post-diphtheritic condition, appearing alone or associated with other paresis.

Both eyes are also normally intimately associated in their movements. They move in response to a stimulus, or a combination of stimuli, emanating from different centres of the brain, but always equally distributed to the corresponding muscles in both eyes, so that the two lines of fixation meet at the succession of points on which attention is directed. The movements are thus associated in the same direction, to the right or left, upwards or downwards, &c. In addition, owing to the space which separates the two eyes, convergent movements, caused by stimuli equally distributed between the two internal recti, are required for the fixation of nearer and nearer-lying objects. These movements would not be necessary in the case of a single eye. It would merely have to accommodate. The converging movements of the double eye occur in association with accommodation, and thus a close connexion becomes established between the stimuli to accommodation and convergence. All combinations of convergent and associated movements are constantly taking place normally, just as if a single centrally-placed eye were moved in all directions and altered its accommodation according to the distance, in any direction, of the object which it fixed.

Associated and convergent movements may be interfered with pathologically in different ways. Cerebral lesions may abolish them altogether or impair them, or may give rise to involuntary spasmodic action, as the result of paralysing or irritating the centres from which the various co-ordinated impulses are controlled or emanate. Lesions which do not involve the centres may prevent the response to associated impulses in one eye alone by interfering with the functional activity of one or more of the nerves along which the stimuli are conveyed. Paralysis of oculo-motor nerves is thus a common cause of defects of association in the movements of the double eye. The great advantage of simultaneous binocular vision—viz., the appreciation of depth, or stereoscopic vision—is thus lost for some, or it may be all directions of fixation. Instead of seeing singly with two eyes, there is then double-vision (*diplopia*). This persists so long as the defect of association continues, or so long as the habit of mentally suppressing the image of the faultily-directed eye is not acquired.

In the absence of any nerve lesions, central or other, interfering with their associated movements, the eyes continue throughout life to respond equally to the stimuli which cause these movements, even when, owing to a visual defect of the one eye, binocular vision has become impossible. It is otherwise, however, with the proper co-ordination of convergent movements. These are primarily regulated by the unconscious desire for binocular vision, and more or less firmly associated with accommodation. When one eye becomes blind, or when binocular vision for other reasons is lost, the impulse is gradually, as it were, unlearnt. This is the cause of *divergent concomitant squint*. Under somewhat similar conditions a degree of convergence, which is in excess of the requirements of fixation, may be acquired from different causes. This gives rise to *convergent concomitant squint*.

B. Taking each eye as a single organ, we find it to be subject to many diseases. In some cases both eyes may be affected in the same way as where the local disease is a manifestation of some general disturbance. Apart from the fibrous coat of the eye, the sclera, which is little prone to disease, and the external muscles and other adnexa, the eye may be looked upon as composed of two elements, (*a*) the dioptric media, and (*b*) the parts more or less directly connected with perception. Pathological conditions affecting either of these elements may interfere with sight.

(*a*) The dioptric media, or the transparent portions which are concerned in the transmission of light to, and the formation of images upon, the retina, are the following:—the cornea, the aqueous humour, the crystalline lens, and the vitreous humour. Loss of transparency in any of these media leads to blurring of the retinal images of external objects. In addition to loss of transparency, the cornea may have its curvature altered by pathological processes. This necessarily causes imperfection of sight. The crystalline lens, on the other hand, may be dislocated, and thus cause image distortion.

(i.) The transparency of the cornea is mainly lost by inflammation, which causes either an infiltration of its tissues with leucocytes, or a more focal, more destructive ulcerative process. In the process of repair the loss of substance sustained in the latter case is made good by cicatricial tissue. This newly-formed tissue is always intransparent, and remains so, except in very young children, in whom it gradually, to a great extent, clears up, owing to the more rapid and more complete tissue changes of early life. The intransparency caused by a mere infiltration generally clears away in the course of time, though often not entirely. The process of clearing is usually associated with the formation of blood-vessels in the cornea. These eventually also undergo absorption. A vascularization of the cornea generally also accompanies ulceration, and is, indeed, often a necessary part of the process of reparation. According to the position occupied by the cicatrix following a corneal ulcer, and to its extent and density, is the degree of the resulting visual defect. Centrally placed intransparencies, which cover the pupil, are relatively the most disturbing. The larger losses of substance, even though marginal, may interfere greatly with sight, by causing changes in the corneal curvature. This is principally the case where the cicatricial tissue yields to the intra-ocular pressure before consolidation, and gives rise to partial *staphyloma* of the cornea. The same yielding may be met with, though rarely, where there has been an excessive degree of infiltration alone. Corneal ulcers, which perforate, lead not infrequently to hernia of the iris, a portion of which then becomes incorporated in the scar. A special form of corneal opacity is what is called *pannus*. This consists of a more or less dense development of superficial blood-vessels, offshoots of the conjunctival arteries and veins, with some infiltration of the outer layers of the cornea. Pannus is a frequent accompaniment of *trachoma*, a chronic destructive form of conjunctival inflammation. A somewhat rare condition of the cornea, by which, without any inflammatory symptoms, a marked change in its curvature is slowly produced, is what is called *conical cornea*. The pathology of this condition is unknown. *Primary tumours* of the cornea are exceedingly rare.

(ii.) Intransparency of the aqueous humour is always due to some exudation. This comes either from the iris or the ciliary processes, and may be blood, pus, or fibrin. An exudation in this situation tends naturally to gravitate to the most dependent part, and, in the case of blood or pus, is known as *hyphæma* or *hypopyon*.

(iii.) Intransparency of the crystalline lens is technically known as *cataract*. Cataract may be idiopathic and uncomplicated, or traumatic, or secondary to disease in the deeper parts of the eye. The modified epithelial structure of which the lens is composed is always being added to throughout life. The older portions of the lens are consequently the more central. They are harder and less elastic. This arrangement seems to predispose to difficulties of nutrition. In many people, in the absence altogether of general or local disease, the transparency of the lens is lost owing to degeneration of the incompletely-nourished fibres. This idiopathic cataract mostly occurs in old people; hence the term *senile cataract*. So-called senile cataract is not, however, necessarily associated with any general senile changes. An idiopathic uncomplicated cataract is also met with as a congenital defect due to faulty development of the crystalline lens. A particular and not uncommon form of this kind of cataract, which may also develop during infancy, is *lamellar* or *zonular cataract*. This is a partial and stationary form of cataract in which, while the greater part of the lens retains its transparency, some of the lamellæ are intransparent. Traumatic cataract occurs in two ways: by laceration or rupture of the lens capsule, or by nutritional changes consequent upon injuries to the deeper structures of the eye. The transparency of the lens is dependent upon the integrity of its capsule. Penetrating wounds of the eye involving the capsule, or rupture of the capsule from severe blows on the eye without perforation of its coats, are followed by rapidly developing cataract. Severe non-penetrating injuries, which do not cause rupture of the capsule, are sometimes followed, after a time, by slowly-progressing cataract. Secondary cataract is due to abnormalities in the nutrient matter supplied to the lens owing to disease of the ciliary body, choroid, or retina. In some diseases, as diabetes, the altered general nutrition tells in the same way on the crystalline lens. Cataract is then rapidly formed. All cases of cataract in diabetes are not, however, necessarily true diabetic cataracts in the above sense. *Dislocations of the lens* are traumatic or congenital. In old-standing disease of the eye the suspensory ligament may yield in part, and thus lead to lens dislocation. The lens is practically always cataractous before this takes place.

(iv.) The vitreous humour loses its transparency owing to exudation from the inflamed ciliary body or choroid. The exudation may be fibrinous or purulent; the latter only as a result of injuries by which foreign bodies or septic matter are introduced into the eye, or in metastatic choroiditis. Blood may also be effused into the vitreous from rupture of retinal, ciliary, or choroidal vessels. The pathological significance of the various effusions into the vitreous depends greatly upon the cause. In many cases effusion and absorption are constantly taking place simultaneously. The extent of possible clearing depends greatly upon the preponderance of the latter process.

(*b*) Inflammations of the *uveal* tract, the iris, ciliary body, and choroid, are of common occurrence. Inflammations of the iris (*iritis*), the causes of which are numerous, may lead, when untreated, to serious consequences. This is owing to the tendency towards adhesions being formed by the consolidation of plastic exudation between the posterior surface of the iris and the lens capsule. These so-called *synechiæ*, besides interfering with the free movements of the pupil, may introduce nutritional difficulties, especially in the case of recurrent attacks of inflammation. Inflammation of the ciliary body (*cyclitis*) leads to effusion into the anterior part of the vitreous. It may coexist with iritis (*irido-cyclitis*) or with inflammation of the choroid (*choroido-cyclitis*). The most serious form of irido-cyclitis is that which may follow penetrating wounds of the eye. Under certain conditions this leads to a similar inflammation in the other eye. This so-called *sympathetic ophthalmitis* is of a malignant type, causing destruction of the sympathizing eye. Choroidal inflammations are generally patchy, various foci of inflammation being scattered over the choroid. These patches may in course of time become more or less confluent. The effect upon vision depends upon the extent to which the external or percipient elements of the retina become involved. It is especially serious when the more centred portions of the retina are thus affected (*choroido-retinitis centralis*).

A peculiar and grave pathological condition of the eye is what is known as *glaucoma*. A characteristic of this condition is increase of the intra-ocular tension, which has a deleterious effect on the optic nerve end and its ramifications in the retina. The cause of the rise of tension is partly congestive, partly mechanical. The effect of glaucoma, when untreated, is to cause ever-increasing loss of sight, although the time occupied by the process before it leads to complete blindness varies within such extraordinarily wide limits as from a few hours to many years. The uveal tract may be the site of *sarcoma*.

The retina is subject to inflammation, to detachment from the choroid, to hæmorrhages from the blood-vessels, and to tumour. Retinal inflammation may primarily affect either the nerve elements or the connective tissue framework. The former is usually associated with some general disease such as albuminuria or diabetes, and is bilateral. The tissue changes are œdema, the formation of exudative patches, and hæmorrhage. Where the connective tissue elements are primarily affected, the condition is a slow one, similar to *sclerosis* of the central nervous system. The gradual blindness which this causes is due to compression of the retinal nerve elements by the connective tissue hyperplasia, which is always associated with characteristic changes in the disposition of the retinal pigment. This retinal sclerosis is consequently generally known as *retinitis pigmentosa*, a disease to which there is a hereditary predisposition. Besides occurring during inflammation, hæmorrhages into the retina are met with in phlebitis of the central retinal vein, which is almost invariably unilateral, and in certain conditions of the blood, as pernicious anæmia, when they are always bilateral.

The optic nerve is subject to inflammation (optic neuritis), and atrophy. Double optic neuritis, affecting, however, only the intra-ocular ends of the nerves, is an almost constant accompaniment of brain tumour. Unilateral neuritis has a different causation, depending upon an inflammation, mainly perineuritic, of the nerve in the orbit. It is analogous to peripheral inflammation of other nerves, such as the third, fourth, sixth, and seventh cranial nerves. (G. A. BE.)

Pathology of Plants.—Phytopathology comprises our knowledge of the symptoms, course, causes, and remedies of the maladies which threaten the life of plants, or which result in abnormalities of structure that are regarded, whether directly injurious or not to life, as unsightly or undesirable. In its systematized form, as a branch of botanical study, it is of recent date, and, as now understood, the subject first received special attention about 1850, when the nature of parasitism began to be intelligible; but many disjointed references to diseased conditions of plants had appeared long before this. The existence of blights and mildews of cereals had been observed and recorded in very ancient times, as witness the Bible, where half a dozen references to such scourges occur in the Old Testament alone. The epidemic nature of wheat-rust was known to Aristotle about 350 B.C., and the Greeks and Romans knew these epidemics well, their philosophers having shrewd speculations as to causes, while the people held characteristic superstitions regarding them, which found vent in the dedication of special festivals and deities to the pests. Pliny knew that flies emerge from galls. The few records during the Middle Ages are borne out by what is known of famines and pestilence. Shakespeare's reference in *King Lear* (Act III., sc. 4) may be quoted as evincing acquaintance with mildew in the 17th century, as also the interesting Rouen law of Loverdo (1660). Malpighi in 1679 gave excellent figures and accounts of leaf-rolling and gall insects, and Grew in 1682 equally good descriptions of a leaf-mining caterpillar. During the 18th century more academic treatment of the subject began to replace the scattered notes. Hales (1727–33) discussed the rotting of wounds, cankers, &c., but much had to be done with the microscope before any real progress was possible, and it is easily intelligible that until the theory of nutrition of the higher plants had been founded by the work of Ingenhouss, Priestley, and De Saussure, the way was not even prepared for accurate knowledge of cryptogamic parasites and the diseases they induce. Even in 1833 Turpin, and a far better observer, Unger, regarded parasitic fungi as diseased outgrowths of the plants themselves, views from which Meyen (1837) and Schleiden (1846) had not yet escaped. We can do no more than refer to the treatises of Wiegmann (1839), Meyer (1841), Raspail (1846), Kühn (1859), and other books as showing the interest the new subject was awakening, but the reader will find an admirable summary of what was known in 1854 in Berkeley's articles in the *Gardener's Chronicle* of that year. It was not till De Bary (1866) made known the true nature of parasitic Fungi, based on his researches between 1853–63, that the vast domain of epidemic diseases of plants was opened up to fruitful investigation, and such modern treatises as those of Frank (1880 and 1895), Sorauer (1886), Kirchner (1890), were gradually made possible.

The proper study of plant pathology involves knowledge of the physiology of plants—*i.e.*, of the normal relations of plants to the environment, and of the normal internal structure and working of the organism itself. It cannot be too strongly emphasized that pathology—disease—is abnormal physiology, and that the commonest misapprehensions and blunders arise from ignorance of this, and of the simplest principles of physiology. It is true, the boundary lines between normal physiology—*i.e.*, health—and disease are not fixed, and are often difficult to draw, but all our knowledge points to the conclusion that the statement, Disease is ill-health, is not a mere matter of words, but expresses the fact.

Plant pathology embraces several branches of study, and may be conveniently divided as follows:—

1. The observation and accurate description of symptoms (*Diagnosis*).

2. The study of causes or agencies inducing disease (*Ætiology*).

3. The practice of preventive and remedial measures (*Therapeutics*).

In plants, however, the *symptoms of disease* are apt to exhibit themselves in a very general manner. Our perceptions differentiate but imperfectly symptoms which are due to very different causes and reactions, probably because the organization of the plant is so much less highly specialized than that of higher animals. The yellowing and subsequent casting of leaves, for instance, is a very general symptom of disease in plants, and may be induced by drought, extremes of temperature, insufficient or excessive illumination, excess of water at the roots, the action of parasitic Fungi, insects, worms, &c., or of poisonous gases, and so forth; and extreme caution is necessary in dealing with amateur descriptions of such symptoms, especially when the untrained eye has taken no cognizance of, or has only vaguely observed, the numerous collateral circumstances of the case. It is chiefly due to these difficulties that most works on plant pathology, which classify the subject according to the causes, themselves often imperfectly understood, leave such vague impressions on the reader. It should be regarded as the distinct aim of future workers to perfect a system whereby classification of symptoms is possible; for, although remedial measures must always depend on the understanding of the causes at work in disease, the rational classification of symptoms is necessary to direct attention to the probable course of events.

The *causes of disease* may be provisionally classified somewhat as follows, but it may be remarked at the outset that no one of these proximal causes, or agents, is ever solely responsible; and it is very easy to err in attributing a diseased condition to any of them, unless the relative importance of primary and subordinate agencies is discoverable. For instance, a Fungus epidemic is impossible unless the climatic conditions are such as to favour the dispersal and germination of the spores; and when plants are killed off owing to the supersaturation of the soil with water, it is by no means obvious whether the excess of water and dissolved materials, or the exclusion of oxygen from the root-hairs, or the lowering of the temperature, or the accumulation of foul products of decomposition should be put into the foreground. In every case there are chains of causation concerned, and the same factors will be differently grouped in different cases.

Bearing in mind these precautions, we may classify the proximal causal agents of disease as—

- I. External agencies.
  - A. Non-living.
    - *a.* Material.
      - 1. Physical—
        - Soil.
        - Water.
        - Atmosphere.
      - 2. Chemical—
        - Soil.
        - Water.
        - Atmosphere.
    - *b.* Non-material—
      - 1. Temperature.
      - 2. Illumination.
      - 3. Other agencies.
  - B. Living.
    - *a.* Animals.
      - 1. Vertebrata.
      - 2. Invertebrata.
    - *b.* Plants.
      - 1. Phanerogams.
      - 2. Cryptogams.
- II. Internal agencies.

While such a classification may serve its purpose as a sort of index, it must be confessed that the limits of its usefulness are soon reached. In the first place, the so-called "internal causes" of disease is probably a mere phrase covering our ignorance of the factors at work, and although a certain convenience attaches to the distinction between those cases where tender breeds of plants apparently exhibit internal predisposition to suffer more readily than others from parasites, low temperatures, excessive growth, &c.—as is the case with some grafted plants, cultivated hybrids, &c.—the mystery involved in the phrase "internal causes" only exists until we find what action of the living or non-living environment of the essential mechanism of the plant has upset its equilibrium.

I. Passing to the recognized *external agencies*, the physical condition of the *soil* is a fruitful source of disease. If too closely packed, the soil particles present mechanical obstacles to growth; if too retentive of moisture, the root-hairs suffer, as already hinted; if too open or over-drained, the plant succumbs to drought. All those properties of soil known as texture, porosity, depth, inclination to the horizon, &c., are concerned here. Many maladies of plants are traceable to the chemical composition of soils—*e.g.*, deficiency of nutritive salts, especially nitrates and phosphates; the presence of poisonous salts of iron, copper, &c., or (in the soil about the roots of trees in towns) of coal-gas, and so forth. But it is worthy of special attention that the mere chemical composition of agricultural and garden soils is, as a rule, the least important feature about them, popular opinion to the contrary notwithstanding. Ordinary soils will almost always provide the necessary chemical ingredients if of proper physical texture, depth, &c. But, as showing how impossible it is sharply to classify the factors concerned, the absence of nitrifying bacteria, of humus constituents and mycorrhiza Fungi, of earth-worms and other organisms which beneficially affect plants, may decide the question of health or disease of plants in soils otherwise admirably suited to them (see articles FUNGI, and BACTERIOLOGY: *Schizomycetes*).

As regards *water*, its deficiency or excess is a relative matter, and although many of the minor maladies of pot-plants in windows and greenhouses controlled by amateurs depend on its misuse, water alone is probably never a primary cause of disease. Its over-supply is, however, a frequent cause of predisposition to the attacks of parasitic Fungi—*e.g.*, the damping off of seedlings—and in saturated soils not only are the roots and root-hairs killed by asphyxiation, but the whole course of soil fermentation is altered, and it takes time to "sweeten" such by draining, because not only must the noxious bodies be gradually washed out and the lost salts restored, but the balance of suitable bacterial and fungal life must be restored.

The *atmosphere* is a cause of disease in the neighbourhood of chemical works, large towns, volcanoes, &c., in so far as it carries acid gases and poisons to the leaves and roots; but it is usual to associate with it the action of excessive humidity which brings about those tender watery and more or less etiolated conditions which favour parasitic Fungi, and diminish transpiration and therefore nutrition. It is customary to speak of the disastrous effects of cold winds, snow, hail and frost, lightning, &c., under the heading of atmospheric influences, which only shows once more how impossible it is to separate causes individually.

Turning to the *non-material external agents*, probably no factors are more responsible for ill-health in plants than *temperature* and light. Every plant is constrained to carry out its functions of germination, growth, nutrition, reproduction, &c., between certain limits of temperature, and somewhere between the extremes of these limits each function finds an optimum temperature at which the working of the living machinery is at its best, and, other things being equal, any great departure from this may induce pathological conditions; and many disasters are due to the failure to provide such suitable temperatures—*e.g.*, in greenhouses where plants requiring very different optimum temperatures and illumination are kept together. Equally disastrous are those climatic or seasonal changes which involve temperatures in themselves not excessive but in wrong sequence: how many more useful plants could be grown in the open in the United Kingdom if the deceptively mild springs were not so often followed by frosts in May and June! The indirect effects of temperature are also important. Trees, of which the young buds are "nipped" by frost, would frequently not suffer material injury, were it not that the small frost-cracks serve as points of entry for Fungi; and numerous cases are known where even high temperatures can be endured on rich, deep, retentive soils by plants which at once succumb to drought on shallow or non-retentive soils. Nay, even on similar soils, a given plant may die where the surface is "caked," and live if the surface has been well stirred, again bringing out the complex interaction of various factors.

All chlorophyll plants require *light*, but in very different degrees, as exemplified even in the United Kingdom by the shade-bearing beech and yew contrasted with the light-demanding larch and birch; and as with temperature so with light, every plant and even every organ has its optimum of illumination. The "drawn" or etiolated condition of over-shaded plants is a case in point, though here again the soft, watery plant often really succumbs to other disease agents—*e.g.*, parasitic Fungi—supervening on its non-resistant condition.

Animals and plants as agents of disease or injury form part of the larger subject of the struggle for existence between living organisms, as is recognized even by those who do not so readily apprehend that diseased conditions in general are always signs of defeat in the struggle for existence between the suffering organism and its environment, living and non-living. Indeed, a comprehensive definition of disease generally would be: Variations in directions which threaten the existence of the patient.

The Vertebrata come within the scope of our subject, chiefly as destructive agents which cause wounds or devour young shoots and foliage, &c. Rabbits and other burrowing animals injure roots, squirrels and birds snip off buds, horned cattle strip off bark, and so forth. It is among the Invertebrata that epidemics of destruction are referred to, though we should bear in mind that it is only the difference in numerical proportion that prevents our speaking of an epidemic of elephants or of rabbits, though we use the term when speaking of blight insects; there is little consistency in the matter, as it is usual to speak of an invasion or scourge of locusts, caterpillars, &c. Insect injuries are very varied in degree and in kind. Locusts devour all before them; caterpillars defoliate the plant, and necessitate the premature utilization of its reserves; other insects (*e.g.*, *Grapholitha*) eat the buds, or the roots (*e.g.*, wireworms), and so maim the plant that its foliage suffers from want of water and assimilation is diminished, or actual withering follows. Many aphides, &c., puncture the leaves, suck out the sap, and induce various local deformations, arrest of growth, pustular swellings, &c., and if numerous all the evils of defoliation may follow. Others (*e.g.*, miners) tunnel into the leaf parenchyma, and so put the assimilating areas out of action in another way. It should be remembered that a single complete defoliation of a herbaceous annual may so incapacitate the assimilation that no stores are available for seeds, tubers, &c., for another year, or at most so little that feeble plants only come up. In the case of a tree matters run somewhat differently: most large trees in full foliage have far more assimilatory surface than is immediately necessary, and if the injury is confined to a single year it may be a small event in the life of the tree, but if repeated the cambium, bud-stores, and fruiting may all suffer. Many larvæ of beetles, moths, &c., bore into bark, and injure the cambium, or even the wood and pith; in addition to direct injury, the interference with the transpiration current and the access of other parasites through the wounds are also to be feared in proportion to the numbers of insects at work. Various local hypertrophies, including galls, result from the increased growth of young tissues irritated by the punctures of insects, or by the presence of eggs or larvæ left behind. They may occur on all parts, buds, leaves, stems, or roots, as shown by the numerous species of *Cynips* on oak, *Phylloxera* on vines, &c. The local damage is small, but the general injury to assimilation, absorption, and other functions may be important if the numbers increase. In addition to insects, various kinds of worms, molluscs, &c., are sometimes of importance as pests. The so-called eel-worms (*Nematodes*) may do immense damage on roots and in the grains of cereals, and every one knows how predatory slugs and snails are.

Plants as agents of damage and disease may be divided into those larger forms which as weeds, epiphytes, and so forth do injury by dominating and shading more delicate species, or by gradually exhausting the soil, &c., and true parasites which actually live on and in the tissues of the plants. It must be remembered that phanerogams also include parasitic species—*e.g.*, *Cuscuta*, *Loranthus*, *Viscum*, *Thesium*, *Rhinanthus*, &c.—with various capacities for injury. These enemies are as a rule so conspicuous that we do not look on their depredations as diseases, though the gradual deterioration of hay under the exhausting effects of root-parasites like *Rhinanthus*, and the onslaught of *Cuscuta* when unduly abundant, should teach us how unimportant to the definition the question of size may be. Weeds often do as much damage indirectly as directly. If grass and herbage are grown in orchards, they may increase the moisture and shade which favour certain Fungi at one season, and dry up the soil over the finer roots of the trees at another, as well as compete with these for nutritive salts. On the other hand, the action of such weeds in checking the development of surface roots has been claimed as advantageous, and it is evident that the nature and composition of the weed herbage in different localities may affect the matter.

It is, however, among the Fungi that we find the most disastrous and elusive agents of disease. *Parasitic Fungi* may be, as regards their direct action, purely local —*e.g.*, *Schinzia*, which forms gall-like swellings on the roots of rushes; *Gymnosporangium*, causing excrescences on juniper stems; numerous leaf Fungi such as *Puccinia*, *Æcidium*, *Septoria*, &c., causing yellow, brown, or black spots on leaves; or *Ustilago* in the anthers of certain flowers. In such cases the immediate damage done may be slight; but the effects of prolonged action and the summation of numerous attacks at numerous points are often enormous, certain of these leaf-diseases costing millions sterling annually to some planting and agricultural communities. In other cases the Fungus is virulent and rampant, and, instead of a local effect, exerts a general destructive action throughout the plant—*e.g.*, *Pythium*, which causes the "damping off" of seedlings, reducing them to a putrid mass in a few hours, and *Phytophthora*, the agent of the potato disease. Many Fungi, in themselves not very aggressive, slowly bring about important and far-reaching secondary effects. Thus, many Hymenomycetes (Agarics, Polyporei, &c.) live on the wood of trees. This wood is in great part already dead substance, but the mycelium gradually invades the vessels occupied with the transmission of water up the trunk, cuts off the current, and so kills the tree; in other cases such Fungi attack the roots, and so induce rot and starvation of oxygen, resulting in "fouling." We may not inaptly compare the procedure to various methods of reducing a besieged community by cutting off or poisoning the water supplies. Numerous Fungi, though conspicuous as parasites, cannot be said to do much individual injury to the host. The extraordinary malformations known as "Witches' Brooms," caused by the repeated branching and tufting of twigs in which the mycelium of *Exoascus* (on birch) or *Æcidium* (on silver fir) are living, may be borne in considerable numbers for years without any very extensive apparent injury to the tree. Again, the curious distortions on the stems of nettles attacked by the *Æcidium* form of the heterœcious *Puccinia caricis* (see FUNGI for Heterœcism), or on maize stems and leaves attacked by *Ustilago Maydis*, or on the inflorescence of cruciferæ infested with *Cystopus*, &c., are not individually very destructive; it is the cumulative effects of numerous attacks or of extensive epidemics which eventually tell. Some very curious details are observable in these cases of malformation. For instance, the *Æcidium Elatinum* first referred to causes the new shoots to differ in direction, duration, and arrangement, and even shape of foliage leaves from the normal; and the shoots of *Euphorbia* infested with the æcidia of *Uromyces pisi* depart so much from the normal in appearance that the attacked plants have been taken for a different species. Similarly with *Anemone* infested with *Puccinia* and *Vaccinium* with *Calyptospora*, and many other cases of deformations due to hypertrophy or atrophy. Instances of what we may term tolerated parasitism, where the host plant seems to accommodate itself very well to the presence of the Fungus, paying the tax it extorts and nevertheless not succumbing but managing to provide itself with sufficient material to go on with, are not rare; and these seem to lead to those cases where the mutual accommodation between host and guest has been carried so far that each derives some benefit from the association—symbiosis (see FUNGI).

II. The *kinds of disease* due to these various agencies are very different. A plant may be diseased as a whole, because nearly all its tissues are in a morbid or pathological condition, owing to some Fungus pervading the whole—*e.g.*, *Pythium* in seedlings—or to a poison diffusing from cell to cell; in the case of unicellular plants—*e.g.*, an alga infested with a *Chytridium*—indeed, matters can hardly be otherwise. But the case is obviously different where a plant dies because some essential organ or tissue-tract has been destroyed, and other parts have suffered because supplies are cut off—*e.g.*, when the upper parts of a tree die off owing to destruction of the roots, or to the ringing of the stem lower down, and consequent interference with the transpiration current. In a large number of cases, however, the disease is purely local, and does not itself extend far into the organ or tissue affected; *e.g.*, when an insect punctures a leaf at some minute point with its proboscis or ovipositor, killing a few cells and irritating those in the immediate neighbourhood; or when a knife-cut wounds the cambium, which soon covers up the injury by means of callus; or when a Fungus such as *Uromyces* infects a leaf by way of a stoma, the mycelium not spreading more than a few millimetres round the point of entry.

Attempts have been made to classify diseases according to the organs or tissues attacked—to speak of leaf diseases, root diseases, timber diseases, diseases of the bark, and so forth. Neither these nor any arrangement according to the functions deranged have proved satisfactory, and it is doubtful if in any circumstances phrases like "general functional disease," diseases of the absorptive organs, or of the respiratory organs can be usefully employed in plant pathology, the various organs and functions of plants being too vaguely marked off one from the other. Current terminology is responsible in part for some confusion of thought in other directions. Strictly speaking, wheat-rust is not a disease, but a symptom betraying the presence of a disease-inducing Fungus; similarly, chlorosis is a symptom of imperfect chlorophyll production. In both cases the fundamental disease itself consists in the starvation of the cell-protoplasm of carbohydrates, in the one case because the parasite steals them as fast as they are made, in the other because the machinery is too imperfect to make them.

If a mass of living plant-tissue is cut, the first change observed is one of colour: the white "flesh" of a potato or an apple turns brown as the air enters, and closer examination shows that cell walls and contents are alike affected. The cut cells die, and oxidized products are concerned in the change of colour, the brown juices exuding and soaking into the cell-walls. The next change observable after some hours is that the untouched cells below the cut grow larger, push up the dead surface, and divide by walls tangential to it, with the formation of tabloid cork-cells. The layer of cork thus formed cuts out the dead débris and serves to protect the uninjured cells below. Such healing by cork formation is accompanied by a rise of temperature: the active growth of the dividing cells is accompanied by vigorous metabolism and respiration, and a state of "wound fever" supervenes until the healing is completed. The phenomena described occur in all cases of cicatrization of wounds in nature—*e.g.*, leaf-tissue, young stems, roots, &c., when cut or pierced by insects, thorns, and so forth. They are concerned in the occlusion of broken twigs and of falling leaves, and it is from the actively growing "callus" developed at the surface of the wounded tissues of cuttings, buddings, prunings, &c., that the healing and renewal of tissues occur of which advantage is taken in the practice of what might well be termed plant surgery. A third phenomenon observable in such healing tissues is the increased flow and accumulation of plastic materials at the seat of injury. The enhanced metabolism creates a current of draught on the supplies of available food-stuffs around. The phenomenon of irritability here concerned is well shown in certain cases where a parasitic organism gains access to a cell—*e.g.*, *Pleotrachelus* causes the invaded *Pilobolus* to swell up, and changes the whole course of its cell metabolism, and similarly with *Plasmodiophora* in the roots of turnips, and many other cases.

Irritation and hypertrophy of cells are common signs of the presence of parasites, as evinced by the numerous malformations, galls, witches'-brooms, &c., on diseased plants. The now well-known fact that small doses of poisonous substances may act as stimuli to living protoplasm, and that respiratory activity and growth may be accelerated by chloroform, ether, and even powerful mineral poisons, such as mercuric chloride, in minimal doses, offers some explanation of these phenomena of hypertrophy, "wound fever," and other responses to the presence of irritating agents. Still further insight is afforded by our increasing knowledge of the enzymes, and it is to be remarked that both poisons and enzymes are very common in just such parasitic Fungi as induce discolorations, hypertrophies, and the death of cells—*e.g.*, *Botrytis*, *Ergot*, &c. Now it is clear that if an organism gains access to all parts of a plant, and stimulates all or most of its cells to hypertrophy, we may have the latter behaving abnormally—*i.e.*, it may be diseased throughout; and such actually occurs in the case of *Euphorbia* pervaded with *Uromyces pisi*, the presence of which alters the whole aspect of the host-plant. If such a general parasite carries its activities further, every cell may be killed and the plant forthwith destroyed—*e.g.*, *Phytophthora* in potatoes. If, on the other hand, the irritating agent is local in its action, causing only a few cells to react, we have the various pimples, excrescences, outgrowths, &c., exhibited in such cases as *Ustilago Maydis* on the maize, various galls, witches'-brooms, &c. If, again, a few cells are killed on one side only of a young organ, they and their progeny can no longer take part in growth, and so the still active cells on the other side of the organ push the newly-forming tissues over to the arrested side, as in lily buds deformed by *Botrytis*, currant leaves pierced by mites, pine shoots contorted by *Cæoma pinitorquam*, &c.

It must not be overlooked that the living cells of the plant react upon the parasite as well as to all external agencies, and the nature of disease becomes intelligible only if we bear in mind that it consists in such altered metabolism—deflected physiology—as is here implied. The reaction of the cells may be in two directions, moreover. For instance, suppose the effect of a lowering temperature is to so modify the metabolism of the cells that they fill up more and more with watery sap; as the freezing-point is reached this may result in destructive changes, and death from cold may result. If, on the contrary, the gradual cooling is met by a corresponding depletion of the cells of water, even intense cold may be sustained without injury.

Or, take another case. If the attack of a parasite is met by the formation of some substance in the protoplasm which is chemotactically repulsive to the invader, it may be totally incapable of penetrating the cell, even though equipped with a whole armoury of cytases, diastatic and other enzymes, and poisons which would easily overcome the more passive resistances offered by mere cell-walls and cell-contents of other plants, the protoplasm of which forms bodies chemotactically attractive to the Fungus. Only in some such way as this can we explain why a given Uredine parasite on one species of grass is quite incapable of penetrating a closely-allied species, and why a Fungus, such as *Penicillium*, one of the most pronounced saprophytes known, may be trained to parasitic habits by artificial treatment of the host-plants.

The various *degrees of parasitism* are to a certain extent explained by the foregoing. In order that a Fungus may enter a plant, it must be able to overcome not merely the resistance of cell-walls, but that of the living protoplasm: if it cannot do this, it must remain outside as a mere epiphyte, *e.g.*, *Fumago*, *Herpotrichia*, &c., or, at most, vegetate in the intercellular spaces and anchor itself to the cell-walls, *e.g.*, *Trichosphæria*. The inability to enter the cells may be due to the lack of chemotactic bodies, to incapacity to form cellulose-dissolving enzymes, to the existence in the host-cells of antagonistic bodies which neutralize or destroy the acids, enzymes, or poisons formed by the hyphæ, or even to the formation and excretion of bodies which poison the Fungus. But even when inside it does not follow that the Fungus can kill the cell, and many cases are known where the Fungus can break through the cell's first lines of defence (cell-wall and protoplasmic lining); but the struggle goes on at close quarters, and various degrees of hypertrophy, accumulation of plastic bodies or secretions, discolorations, &c., indicate the suffering of the still living cell. Finally, cases occur where the invaded cell so adapts itself to the presence of the intruder that life in common—symbiosis—results.

The *dissemination* of plant parasites is favoured by many circumstances not always obvious, whence an air of mystery regarding epidemics was easily created in earlier times. The spores of Rusts, Erysipheæ, and other Fungi may be conveyed from plant to plant by snails; those of tree-killing polyporei, &c., by mice, rabbits, rats, &c., which rub their fur against the hymenophores. Bees carry the spores of *Sclerotinia* as they do the pollen of the bilberries, and flies convey the conidia of ergot from grain to grain. Insects, indeed, are largely concerned in disseminating Fungi, either on their bodies or *viâ* the alimentary canal. Worms bring spores to the surface of soil, ducks and other birds convey them on their muddy feet, and, as is well known, wind and other physical agencies are very efficient in dissemination. The part played by man also counts for much. Gardeners and farm labourers convey spores from one bed or field to another; carted soil, manure, &c., may abound in spores of Smuts, Fusarium, Polyporei, and in sclerotia; and articles through the post and so forth often carry infective spores. Every time a carpenter saws fresh timber with a saw recently put through wood attacked with dry-rot, he risks infecting it with the Fungus; and similarly in pruning, in propagating by cuttings, &c. Nor are the Fungi themselves always passive agents, as their odours, mechanisms for disjunction, ejaculation, &c., show.

The annual losses due to epidemic plant diseases attain proportions not easily estimated. As regards money value alone the following figures may serve in illustration. In 1882 the United States was calculated to have lost £40,000,000 to £60,000,000 from insect and other pests. The wheat-rust costs Australia £2,000,000 to £3,000,000 annually, and in 1891 alone the loss which Prussia suffered from grain-rusts was estimated at £20,000,000 sterling. These and numerous similar statistics lead to the conclusion that it is probable that we might put the average annual loss the world endures from epidemic and other plant diseases at not less than £100,000,000 sterling.

The terrible losses sustained by whole communities of farmers, planters, foresters, &c., from plant diseases have naturally stimulated the search for remedies, but even now the search is too often conducted in the spirit of the believer in quack medicines, although the agricultural world is awakening to the fact that before any measures likely to be successful can be attempted, the whole chain of causation of the disease must be investigated. Experience with epidemics, dearly bought in the past, has shown that one fruitful cause is the laying open to the inroads of some Fungus or insect, hitherto leading a quiet endemic life in the fields and forests, large tracts of its special food, along which it may range rampant without check to its dispersal, nutrition, and reproduction. Numerous wild hypotheses as to changes in the constitution of the host-plant, leading to supposed vulnerability previously non-existent, would probably never have seen the light had the full significance of the truth that an epidemic results when the external factors favour a parasite somewhat more than they do the host, been grasped. It may be that in particular cases particular modes of cultivation disfavour the host; or that the soil, climate, or seasons do so; but overwhelming evidence exists to show that the principal causes of epidemics reside in circumstances which favour the spread, nutrition, and reproduction of the pest, and the lesson to be learnt is that precautions against the establishment of such favouring conditions must be sought. Nevertheless, epidemics occur, and practical measures are devised to meet the various cases and to check the ravages already begun. The procedure consists in most cases in spraying the affected plants with poisonous solutions or emulsions, or in dusting them with fungicidal or insecticidal powders, or applying the fumes of lethal gases. For the composition of the numerous liquids and powders special works must be consulted, but the following principles apply generally. The poison must not be strong enough to injure the roots, leaves, &c., of the host-plant, or allowed to act long enough to bring about such injury. Care and intelligence are especially needful with certain insecticides such as poisonous gases, or the operators may suffer. It is worse than useless to apply drastic remedies if the main facts of the life-history of the pest are not known; *e.g.*, the application of ordinary antiseptic powders to leaves inside which a Fungus, such as a *Uredo* or *Ustilago*, is growing can only result in failure, and similarly if tobacco fumes, for instance, are applied when the insects concerned are hibernating in the ground beneath. Such applications at the moment when spores are germinating on the leaves, *e.g.*, *Peronospora*, or to the young mycelia of epiphytic parasites, *e.g.*, *Erysiphe*, or the steeping in hot water of thoroughly ripe hard grains to which spores are attached, *e.g.*, *Ustilago*, and filling a greenhouse with hydrocyanic acid gas when young insects are commencing their ravages, *e.g.*, Red-spider—all these and similar procedures timed to catch the pest at a vulnerable stage are intelligent and profitable prophylactic measures, as has been repeatedly shown. Numerous special methods of preventing the spread of Fungi, or the migrations of insects, or of trapping various animals; of leaving infested ground fallow, or of growing another crop useless to the pest, &c., are also to be found in the practical treatises. More indirect methods, such as the grafting of less resistant scions on more vigorous stocks, of raising special late or early varieties by crossing or selection, and so on, have also met with success; but it must be understood that "resistant" in such cases usually means that some peculiarity of quick growth, early ripening, or other life-feature in the plant is for the time being taken advantage of. Although we are not devoid of hope that certain varieties may prove inimical in other ways to Fungi or insects, very few of the alleged cases of "disease-resisting" plants will bear scientific examination. Among the most interesting modern means of waging war against epidemic pests is that of introducing other epidemics among the pests themselves—*e.g.*, the infection of rats and mice with disease bacilli, or of locusts with insect-killing Fungi, and signs of the successful carrying out of such measures are not wanting. That the encouragement of insectivorous birds has been profitable is well established, and it is equally well known that their destruction may lead to disastrous insect plagues. Much can be done, in forests for instance, by growing mixed crops, thus avoiding the risks of epidemics due to the rapid spread of Fungi over large continuous tracts of suitable host-plants.

Diseases and Symptoms.—The symptoms of plant diseases are, as already said, apt to be very general in their nature, and are sometimes so vaguely defined that little can be learned from them as to the causes at work. We may often distinguish between primary symptoms and secondary or subordinate symptoms, but for the purposes of classification in an article of this scope I shall only attempt to group the various cases under the more obvious signs of disease exhibited.

1. *Discolorations* are among the commonest of all signs that a plant is "sickly" or diseased. The principal symptom may show itself in general pallor, including all cases where the normal healthy green hue is replaced by a sickly yellowish hue indicating that the chlorophyll apparatus is deficient. It may be due to insufficient illumination (*Etiolation*), as seen in geraniums kept in too shaded a situation, and is then accompanied by soft tissues, elongation of internodes, leaves usually reduced in size, &c. The laying of wheat is a particular case. False etiolation may occur from too low a temperature, often seen in young wheat in cold springs. Cases of pallor due to too intense illumination and destruction of chlorophyll must also be distinguished. *Chlorosis* is a form of pallor where the chlorophyll remains in abeyance owing to a want of iron, and can be cured by adding ferrous salts. Lack of other ingredients may also induce chlorotic conditions. Yellowing is a common sign of water-logged roots, and if accompanied by wilting may be due to drought. Over-transpiration in bright wintry weather, when the roots are not absorbing, often results in yellowing. In other cases the presence of insects, Fungi, or poisons at the roots may be looked for. *Albinism*, with which variegated foliage may be considered, concerns a different set of causes, still obscure, and usually regarded as internal, though experiments go to show that some variegations are infectious.

2. *Spotted Leaves, &c.*—Discoloured spots or patches on leaves and other herbaceous parts are common symptoms of disease, and often furnish clues to identification of causes, though it must be remembered that no sharp line divides this class of symptoms from the preceding. By far the greater number of spot-diseases are due to Fungi, as indicated by the numerous "leaf-diseases" described, but such is by no means always the case. The spot or patch is an area of injury; on, or in, it the cell-contents are suffering destruction from shading, blocking of stomata, loss of substance, or direct mechanical injury, and the plant suffers in proportion to the area of leaf surface put out of action. It is somewhat artificial to classify these diseases according to the colour of the spots, and often impossible, because the colour may differ according to the age of the part attacked and the stage of injury attained; many Fungi, for instance, induce yellow spots which become red, brown, or black as they get older, and so on. White or grey spots may be due to *Peronospora, Erysiphe, Cystopus, Entyloma*, and other Fungi, the mycelium of which will be detected in the discoloured area; or they may be scale insects, or the results of punctures by Red-spider, &c. Yellow spots, and especially bright orange spots, commonly indicate Rust Fungi or other Uredineæ; but *Phyllosticta, Exoascus, Clasterosporium, Synchytrium*, &c., also induce similar symptoms. Certain Aphides, Red-spider, Phylloxera, and other insects also betray their presence by such spots. It is a very common event to find the early stages of injury indicated by pale yellow spots, which turn darker, brown, red, black, &c., later—*e.g.*, *Dilophia, Rhytisma*, &c. Moreover, variegations deceptively like these disease spots are known—*e.g.*, *Senecio Kæmpferi*. Red spots may indicate the presence of Fungi—*e.g.*, *Polystigma*—or insects—*e.g.*, *Phytoptus*. Brown spots are characteristic of *Phytophthora, Puccinia*, &c., and black ones of *Fusicladium, Ustilago, Rhytisma*, &c. Both are common as advanced symptoms of destruction by Fungi and insects. Brilliantly-coloured spots and patches follow the action of acid fumes on the vegetation near towns and factories, and such parti-coloured leaves often present striking resemblances to autumn foliage. Symptoms of scorching owing to abnormal insolation—*e.g.*, in greenhouses where the sun's rays are concentrated on particular spots—and a certain class of obscure diseases, such as "silver-leaf" in plums, "foxy leaves" in various plants, may also be placed here.

3. *Wounds.*—The principal phenomena resulting from a simple wound, and the response of the irritated cells in healing by cork and in the formation of callus, have been indicated above. Any clean cut, fracture, or bruise which injures the cambium over a limited area is met with the same response. The injured cells die and turn brown; the living cells beneath grow out, and form cork, and under the released pressure bulge outwards and repeatedly divide, forming a mass of succulent regenerative tissue known as *callus*. Living cells of the pith, phloem, cortex, &c., may also co-operate in this formation of regenerative tissue, and if the wound is a mere knife-cut in the "bark," the protruding lips of callus formed at the edges of the wound soon meet, and the slit is healed over—occluded. If a piece of bark and cortex are torn off, the occlusion takes longer, because the tissues have to creep over the exposed area of wood; and the same is true of a transverse cut severing the

branch, as may be seen in any properly pruned tree. The details of healing by occlusion with callus must be sought in the special works, and are important in order to understand the results due to various checks and delays in the process, which have for their consequences the formation of cankers, wood-rot, &c. Here it must suffice to point out that wounds open the way to numerous Fungi and insects incapable of penetrating sound timber, and that their occurrence in nature is due to a variety of accidents, breakage by wind, overweighting by snow, abrasions, lightning strokes, hail, the gnawing of animals, such as rabbits, rats, squirrels, &c., the rubbing of horns by cattle and deer, and all kinds of minor injuries due to small animals being among the causes. Wounds may be artificially grouped under such heads as the following: Burrows and excavations in bark and wood due to boring insects, especially beetles. Breakages and abrasions due to wind, snow, lightning, and other climatic agents. Cuts, breakages, &c., due to man and other vertebrate animals. Erosions of leaves and herbaceous parts by caterpillars, slugs, earwigs, and so forth. Frost-cracks, scorching of bark by sun and fire, &c., and wounds due to plants which entwine, pierce, or otherwise materially injure trees, &c., on a large scale.

4. *Excrescences.*—Outgrowths, more or less abnormal in character, are frequent signs of diseased organs. They are due to hypertrophy of young tissues, which may undergo profound alterations subsequently, and occur on all parts of the plants. The injury which initiates them may be very slight in the first place—a mere abrasion, puncture, or Fungus infection—but the minute wound or other disturbance, instead of healing over normally, is frequently maintained as a perennial source of irritation, and the regenerative tissues grow on month after month or year after year, resulting in extraordinary outgrowths often of large size and remarkable shape. Excrescences may be divided into those occurring on herbaceous tissues, of which *Galls* are well-known examples, and those found on the woody stem, branches, &c., and themselves eventually woody, of which *Burrs* of various kinds afford common illustrations. Among the simplest examples of the former are the hairs which follow the irritation of the cells by mites. These hairs often occur in tufts, and are so coloured and arranged that they were long taken for Fungi and placed in the "genus" *Erineum.*

Cecidia or galls arise by the hypertrophy of the subepidermal cells of a leaf, cortex, &c., which has been pierced by the ovipositor of an insect, and in which the egg is deposited. The irritation set up by the hatching egg and its resulting larva appears to be the stimulus to development, and not a poison or enzyme injected by the insect. The extraordinary forms, colours, and textures of the true galls have always formed some of the most interesting of biological questions, for not only is there definite co-operation between a given species of insect and of plant, as shown by the facts that the same insect may induce galls of different kinds on different plants or organs, while different insects induce different galls on the same plant—*e.g.*, the numerous galls on the oak—but the gall itself furnishes well adapted protection and abundant stores of nutriment to its particular larva, and often appears to be borne without injury to the plant. This latter fact is no doubt due to the production of an excess of plastic materials over and above what the tree requires for its immediate needs. Galls in the wide sense—technically *Cecidia*—are not always due to insects. The nodules on the roots of leguminous plants are induced by the presence of a minute organism now known to do no injury to the plant (see BACTERIOLOGY: *Schizomycetes*). Those on turnips and other Cruciferæ are due to the infection of *Plasmodiophora*, a dangerously parasitic Myxomycete. Nodules due to "eel-worms" (Nematodes) are produced on numerous classes of plants, and frequently result in great losses—*e.g.*, tomatoes, cucumbers, &c.; and the only too well known Phylloxera, which cost France and other vine-growing countries many millions sterling, is another case in point. Fungus-galls on leaves and stems are exemplified by the "pocket-plums" caused by the *Exoasceæ*, the black blistering swellings of *Ustilago Maydis*, the yellow swellings on nettles due to *Æcidium*, &c.

In many cases the swellings on leaves are minute, and may be termed *pustules*—*e.g.*, those due to *Synchytrium*, *Protomyces*, *Cystopus*, many Ustilagineæ, &c. These cases are not easily distinguished superficially from the pustular outgrowth of actual mycelia and spores (stromata) of such Fungi as *Nectria*, *Puccinia*, &c. The cylindrical stem-swellings due to *Calyptospora*, *Epichloe*, &c., may also be mentioned here, and the tyro may easily confound with these the layers and cushions of eggs laid on similar organs by moths. There is a class of gall-like or pustular outgrowths for which no external cause has as yet been determined, and which are therefore often ascribed to internal causes of disease. Such are the cork-warts on elms, maples, &c., and the class of outgrowths known as *Intumescences*. Recent researches point to definite external conditions of moisture, affecting the processes of respiration and transpiration, &c., as being responsible for some of these. The "scab" of potatoes is another case in point. Frost blisters are pustular swellings due to the up-growth of callus-tissue into cavities caused by the uprising of the superficial cortex under the action of intense cold.

Turning now to outgrowths of a woody nature, the well-known *burrs*, or "knaurs," so common on elms and other trees are cases in point. They are due to some injury—*e.g.*, bruising by a cart-wheel, insects—having started a callus on which adventitious buds arise, or to the destruction of buds at an early stage. Then, stores of food-material being accumulated at the injured place, other buds arise at the base of or around the injured one. If matters are propitious to the development of these buds, then a tuft of twigs is formed and no burr; but if the incipient twigs are also destroyed at an early stage, new buds are again formed, and in larger numbers than before, and the continued repetition of these processes leads to a sort of conglomerate woody mass of fused bud-bases, not dead, but unable to grow out, and thus each contributing a crowded portion of woody material as it slowly grows. There are many varieties of burrs, though all woody outgrowths of old trees are not to be confounded with them, *e.g.*, the "knees" of *Taxodium*, &c. Many typical burrs might be described as witches'-brooms, with all the twigs arrested to extremely short outgrowths. Witches'-brooms are the tufted bunches of twigs found on silver firs, birches, and other trees, and often present resemblances to birds' nests or clumps of mistletoe if only seen from a distance. They are branches in which a perennial Fungus (*Æcidium*, *Exoascus*, &c.) has obtained a hold. This Fungus stimulates the main twig to shoot out more twigs than usual; the mycelium then enters each incipient twig and stimulates it to a repetition of the process, and so in the course of years large broom-like tufts result, often markedly different from the normal.

But undoubtedly the most important of the woody excrescences on trees are *cankers*. A canker is the result of repeated frustrated attempts on the part of the callus to heal up a wound. If a clean cut remains clean, the cambium and cortical tissues soon form callus over it, and in this callus—regenerative tissue—new wood, &c., soon forms, and if the wound was a small one, no trace is visible after a few years. But the occluding callus is a mass of delicate succulent cells, and offers a dainty morsel to certain insects—*e.g.*, Aphides—and may be easily penetrated by certain Fungi such as *Peziza*, *Nectria*; and when thus attacked, the repeated conflicts between the cambium and callus, on the one hand, trying to heal over the wound, and the insect or Fungus, on the other, destroying the new tissues as they are formed, results in irregular growths: the still uninjured cambium area goes on thickening the branch, the dead parts, of course, remain unthickened, and the portion in which the Fungus is at work may for the time being grow more rapidly. Such cankers often commence in mere insect punctures, frosted buds, cracks in the cortex, &c., into which a germinating spore sends its hypha. The seriousness of the damage done is illustrated by the ravages of the larch disease, apple canker, &c.

5. *Exudations and Rotting.*—The outward symptoms of many diseases consist in excessive discharges of moisture, often accompanied by bursting of over-turgid cells, and eventually by putrefactive changes. Conditions of hyper-turgescence are common in herbaceous plants in wet seasons, or when overcrowded and in situations too moist for them. This unhealthy state is frequently combined with etiolation: what is termed rankness is a particular case, and if the factors concerned are removed by drainage, weeding out, free transpiration, &c., no permanent harm may result. With seedlings and tender plants, however, matters are frequently complicated by the onslaughts of Fungi—*e.g.*, *Pythium*, *Peronospora*, *Completoria*, *Volutella*, *Botrytis*, &c. That such over-turgescence should lead to the bursting of fleshy fruits, such as gooseberries, tomatoes, and grapes, is not surprising, nor can we wonder that fermentation and mould Fungi rapidly spread in such fruits; and the same is true for bulbs and herbaceous organs generally. The rotting of rhizomes, roots, &c., also comes into this category; but while it is extremely difficult in given cases to explain the course of events in detail, certain Fungi and bacteria have been so definitely associated with these rots—*e.g.*, beet-rot, turnip disease, wet-rot of potatoes—that we have to consider each case separately. It is, of course, impossible to do this here, but I will briefly discuss one or two groups of cases.

Honey-dew.—The sticky condition of leaves of trees—*e.g.*, lime—in hot weather is owing to exudations of sugar. In many cases the punctures of Aphides and Coccideæ are shown to be responsible for such exudations, and at least one instance is known where a Fungus—*Claviceps*—causes it. But it also appears that honey-dew may be excreted by ordinary processes of over-turgescence pressing the liquid through water-pores, as in the tropical *Cæsalpinia*, *Calliandra*, &c. That these exudations on leaves should afterwards serve as pabulum for Fungi—*e.g.*, *Fumago*, *Antennaria*—is not surprising, and the leaves of limes are often black with them.

Flux.—A common event is the exudation of turbid, frothing liquids from wounds in the bark of trees, and the odours of putrefaction and even alcoholic fermentation in these are sufficiently explained by the coexistence of albuminous and saccharine matters with Fungi, yeasts, and bacteria in such fluxes. It is clear that in these cases the obvious symptom—the flux—is not the primary one.

Some wound in the succulent tissues has become infected by the organisms referred to, and their continued action prevents healing. At certain seasons the wound "bleeds," and the organisms—some of which, by the bye, are remarkable and interesting forms—multiply in the nutritious sap and ferment it. The phenomenon is, in fact, very like that of the fermentation of palm wine and pulque, where the juices are obtained from artificial cuts.

Comparable with these cases is that of *Cuckoo-spit*, due to the juices sucked out by *Aphrophthora* on herbaceous plants of all kinds. Outflows of resin—*Resinosis*—also come under this general heading; but although some resin-fluxes are traced to the destructive action of *Agaricus melleus* in Conifers, others, as well as certain forms of Gummosis, are still in need of explanation.

Bacteriosis.—Many of the plant diseases involving rot have been ascribed to the action of bacteria, and in some cases—*e.g.*, cabbage-rot, bulb-rot of hyacinths, &c., carnation disease—the evidence supports the contention that bacteria are causally connected with the disease. It is not sufficient to find bacteria in the rotting tissues, however, nor even to be successful in infecting the plant through an artificial wound, unless very special and critical precautions are taken, and in most of the alleged cases of bacteriosis the saprophytic bacteria in the tissues are to be regarded as merely secondary agents.

(For further details the reader is referred to special works and to the article BACTERIOLOGY.)

6. *Necrosis.*—A number of diseases the obvious symptoms of which are the local drying up and death of tissues, in many cases with secondary results on organs or parts of organs, may be brought together under this heading. No sharp line can be drawn between these diseases and some of the preceding, inasmuch as it often depends on the external conditions whether necrosis is a dry-rot, in the sense I employ the term here, or a wet-rot, when it would come under the preceding category. The "dying back" of the twigs of trees and shrubs is a frequent case. The cortical tissues gradually shrink and dry up, turning brown and black in patches or all over, and when at length the cambium and medullary ray tissues dry up the whole twig dies off. This may be due to frost, especially in "thin-barked" trees, and often occurs in beeches, pears, &c.; or it may result from bruising by wind, hailstones, gun-shot wounds in coverts, &c., the latter of course very local. It is the common result of fires passing along too rapidly to burn the trees; and "thin-barked" trees—hornbeam, beech, firs, &c.—may exhibit it as the results of sunburn, especially when exposed to the south-west after the removal of shelter. The effects of frost and of sunburn are frequently quite local. The usual necrosis of the injured cortex occurs—drying up, shrivelling, and consequent stretching and cracking of the dead cortex on the wood beneath. Such frost-cracks, sun-cracks, &c., may then be slowly healed over by callus, but if the conditions for necrosis recur the crack may be again opened, or if Fungi, &c., interfere with occlusion, the healing is prevented; in such cases the local necrosis may give rise to cankers. The dying back of twigs may be brought about by many causes. General attacks of leaf-diseases invariably lead to starvation and necrosis of twigs, and similarly with the ravages of caterpillars and other insects. Drought and consequent defoliation result in the same, and these considerations help us to understand how old-established trees in parks, &c., apparently in good general health, become "stag-headed" by the necrosis of their upper twigs and smaller branches: the roots have here penetrated into subsoil or other unsuitable medium, or some drainage scheme has deprived them of water, &c., and a dry summer just turns the scale. Such phenomena are not uncommon in towns, where trees with their roots under pavement or other impervious covering do well for a time, but suddenly fail to supply the crown sufficiently with water during some hot summer.

7. *Monstrosities.*—A large class of cases of departure from the normal form, depending on different and often obscure causes, may be grouped together under this heading; most of them are of the kind termed *Teratological*, and it is difficult to decide how far they should be regarded as pathological if we insist that a disease threatens the existence of the plant, since many of these malformations—*e.g.*, double flowers, phyllody of floral parts, contortions and fascinations, dwarfing, malformed leaves, &c.—can not only be transmitted in cultivation, but occur in nature without evident injury to the variety. In many cases, however, monstrosities of flowers have been shown to be due to the irritating action of minute insects or Fungi, and others are known which, although induced by causes unknown to us, and regarded as internal, would not be likely to survive in the wild condition. This subject brings the domain of pathology, however, into touch with that of variation, and we are profoundly ignorant as to the complex of external conditions which would decide in any given case how far a variation in form would be prejudicial or otherwise to the continued existence of a species. Under the head of malformations we place cases of atrophy of parts or general dwarfing, due to starvation, the attacks of Fungi or minute insects, the presence of unsuitable food-materials, and so on, as well as cases of transformation of stamens into petals, carpels into leaves, and so forth. Roots are often flattened, twisted, and otherwise distorted by mechanical obstacles; stems by excess of food in rich soils, the attacks of minute parasites, overgrowth by climbing plants, &c. Leaves are especially apt to vary, and although the formation of crests, pitchers, puckers, &c., must be put down to the results of abnormal development, it is often difficult to draw the line between teratological and merely varietal phenomena. For instance, the difference between the long-stalked and finely-cut leaves of *Anemone* attacked with rust and the normal leaves with broad segments, or between the urceolate leaves occasionally found on cabbages and the ordinary form—in these cases undoubtedly pathological and teratological respectively—is nothing like so great as between the upper and lower normal leaves of many Umbelliferæ or the submerged and floating leaves of an aquatic *Ranunculus* or *Cabomba*. When we come to phenomena such as proliferations, vivipary, the development of "Lammas shoots," adventitious buds, epicormic branches, and to those malformations of flowers known as peloria, phyllody, virescence, &c., while assured that definite, and in many cases recognizable, physiological disturbances are at work, we find ourselves on the borderland between pathological and physiological variation, where each case must be examined with due regard to all the circumstances, and no generalization seems possible beyond what has been sketched. This is equally true of the phenomena of apogamy and apospory in the light of recent researches into the effects of external conditions on reproduction.

In conclusion, this sketch of an enormous subject shows us that the pathology of plants is a special department of the study of variations which threaten injury to the plant, and passes imperceptibly into the study of variations in general. Moreover, we have good reasons for inferring that different constellations of external causes may determine whether the internal physiological disturbances induced by a given agent shall lead to pathological and dangerous variation, or to changes which may be harmless or even advantageous to the plant concerned. This position seems fully warranted by the recent progress of œcology and the study of the influence of external conditions on plants in a state of nature, and especially by what we now know of symbiosis, artificial cultures, grafting, and cross-breeding.

Patiala, or PUTTIALA, a native state of India, within the Punjab. Area, 5951 square miles; population (1881), 1,467,433; (1891), 1,583,521; (1901), 1,586,030, showing an increase of 8 per cent. between 1881 and 1891, but of less than ·2 per cent. between 1891 and 1901; average density, 266 persons per square mile; estimated gross revenue, Rs.68,54,000; military force (including police), 8673 men; no tribute. The late maharaja, who died in 1900, was devoted to riding and sport. He personally took part in the Tirah campaign of 1897–98 with a battalion of his own Imperial Service infantry and a field troop of Imperial Service lancers. In recognition of his services on this occasion he received the G.C.S.I. The financial administration of the state is not altogether satisfactory. It is crossed by two lines of railway, and irrigated by the Sirhind canal and its branches. In 1896–97 the total number of schools was 186, attended by 9197 pupils, of whom 479 were girls; the proportion of boys at school was 1 to every 94 of the total male population. There is one college, with 86 students (including 52 in the Oriental department), of whom 13 passed university examinations; also thirteen Anglo-vernacular schools, with 2268 pupils, of whom 14 matriculated. The town of PATIALA is situated in 30° 20′ N. and 76° 25′ E., and has a station on the branch railway from Rajpura to Bhatinda. Population (1891), 55,785.

Patmore, Coventry Kersey Dighton (1823–1896), English poet and critic, the eldest son of Peter George Patmore, himself an author, was born at Woodford in Essex, 23rd July 1823. He was privately educated, being his father's intimate and constant companion, and derived from him his early literary enthusiasm. It was his first ambition to become an artist, and he showed much promise, being awarded the silver palette of the Society of Arts in 1838. In the following year he was sent to school in France, where he studied for six months, and began to write poetry. On his return his father contemplated the publication of some of these youthful poems; but in the meanwhile Coventry had evinced a passion for science, and the poetry was set aside. He soon, however, returned to literary interests, moved towards them by the sudden success of Tennyson; and in 1844 he published a small volume of *Poems*, which was not without individuality, but marred by inequalities of workmanship. It was widely criticized, both in praise and blame; and Patmore, distressed at its reception, bought up the remainder of the edition and caused it to be destroyed. What chiefly wounded him was a cruel review in *Blackwood*, written in the worst style of unreasoning abuse; but the enthusiasm of private friends, together with their wiser criticism, did much to help him and to foster his talent. Indeed, the publication of this little volume bore immediate fruit in introducing its author to various men of letters, among whom was Dante Gabriel Rossetti, through whose offices Patmore became known to Mr Holman Hunt, and was thus drawn into the eddies of the Pre-Raphaelite movement, contributing his poem "The Seasons" to *The Germ.* At this time Patmore's father became involved in financial embarrassments, which obliged the son to adopt some professional calling; and in 1846 Monckton Milnes secured him an assistant-librarianship in the British Museum, a post which he occupied industriously for nineteen years, devoting his spare time to poetry. In 1847 he married Emily, daughter of Dr Andrews of Camberwell. At the Museum he was austere and remote among his companions, but was nevertheless instrumental in 1852 in starting the Volunteer movement. He wrote an important letter to *The Times* upon the subject, and stirred up much martial enthusiasm among his colleagues. In the next year he republished, in *Tamerton Church Tower*, the more successful pieces from the *Poems* of 1844, adding several new poems which showed distinct advance, both in conception and treatment; and in the following year (1854) appeared the first part of his best known poem, "The Angel in the House," which was continued in "The Espousals" (1856), "Faithful for Ever" (1860), and "The Victories of Love" (1863). In 1862 he lost his wife, after a long and lingering illness, and shortly afterwards joined the Roman Catholic Church. In 1865 he married again, his second wife being Miss Mariane Byles, second daughter of James Byles of Bowden Hall, Gloucester; and a year later purchased an estate in East Grinstead, the history of which may be read in *How I managed my Estate*, published in 1886. In 1877 appeared *The Unknown Eros*, which unquestionably contains his finest work in poetry, and in the following year *Amelia*, his own favourite among his poems, together with an interesting, though by no means undisputable, essay on *English Metrical Law.* This departure into criticism he continued further in 1879 with a volume of papers, entitled *Principle in Art*, and again in 1893 with *Religio Poetæ.* Meanwhile his second wife died in 1880, and in the next year he married Miss Harriet Robson. The last years of his life were spent at Lymington, where he died 26th November 1896. A collected edition of his poems appeared in two volumes in 1886, with a characteristic preface which might serve as the author's epitaph. "I have written little," it runs; "but it is all my best; I have never spoken when I had nothing to say, nor spared time or labour to make my words true. I have respected posterity; and should there be a posterity which cares for letters, I dare to hope that it will respect me." The obvious sincerity which underlies this statement, combined with a certain lack of humour which peers through its naïveté, points to two of the principal characteristics of Patmore's earlier poetry; characteristics which came to be almost unconsciously merged and harmonized as his style and his intention drew together into unity. Earnestness of view and purpose marks every line which he wrote; and yet a rather keener appreciation of the unpoetic aspects of a too naked simplicity would have saved him from many of those sublimations of the trivialities of life which have already begun to seem old-fashioned, and were, indeed, never in the fashion of high poetry at all. But when Patmore is not occupied with the railway guard and the shop assistant, and when he discards pure narrative for philosophic reflection, he is a poet of the first and indisputable rank. His initial misfortune was that of subject, commonplace married life not being a topic rich in poetic opportunities; in particular, to one who saw details with Patmore's minuteness the theme was particularly dangerous. But in the higher flights, to which he arose as his practice in the art grew perfected, he is always noble and often sublime. His best work is found in the volume of odes called *The Unknown Eros*, which is full not only of passages but of entire poems in which exalted thought is expressed in poetry of the richest and most dignified melody. The animating spirit of love, moreover, has here deepened and intensified into a crystalline harmony of earthly passion with the love that is divine and transcending; the outward manifestation is regarded as a symbol of a sentiment at once eternal and quintessential. Spirituality informs his inspiration; the poetry is of the finest elements, glowing and alive. The magnificent piece in praise of winter, the solemn and beautiful cadences of "Departure," and the homely but elevated pathos of "The Toys," are in their various manners unsurpassed in English poetry for sublimity of thought and perfection of expression. Patmore is one of the few Victorian poets of whom it may confidently be predicted that the memory of his greater achievements will outlive all consideration of occasional lapses from taste and dignity. He wrote, at his best, in the grand manner, melody and thought according with perfection of expression, and his finest poems have that indefinable air of the inevitable which is after all the touchstone of the poetic quality. (A. WA.)

Patna, a city, district, and division of British India, in the Behar province of Bengal. The city lies on the right bank of the Ganges, a little distance below the confluence of the Soane and the Gogra, and opposite the confluence of the Gandak; it has a railway station, 332 miles north-west of Calcutta. Including the civil station of Bankipur to the west, the city stretches along the river bank for nearly 9 miles. Still farther west is the military cantonment of Dinapur. Municipal area, 6184 acres; population (1881), 170,654; (1891), 165,192; (1901), 135,172. One of the most interesting buildings in the city is the huge *gola*, or storehouse for grain, constructed in 1786, but never seriously used. Patna is the headquarters of the Government opium agency, where the drug grown throughout Behar is prepared for the Chinese market. Government College, founded in 1862, had 188 pupils in 1896–97. Other educational institutions include collegiate and *zilla* high schools, with 558 pupils; a law class, with 32 students; the Temple medical school, with 132 students, of whom 4 were women; the Behar school of engineering, organized in 1897, with 194 students; a normal school, with 51 students. There are nine printing-presses, most of which issue a newspaper either in English or in the vernacular, and there is an Oriental public library.

The district of PATNA has an area of 2076 square miles; population (1881), 1,751,834; (1891), 1,772,352; (1901), 1,623,856, showing an increase of only 1 per cent. between 1881 and 1891, but a decrease of 8·4 per cent. between 1891 and 1901; average density, 782 persons per square mile. Classified according to religion, Hindus in 1891 numbered 1,568,131; Mahommedans, 201,106; Christians, 2833, of whom 1662 were Europeans; "others," 282. The land revenue and rates in 1897–98 were Rs.17,17,939; number of police, 1325; boys at school (1896–97), 43,895, being 33·8 per cent. of the male population of school-going age; registered death-rate (1897), 31·92 per thousand. The district is traversed throughout by the main line of the East Indian Railway (84 miles), with a branch south to Gaya.

The division of PATNA extends across both sides of the Ganges. It comprises the seven districts of Patna, Gaya, Shahabad, Saran, Champaran, Muzaffarpur, and Darbhangarh. Total area, 23,675 square miles; population (1891), 15,811,014.

Patna, a feudatory state of India, in the Chhattisgarh division of the Central Provinces. Area, 2399 square miles; population (1881), 257,959; (1891), 332,197; (1901), 277,566; average density, 134 persons per square mile; estimated revenue, Rs.1,47,000; tribute, Rs.8500. The chief is a rajput of high lineage, whose ancestors formerly ruled over a large territory. The state was for many years under British administration, and the present chief was educated at the Rajkumar College.

Paton, Sir Joseph Noel (1821–1901), British painter, was born, on 13th December 1821, in Woolers Alley, Dunfermline, where his father, a fellow of the Scottish Society of Antiquaries, carried on the trade of a damask manufacturer. He showed strong artistic inclinations in early childhood, but had no regular art training, except a brief period of study in the Royal Academy School in 1843. He gained a prize of £200 in the first Westminster Hall competition, in 1845, for his cartoon, "The Spirit of Religion," and in the following year he exhibited at the Royal Scottish Academy his "Quarrel of Oberon and Titania" (see Plate). A companion fairy picture, "The Reconciliation of Oberon and Titania" (see Plate), went to Westminster Hall in 1847, and for it and his picture of "Christ bearing the Cross" he was awarded a prize of £300 by the Fine Arts Commissioners. The two Oberon pictures are in the National Gallery of Scotland, where they have long been a centre of attraction. His first exhibited picture, "Ruth Gleaning," appeared at the Royal Scottish Academy in 1844. He began to contribute to the Royal Academy of London in 1856. Throughout his career his preference was for allegorical, fairy, and religious subjects. Among his most famous pictures are "The Pursuit of Pleasure" (1855), "Mors Janua Vitæ" (1866), "Oskold and the Ellé-maids" (1874), and "In Die Malo" (1882). Sir Noel Paton also produced a certain amount of sculpture, more notable for design than for searching execution. He was elected an associate of the Royal Scottish Academy in 1847, and a full member in 1850; he was appointed Queen's Limner for Scotland in 1866, and received knighthood in 1867. In 1878 the University of Edinburgh conferred upon him the degree of LL.D. He was a poet of distinct merit, as his *Poems by a Painter* (1861) and *Spindrift* (1867) pleasantly exemplified. He was also well known as an antiquary, his hobby, indeed, being the collection of arms and armour. Sir Noel died in Edinburgh on the 26th of December 1901.

Patras (Greek, *Patrai*), the chief fortified seaport town on the west coast of Greece, and chief town of the province of Achaia and Elis, on a gulf of the same name, 70 miles west-north-west of Corinth. It has been rebuilt since 1821 (the War of Liberation), and is the seat of a Greek archbishop and an appeal court. It has a citadel and castle, and is the chief port of Greece, from which the great bulk of its currants are despatched. The port, formed by a mole and a breakwater, offers a fair harbour for vessels drawing up to 22 feet. The exports consist of currants, sultanas, valonea, tobacco, olive oil, olives in brine, figs, citrons, wine, brandy, cocoons, and lamb, goat, and kid skins. The imports consist chiefly of colonial produce, manufactured goods, and sulphate of copper. There are two railway stations, one in the north-east on the line to Athens (*viâ* Corinth), the other on the line to Pyrgos. Population (1889), 33,529; (1896), 37,958.

Patti, a town and episcopal see of the province of Messina, Sicily, Italy, 43 miles west by south of Messina by the north coast railway to Palermo, one mile from the shore of the Gulf of Patti. It has a modern cathedral, and silk and olive-oil mills, lime-kilns, sandstone quarries,

"The Quarrel of Oberon and Titania." By Sir J. Noel Paton.

"The Reconciliation of Oberon and Titania." By Sir J. Noel Paton.

(*The National Gallery, Edinburgh.*)

flour-mills, terra-cotta works, and tunny fishing. A little to the east are the ruins of the ancient city of *Tyndaris*. Population (1881), 7612; (1899), 9500.

Patti, Adelina (Baroness Cederström), the famous vocalist, daughter of an Italian, Salvalin Patti, was born at Madrid, 19th February 1843. Gifted with a fine soprano voice, she was trained in America under Maurice Strakosch, her brother-in-law, and made her first appearance as Lucia in *Lucia di Lammermoor* in New York in 1859. Her marvellous execution and brilliant singing at once made her famous. In 1861 she sang in *La Sonnambula* at Covent Garden, and from this time she became the leading operatic *prima donna*, her appearances in London, Paris, and the other principal musical centres being a long succession of triumphs, and her *rôles* covering all the great parts in Italian opera. In 1868 she married the marquis de Caux, from whom she was divorced in 1885; she then married Nicolini, the tenor, who died in 1898; and in 1899 she became the wife of Baron Cederström, a Swede, who was naturalized as an Englishman. Madame Patti ceased to appear on the operatic stage in public after the 'eighties, but at Craig-y-Nos, her place in Wales, she built a private theatre, and her occasional appearances for enormous fees at concerts at the Albert Hall continued to attract enthusiastic audiences, her singing of "Home, Sweet Home" becoming peculiarly associated with those events. Partly owing to her fine original training, partly to her splendid method, and partly to her avoidance of Wagnerian *rôles*, Madame Patti wonderfully preserved the freshness of her voice and her beautiful execution, and she will be remembered as, after Jenny Lind, the greatest singer of the 19th century.

Pattison, Mark (1813–1884), rector of Lincoln College, Oxford, born 10th October 1813, was the son of the rector of Hauxwell, Yorkshire, where he spent his younger days, being privately educated by his father. His youngest sister was the well-known Sister Dora. In 1832 he matriculated at Oriel College, where he took his B.A. degree in 1836 with second-class honours. After failing four times to obtain a fellowship, he was elected in 1839 to a Yorkshire fellowship at Lincoln, an anti-Puseyite College, then described as "low and slow." Pattison was at this time a Puseyite, and greatly under the influence of J. H. Newman, for whom he worked, translating *Aquinas*, and writing in the *British Critic* and *Christian Remembrancer*. He was ordained priest in 1843, and in the same year became tutor of Lincoln College, where he rapidly made a reputation as a clear and stimulating teacher and as a sympathetic friend of youth. The management of the college was practically in his hands, and his reputation as a scholar became high in the University. In 1851 the rectorship of Lincoln became vacant, and it seemed certain that Pattison would be elected, but he lost it by a disagreeable intrigue. The disappointment was acute, and his health suffered. In 1855 he resigned the tutorship, travelled in Germany to investigate Continental systems of education, and began his researches into the lives of Casaubon and Scaliger, which occupied the remainder of his life. In 1861 he was elected rector of Lincoln, marrying in the same year Emilia Frances Strong (afterwards Lady Dilke). The rector contributed largely to various reviews on literary subjects, and took a considerable interest in social science, even presiding over a section at a congress in 1876. The routine of university business he avoided with contempt, and refused the vice-chancellorship. But while living the life of a student, he was fond of society, and especially of female society. He was a keen fisherman, and interested in Nature. He died on the 30th of July 1884 at Harrogate, where he was buried. His principal works are *Isaac Casaubon*, 1875; *Milton*, in Macmillan's English Men of Letters series, 1879. The 18th century, alike in its literature and its theology, was a favourite study, as is illustrated by his contribution to the once famous *Essays and Reviews* (1860), and by his edition of Pope's *Essay on Man* (1869), &c. His *Sermons* and *Collected Essays* were published posthumously, as well as the painfully interesting *Memoirs*, an autobiography deeply tinged with melancholy and bitterness. His projected *Life of Scaliger* was never finished. Mark Pattison possessed an extraordinary distinction of mind. He was a true scholar, who lived entirely in the things of the intellect. He writes of himself, excusing the composition of his memoirs, that he has known little or nothing of contemporary celebrities, and that his memory is inaccurate: "All my energy was directed upon one end —to improve myself, to form my own mind, to sound things thoroughly, to free myself from the bondage of unreason. . . . If there is anything of interest in my story, it is as a story of mental development" (*Memoirs*, pp. 1, 2). He was never satisfied with his work: "It is impossible," he writes, "for me to see anything done without an immediate suggestion of how it might be better done" (*Memoirs*, p. 254). His aim was purely intellectual; he says of himself in 1857, "My ideal at this time was polluted and disfigured by literary ambition" (*Memoirs*, p. 309). Again, he says: "Since the year 1851, I have lived wholly for study. There can be no vanity in making this confession, for, strange to say, in a university ostensibly endowed for the cultivation of science and letters such a life is hardly regarded as a creditable one" (*Memoirs*, p. 331). The *Memoirs* is a morbid book, and Mark Pattison is merciless to himself throughout. He certainly cherished a rare and unique ideal, which he pursued through disappointments which nearly unhinged his mind. It is evident from his *Memoirs* that he carried rationalism in religion to an extent that seems hardly consistent with his position as an ordained minister of the English Church. (A. C. Be.)

Pau, chief town of the department of Basses-Pyrénées, France, 470 miles south-south-west of Paris, on the railway from Toulouse to Bayonne. A winter palace was erected in 1896 in Beaumont Park (24 acres), at the east end of the town. A statue of Maréchal Bosquet was unveiled in 1894. Pau is the seat of a Court of Appeal for the departments Basses- and Hautes-Pyrénées and Landes. It has a library of 55,000 volumes, and a museum. Population (1881), 25,734; (1901), 30,811.

Pauli, Georg Reinhold (1823–1882), German historian, was born in Berlin, 25th May 1823. After an education at Berlin and Bonn Universities, he went to England in 1847, and before long was immersed in the study of English literature and history. From 1850 to 1852 he acted as private secretary to the Prussian ambassador in London. In 1851 he published his *König Aelfred und seine Stelle in der Geschichte Englands*, a work which aroused considerable interest and was translated into English in the following year. On his return to Germany in 1855 he was for a short time at the University of Bonn as *privat-docent*, and subsequently at Rostock from 1857 to 1859, and at Tübingen from 1859 to 1867 as professor of history. His political convictions, which strongly favoured the Prussians, were the cause of his removal from Tübingen to Marburg in 1867. From there he went, in 1870, to Göttingen, where he filled the chair of history till his death. He was an enthusiastic and successful teacher, and may be said to have founded the school of historical research with which Sir John Seeley's reputation is associated in England. Besides the work on King Alfred mentioned above, his chief publications were a continuation in three volumes of Lappenberg's *Geschichte von England* (1853–58); *Bilder aus Alt-England* (1860); three volumes, dealing with the history of England from 1815 to 1852, in the *Staatengeschichte der neueren Zeit; Simon de Montfort* (1867); *Aufsätze zur englischen Geschichte*, 2 series (1869, 1883). His historical researches gained him honorary degrees from the Universities of Oxford and Edinburgh. He died at Bremen, 3rd June 1882. (R. F. S.)

Paulicians.—An important Oriental sect, probably named after Paul of Samosata. Their older name was Pauliani; the form *Paulicians* is from an Armenian diminutive meaning "contemptible Paul," as *Manichean* from Manes. Paul was bishop of Antioch from *c.* 260 to 268, and was affected by the Jewish tone, which spread from the Jewish population of Antioch, and long influenced the Christians there. He taught what is now called Adoptionist Monarchianism, *i.e.*, a form of unitarianism which denied that Jesus is God incarnate, but held that at His baptism He was made a partial sharer of the divine nature, and thus the adopted son of God. Opinions like those of Paul were held earlier by the Ebionites, and were introduced at Rome *c.* 190. Recent attempts to trace them in Palestine to the apostolic age, or in Rome before 190, rest merely on conjecture or error. Paul's teaching spread among the Syrians. The *Acts of Archelaus*, *c.* 300, represent a Syriac-speaking bishop of Karkhar upholding it against the views of Manes.

The followers of Paul are mentioned by the council of Nicaea and Athanasius (4th century); Innocent I., Augustine, Theodoret (5th century). For a long time they are no more heard of: when they reappear it is as a religious sect in or near Armenia (see *Ency. Brit.*, 9th ed., vol. xviii. p. 433). We learn of it from various Armenian and Greek writers. Among the latter are Photius (*c.* 850) and his contemporary, Peter Siculus, and Georgius Monachus (especially the Madrid MS.): all these use one older document, now lost. About 654 the Armenian "Catholicos" Nerses tried to suppress it; about the same date Constantine Silvanus was born, and preached Paulicianism with success at Cibossa. In 719 the Armenian, John of Otzun, spoke and wrote against it. Evidence contradicts the recent theory that the earliest Armenian church was Paulician, but from the 5th century there was a nationalist anti-Greek Armenian Christianity which opposed the Armenian Church. Out of this tendency Smbat, *c.* 840, organized a strong Paulician sect, named Thonraki from the region of Thonrak, where he laboured. It is hard to determine the exact nature of his teaching. Old writers describe the Paulicians as Manichean. On the other hand, the *Key of Truth*,[1] the only known Paulician book (Armenian) is not Manichean, but Adoptionist. Nevertheless, as the Armenian Paulicians hated infant baptism, perhaps deferred communion till old age, rejected the ministry and ritual of the Church, gave divine honours to their "elect," "anointed ones," or ministers, denied that Christ is God while they worshipped Him, and apparently denied that He took His flesh really of Mary, it is not strange that the Greeks confused them with the Manicheans. According to the *Key*, Jesus Christ "in the season of His maturity . . . received baptism . . . received authority, received the priesthood, received the kingdom and the office of chief shepherd. Moreover, He was then chosen, then He won lordship . . . then He became the chief of beings heavenly and earthly, then He became the light of the world, then He became the way, the truth, and the life." And the fact that their teaching incorporates many Catholic survivals, such as a trine affusion in baptism, and that they made use of the Armenian authorized version of the New Testament and not the older version, shows clearly that their position is a "protestant" one—*i.e.*, that it is a reaction against and a dissension from a developed ecclesiastical system, not a primitive type which has survived side by side with a later development. About 750 Constantine Copronymus, himself probably a Paulician, removed many from Armenia to Thrace as a barrier against the Slavs. Later Byzantine rulers persecuted them. From 845 to 880 they fought desperately, and, joining with the Moslems, plundered Asia Minor. In 874 Tephricé, their stronghold, was taken by the emperor Basil. About 980 many were moved to Thrace by John Zimisces to prevent an alliance between the Paulicians and the Moslems. About 1110 the Thracian Paulicians were harried by Alexius Comnenus for deserting him in war. At the end of the 17th century they lingered in the valleys of Haemus. In 1717 Lady Mary Wortley Montagu found some at Philippopolis. By 1819 the last Thracian Paulicians had become Roman Catholics. That they greatly influenced the Bulgarian Manicheans, known as Bogomils, who arose *c.* 950, and through them the Western movements of the Cathars and the Albigenses, seems to be indicated by the fact that not a few of their beliefs and practices were held in common—*e.g.*, their eucharistic doctrine and the worship offered to their "anointed ones."

In the East they survived later. After the Russo-Turkish war of 1828–29 a body of Thondraketzi (Thonraki), who had left their homes in the Turkish canton of Khnus, settled in the village of Arkhivêli, in the newly-acquired Russian territory between Akhaltzik and Erivan. Here they were before long subjected to persecution by the authorities of the Armenian Church; and in 1837, in the course of the persecution, the *Key* (in which they said "everything was written") was taken from them, having been mutilated previously in order to hide some of the more objectionable tenets, and deposited in the library of the Holy Synod at Etchmiadzin, where Mr Conybeare found it. According to its colophon, it was "written [*i.e.*, it would appear, copied, for the substance of the book must be much earlier] in the province of Taron in the year of the Lord 1782"; and the evidence of five Paulician witnesses tells us that it was "composed" by an Armenian priest Ohannes (John) who had joined the sect, and who subsequently, under pressure from the government, became a Mahommedan. The Paulicians still existed in 1845, since which date they have been unmolested, and have probably died out. Mr H. F. B. Lynch (*Armenia, Travels and Studies*, London, 1901, i. 285) asserts that those who survived have been absorbed by the American Protestant missions in Armenia, but gives no authority for the statement.

For authorities see Professor Bury's edition of Gibbon's *Decline and Fall of the Roman Empire*, vol. vi., appendix 6. But Professor Bury copies the mistake of Mr Conybeare in calling the *Shepherd of Hermas* Adoptionist. See also A. LOMBARD, *Pauliciens, Bulgares, et Bons-Hommes en Orient et en Occident*, Geneva and Basel, 1879. (L. P.; W. E. Co.)

Pauline Epistles.—The familiar grouping of the Pauline Epistles, (1) 1 and 2 Thessalonians, (2) Galatians, 1 and 2 Corinthians, Romans, (3) Colossians, Philemon, Ephesians, Philippians, (4) Pastorals, may help in considering this subject in regard to the later research on (*a*) authenticity, (*b*) date, (*c*) contents.

[1] Edited by F. C. Conybeare (Oxford, 1898). Much of the introduction is seriously marred by the editor's slight acquaintance with Greek theology.

(*a*) Recent attacks upon the generally received second group (the *Hauptbriefe*) are mainly confined to a school of Dutch theologians, as isolated attacks elsewhere can scarcely be credited to a "school" (Holtzmann, *Einleitung*[3], p. 183; Clemen, *Chronologie der Paulinischen Briefe*, p. 30). Van Manen, chief representative of this hypercritical movement, has set forth his views in the *Expository Times*, 1898; *Encycl. Bibl.* iii.; and more especially in the three parts of his *Paulus*. But as he maintains that these Epistles, as well as the rest referred to Paul, are pseudepigrapha dating at least from the close of the 1st century, we cannot be surprised that the positive external evidence of Clement of Rome, *Corinthians*, xlvi. (Salmon, *Introd.*, 36o, and so Schmiedel, *Encycl. Bibl.* ii., "Galatians"), is entirely disregarded, to say nothing of that of other writers, and that Clement is relegated "at any rate to the 2nd century." But if an imposing array of names may fairly be quoted for the *Hauptbriefe*, similar strong testimony accepts 1 Thessalonians (Holsten, only notable exception), Philemon, Philippians, and, with a few interpolations, Colossians (Clemen, *u.s.* p. 37; Weiss, *Einleitung*, p. 149). In group 1, 2 Thessalonians was rejected by advanced critics, until it became almost an axiom to accept 1 Thessalonians and not 2 (see Holtzmann, *Zeitschrift für die neutest. Wissenschaft*, ii., 1901). But Jülicher, if he does not positively accept 2 Thessalonians, regards the doubts raised against it as not insurmountable (*Einleitung*, pp. 34, 40), whilst in England Dr J. Drummond (*International Handbooks*, 1899) accepts it at least provisionally, and in America Bacon (*Introd.* 75; cf. also Moffatt, *Historical N. T.*, p. 144 ff.).

Authenticity.

The chief objection alleged is the representation of the Man of Sin. Not only, however, is it unlikely that a forger would introduce a passage so unlike anything in Paul's writings, but no one has defended the Epistle more acutely than Clemen in maintaining that the Apostle might easily have derived his picture from Jewish sources (so Jülicher), although the Jewish *traditional* element may be pushed too far (cf. Bousset, *Der Antichrist*; Charles, *Ascension of Isaiah*, Introd.; and on the other hand, Askwith, *Introduction to Thessalonians*, 1902).

Of Ephesians and Colossians, Arnold Meyer writes that the recent criticism of Jülicher and Harnack is much more friendly than that of Weizsäcker and others (*Die moderne Forschung über die Geschichte des Urchristentums*, p. 39, 1898), and admits that a much earlier stage of Gnosis is represented than that of the great Gnostic systems, whilst English readers will remember that the specious appeal to advanced Gnosticism was repudiated by Dr Hort in tracing the Colossian heresy to Jewish soil and influences (Hastings, *B. D.*, "Colossians," and for additional influences Ramsay, "Colossæ"). No criticism of any wide acceptance reckons Philemon spurious, although Van Manen would refer it to some unknown writer, A.D. 125–130. But he has no word of explanation as to how the epistle found a place some ten years later in the heretic Marcion's canon. But Philemon carries with it Colossians, and if Colossians is Paul's, "the subtle intricacies of likeness and unlikeness between it and Ephesians are a peculiarly strong kind of evidence for identical authorship" (Hort, *Proleg. to Ephesians*, 168; Robertson, *B. D.*[2] (Smith), "Ephesians"; Harnack, *Chron.* i. 239).

Group 4 Clemen ranks as "doubtless unauthentic" with the majority of advanced critics. But Ramsay, by his searching inquiry into the historical position which the Pastorals presuppose, maintains that their tone is inconsistent with a late date; the undeveloped type of persecution which they represent cannot be referred to the middle of the 2nd century, or to the formulated persecutions of the 1st (*C. R. E.* 246, 345, Weiss, Meyer's *Kommentar*, p. 40, 1894).

Another adverse argument is weakened by the fact that much of the language formerly regarded as characteristic of the 2nd century may be referred to early Jewish sources, *e.g.*, the reference of "endless genealogies" to pseudo-Philo's *Book concerning Biblical Antiquities* (before A.D. 70); Dr James, *N. T. Apocrypha*, Church Congress, 1898; Hort, *Judaistic Christianity*, p. 130. From another point of view such references are of value, because, whilst in our best commentaries it is usual to illustrate freely from contemporary and other Jewish documents, these and similar illustrations mark not only comparisons, but also contrasts (see, *e.g.*, Charles, *Apoc. of Baruch*, Introd.).

A peculiar stumbling-block to the rejection of these Epistles lies in their abundance of personal notices (Zahn, *Einleitung*, ii. 457; Salmon, *Introd.* 409; and Weiss, *Einleitung*[3], p. 304). It is difficult to see why a later writer should introduce these, since he ran the serious risk of making some fatal mistake; but if, as genuine Pauline fragments, they were introduced into letters the avowed aim of which was to secure the healthful development of the Church, it is evident that, as they are not in themselves connected with this aim, they could only have been designedly inserted to palm off the letter in which they occur as the work of Paul. In such case the language of Weiss, *u.s.*, will not seem too strong.

The acceptance of the Pastorals naturally implies a liberation and second imprisonment, as the attempts to fit them into an earlier part of Paul's life have not been successful (Steinmetz, *Die zweite römische Gefangenschaft des Apostels Paulus*, 121, 1897). Mr Vernon Bartlet has lately made an ingenious attempt in this direction (*Apostolic Age*, 198); *e.g.*, he asks us to transfer 2 Timothy iv. 20 to the close of 1 Timothy as a postscript, and to suppose that the reference to Trophimus is connected with the voyage from Miletus to Jerusalem, Acts xx. 21. Trophimus falls sick at the last moment, and could not sail with Paul from Miletus, and Paul refers to this in 1 Timothy—a letter written on board ship to his son in the faith at, or soon after leaving, Miletus. But Trophimus, it would seem, was certainly at Jerusalem very soon after, Acts xxi. 29, and on Mr Bartlet's theory it is difficult to see any sense in such a notice as 1 Timothy iii. 14, which he apparently admits to be from Paul. If Paul, Acts xx. 25, had just told the Ephesian elders that they should see his face no more, upon which Mr Bartlet insists (p. 201), it is difficult to believe that he had no sooner left Miletus than he writes to Timothy at Ephesus (p. 180) that he hopes to come unto him shortly. Moreover, the positive evidence for Paul's release and subsequent labours cannot be calmly ruled out of court. Amongst moderns Spitta and Harnack accept it, and both lay stress upon the fact that in Clem. Rom., *Cor.* v. 7, "the limit of the West" could not be used of Rome by one writing in Rome (cf. Ramsay, *St Paul*, 455; Zahn, *u.s.*, p. 448).

(*b*) With regard to *dates*, Clemen, in accordance with his view of development of Pauline thought, placed 1 and 2 Thessalonians, 47, 48, *before* the Apostolic Council (see below), while Harnack places them 48, 49 (47, 48), and McGiffert, c. 48, in accordance with their early chronology, but *after* the Council. The greatest diversity of opinion gathers round Galatians. McGiffert places it earliest of the Epistles, at Antioch, before the second missionary journey, whilst Rendall, holding with McGiffert the South Galatian theory, maintains that it was written during this journey, at Corinth. Mr V. Bartlet would apparently place it earlier still, either on Paul's way to Jerusalem for the Council or during the dispute at Antioch with the Judaizers before the Council. These writers thus agree in so far that they rank Galatians earliest. In Germany Prof. V. Weber, the fullest advocate of the South Galatian theory and of the identification of Gal. ii. with Acts xi. 30, places Galatians earliest, in 49, during the period Acts xiv. 28; and he is now followed by Belser, *Einleitung*, pp. 170, 436 ff., 1901. Zahn also places it earliest, but in the beginning of 53, and 1, 2 Thessalonians within the first half of the year, these three Epistles thus forming his first group. He too, holding the South Galatian theory for the Epistle, dates it with Rendall from Corinth, and both writers consider vi. 17 a reference to the scourging at Philippi, of which Paul still bore the scars. Ramsay, however,

Date.

gives strong reasons for placing Galatians later in Paul's life, at Antioch, at the close of the second journey. The most remarkable change of opinion in favour of the early date of Galatians is that of Clemen, who, after placing it subsequent to Romans (1897), now considers it the earliest of all, in view of the South Galatian theory, placing it in the second missionary journey before 1 and 2 Thess.; on this cf. *Theol. Rundschau*, 12, 1901.

The inquiry gains additional interest from Mr Askwith's discussion (*Galatians*, 1899) of points at issue between Ramsay and Lightfoot, and his contention that the later date assigned by the latter, during the third missionary journey, need not interfere with maintaining the South Galatian theory. The later date is adopted by Lightfoot chiefly from similarity of style and language between Galatians and Romans, but undoubted resemblance of language between two writings does not of necessity involve any certain inference as to date (Sanday and Headlam, *Romans*, xxxviii.). Sieffert (Meyer's *Kommentar*, 1899) follows most Continental critics, placing Galatians first in the second group, but, as an upholder of the North Galatian theory, in the third journey, at Ephesus, 54–55. There is no reason, he argues, for assigning a later date because of the developed teaching on justification, since the essential features of that doctrine belong so inseparably to the foundations of Paul's Gentile Gospel that they must have been early fixed, and would find at different times a kindred representation. It is not surprising that Harnack should find it impossible to assign any date precisely; see further Hastings, *B. D.*, "Galatians." Halmel (1895) stands almost alone in supporting the view, once widely held, that Galatians was written in Rome, or elsewhere in Italy, because of the terms of Roman law. But Sieffert (p. 24) points out that in the Roman provinces there were numbers of Roman citizens, and the Roman legal rights would be widely known amongst other provincials; and still more strikingly Ramsay maintains that the peculiar legal procedures are applicable to South Galatian cities of the first missionary journey, in which Seleucid and Greek law, not Roman law, prevailed (*Galatians*, p. 370).

In group 3 Philippians is now often placed last (first, by Lightfoot). Ramsay maintains that Paul's trial had begun, and favourably; hence the undercurrent of hope and eagerness for the issue (*St Paul*, 357). From this standpoint Mommsen's interpretation of i. 13 as the supreme imperial court carries weight: before these judges Paul had appeared, his bonds became manifest in Christ, sympathy was awakened, inasmuch as he is no longer regarded as a dangerous seditious leader, a sympathy corroborated perhaps by the greetings, iv. 22.

In i. 7 two legal terms afford confirmatory evidence, ἀπολογία, βεβαίωσις, whilst i. 14 (Job xiii. 6, LXX.) indicates speedy deliverance from imprisonment (Zahn, *Einleitung*, i. 380, although differing from Mommsen; Kennedy, *Expository Times*, 1898; R. R. Smith, *Epistle of the Trial*, 1899; Belser, *Einleitung*, p. 570, 1901).

Contents.

(*c*) With regard to the *contents* of these Epistles, recent criticism strengthens the subtle but undesigned coincidences with Acts. In group 1, topics referred to in Thessalonian Epistles may well have given colour to the charge of proclaiming "another Emperor," Acts xvii. 7, in Thessalonica (Findlay, *Paul;* Hastings, *B. D.*, and, further, McGiffert, *Apostolic Age*, 246). In *Commentary on Galatians*, p. 399, Ramsay strikingly enumerates many coincidences between this Epistle and the address at Pisidian Antioch, Acts xiii., and thus affords additional support to the South Galatian theory. The stress laid upon the collection for the saints, so marked in these Epistles of group 2, and the fuller recognition of its importance in creating a deeper sense of Church unity, give fresh vividness to Paley's argument from undesigned coincidences, Acts xxiv. 7, Romans xv. 25 ff.; whilst the tone of apprehension with which Paul regarded his final visit to Jerusalem fitly agrees with the sense of danger, Romans xv. 30, 31 (also emphasized by Paley) (Hort, *Proleg. to Romans*, 42; Ramsay, *u.s.* 459; Rendall, *Expositor*, 1893).

In connexion with the great (circular) Epistle of group 3, Ephesians, Paley remarked that we cannot expect many agreements with Acts, but if Ephesians was addressed to various Churches, a strong tradition makes Ephesus one of them, and resemblances between Paul's address of Miletus and the phraseology of Ephesians may not unfairly help to confirm this tradition (Lock, *Ephesians;* Hastings, *B. D.*).

These writings supply another evidential argument from their corroborative witness to facts and teaching of the Gospels, as also from the knowledge of these facts which they presuppose in their readers (Zahn, *Einleitung*, ii. 158, 166; Uhlhorn, *Das Leben Jesu in seinen neueren Darstellungen*, p. 113; Drescher, *Das Leben Jesu bei Paulus*, 1900; for literature, Findlay, *Paul;* Hastings, *B. D.*).

If we confine ourselves to those Epistles which we claim as authentic, and if we take the earliest, *e.g.*, 1 Thessalonians or Galatians, this testimony is forthcoming—a testimony which can be further traced through each of the four groups—Zahn, *u.s.*; *e.g.*, 1 Thessalonians i. 10; ii. 15, 19; iii. 13; iv. 2, 16; v. 1–5, 23; and especially Zahn, *u.s.*, p. 159; Galatians, i. 1, 4, 17–19; ii. 9, 20; iii. 1, 13; iv. 4, 6; v. 24; vi. 2; and for evidence of probable Johannine tradition, P. Ewald, *Hauptproblem der Evangelienfrage*, pp. 84–94.

The Epistles thus constitute "a fifth Gospel," and it is not surprising that even Pfleiderer acknowledges that the Apostle's work would be a castle in the clouds without some historical data of the personal life of Jesus.

Moreover, Dr Sanday has forcibly urged that the teaching of Paul, a Jewish monotheist, as to our Lord's relation to the Father in 1 and 2 Thessalonians is best explained by believing that behind it lay the knowledge of teaching of Jesus in the Gospels (Hastings, *B. D.*, "Jesus Christ"). But this may also be said of the Galatian Epistle, cf. 1, 2 Corinthians; *e.g.*, Galatians i. 1, 3; ii. 20; iv. 4; 1 Corinthians viii. 6; 2 Corinthians xiii. 14, to say nothing of others. Thus, whilst the doctrine of the divine Person of Christ received in later Epistles its greatest prominence —as, *e.g.*, Colossians i. 18—in answer to the angel-worship of false Jewish teaching, and whilst the language of Hellenism may have enabled Paul to give adequate expression to his thoughts, the doctrine itself "had underlain all his teaching and each earlier Epistle" (Hicks, *Studia Biblica*, iv. 10).

Another point emphasized by recent criticism is the naturalness, the conventionality of these Epistles; *i.e.*, not merely the directness and simplicity with which the writer passes, as in Colossians and Ephesians, from highest doctrinal themes to commonest relationships of life, but the "manner of men" which he adopts in phraseology, salutations, prayers. The instances in Deissmann, *Bibelstudien*, i. 210–216 (cf. *Neue Bibelstudien*, 65, 76–84), afford parallels and illustrations to each of the four groups—*e.g.*, the unceasing mention of Paul's converts in his prayers: 1 Thessalonians i. 2; Romans i. 9; Philemon, v. 1; Ephesians i. 6; 2 Timothy i. 3, has an interesting parallel in an Egyptian letter (172 B.C.), οἱ εν οἴκῳ πάντες σου διαπαντὸς μνείαν ποιούμενοι ("all at home make constant mention of you"), especially as the context mentions constant prayer to the gods. The simplest letters, moreover, took in earliest times the form of conversation between people separated, and hence the possibility of restoring a lost letter, to which we have a reply in some extant epistle, by noting the conversational elements which have been incorporated in the answer. This possibility has been skilfully maintained by Dr Rendel Harris with reference to 1 Thessalonians (*Expositor*, September 1898), with which we may compare Dr Lock's valuable contribution to *Expositor* (July 1897), in which he explains how many passages of St Paul's Epistles—*e.g.*, in 1 and 2 Corinthians—are best understood by supposing that he had before him the actual words, written perhaps, or at least employed, by his opponents in taunt, question, argument, and that the phrase so used is caught up, as it were, by the Apostle in his reply, according to the common custom of letter-writers; cf. a similar suggestion, Ramsay, *Galatians*, p. 462; Findlay, *Expositor* (June 1900). Such traits do not render Paul's letters weak or contemptible, like his presence and speech in the estimation of his foes; rather do they help to confer a power and a charm which make them known and read of all men.[1]

(R. J. K*.)

[1] With regard to attempts to break up 2 Corinthians, it cannot be said that they have proved successful (see Sanday, *Encycl. Bibl.* i., "Corinthians" (1899); Jülicher, *Einleitung*, p. 43 ff., who also pronounces in favour of the integrity of the Epistle, and even against the hypothesis of *Vierkapitel Brief*, x.–xiii. or x. 1–xiii. 10, as a separate letter). Dr J. H. Kennedy's articles (*Expositor*, September, October 1897) and Mr White's reply in favour of the integrity of 2 Corinthians, February 1898, should also be consulted. See further Schmiedel, *Theol. Rundschau*, 12, 1901.

Pavia, capital of the province of the same name, Lombardy, Italy, 18 miles south of Milan by rail. The population remained stationary during the last thirty years of the 19th century, since its increase from 34,614 in December 1871 to 36,107 in December 1899 was due to the inclusion of part of the commune of Mirabello in 1883. In consequence of this change the area, previously less than 700 acres, was increased to nearly 7000 acres. Having in 1872 ceased to be a fortress, the fortifications were ceded to the commune in 1876, and the bastions have been gradually transformed into boulevards and public gardens. Inside the city, changes have been limited to partial straightening of old streets and the construction of some new ones, and to the arrangement of public squares in front of the Castle, the Municipal Palace, and other sites. Among the public buildings may be mentioned the Palazzo Mezzabarba, converted into the Municipal Palace; the Prefecture, enlarged and rebuilt; the covered market, with post, telegraph and telephone offices; the new people's agricultural bank; and the public slaughter-house. The University, founded in 1361, has been increased by the addition of schools of general chemistry, pharmaceutical chemistry, physiology, and by the foundation of chairs of pathological anatomy, histology, legal medicine and hygiene, while in the old University building the geological, palæontological, and mineralogical collections have been enlarged. The number of students in 1899–1900 was 1308, of whom 503 were inscribed in the faculty of medicine. The buildings devoted to secondary education and technical instruction have been enlarged and improved. In 1881 a new cemetery was laid out and the old cemetery of Borgo Ticino suppressed. For the promotion of athletics a rifle club, a gymnastic hall, and several boating clubs have been established. In 1884 a monument was erected to Garibaldi, and in 1900 another monument to the Cairoli family. The communal fine arts museum has been enlarged and reorganized to make room for numismatic, archæological, and natural history departments. The cathedral, begun at the end of 1500, has been crowned with a cupola and the façade begun. The old basilicas of S. Michele Maggiore, S. Pietro in Ciel d'Oro, and S. Teodoro have been restored and isolated. Since 1880 there has been a considerable increase in iron foundries, military engineering works, and electrical production works. In addition, numerous cement factories, factories of antiseptic preparations, and establishments for rearing silk-worms have been founded.

Pavia y Albuquerque, Manuel (1828–1895), Spanish general, was born at Cadiz on 2nd August 1828. He was the son of Admiral Pavia, a naval officer of some note in the early part of the 19th century. He entered the Royal Artillery College at Segovia in 1841; became a lieutenant in 1846, a captain in 1855, and major in 1862. Three years later he joined the staff of Marshal Prim, and was his devoted follower during the last years of Isabella's reign, when Prim was the moving spirit of the Progressist party. Pavia took part in the two unsuccessful revolutionary movements concerted by Prim in 1866, and, after two years of exile, in the successful revolution of 1868. Prim employed him in high commands, in which Pavia showed much vigour against the republican risings in the southern provinces; the governments of King Amadeus of Savoy, from 1871 to 1873, also showed him much favour. After the abdication of that prince, General Pavia was called upon by the short-lived cabinets of the federal republic to lead their armies first against the Carlists and then against the cantonal insurrections of the chief towns of the south, which he quelled with great energy. On three occasions during the eventful year 1873, as captain-general of Madrid, he frankly offered his services to the governments of the day to put an end to the anarchy that was raging in the provinces and to the disorganization prevalent in the Cortes. To all he used the same arguments, namely, that they had to choose between an Alphonsist restoration or a dictatorial, military, and political republic, which would rally round its standard all the most Conservative groups that had made the revolution of 1868. This he hoped to realize with Castelar, but the plan was interrupted by the military *pronunciamiento* for the purpose of dissolving the Cortes of 1873. As soon as the federal Cortes had defeated Castelar, Pavia made his *coup d'état* of 3rd January 1874, for which he had, on his own confession in his memoirs, prepared the garrison of Madrid under his command, with the assent of all the leaders of the army in the provinces. After his *pronunciamiento*, Pavia was absolute master of the situation, and might have played the part of a Cromwell, Prim, or Monk. Having no personal ambition, he sent for Marshal Serrano to form a government with Sagasta, Martos, Ulloa, and other Conservatives and Radicals of the revolution. From that moment Pavia carefully abstained from taking an active part in politics; but he sat in the Cortes of the Restoration several times, and once in a famous retrospective debate he defended himself skilfully against no less an orator than Emilio Castelar, who upbraided him for the part he had played on 3rd January 1874. He died suddenly on 4th January 1895, at the age of sixty-seven. (A. E. H.)

Pavlodar, a town of Asiatic Russia, in the province and 225 miles north-west of the town of Semipalatinsk, 259 miles south-east of Omsk railway station, on the right bank of the Irtysh. It has regular steamer communication with the Ob and Irtysh ports, and is a centre for trade with the Kirghiz, who exchange animals and animal products for grain, flour, and manufactured goods. Population (1897), 7730.

Pavlovo, an industrial town of Russia, in the government and 40 miles south-west of the town of Nijni-Novgorod, on the Oka river. It is the centre of a considerable cutlery, hardware, and locksmith trade, which, carried on in cottages and small workshops, engages, besides Pavlovo itself, no less than 119 villages, and the output of which reaches an annual value of over £200,000. There are also steel works and match factories. Pavlovo is well provided with schools, and has a museum of cutlery models and a library. Population (1897), 12,200.

Pavlovskiy Posad, or Vokhna, a town of Russia, in the government and 42 miles by rail east of the town of Moscow, on the Klyazma river. It is the centre of an important manufacturing district, comprising woollen mills, and dyeing and printing works, turning out goods to the value of £111,300 annually. Population (1897), 10,020.

Pawnbroking.—If we desire to trace with minuteness the history of pawnbroking, we must go back to the earliest ages of the world, since the business of lending money on portable security is one of the most ancient of human occupations. Even in the remote ages when the Old Testament was being written, the practice was already familiar, although it was hardly regarded with a benevolent eye. "If a man be poor, thou shalt not sleep with his pledge," says the Pentateuch; "and if thou at all take his raiment to pledge, thou shalt deliver it to him by that the sun goeth down . . . that he may sleep in his own raiment, and bless thee." No man might take the upper or the nether millstone in pawn, since that was equivalent to taking a man's life in pledge.

History.

Nor might the widow's ox be taken. The Mosaic Law struck at the root of pawnbroking as a profitable business, since it forbade the taking of interest from a poor borrower, while no Jew was to pay another for timely accommodation. And it is curious to reflect that, although the Jew was the almost universal usurer and money-lender upon security of the Middle Ages, it is now very rare in Great Britain to find a Hebrew pawnbroker.

In China, which was venerable before most of the rest of the world had learned the elements of civilization, the pawnshop was probably as familiar two or three thousand years ago as it is to-day, and its conduct is still regulated quite as strictly as in England. The Chinese conditions, too, are decidedly favourable to the borrower. He may, as a rule, take three years to redeem his property, and he cannot be charged a higher rate than 3 per cent. per annum—a regulation which would close every pawnshop in England in a month. Both Rome and Greece were as familiar with the operation of pawning as the modern poor all the world over; indeed, from the Roman jurisprudence most of the contemporary law on the subject is derived. The chief difference between Roman and English law is that under the former certain things, such as wearing apparel, furniture, and instruments of tillage, could not be pledged, whereas there is no such restriction in English legislation. The Emperor Augustus was himself an illustrious pawnbroker. He converted the surplus arising to the State from the confiscated property of criminals into a fund from which sums of money were lent, without interest, to those who could pledge valuables equal to double the amount borrowed. It was, indeed, in Italy, and in more modern times, that the pledge system which is now almost universal on the continent of Europe arose. In its origin that system was purely benevolent, the early *Monts de Piété* established by the authority of the Popes lending money to the poor only, without interest, on the sole condition of the advances being covered by the value of the pledges. This was virtually the Augustan system, but it is obvious that an institution which costs money to manage and derives no income from its operations must either limit its usefulness to the extent of the voluntary support it can command, or must come to a speedy end. This is probably the explanation of the failure of some very early attempts to establish charitable pawnshops. Thus as early as 1198 something of the kind was started at Freising in Bavaria; while in 1350 a similar endeavour was made at Salins in Franche Comté, where interest at the rate of $7\frac{1}{2}$ per cent. was charged. Nor was England backward, for in 1361 Michael Northbury, or de Northborough, bishop of London, bequeathed 1000 silver marks for the establishment of a free pawnshop. These primitive efforts, like the later Italian ones, all failed. The Vatican was therefore constrained to allow the Sacri Monti di Pietà—no satisfactory derivation of the phrase has yet been suggested—to charge sufficient interest to their customers to enable them to defray expenses. Thereupon a learned and tedious controversy arose upon the lawfulness of charging interest. In time it died away, extinguished by its own futility, but about the beginning of the 16th century it was revived, and was only finally set at rest by the issue of a papal bull. By that document Pope Leo X., in the tenth sitting of the Council of the Lateran, declared that the pawnshop was a lawful and valuable institution, and threatened with excommunication those who should presume to express doubts on the subject. The Council of Trent inferentially confirmed this decision, and at a somewhat later date we find St Charles Borromeo counselling the establishment of State or municipal pawnshops.

The pledge system.

Long before this, however, Monti di Pietà charging interest for their loans had become common in Italy. The precise date of their establishment is not clear, but it is certain that it was not later than 1464, when the earliest of which there appears to be any record in that country—it was at Orvieto—was confirmed by Pius II. Three years later another was opened at Perugia by the efforts of two Franciscans, Barnabus Interamnensis and Fortunatus de Copolis. The one had been a physician and the other a lawyer, and both had gone to the cloister late in life. They collected the necessary capital by preaching, and the Perugian pawnshop was opened with such success that there was a substantial balance of profit at the end of the first year. The Dominicans, who were perhaps jealous of the Franciscans, endeavoured to preach down the "lending-house," but without avail, and others were established in rapid succession. Thus Viterbo obtained one in 1469, and Sixtus IV. confirmed another to his native town of Savona in 1479. After the death of Brother Barnabus in 1474, a strong impulse was given to the creation of these establishments by the preaching of another Franciscan, Father Bernandino di Feltre, who was in due course canonized. By his efforts Monti di Pietà were opened at Assisi, Mantua, Parma, Lucca, Piacenza, Padua, Vicenza, Pavia, and a number of places of less importance. At Florence the veiled opposition of the municipality and the open hostility of the Jews prevailed against him, and it was reserved to Savonarola, who was a Dominican, to create the first Florentine pawnshop, after the local theologians had declared that there was "no sin, even venial," in charging interest. The activity of the Church in this matter, and the readiness of the Popes to give permission for pawnshops all over Italy, make it the more remarkable that the papal capital itself possessed nothing of the kind until 1539, and that even then Rome, like so many other cities, owed the convenience to the exertions of a Franciscan. The Naples establishment, opened about the same year, became famous in time as not only the largest in Europe, but as containing a larger accumulation of valuable articles than any other. From Italy the pawnshop spread gradually all over Europe. Augsburg adopted the system in 1591, Nuremberg copied the Augsburg regulations in 1618, and by 1622 it was established at Amsterdam, Brussels, Antwerp, and Ghent. Madrid followed suit in 1705, when a priest opened a charitable pawnshop with a capital of fivepence taken from an alms-box.

Italian Monti di Pietà.

The institution was, however, very slow in obtaining a footing in France. It was adopted at Avignon in 1577, and at Arras in 1624. The doctors of the once powerful Sorbonne could not, despite the action of the Popes, reconcile themselves to the idea of the lawfulness of interest, and when a pawnshop was opened in Paris in 1626, it had to be closed within a year. Then it was that Jean Boucher published his *Défense des Monts de Piété.* Marseilles obtained one in 1695; but it was not until 1777, after the idea had been pressed upon the Government for more than a century, that the first Mont de Piété was founded in Paris by royal patent, to the great satisfaction of M. Necker. The statistics which have been preserved relative to the business done in the first few years of its existence show that it was resorted to by a much better class than that from which most pawnshops now draw their customers. In the twelve years between 1777 and the Revolution, the average value of the pledges was 42 francs 50 centimes, which is double the present average. The interest charged was 10 per cent. per annum, and large profits were made upon the sixteen million livres that were lent every year. The National Assembly, in an evil moment, destroyed the monopoly of the Mont de Piété, but it struggled on until 1795, when the competition of the money-lenders compelled it to close its doors. So great, however, were the extortions of the usurers that the people began to clamour for its reopening, and in July 1797 it recommenced business with a fund of £20,000 found by five private capitalists. At first it charged interest at the rate of 36 per cent. per annum, which was gradually reduced, the gradations being 30, 24, 18, 15, and finally 12 per cent. in 1804. In 1806 it fell to 9 per cent., and in 1887 to its present level of 7 per cent. In 1806 Napoleon I. re-established its monopoly, while Napoleon III., as Prince-President, regulated it by new laws that are still in force. In Paris the pledge-shop is, in effect, a department of the Administration; in the French provinces it is a municipal monopoly; and this remark holds good, with modifications, for most parts of the continent of Europe.

Introduction in France.

In England the pawnbroker, like so many other distinguished personages, "came in with the Conqueror." From that time, indeed, to the famous legislation of Edward I., the Jew money-lender, who as often as not advanced money upon the security of valuable property which passed into his temporary possession pending its redemption, was the only pawnbroker. Yet, despite the valuable services which the class rendered, not infrequently to the Crown itself, it is matter of familiar history that the usurer was treated with studied cruelty—Sir Walter Scott's Isaac of York was no mere creation of fiction. These barbarities, by diminishing the number of Jews in the country, had, long before Edward's decree of banishment, begun to make it worth the while of the Lombard merchants to settle in England. It is now as well established as anything of the kind can be that the three golden balls, which have for so long been the trade sign of the pawnbroker, were the symbol which these Lombard merchants hung up in front of their houses, and not, as has often been suggested, the arms of the Medici family. It has, indeed, been conjectured that the golden balls were originally three flat yellow effigies of byzants, or gold coins, laid heraldically upon a sable field, but that they were presently converted into balls the better to attract attention. That these sharp, and not always very scrupulous, men of business from the South did actually advance money on pledges can hardly be questioned when we remember that in 1338 Edward III.

Great Britain.

pawned his jewels to the Lombards to raise money for his war with France. An equally great king—Henry V.—did much the same in 1415. It has indeed been said, with no great touch of extravagance, that both Creçy and Agincourt owed something to the pawnbroker.

The Lombards were not a popular class, and Henry VII. harried them a good deal. But, whatever parliaments and kings might enact, usury and broking went on clandestinely when the business was too perilous to be conducted openly, and it would appear that the principal City companies were not above acting as pawnbrokers. By the time Bacon wrote his essay on *Usury* a juster estimate of the subject had begun to prevail. "Brokers of pawn" were, however, still regarded as the lineal business descendants of the 14th-century Jew usurers and the unpopular Lombards, and in the very first year of James I. "An Act against Brokers" was passed and remained on the statute-book until Queen Victoria had been thirty-five years on the throne. It was aimed at "counterfeit brokers," of whom there were then many in London. They were described as men of "manual occupations and handicraftsmen," and were denounced for having "set up a trade of buying and selling and taking in pawn of all kinds of wearing apparel, household stuff, and goods of all kinds soever, finding thereby that the same is a more idle and easier kind of trade and living, and that there ariseth and groweth to them a more ready, more great, more profitable, and speedier advantage and gain than by their former manual labours." This type of broker was evidently regarded as a mere receiver of stolen goods, for the Act provided that "no sale or pawn of any stolen jewels, plate, or other goods, to any pawnbroker in London, Westminster, or Southwark, shall alter the property therein," and that "pawnbrokers refusing to produce goods to their owner from whom stolen shall forfeit double the value."

In the time of Charles I. there was another Act which made it quite clear that the pawnbroker was not deemed to be a very respectable or trustworthy person. Nevertheless a plan was mooted for setting that king up in the business. The Civil War was approaching and supplies were badly needed, when a too ingenious Royalist proposed the establishment of a State "pawnhouse." The preamble of the scheme recited how "the intolerable injuries done to the poore subjects by brokers and usurers that take 30, 40, 50, 60, and more in the hundredth, may be remedied and redressed, the poor thereby greatly relieved and eased, and His Majestie much benefited." That the king would have been "much benefited" is obvious, since he was to enjoy two-thirds of the profits, while the working capital of £100,000 was to be found by the City of London. The reform of what Shakespeare calls "broking pawn" was in the air at that time, although nothing ever came of it, and in the early days of the Commonwealth it was proposed to establish a kind of Mont de Piété. The idea was emphasized in a pamphlet of 1651 entitled *Observations manifesting the Conveniency and Commodity of Mount Pieteyes, or Public Bancks for Relief of the Poor or Others in Distress, upon Pawns.* No doubt many a ruined Cavalier would have been glad enough of some such means of raising money, but this radical change in the principles of English pawnbroking was never brought about. It is said that the Bank of England, under its charter, has power to establish pawnshops; and we learn from *A Short History of the Bank of England,* published in its very early days, that it was the intention of the directors, "for the ease of the poor," to institute "a Lombard" "for small pawns at a penny a pound interest per month."

Throughout both the 17th and 18th centuries the general suspicion of the pawnbroker appears to have been only too well founded. It would appear from the references Fielding makes to the subject in *Amelia,* which was written when George II. was on the throne, that, taken in the mass, he was not a very scrupulous tradesman. The householder, whose stolen property had been pledged much below its value, appeals to the justice for some penalty on the pawnbroker, "who plainly appears to have known that these goods were stolen"; and he adds, "The shops of these fellows are, indeed, the fountains of theft." Down to about that time it had been customary for publicans to lend money on pledges that their customers might have the means of drinking, but the practice was at last stopped by Act of Parliament. Nor was respect for the honesty of the business increased by the attempt of "The Charitable Corporation" to conduct pawnbroking on a large scale. Established by charter in 1707, "this nefarious corporation," as Smollett called it, was a swindle on a large scale. Its ostensible object was benevolence—it would lend money at legal interest to the poor upon the smallest pledges. The capital was £30,000, which before long was increased to £600,000. With an office in the City and another at the West End, the undertaking was an almost immediate success for the promoters; but there was no attempt at circumspection in the conduct of the business, and the facilities which it offered for the disposal of stolen goods were far greater than had ever been reproached against the private broker. The directors gambled wildly with the shareholders' money, and in the end the Common Council of the City of London petitioned Parliament for the dissolution of this dishonest concern, on the ground that "the corporation, by affording an easy method of raising money upon valuables, furnishes the thief and pickpocket with a better opportunity of selling their stolen goods, and enables an intending bankrupt to dispose of the goods he buys on credit for ready money, to the defrauding of his creditors." Yet the corporation had managed to keep its doors open for a good many years, and was, as is not unusual with such schemes, officered by persons of the greatest outward respectability. When the concern collapsed in 1731 its cashier was Mr George Robinson, M.P. for Marlow. In company with another principal official he disappeared, less than £30,000 being left of a capital which had once been twenty times as much.

Modern regulations in England.

The pawnbroker's licence dates from 1785, the duty being fixed at £10 in London and £5 in the country; and at the same time the interest chargeable was settled at $\frac{1}{2}$ per cent. per month, the duration of loans being confined to one year. Five years later the interest on advances over £2 and under £10 was raised to 15 per cent. The modern history of legislation affecting pawnbroking begins, however, in 1800, when the Act of 39 and 40 George III. c. 99 was passed, in great measure by the influence of Lord Eldon, who never made any secret of the fact that, when he was a young barrister without briefs, he had often been indebted to the timely aid of the pawnshop. The pawnbrokers were grateful, and for many years after Lord Eldon's death they continued to drink his health at their trade dinners. The measure treated the broker a good deal less like an outcast and a potential criminal than the legislation of the previous two centuries, but it was far from being a liberal enactment. It increased the rate of interest to a halfpenny per half-crown per month, or fourpence in the pound per mensem—that is to say, 20 per cent. per annum. Loans were to be granted for a year, although pledges might be redeemed up to fifteen months, and the first week of the second month was not to count for interest. The Act worked well, on the whole, for three-quarters of a century, but it was thrice found necessary to amend it. Thus in 1815 the licence duties were raised to £15 and £7, 10s. for London and the country respectively; another Act of 1840 abolished the reward to the "common informer" for reporting illegal rates of interest; while in 1860 the pawnbroker was empowered to charge a halfpenny for the pawn-ticket when the loan was under five shillings. As time went on, however, the main provisions of the Act of 1800 were found to be very irksome, and the Pawnbrokers' National Association and the Pawnbrokers' Defence Association worked hard to obtain a liberal revision of the law. It was argued that the usury laws had been abolished for the whole of the community with the single exception of the pawnbroker who advanced less than £10. The limitations of the Act of 1800 interfered so considerably with the pawnbrokers' profits that, it was argued, they could not afford to lend money on bulky articles requiring extensive storage room. So many books and documents and official forms had to be filled up that an undue amount of clerical assistance was required, and the profit upon short pledges was so small that he was only able to keep his shutters down by what he could make on those for longer terms. Yet, however seriously the old law may have checked the prosperity of the lender, it was evidently no deterrent to borrowers. In 1870 the House of Commons appointed a Select Committee on Pawnbrokers, and it was stated in evidence before that body that in the previous year 207,780,000 pledges were lodged, of which between thirty and forty millions were lodged in London. The average value of pledges appeared to be about 4s., and the proportion of articles pawned dishonestly was found to be only 1 in 14,000. More recent official statistics show that of the forfeited pledges sold in London less than 20 per million are claimed by the police. Another interesting fact brought out in the inquiry of 1870 was that, contrary to the popular belief, the profits of the pawnbroker were small, rarely indeed exceeding 6 per cent.

The result of the Select Committee was the Pawnbrokers Act of 1872, which repealed, altered, and consolidated all previous legislation on the subject, and is still the measure which regulates the relations between the public and the "brokers of pawn." Based mainly upon the Irish law passed by the Union Parliament, it put an end to the old irritating restrictions, and reduced the annual tax in London from £15 to the £7, 10s. paid in the provinces. By the provisions of the Act (which does not affect loans above £10), a pledge is redeemable within one year, and seven days of grace added to the year. Pledges pawned for 10s. or under and not redeemed in time become the property of the pawnbroker, but pledges above 10s. are redeemable until sale, which must be by public auction. In addition to one halfpenny for the pawn-ticket—which is sometimes not charged for very small pawns—the pawnbroker is entitled to charge as interest one halfpenny per month on every 2s. or part of 2s. lent where the loan is under 40s., and on every 2s. 6d. where the loan is above 40s. "Special contracts" may be made where the loan is above 40s., at a rate of interest agreed upon between lender and borrower. Unlawful pawning of goods not the property of the pawner, and taking in pawn any article from a person under the age of twelve, or intoxicated, or any linen, or apparel, or unfinished goods or materials entrusted to wash, make up, &c., are (*inter alia*) made offences punishable by summary conviction. A new pawnbroker must produce a magistrate's certificate before he can receive a licence; but the permit cannot be refused if the applicant gives sufficient evidence that he is a person of good character. The word "Pawnbroker" must always be inscribed in large letters over the door of the shop. Elaborate provisions are made to safeguard the interests of borrowers whose unredeemed pledges are sold under the Act. Thus the sales by auction may take place only on the first Monday of January, April, July, and October, and on the following days should one not be sufficient. This legislation was, no doubt, favourable to the pawnbroker rather than to the borrower. The annual interest on loans of 2s. had been increased by successive Acts of Parliament from the 6 per cent. at which it stood in 1784 to 25 per cent. in 1800, and to 27 in 1860—a rate which was continued by the measure of 1872. The annual interest upon a loan of half-a-crown is now 260 per cent., as compared with 173 in 1860 and 86 in 1784; while the extreme point is reached in the case of a loan of 1s. for three days, in which case the interest is at the rate of 1014 per cent. per annum. It must be remembered, however, that it has always been contended by the pawnbrokers that under the old arrangement there was no profit at all upon the small transactions, in which the bulk of their business consists. The foreign Mont de Piété often disposes of this difficulty in a manner not possible to the English trader, by refusing to advance very small sums. It thus retains the profitable work, while rejecting that which is unremunerative. An English Mont de Piété was once projected by the Salvation Army, and in 1894 the London County Council considered the practicability of municipal effort on similar lines; but in neither case was anything done.

Scotland and Ireland.

The growth of pawnbroking in Scotland, where the law as to pledge agrees generally with that of England, is remarkable. Early in the 19th century there was only one pawnbroker in that country, and in 1833 the number reached only 52. Even in 1865 there were no more than 312. It is probable that at the present moment Glasgow and Edinburgh together contain nearly as many as that total. There was a time, however, when the second city of the Empire supported an enormous number of illegitimate pawnbrokers. Thus in 1840 there were known to be some 700 "leaving shops," advancing money chiefly upon objects of exceedingly small value, and charging, as usual with such contraband places—which are still numerous in great towns, and especially in the poor districts of London—interest at the rate of 400 or 500 per cent. per annum. In Ireland the rates for loans are practically identical with those charged in England, but a penny instead of a halfpenny is paid for the ticket. Articles pledged for less than £1 must be redeemed within six months, but nine months are allowed when the amount is between 30s. and £2. For sums over £2 the period is a year, as in England. In Ireland, too, a fraction of a month is calculated as a full month for purposes of interest, whereas in England, after the first month, fortnights are recognized. In 1838 there was an endeavour to establish Monts de Piété in Ireland, but the mistake was made of opening establishments in small towns and ignoring large ones, and the scheme was so unsuccessful that in 1841 the eight charitable pawnshops that had been opened had a total adverse balance of £5340. By 1847 only three were left, and eventually they collapsed likewise.

United States.

The pawnbroker in the United States is, generally speaking, controlled very stringently. There are no federal laws on the subject, each state having its own regulations, but those of New York and Massachusetts may be taken as fairly representative. "Brokers of pawn" are usually licensed by the mayors, or by the mayors and aldermen, but in Boston the police commissioners are the licensing authority. In the state of New York permits are renewable annually on payment of $500, and the pawnbroker must file a bond with the mayor, executed by himself and two responsible sureties, in the sum of $10,000. The business is conducted on much the same lines as in England, and the rate of interest is 3 per cent. per month for the first six months, and 2 per cent. monthly afterwards. Where, however, the loan exceeds 100 dollars, the rates are 2 and 1 per cent. respectively. To exact higher rates is a misdemeanour. Unredeemed pledges may be sold at the end of a year. Pawnbrokers are not allowed to engage in any kind of second-hand business. New York contains one pawnshop to every 12,000 inhabitants, and most of the pawnbrokers are Jews. In the state of Massachusetts unredeemed pledges may be sold four months after the date of deposit. The licensing authority may fix the rate of interest, which may vary for different amounts, and in Boston every pawnbroker is bound to furnish to the police daily a list of the pledges taken in during the preceding twenty-four hours, specifying the hour of each transaction and the amount lent.

Municipal pawnshops.

The fact that on the continent of Europe Monts de Piété are almost invariably either a State or a municipal monopoly necessarily places them upon an entirely different footing from the British pawnshop, which, as we have seen, any respectable person is at liberty to open. It has often been argued that the foreign system might be introduced into England with advantage. Indeed, unsuccessful attempts have been made to introduce it; but, compared with the English system, it is very elaborate and rather cumbersome. Moreover, in addition to being slow in its operation, it is, generally speaking, based upon the supposition that the borrower carries in his pocket "papers" testifying to his identity. On the other hand, it is argued that the English borrower of more than £2 is at the mercy of the pawnbroker in the matter of interest, that sum being the highest for which a legal limit of interest is fixed. The rate of interest upon a "special contract" may be, and often is, high. For the matter of that, indeed, this system of obtaining loans is always expensive, either in actual interest or in collateral disadvantages, whether the lender be a pawnbroker intent upon profit, or the official of a Mont de Piété. In Paris the rate charged is 7 per cent., and even then the business is conducted at a loss except in regard to long and valuable pledges. Some of the French provincial rates are as high as 12 per cent., but in almost every case they are less than they were prior to the legislation of 1851 and 1852. The French establishments can only be created by decree of the President of the Republic, with the consent of the local Conseil Communal. In Paris the prefect of the Seine presides over the business; in the provinces the mayor is the president. The administrative council is drawn one-third each from the Conseil Communal, the governors of charitable societies, and the townspeople. A large proportion of the capital required for conducting the institutions has to be raised by loan, while some part of the property they possess is the product of gifts and legacies. The profits of the Paris Mont de Piété are paid over to the "Assistance Publique," the comprehensive term used by France to indicate the body of charitable foundations. Originally this was the rule throughout France, but now many of them are entirely independent of the charitable institutions. Counting the head office, the branches, and the auxiliary shops, the Paris establishment has its doors open in some fifty or sixty districts; but the volume of its annual business is infinitely smaller than that transacted by the London pawnbrokers. This may be the result of the system, or it may be explained by the thriftier character of the French people—while something must of course be allowed for smaller population. The amount to be advanced by a municipal pawnshop is fixed by an official called the *commissaire-priseur*, who is compelled to load the scales against the borrower, since, should the pledge remain unredeemed, and be sold for less than was lent upon it, he has to make good the difference. This official is paid at the rate of ½ per cent. upon loans and renewals, and 3 per cent. on the amount obtained by the sales of forfeited pledges. This is obviously the weakest part of the French system. The Paris Mont de Piété undertakes to lend four-fifths of the intrinsic value of articles made from the precious metals, and two-thirds of that of other articles. The maximum and minimum that may be advanced are also fixed. The latter varies in different parts of the country from one to three francs, and the former from a very small sum to the 10,000 francs which is the rule in Paris. Loans are granted for twelve months with right of renewal, and unredeemed pledges may then be sold by auction, but the proceeds may be claimed by the borrower at any time within three years. Pledges may be redeemed by instalments.

Somewhere between forty and fifty French towns possess municipal pawnshops, a few of which, like those of Grenoble and Montpellier, having been endowed, charge no interest. Elsewhere the rate varies from *nil* in some towns, for very small pledges, to 10 per cent. The constant tendency throughout France has been to reduce the rate. The great establishment in Paris obtains part of its working capital—reserves and surplus forming the balance—by borrowing money at a rate varying from 2 to 3 per cent. according to the length of time for which the loan is made. Under a law passed in 1891 the Paris Mont de Piété makes advances upon securities at 6 per cent., plus a duty of 5 centimes upon every hundred francs. The maximum that can be lent in this way is £20. Up to 80 per cent. is lent on the face value of Government stock and on its own bonds, and 75 per cent. upon other securities; but 60 per cent. only may be advanced on railway shares. These advances are made for six months. Persons wishing to borrow a larger sum than sixteen francs from the Paris Mont de Piété have to produce their papers of identity. In every case a numbered metal check is given to the customer, and a duplicate is attached to the article itself. The appraising clerks decide upon the sum that can be lent, and the amount is called out with the number. If the borrower is dissatisfied he can take away his property, but if he accepts the offer he has to give full particulars of his name, address, and occupation. The experts calculate that every transaction involving less than twenty-two francs results in a loss to the Paris Mont de Piété, while it is only those exceeding eighty-five francs which can be counted upon to be invariably profitable. The average loan is under thirty francs.

Holland and Belgium.

The borrowing of money on the security of goods deposited has been the subject of minute regulations in the Low Countries from an early date. So far back as the year 1600 the "Archdukes" Albert and Isabella, Governors of the Spanish Netherlands under Philip III., reduced the lawful rate of interest from 32½ to 21⅔ per cent.; but since extortion continued, they introduced the Mont de Piété in 1618, and, as we have already seen, in the course of a dozen years the institution was established in all the populous Belgian towns, with one or two exceptions. The interest chargeable to borrowers was fixed originally at 15 per cent., but was shortly afterwards reduced, to be again increased to nearly the old level. The early history of these offices was chequered; the interest on the stock which had been created to provide working capital could not always be paid, and many changes in management were necessary before a stable equilibrium could be established. Meanwhile various towns possessed charitable funds for gratuitous loans, apart from the official institutions. Shortly after the Mont de Piété was introduced in the Spanish provinces, the prince-bishop of Liége (Ferdinand of Bavaria) followed the example set by the archdukes. He ordained that the net profits were to accumulate, and the interest upon the fund to be used in reduction of the charges. The original rate was 15 per cent., when the Lombard money-lenders had been charging 43; but the prince-bishop's Monts de Piété were so successful that for many years their rate of interest did not exceed 5 per cent.—it was, indeed, not until 1788 that it was increased by one-half. These flourishing institutions, along with those in Belgium proper, were ruined by the French Revolution. They were, however, re-established under French dominion, and for many years the laws governing them were constantly altered by the French, Dutch, and Belgian Governments in turn. The whole subject is now regulated by a law of 1848, supplemented by a new constitution for the Brussels Mont de Piété dating from 1891.

The working capital of these official pawnshops is furnished by charitable institutions or the municipalities, but the Brussels one possesses a certain capital of its own in addition. The rate of interest charged in various parts of the country varies from 4 to 16 per cent., but in Brussels it is usually less than half the maximum. The management is very similar to that of the French Monts de Piété, but the arrangements are much more favourable to the borrower. The ordinary limit of loans is £120. In Antwerp there is an "anonymous" pawnshop, where the customer need not give his name or any other particulars. In Holland private pawnbrokers flourish side by side with the municipal "Banken van Leening," nor are there any limitations upon the interest that may be charged. The rules of the official institutions are very similar to those of the Monts de Piété in the Latin countries, and unredeemed pledges are sold publicly fifteen months after being pawned. A large proportion of the advances are made upon gold and diamonds; workmen's tools are not taken in pledge, and the amount lent varies from 8d. upwards. On condition of finding such sum of money as may be required for working capital over and above loans from public institutions, and the "caution money" deposited by the city officials, the municipality receives the profits.

Pawnbroking in Germany is conducted at once by the State, by the municipalities, and by private enterprise; but of all these institutions the State loan office in Berlin is the most interesting. It dates from 1834, and the working capital was found, and still continues to be in part provided, by the Prussian State Bank. The profits are invested, and the interest devoted to charitable purposes. The maximum and minimum rates of interest are fixed, but the rate varies, and often stands at about 12 per cent. Two-thirds of the estimated value is the usual extent of a loan; four-fifths is advanced on silver, and five-sixths on fine gold. State and municipal bonds may be pledged up to a maximum of £150, the advance being 80 per cent. of the value, and a fixed interest of 6 per cent. is charged upon these securities. The values are fixed by professional valuers, who are liable to make good any loss that may result from over-estimation. The bulk of the loans are under £5, and the State office is used less by the poor than by the middle classes. Loans run for six months, but a further six months' grace is allowed for redemption before the article pledged can be sold by auction. The net annual profit usually amounts to little more than 1 per cent. upon the capital employed. The pawnbroking laws of Austria-Hungary are very similar to those which prevail in England. Free trade exists, and the private trader, who does most of the business, has to obtain a Government concession, and deposit caution-money varying in amount from £80 to £800, according to the size of the town. He has, however, to compete with the Monts de Piété or Versatzaemter, which are sometimes municipal and sometimes State institutions. The chief of these is the imperial pawn office of Vienna, which was founded with charitable objects by the Emperor Joseph I. in 1707, and one-half of the annual surplus has still to be paid over to the Vienna poor fund. Here, as in Berlin, the profits are relatively small. Interest is charged at the uniform rate of 10 per cent., which is calculated in fortnightly periods, however speedily redemption may follow upon pawning. For small loans varying from two to three kronen, 5 per cent. only is charged. Many of the poorest clients of the "Lombard merchants" resort to the private pawnbroker, partly because of the high rates of the State office, and partly because it is open only from eight in the morning until two in the afternoon. There is the usual Mont de Piété arrangement of official values. The Hungarian State and municipal institutions appear, on the whole, to compete somewhat more successfully with the private firms than is the case in Vienna.

Germany and Austria.

In Italy, the "country of origin" of the Mont de Piété, the institution still flourishes. It is, as a rule, managed by a committee or commission, and the regulations follow pretty closely the lines of the one in Rome, which never lends less than 10d. or more than £40. Four-fifths of the value is lent upon gold, silver, and jewels, and two-thirds upon other articles. The interest, which is reckoned monthly, varies with the amount of the loan from 5 to 7 per cent., but no interest is chargeable upon loans up to 5 lire. A loan runs for six months, and may be renewed for similar periods up to a maximum of five years. If the renewal does not take place within a fortnight of the expiration of the ticket, the pledge is sold, any surplus there may be being paid to the pawner. When more than 10 lire is lent there is a charge of 1 per cent. for the ticket. Agencies of the Mont de Piété are scattered about Rome, and carry on their business under the same rules as the central office, with the disadvantage to the borrower that he has to pay an "agent's fee" of 2 per cent., which is deducted from the loan. Private pawnshops also exist in Italy, under police authority; but they charge very high interest—sometimes as much as 60 per cent.—and those who conduct them, by buying pawn-tickets, speculate upon the proceeds of the sale of the pledges.

Italy.

The Monts de Piété in Spain have for a generation past been inseparably connected with the savings banks. We have already seen that the institution owes its origin in that country to the charitable exertions of a priest who charged no interest, and the system grew until in 1840, a century after his death, the Mont de Piété began to receive the sums deposited in the savings bank, which had just been established, for which it paid 5 per cent. interest. In 1869 the two institutions were united. This official pawnshop charges 6 per cent. upon advances which run for periods varying from four to twelve months, according to the nature of the article pledged, and a further month's grace is allowed before the pledges are sold by auction. The system has been very successful, and the Mont de Piété has increased its capital without any assistance from public authorities, while enabling the poor to borrow at a reasonable rate. Private pawnbrokers are also very numerous, especially in Madrid; but their usual charges amount to about 60 per cent. per annum. They appear, however, to derive advantage from making larger advances than their official rivals, and from doing business during more convenient hours. In Portugal the Monte Pio is an amalgamation of bank, benefit society, and pawnshop. Its business consists chiefly in lending money upon marketable securities, but it also makes advances upon plate, jewellery, and precious stones, and it employs officially-licensed valuers. The rate of interest varies with the bank rate, which it slightly exceeds, and the amount advanced upon each article is about three-fourths of its certified value. There is in Portugal a second class of loan establishment answering exactly to the English pawnshop. The pawnbroker is licensed and strictly controlled, but this class of business is practically limited to the larger towns. When he starts in business he is compelled to deposit a sum, in acceptable securities, equal to the capital he proposes to embark, and the register of his transactions must be submitted quarterly to the chief of the police for examination. As regards small transactions, there appears to be no legal limit to the rate of interest. The sale of unredeemed pledges is governed by the law affecting the "Monte Pio Geral."

Spain and Portugal.

In Russia the State maintains two pawnbroking establishments, one at St Petersburg and the other at Moscow, but only articles of gold and silver, precious stones, and ingots of the precious metals are accepted by them. Advances are made upon such securities at 6 per cent. per annum, and the amounts of the loans are officially limited. Loans run for twelve months, with a month's grace before unredeemed pledges are put up to auction. The bulk of this class of business in Russia is, however, conducted by private companies, which advance money upon all descriptions of movable property except stocks and shares. The interest charged is not allowed to exceed 1 per cent. per month, but there is an additional charge of ½ per cent. per month for "insurance and safe keeping." The loan runs for a year, with two months' grace for redemption before sale. There are also a certain number of pawnshops conducted by individuals, who find it very difficult to compete with the companies. These shops can only be opened by a police permit, which runs for five years, and security, varying from £100 to £700, has to be deposited. Two per cent. per month is the limit of interest fixed, and two months' grace is allowed for redemption after the period for which an article is pledged.

Russia.

Pawnbroking in Denmark dates from 1753, when the Royal Naval Hospital was granted the monopoly of advancing money on pledges and of charging higher interest than the law permitted. The duration of a loan is three months, renewals being allowed. The old law was extended in 1867, and now all pawnbrokers have to be licensed by the municipalities and to pay a small annual licence fee. The rate of interest varies from 6 to 12 per cent., according to the amount of the loan, which must not be less than 7d., and unredeemed pledges must be sold by auction. In Sweden there are no special statutes affecting pawnbroking, with the exception of a proclamation by the governor of Stockholm prohibiting the lending of money upon articles which may be suspected of having been stolen. Individuals still carry on the business on a small scale, but the bulk of it is now conducted by companies, which give general satisfaction. The change from private pawnbrokers to the companies was caused by the extortionate interest formerly charged, which often amounted to 60 per cent. per annum. For many years there was in Stockholm a municipal establishment charging 10 per cent. for loans paid out of the city funds. The cost of administration was, however, so great that there was an annual loss upon its working, and the opportunity was taken to abolish it when, in 1880, a private company was formed called the "Pant Aktie Bank," to lend money on furniture and wearing apparel at the rate of 3 öre per krona a month, and 2 öre per krona a month on gold, silver, and other valuables: a krona, which equals 1s. 1½d., contains 100 öre. Some years later an opposition was started which charged only half these rates, with the result that the original enterprise reduced its interest to the same level, charging, however, 2 öre per krona per mensem for bulky articles—a figure which is now usual for pledges of that description. The money is lent for three months, and at the end of five months the pledge, if unredeemed, is sold by auction under very carefully prescribed conditions. In Norway a police licence is required for lending money on pawn where the amount advanced does not exceed £4, 10s. Beyond that sum no licence is necessary, but the interest charged must not exceed such a rate as the king may decide.

Denmark and Norway.

The fate of pawnbroking in Switzerland appears to be not very dissimilar from that of the Jew who is fabled to have once started in business at Aberdeen. Nevertheless the cantons of Bern and Zürich have elaborate laws for the regulation of the business. In Zürich the broker must be licensed by the cantonal government, and the permit can be refused only when the applicant is "known to be a person undeserving of confidence." Regular books have to be kept, which must be at all times open to the inspection of the police, and not more than 1 per cent. interest per month must be charged. A loan runs for six months, and unredeemed pledges may be sold by auction a month after the expiration of the fixed period, and then the sale must take place in the parish in which the article was pledged. No more than two persons at a time have ever been licensed under this law, the business being unprofitable owing to the low rate of interest. In the canton of Bern there were once two pawnbrokers. One died and the other put up his shutters. The Zürich cantonal bank, however, conducts a pawnbroking department, which lends nothing under 4s. or over £40 without the special sanction of the bank commission. Loans must not exceed two-thirds of the trade value of the pledge, but 80 per cent. may be lent upon the intrinsic value of gold and silver articles. The establishment makes practically no profit. The Swiss disinclination to go to the pawnshop is, perhaps, accounted for in some measure by the growing number of dealers in second-hand articles, to whom persons in want of ready money sell outright such things as are usually pledged, in the hope of subsequently buying them back. Since, however, the dealer is at liberty to ask his own price for re-purchase, the expectation is often illusory, and can usually be fulfilled only upon ruinous terms. (J. G. J. P.-B.)

Switzerland.

Pawtucket, a city of Providence county, Rhode Island, U.S.A., on the Pawtucket river, four miles north of Providence, and on the New York, New Haven, and Hartford Railroad, in the north-eastern part of the state, at an altitude of 76 feet. The plan of the city is irregular, it is divided into five wards, has a water-supply from works owned by the city, and good sewerage. It has fine water-power in the river, which has been utilized in extensive manufactures, mainly cotton goods, in which industry this city was the pioneer in America. In 1900 the total number of manufacturing establishments was 534, with a total capital of $22,399,187. They employed 12,776 hands, and the product was valued at $24,080,328. Of this, $4,935,309 consisted of cotton goods, while $1,600,916 was the value of dyed and finished textiles. Worsted goods were manufactured to the value of $3,733,219. The product of foundries and machine shops was valued at $1,833,379. The assessed valuation of real and personal property was, in 1900, $33,570,000, the net debt $4,251,106, and the rate of taxation $16.50 per $1000. Population (1890), 27,633; (1900), 39,231, of whom 13,087 were foreign-born and 173 negroes.

Payn, James (1830–1898), English novelist, was born at Cheltenham, 28th February 1830, his father being clerk to the Thames Commissioners and treasurer to the county of Berks. He was educated at Eton, and afterwards entered the Military Academy at Woolwich; but his health was not equal to the demands of a military career, and he proceeded to Trinity College, Cambridge. He was not an assiduous "reading man," but was among the most popular men of his time, and served as president of the Union. Before going to Cambridge he had published some verses in Leigh Hunt's *Journal*, and while still an undergraduate put forth a volume of *Stories from Boccaccio* in 1851, and another collection of *Poems* in 1853. In the same year he left Cambridge, and shortly afterwards married Miss Louisa Adelaide Edlin, sister of Sir Peter Edlin. He then settled down to a literary career, contributed to *Household Words* and *Chambers's Journal*, and was in 1858 appointed editor of the latter periodical, conducting it with much success for sixteen years. In its pages he published in 1864 his most popular story, *Lost Sir Massingberd*, a serial which attracted so much attention that its appearance in *Chambers's* is said to have increased the circulation by 20,000 copies. From this time he was always engaged in novel-writing, among the most popular of his productions being *Married Beneath Him* (1865), *Carlyon's Year* (1868), *By Proxy* (1878), and *The Talk of the Town* (1885). In 1882 he succeeded Mr Leslie Stephen as editor of the *Cornhill Magazine*, and continued in the post until the breakdown of his health in 1896. He was also literary adviser to Messrs Smith, Elder and Company, and may be described as one of the last of the old-fashioned school of "readers"—a school which did much to foster literary talent, and to surround the individual firm with a loyal and competent body of men of letters. Payn was the means of introducing many promising writers to the public, and his advice and tact were in harmony with the highest traditions of the literary profession. As a novelist he was entertaining rather than profound. He told a good story easily and naturally; he possessed some dramatic force, and was skilful in the arrangement of incidents. He was not without a Dickensian sense of character, but his female figures are ingenuous and simple rather than subtly interesting. In other departments of the literary life he was a prolific writer. He published a *Handbook to the English Lakes* (1859), and various volumes of occasional essays, such as *Maxims by a Man of the World* (1869), *Some Private Views* (1881), *Literary Recollections* (1884), and a posthumous work, *The Backwater of Life*, revealed much of his own personality in a mood of kindly, sensible reflection upon familiar topics. For years he contributed a weekly column of literary and social gossip to the *Illustrated London News*. He died in London, 25th March 1898. (A. W.)

Paysandu, a city of Uruguay and capital of the department of the same name, situated on the Rio Uruguay, 131 miles above Montevideo. It is the third city of the republic in importance, with fine public buildings, good streets, and tramways. In 1898 the imports were valued at $750,892, and exports at $3,964,548. In other words, it has about 3 per cent. of the total import trade of the republic, and over 12 per cent. of the export trade. In 1900 the imports were valued at $626,214 (gold), and the exports at $2,720,870 (gold). In 1898 the entries were 787 steamers of 460,492 tons and 461 sailing ships of 23,177 tons. Population, 14,000.

Paz Soldan, Mariano Felipe (1821–1886), Peruvian historian and geographer, was born at Arequipa, 22nd August 1821. He studied law, and after holding some minor judicial offices, was minister to Colombia in 1853. After his return he occupied himself with plans for the establishment of a model penitentiary at Lima, which he was enabled to accomplish through the support of General Castilla, the most eminent of the rulers of Peru. In 1860 Castilla made him director of public works, in which capacity he superintended the erection of the Lima statue of Bolivar, the finest work of sculpture in South America. He was also concerned in the reform of the currency by the withdrawal of the debased Bolivian coins, which had long circulated at the same nominal value as the Peruvian. In 1861 he published his great atlas of the republic of Peru, and in 1868 the first volume of his history of Peru after the acquisition of her independence. A second volume followed, and a third, bringing the history down to 1839, was published after his death by his son. In 1870 he was minister of justice and worship under President Balta, but shortly afterwards retired from public life to devote himself to his great geographical dictionary of Peru, which was published in 1877. During the disastrous war with Chile he sought refuge at Buenos Aires, where he was received with distinguished hospitality and made professor in the National College, and where he wrote and published the history of his country's misfortunes. He died on 31st December 1886.

Peabody, a town of Essex county, Massachusetts, U.S.A., containing an area of 17 square miles of level country, dotted over with glacial hills, situated in the north-eastern part of the state, adjoining Salem on the west. The principal village bears the same name as the town, is laid out very irregularly, and is on a line of the Boston and Maine Railroad. Its chief industry is the manufacture of leather, for which there are several establishments. Population (1890), 10,158; (1900), 11,523, of whom 2870 were foreign-born.

Peace Conference, the official name of the International Conference, held at the instance of the emperor of Russia in 1899, at The Hague, "with the object of seeking the most efficacious means of assuring to all peoples the blessings of real and lasting peace, and, above all, in order to put a stop to the progressive development of the present armaments." The subject matter proposed for discussion embraced the following elements:—

1. An understanding not to increase for a fixed period the present effective of the armed military and naval forces, and at the same time not to increase the budgets pertaining thereto; and a preliminary examination of the means by which a reduction might even be effected in future.

2. To prohibit the use in the armies and fleets of any new kinds of firearms whatever, and of new explosives or any powder more powerful than those now in use either for rifles or cannon.

3. To restrict the use in military warfare of the formidable explosives already existing, and to prohibit the throwing of projectiles or explosives of any kind from balloons or by any similar means.

4. To prohibit the use in naval warfare of submarine torpedo-boats or plungers, or other similar engines of destruction; to give an undertaking not to construct vessels with rams in future.

5. To apply to naval warfare the stipulations of the Geneva Convention of 1864 on the basis of the Additional Articles of 1868.

6. To neutralize ships and boats employed in saving those overboard during or after an engagement.

7. To revise the Declaration concerning the laws and customs of war, elaborated in 1874, by the Conference of Brussels, which remained unratified.

8. To accept in principle the employment of good offices of mediation and facultative arbitration in cases lending themselves thereto, with the object of preventing armed conflicts between nations; to come to an understanding with respect to the mode of applying these good offices, and to establish a uniform practice in using them.

In accepting the invitation to attend the Conference, Lord Salisbury, referring to the 8th point, specially mentioned Great Britain's "earnest desire to promote by all possible means the principle of recourse to mediation and arbitration for the prevention of war."

The delegates appointed by the respective governments met at The Hague on 20th May 1899. The work, set out as above in the Russian scheme, was divided up among three committees, appointed: the first, to deal with points 1, 2, 3, and 4; the second with points 5, 6, and 7; and the third with point 8. The work of the third committee, which resulted in an "International Convention for the Pacific Settlement of International Disputes," has already been summarized in the article on ARBITRATION (INTERNATIONAL).[1] The work of the second committee was embodied in declarations to which Great Britain was not a party, and that of the third in two International Conventions—the one completing and adopting the work prepared by the Brussels Conference in 1874 on "the laws and customs of war by land," and the other "adapting to maritime warfare the principles of the Geneva Convention of 22nd August 1864." These two Conventions will be dealt with in the article on WAR. The question of restriction of armaments, which was placed at the head of the Russian proposal and referred to the first committee, was abandoned as impracticable. All three Conventions are dated 29th July 1899. (T. BA.)

[1] The United States representatives signed it subject to the recording alongside of it of the following declaration:—

"Nothing contained in this Convention is to be interpreted as obliging the United States of America to depart from their traditional policy, in accordance with which they abstain from intervening, meddling, or mixing in the political questions, policy, or internal administration of a foreign State. It is also understood that nothing in the Convention is to be construed as implying that the United States of America abandon their traditional attitude with respect to purely American questions."

Peace River. See MACKENZIE.

Peacock, Sir Barnes (1810–1890), English judge, was born in 1810, and was the son of Lewis Peacock, a solicitor. After practising as a special pleader, he was called to the bar in 1836, and in 1844 obtained great reputation by pointing out the flaw which invalidated the conviction of Daniel O'Connell and his fellow-defendants. In 1852 he went to India as legal member of the Governor-General's Council. He here displayed great activity as a law reformer, but sometimes, in his laudable anxiety to extirpate abuses, manifested too little consideration for native susceptibilities, and too imperfect a recognition of the limited extent of his own acquaintance with the country. The Legislative Council was established soon after his arrival, and although no orator, he was so frequent a speaker that legislation enjoining councillors to deliver their speeches sitting was said to have been devised with the sole object of restraining him. As a member of Lord Dalhousie's council he supported the annexation of Oudh, and he stood by Lord Canning all through the Mutiny. In 1859 he became chief justice of the Supreme Court, and presided over it with great industry and efficiency, although upon one important occasion, a case involving the rights of landholders, he found himself in a minority of one. He returned to England in 1870, and in 1872 was placed upon the judicial committee of the Privy Council, where his Indian experience rendered him invaluable. He laboured there for the rest of his life with unremitting energy, having sat only three days before his decease on 3rd December 1890.

Pearsall, Robert Lucas de (1795–1856), English composer, was born, 14th March 1795, at Clifton, educated for the bar, and practised till 1825, when he left England for Germany. He studied composition under Panny of Mainz; and with the exception of three comparatively short visits to England, during one of which he made the acquaintance of the English school of madrigals, he lived abroad for the remainder of his life, selling his family property of Willsbridge and settling in the castle of Wartensee, on the Lake of Constance, where he emulated the style of the grandees of the Middle Ages, and devoted himself to the arts, with special preference for music. Notwithstanding the diffusion of his gifts and the circumstances of his career, he produced many works of lasting beauty, nearly all of them for voices in combination: from his part songs, such as "Oh, who will o'er the downs," to his elaborate and scholarly madrigals, such as the admirable eight-part compositions, "Great God of Love" and "Lay a Garland," or the beautiful "Light of my Soul," his genius ranged over a wide field. He combined great technical knowledge of the various styles he employed with a spontaneity of invention that gives his works a peculiar beauty. His reception into the Roman Church in his later years may have suggested the composition of some beautiful sacred music, among other things a "Salve Regina" that will not soon be forgotten. He wrote many valuable treatises on music, and edited a Catholic hymn-book of considerable merit. He died 5th August 1856.

Pearson, Charles Henry (1830–1894), British historian and colonial statesman, was born in London on 7th September 1830. After receiving his early education at Rugby and King's College, London, he went up to Oxford, where he was generally regarded as the most brilliant of an exceptionally able set, and in 1854 obtained a fellowship at Oriel College. His constitutional weakness and bad eyesight forced him to abandon his chosen profession of medicine, and in 1855 he returned to King's College as lecturer in English language and literature, a post which he almost immediately quitted for the professorship of modern history. From his undergraduate days he had been a keen student of foreign countries and literatures. Of his numerous journeys abroad the most important were his visit to Russia in 1858, his account of which was published anonymously in 1859 under the title of *Russia, by a Recent Traveller*; an adventurous journey through Poland during the insurrection of 1863, of which he gave a sympathetic and much-praised account in the *Spectator*; and a visit to the United States in 1868, where he gathered materials for his subsequent discussion of the negro problem in his *National Life and Character*. In the meantime, besides contributing regularly, first to the *Saturday Review* and then to the *Spectator*, and editing the *National Review*, he wrote the first volume of *The Early and Middle Ages of England* (1861). The work was bitterly attacked by Freeman, whose "extravagant Saxonism" Pearson had been unable to adopt. It appeared in 1868 in a revised form with the title of *History of England during the Early and Middle Ages*, accompanied by a second volume which met with general recognition. Still better was the reception of his admirable *Maps of England in the First Thirteen Centuries* (1870). But as the result of these labours he was threatened with total blindness; and, disappointed of receiving a professorship at Oxford, the goal of his ambition, he threw up the lectureship of modern history at Trinity College, Cambridge, which he had held for a short time, and in 1871 emigrated to Australia, which he had already visited on a voyage undertaken for his health's sake. Here he married and settled down to the life of a sheep-farmer; but finding his health and eyesight greatly improved, he came to Melbourne as lecturer on history at the University. Soon afterwards he became headmaster of the Presbyterian Ladies' College, and in this position practically organized the whole system of higher education for women in Victoria. In 1877 he was appointed by the Liberal Government to inquire into the state of education in the colony. His report, issued in the following year, was recognized as a classic, and many of its suggestions were adopted both in Europe and in the other Australian colonies. He had for some time been an influential contributor to the great Liberal organ, *The Age*, and on his election in 1878 to the Legislative Assembly definitely adopted politics as his career. His views on the land question and secular education aroused the bitter hostility of the rich squatters and the clergy; but his singular nobility of character, no less than his powers of mind, at once made him one of the most influential men in the Assembly. He was minister without portfolio in the Berry cabinet (1880–81), and when the ministry was on the eve of quitting office, was offered the post of Agent-General, but felt that in the circumstances he could not honourably accept it. As minister of education in the coalition government of 1886 to 1890, he was able to pass into law many of the recommendations of his report. His reforms, which entirely remodelled state education in Victoria, included the establishment of a system of state scholarships, the reorganization of industrial schools and of the teaching of art, and the improvement of the position of teachers. He obtained the appointment of a commission on technical education, as chairman of which he drew up a valuable report. During the intervals of his public work he prepared an edition of Juvenal in collaboration with Professor Strong (1887). In 1892 a fresh attack of illness decided him to return to England. Here he published in 1893 the one of his works which attracted most general notice, *National Life and Character*. It is an attempt to show that the white man can flourish only in the temperate zones, that the yellow and black races must increase out of all proportion to the white, and must in time by their industrial competition crush out his civilization, both material and intellectual. He died in London on 29th May 1894. A volume of his *Reviews and Critical Essays* was published in 1896, and was followed in 1900 by his autobiography, completed by his friends, a work of great interest. (H. SY.)

Pearson, John Loughborough (1817–1897), English architect, son of William Pearson, etcher, of Durham, was born in Brussels on 5th July 1817. He was articled at the age of fourteen to Ignatius Bonomi, architect, of Durham, but soon removed to London, and worked under the elder Hardwicke. Durham Cathedral and the churches and abbeys of Yorkshire seem to have influenced his studies. He revived and practised largely the art of vaulting, and acquired in it a proficiency unrivalled in his generation. He was, however, by no means a Gothic purist, and was also fond of Renascence and thoroughly grounded in classical architecture. From the erection of his first church of Ellerker, in Yorkshire, in 1843, to that of St Peter's, Vauxhall, in 1864, his buildings are Geometrical in manner and exhibit a close adherence to precedent, but elegance of proportion and refinement of detail lift them out of the commonplace of mere imitation. Holy Trinity, Westminster (1848), and St Mary's, Dalton Holme (1858), are notable examples of this phase. St Peter's, Vauxhall (1864), his first groined church, was also the first of a series of buildings which brought Pearson to the forefront among his contemporaries. In these he applied the Early English style to modern needs and modern economy with unrivalled success. St Augustine's, Kilburn (1871), St John's, Red Lion Square, London (1874), St Alban's, Birmingham (1880), St Michael's, Croydon (1880), St John's, Norwood (1881), St Stephen's, Bournemouth (1889), and All Saints', Hove (1889), are characteristic examples of his matured work. He is best known by Truro Cathedral (1880), which has a special interest in its apt incorporation of the south aisle of the ancient church. Pearson's conservative spirit fitted him for the reparation of ancient edifices, and among cathedrals and other historical buildings placed under his care were Lincoln, Chichester, Peterborough, Bristol, and Exeter Cathedrals, St George's Chapel, Windsor, Westminster Hall, and Westminster Abbey, in the surveyorship of which last he succeeded Sir G. G. Scott. Except as to the porches, the work of Scott, he re-faced the north transept of Westminster Abbey, and also designed the vigorous organ cases. In his handling of ancient buildings he was repeatedly opposed by the ultra anti-restorers (as in the case of the west front of Peterborough Cathedral in 1896), but he generally proved the soundness of his judgment by his executed work. Pearson's practice was not confined to church building. Treberfydd House (1850), Quar Wood (1858), Lechlade Manor, an Elizabethan house (1873), Westwood House, Sydenham, in the French Renaissance style (1880), the Astor estate offices (1892) upon the Victoria Embankment, London, the remodelling of the interiors of Clieveden House (1893) and No. 18 Carlton House Terrace (1894), with many parsonages, show his aptitude for domestic architecture. Pearson's church plans possess great variety and interest. The management of choir and sanctuary evidences much individuality, and the side chapel is frequently treated so as to give additional scale to the rest of the building. In general design he first aimed at form, embracing both proportion and contour; and his work may be recognized by accurate scholarship coupled with harmonious detail. Its keynotes are cautiousness and refinement rather than boldness. After a continuous progress up to the last days of his long career, he died on the 11th of December 1897, and was buried in the nave of Westminster Abbey, where his grave is marked by the appropriate motto *Sustinuit et abstinuit.* He was elected A.R.A. in 1874, R.A. in 1880, was a fellow of the Society of Antiquaries, and a fellow and member of the Council of the Royal Institute of British Architects.

The following are some of Pearson's more important works, not already named :—Ferriby Church, 1846 ; Stow, Lincolnshire (restoration), 1850 ; Weybridge, St James's, 1853 ; Freeland Church, Parsonage, and Schools, 1866 ; Kilburn, St Peter's Home, 1868 ; Wentworth Church, 1872 ; Horsforth Church, 1874 ; Cullercoats, St George's, 1882 ; Chiswick, St Michael's (restoration), 1882 ; Great Yarmouth Church (restoration), 1883 ; Liverpool, St Agnes', 1883 ; Woking Convalescent Home, 1884 ; Headingley Church, 1884 ; Torquay, All Saints', 1884 ; Maidstone, All Saints' (restoration), 1885 ; Shrewsbury Abbey, 1886 ; Ayr, Holy Trinity, 1886 ; Hythe Church (restoration), 1887 ; Oxford, New College, Reredos (completion), 1889 ; Cambridge University Library (additions), 1889 ; Friern Barnet, St John's, 1890 ; Cambridge, Sidney Sussex College (additions), 1890 ; Middlesex Hospital Chapel, 1890 ; Bishopsgate, St Helen's (restoration), 1891 ; Maida Hill (Irvingite) Church, 1891 ; Barking, All Hallows' (restoration), 1893 ; Cambridge, Emmanuel College (additions), 1893 ; Ledbury, St Michael's (restoration), 1894 ; Malta, Memorial Church, 1894 ; Port Talbot Church, 1895. (W. D. C.)

Pécs (German, *Fünfkirchen*), a municipal town, capital of the province of Baránya, Hungary. It has an upper *real*-school, a commercial academy, an orphanage, and a foundling hospital. In the 14th century it possessed also a university, which existed until the disaster of Mohács. Its industry and commerce are thriving. It is famous for its porcelain, organs, and sparkling wine. There are in the vicinity extensive coal-mines, which produce yearly five million tons of good coal. Population (1890), 34,100 ; (1900), 43,982.

Pedro II. (1825–1891), EMPEROR OF BRAZIL, came to the throne in childhood, having been born on 2nd December 1825, and proclaimed emperor in April 1831, upon the abdication of his father. He was declared of full age in 1840, and, after some troubles had been overcome, found himself reigning peacefully over a united people. For a long period few thrones appeared more secure, and his prosperous and beneficent rule might have endured throughout his life, but for his want of energy and inattention to the signs of the times. The rising generation had become honeycombed with republicanism, the prospects of the imperial succession were justly regarded as unsatisfactory, the higher classes had been estranged by the emancipation of the slaves, and all these causes of discontent found expression in a military revolt, which in November 1889 overthrew the seemingly solid edifice of the Brazilian empire in a few hours. Dom Pedro retired to Europe, and died in Paris on the 5th of December 1891. The chief events of his long reign had been the emancipation of the slaves already adverted to, and the sanguinary and costly, though ultimately successful, war with Paraguay in 1864–1870. Dom Pedro was a model constitutional sovereign, and, like Prospero, carried study to such an extent as to undermine his authority by impairing his efficiency as a ruler. He was a munificent patron of science and letters, travelled in the United States (1876), and thrice visited Europe (1871–72, 1876–77, 1886–89).

Peebles, a midland county of Scotland, bounded on the N. and N.E. by Midlothian, on the E. and S.E. by Selkirk, on the S. by Dumfries, and on the W. by Lanark.

Area and Population.—In 1891 the boundaries between Peebles and Selkirk were rearranged, the parishes of Innerleithen and Peebles being placed wholly in Peeblesshire, and a detached portion of the Peebles parish of Lyne and Megget transferred to the Selkirk parish of Yarrow; the boundary was also rearranged between Peebles and Lanark shires in the parish of Coulter, which was placed wholly in the latter county, its Peebles portion being transferred to the Peebles parish of Broughton. The area of the county is 223,295 acres, or about 349 square miles. The population was, in 1881, 13,822; in 1891, 14,761; in 1891 on the above area 14,750; and in 1901, 15,066, of whom 7129 were males and 7937 females. On the old area, taking land only (226,899 acres, or 354·5 square miles), the number of persons to the square mile in 1891 was 42, and the number of acres to the person 15·4. In the registration county the increase of population between 1881 and 1891 was 6·9. Between 1881 and 1891 the excess of births over deaths was 1902, and the increase of the resident population 950. The following table gives particulars of births, deaths, and marriages in 1880, 1890, and 1899:—

Year.	Deaths.	Marriages.	Births.	Percentage of Illegitimate.
1880	194	71	423	10·4
1890	198	78	302	5·63
1899	209	74	363	4·7

The following table gives the birth-rate, death-rate, and marriage-rate per thousand of the population for a series of years:—

	1880.	1881–90.	1890.	1891–98.	1899.
Birth-rate . .	31·17	27·45	20·73	23·91	23·41
Death-rate . .	14·29	14·02	13·58	14·41	13·48
Marriage-rate .	5·23	5·20	5·35	6·14	4·77

In 1891 there were 68 Gaelic-speaking persons in the county, and 15 foreigners. Valuation in 1889–90, £144,036; 1899–1900, £144,066.

Administration.—The county unites with Selkirkshire in sending a member to Parliament. Peebles (5266) is the only royal burgh, and its constituency is merged in that of the county. There are 14 civil parishes, of which four are not assessed for poor. The number of paupers and dependants in September 1899 was 214, and there is a combination poorhouse at Peebles. Peebles forms a sheriffdom with the Lothians, and a sheriff-substitute sits in the county town.

Education.—Fourteen school boards manage 20 schools, with an average attendance of 1995 in 1898–99, and three other schools (one Episcopal) had an average attendance of 80 in the same year. Peebles has a high school, and another school in the county earned grants in 1898 for giving secondary education. Most of the "residue" grant is spent by the county council in subsidizing science and art, and technical classes and evening classes in Peebles, Innerleithen, and elsewhere.

Agriculture.—In 1898, 21·5 per cent. of the acreage was under cultivation. The following table gives the principal acreages for the years specified:—

Year.	Area under Crops.	Corn Crops.	Green Crops.	Clover.	Permanent Pasture.	Fallow.
1880	42,010	10,382	6245	13,995	11,297	91
1885	42,514	9,600	5441	11,301	16,168	4
1890	42,731	8,988	5500	13,372	14,824	41
1895	46,814	8,782	5237	17,938	14,846	6
1899	48,607	8,648	5018	18,254	16,669	5

The following table gives particulars of the live stock for the same years:—

Year.	Total Horses.	Total Cattle.	Cows or Heifers in Milk or Calf.	Sheep.	Pigs.
1880	1184	5934	1991	199,512	719
1885	1164	6530	2128	192,367	1043
1890	1046	6843	1929	188,033	876
1895	1176	6789	2112	186,221	707
1899	1098	7498	2204	201,538	618

In 1891, 1407 men and 108 women in the county were engaged in agriculture. There were 9490 acres under wood in 1895. Of the 300 holdings in the county in the same year, the average size was 156 acres; 8 per cent. were under 5 acres, 27 per cent. between 5 and 50 acres, and 65 per cent. over 50. There were 29 farms between 50 and 100 acres, 115 between 100 and 300, 42 between 300 and 500, and 9 over 500. A normal farm is about 200 acres arable, with pasturage for 600 or 800 sheep.

Industry.—The minerals—coal, limestone, and iron ore—scarcely repay working. Of 3686 persons registered in 1891 as being connected with industrial pursuits, 1008 men and 1082 women were employed about textiles.

(W. WA.)

Peebles, a royal burgh and the county town of Peeblesshire, at the junction of the Eddlestone water with the Tweed, 23 miles south of Edinburgh by road. The town grows in favour as a health resort. Tweed bridge has been widened, and an Established church has been erected. Population (1881), 3495; (1901), 5266.

Peekskill, a village of Westchester county, New York, U.S.A., on the east bank of the Hudson river and on the New York Central and Hudson River Railroad, 43 miles above New York, in the south-eastern part of the state. Its site is hilly and its street plan irregular. It has a good water-supply and sewerage system, and contains a number of private schools for boys and girls. Its manufactures are varied, and include iron-works, flour-mills, and cigar factories. It is the site of the annual camp of the State National Guard. Population (1890), 9676; (1900), 10,358, of whom 1341 were foreign-born and 243 negroes.

Peel, Arthur Wellesley Peel, 1st VISCOUNT (1829– ——), youngest son of the eminent statesman, Sir Robert Peel, was born on 3rd August 1829, and was educated at Eton and Balliol College, Oxford. Destined for a political career, he unsuccessfully contested Coventry in 1863; but two years later he was elected in the Liberal interest for Warwick, for which he sat until his elevation to the peerage. Soon after his entrance into the House of Commons, he evinced great business capacity and wide knowledge of constitutional forms, and in December 1868 was appointed parliamentary secretary to the Poor Law Board. This office he filled until 1871, when he became secretary to the Board of Trade, an appointment which he held for two years. In 1873–74 he was patronage secretary to the Treasury, and when the Liberals again returned to power in 1880 he became under-secretary for the Home Department. On the retirement of Mr Brand (afterwards Viscount Hampden) in 1884, Mr Peel was elected Speaker, and his speech on accepting the office was one of marked dignity. He was thrice re-elected to the post, twice in 1886, and again in 1892. Throughout his career as Speaker he exhibited the greatest impartiality, combined with a perfect knowledge of the traditions, usages, and forms of the House, soundness of judgment, and readiness of decision upon all occasions. On 8th April 1895, in a very full gathering of the House of Commons, Speaker Peel announced that in consequence of failing health he was compelled to retire from the chair. The farewell ceremony was of a most impressive character, and warm tributes were paid from all parts of the House. The dignity of a viscount was subsequently conferred upon him, and he was granted by statute a pension of £4000 for life. Lord Peel received the honorary degree of D.C.L. from Oxford University in 1887, and he was presented with the freedom of the City of London in a gold casket in July 1895. A Royal Commission was appointed in April 1896 to inquire into the operation and administration of the licensing laws. The Commission was of a most comprehensive and representative character, and Viscount

Peel was appointed chairman. It held 123 sittings and examined 260 persons. The taking of evidence was concluded in July 1898, when the commissioners adjourned, and Lord Peel drew up a draft report for discussion, in five parts, dealing with England, Wales, Scotland, Ireland, Clubs, and the Reduction of Licences, Compensation, Local Option or Prohibition, and Municipal Management. Some differences of opinion arose in connexion with the report, and at a meeting of the commissioners on 12th April 1899, when part 5 of the draft report was to be considered, a proposal was made to substitute an alternative draft for Lord Peel's, and also a series of alternative drafts for the four sections already discussed. Lord Peel declined to put these proposals, and left the room. Sir Algernon West was elected to the chair, and ultimately two main reports were presented, one section agreeing with Lord Peel, and the other—including the majority of the commissioners—presenting a report which differed from his in several important respects. The Peel Report recommended that a large reduction in the number of licensed houses should be immediately effected, and that no compensation should be paid from the public rates or taxes, the money for this purpose being raised by an annual licence-rental levied on the rateable value of the licensed premises. Lord Peel's Report at once became a valuable weapon in the hands of temperance reformers.

Peesemsky, Alexey Feofilactovich (1820–1881), a well-known Russian novelist of an extremely sceptical and pessimistic character, was born on his father's estate, in the province of Kostroma, 10th/22nd March 1820. In his autobiography he describes his family as belonging to the ancient Russian nobility, one of his ancestors having been sent as ambassador to London by Ivan the Terrible to see a niece of Queen Elizabeth, whom the Tsar wished to marry, and another having been canonized after death as a saint. His more immediate progenitors, however, were all very poor, and quite unable to read or write. His grandfather ploughed the fields as a simple peasant, and his father, as Peesemsky himself said, was washed and clothed by a rich relative, and placed as a soldier in the army, from which he retired, after thirty years' service, with the rank of major. Peesemsky's first teachers were a village curate, and a priest expelled from the Church for drunkenness. During childhood he read eagerly the translated works of Walter Scott and Victor Hugo, and later those of Shakespeare, Schiller, Goethe, Rousseau, Voltaire, and George Sand. From the gymnasium of Kostroma, where he exhibited some talent for acting, he passed through Moscow University, and in 1884 entered the Government service as a clerk in the office of the Crown Domains in his native province. Between 1854 and 1872, when he finally quitted the civil service, he occupied similar posts in St Petersburg and Moscow. His early works exhibit a profound disbelief in the higher qualities of humanity, and one of his singular traits was a disdain for the other sex, although he appears to have been attached to a particularly devoted and sensible wife. His first novel, *Boyarstchina*, was forbidden for its unflattering description of the Russian nobility. His principal novels are *Tufak* ("A Muff"), 1850; *Teesicha Doush* ("A Thousand Souls"), 1862, which is considered his best work of the kind; and *Vzbalomoucheneoe More* ("A Troubled Sea"), giving a picture of the excited state of Russian society about the year 1862. He also produced a comedy, *Gorkaya Soudbina* ("A Bitter Fate"), depicting the dark sides of the Russian peasantry, and resembling Zola's *La Terre*, which obtained for him the Ouvaroff prize of the Russian Academy. In 1856 he was sent, together with other literary men, to report on the ethnographical and commercial condition of the Russian interior, his particular field of inquiry having been Astrakhan and the region of the Caspian Sea. His scepticism in regard to the liberal reforms of the 'sixties made him very unpopular among the more progressive writers of that time. His death occurred at Moscow on the 2nd February 1881 (21st January, Russian style). (G. D.)

Pegu, a division of Lower Burma comprising the districts of Rangoon town, Hanthawaddy, Pegu, Tharrawaddy, and Prome, with a total area of 13,083 square miles and a population in 1891 of 1,522,511, and of 1,818,845 in 1901. In 1898–99 it paid a revenue of Rs.74,14,902. PEGU district is the largest in the division, and has an area of 4276 square miles, with a population in 1891 of 237,594, and in 1901 of 339,942, with 782 villages paying a revenue in 1898–99 of Rs.17,61,123. Of the population in 1891, 218,889 were Buddhists and Jains, 7777 were Hindus, 2407 Mahommedans, 2939 aborigines (mostly Karens), and 5582 Christians, 5387 of whom were natives, chiefly Karens. Of a total acreage of 2,736,640, there were 612,968 acres cultivated in 1898–99, 741,618 remained uncultivable, and 481,168 acres apart from fallow were cultivable. The rainfall in 1898–99 was 114·42 inches, taken at Pegu town. The vast bulk of the cultivation is rice. The chief town, PEGU, has increased greatly in prosperity since the opening of the railway. It had a population of 5891 in 1881, and in 1891 of 10,762. It has a municipal committee of twelve elective and four *ex officio* members.

Peine, a town of Prussia, province of Hanover, 16 miles by rail west-north-west of Brunswick. It has ironworks, breweries, manufactures of starch and artificial manure, brickworks, and distilleries. There are also large horse and cattle markets. Population (1885), 7868; (1900), 15,427.

Pekin, a city of Illinois, U.S.A., capital of Tazewell county, is on the Illinois river, at the intersection of six large railways, north-west of the centre of the state. It has a level site, and its street plan is regular. It is in a rich agricultural region and in the Illinois coalfield, and is a shipping point and grain market of great importance. Its manufactures are varied, including agricultural implements, lumber, brick and tiles, &c. Population (1890), 6347; (1900), 8420, of whom 1366 were foreign-born.

Peking, the capital of the Chinese empire, on a sandy alluvial plain on the Peiho and its tributary the Hunho, nearly equidistant from both, 36 miles south-east of the Great Wall, at the head of the Great Canal. Not being open to foreign trade, there is no general right of residence for foreign merchants at Peking, and consequently it has not shared in the industrial growth and progress that have benefited so many other Chinese cities. The only foreign commercial institution which has so far succeeded in gaining a foothold within the walls is the Hong Kong and Shanghai Bank, a branch of which has been established there for several years. A branch of the Russo-Chinese Bank has also been opened. With these exceptions the foreign residents are either the diplomatic representatives, or employés of the Chinese Government, or missionaries. The most important fact to be noted is the opening of the railway between Tientsin and Peking in 1897. This was only accomplished after great opposition from the ultra-Conservatives, but once accomplished the facilities were gladly accepted by all classes, and the traffic both in goods and passengers is already enormous. Out of deference to the scruples of the ultra-Conservatives, the terminus was fixed at a place called Lu-Ko-chiao, some four miles outside the walls, but this distance has since been covered by an electric tramway. The trunk line constructed by the Franco-Belgian syndicate will connect Lu-Ko-chiao, the original terminus, with Hankow—hence the name Lu-Han by which this trunk line is generally spoken of, Lu being short for Lu-Ko-chiao and Han for Hankow. Since the first advent of foreigners in Peking in 1860 nothing whatever had been done until 1900 to improve the streets or the drainage. The streets as originally laid out were wide and spacious, but being unpaved and undrained they were no better than mud tracks diversified by piles of garbage and foul-smelling stagnant pools. Such drainage as had at one time existed was allowed to get choked up, giving rise to typhoid fever of a virulent type. Some attempt has been made to improve matters by macadamizing one of the principal thoroughfares, but it will be the labour of a Hercules to cleanse this vast city from the accumulated filth of ages of neglect. Fortunately the space inside the walls is so great that the houses are not crowded together, and there is a great number of large enclosures, mostly garden ground, the residence of one or other of the Manchu princes and nobility. One of such enclosures constitutes the British legation, and most of the other foreign legations are similarly, though not so sumptuously, lodged. The exact population of Peking is not known even to the Chinese themselves. In the ninth edition of this work it was stated to be about one million, and this figure is probably the highest at which it can yet be put. Many estimates make it considerably less. Peking suffered severely during the Boxer movement and the siege of the legations in the summer of 1900. Not only were most of the foreign buildings destroyed, but also a large number of important Chinese buildings in the vicinity of the foreign quarter, including the ancient Hanlin, the Boards of War, of Rites, &c. Almost the whole of the business quarter, the wealthiest part of the Chinese city, was laid in ashes. (For a fuller account of the siege, see CHINA: *History*.)

Pelew Islands. See MICRONESIA.

Pelloux, Luigi (1839-——), Italian general and politician, was born, on 1st March 1839, at La Roche, in Savoy, of parents who retained their Italian nationality when Savoy was annexed to France. Entering the army as lieutenant of artillery in 1857, he gained the medal for military valour at the battle of Custozza in 1866, and in 1870 commanded the brigade of artillery which battered the breach in the wall of Rome at Porta Pia. Manifesting aptitude for a political career, he was elected deputy in 1880, and, after having been secretary-general of the War Office, became minister of war in the Rudini and Giolitti Cabinets of 1891–93. In July 1896 he resumed the portfolio of war in the Rudini Cabinet, and was appointed senator. In May 1897 he secured the adoption of the Army Reform Bill, fixing Italian military expenditure at a maximum of £9,560,000 a year, but in December of that year he was defeated in the Chamber on a technical issue. Resigning office, he was in May 1898 sent as royal commissioner to Bari, where, without recourse to martial law, he succeeded in restoring public order. Upon the fall of Rudini, in June 1898, General Pelloux was entrusted by King Humbert with the formation of a Cabinet. An excellent administrator but an indifferent politician, he accomplished little in the legislative field, and turned his attention chiefly to the maintenance of order and to sound management of public affairs. The Public Safety Bill for the reform of the police laws, taken over by him from the Rudini Cabinet, and eventually promulgated by royal decree, was fiercely obstructed by the Socialist party, which, with the help of the other groups of the Left and Extreme Left, succeeded in forcing General Pelloux to dissolve the Chamber in May 1900, and to resign office shortly after the general election in the following June. In the autumn of 1901 he was appointed to the command of the Turin army corps.

Pembroke, a maritime county of South Wales, bounded on the E. by Carmarthen, on the N.E. by Cardigan, on the S.E. and S. by the Bristol Channel, and on the W. and N.W. by St George's Channel.

Area and Population.—The area of the ancient county is 395,151 acres, or 617 square miles, with a population in 1881 of 91,824; in 1891 of 89,133, of whom 41,685 were males and 47,448 females; in 1901 of 88,749, the number of persons per square mile being 144, and of acres to a person 4·4. The area of the administrative county is 392,710 acres, with a population in 1891 of 80,296. The registration county comprises 357,118 acres, with a population in 1891 of 82,003. Within this area the decrease of population between 1881 and 1891 was 2·00 per cent. The excess of births over deaths between 1881 and 1891 was 9914, but the resident population nevertheless decreased by 1674. The following table gives the numbers of marriages, births, and deaths, with the number and percentage of illegitimate births, for 1880, 1890, and 1898:—

Year.	Marriages.	Births.	Deaths.	Illegitimate Births.	
				No.	Per cent.
1880	563	2604	1540	163	6·3
1890	574	2305	1566	153	6·5
1898	564	2222	1448	115	5·2

In 1891 there were in the county 342 natives of Scotland, 784 natives of Ireland, and 127 foreigners, while 51,959 persons could speak English, 13,673 Welsh, and 10,804 English and Welsh.

Constitution and Government.—The county returns one member to Parliament, and it also includes the Pembroke and Haverfordwest district of parliamentary boroughs (consisting of Fishguard, Haverfordwest, Milford, Narberth, Pembroke, Tenby, and Weston), returning one member. There are three municipal boroughs: Haverfordwest (6007), Pembroke (15,853), and Tenby (4400). Haverfordwest is a county in itself and has its own lord-lieutenant. There is only one urban district, Milford Haven (5101). Pembrokeshire is in the South Wales and Chester circuit, and assizes are held at Haverfordwest. The boroughs of Haverfordwest, Pembroke, and Tenby have separate commissions of the peace, and Haverfordwest has also a separate court of quarter sessions. The ancient county, which is entirely in the diocese of St Davids, contains 114 entire ecclesiastical parishes and districts and parts of 5 others.

Education.—The total number of elementary schools on 31st August 1899 was 127, of which 57 were board and 70 voluntary schools, the latter including 58 National Church of England schools, 1 Wesleyan, and 11 "British and other." The average attendance at board schools was 6413, and at voluntary schools 5790. The total school board receipts for the year ended 29th September 1899 were over £22,198. The income under the Agricultural Rates Act was over £1424.

Agriculture.—About four-fifths of the total area of the county is under cultivation, and of this about two-thirds is in permanent pasture. Only about 33,000 acres are in hill pasture, and less than 10,000 acres are under woods. Of the corn crops oats are the principal, occupying considerably more than half the acreage, while barley occupies about three-eighths, and wheat not much more than a fourteenth. The acreage under green crops is not large, but about seven-twelfths is occupied by turnips, cattle being largely kept both for feeding and milking. Only about one-fifth of the green crop acreage is occupied by potatoes, and about one-fifth also is under mangold, cabbage, &c. The following table gives the larger main divisions of the cultivated area at intervals from 1880:—

Year.	Total Area under Cultivation.	Corn Crops.	Green Crops.	Clover.	Permanent Pasture.	Fallow.
1880	302,780	57,573	12,471	28,789	199,913	4034
1885	306,783	52,250	13,633	31,214	207,808	1878
1890	309,293	52,455	13,455	42,365	199,507	1503
1895	315,303	49,689	13,222	41,655	209,661	1041
1900	313,346	49,929	12,191	39,998	210,485	716

The table on the next page gives particulars regarding the principal live stock for the same years.

Year.	Total Horses.	Total Cattle.	Cows or Heifers in Milk or in Calf.	Sheep.	Pigs.
1880	14,376	85,138	31,817	99,030	21,537
1885	14,667	90,250	33,567	102,655	20,318
1890	14,682	88,266	33,186	115,334	31,095
1895	16,131	87,543	32,280	119,817	32,278
1900	15,984	93,744	32,998	138,199	29,482

Industries and Trade.—According to the report for 1898 of the chief inspector of factories (1900), the total number of persons employed in factories and workshops in 1897 was 4654, as compared with 4217 in 1896. Of the 3370 persons employed in non-textile factories, 2736 were employed in the manufacture of machines, appliances, conveyances, and tools, mostly in connexion with the shipbuilding yards at the different ports. Only 1133 persons were employed in workshops. The number of persons employed in connexion with mines and quarries in 1899 was 946. In the same year 246,330 tons of igneous rocks were raised, and 22,998 tons of limestone. Lead mining has practically ceased, and little or no iron ore is obtained. The coal production (wholly anthracite) is rather fluctuating, 52,642 tons valued at £13,160 being obtained in 1885, 71,908 tons valued at £35,954 in 1890, 82,384 tons valued at £45,311 in 1898, and 59,419 tons valued at £32,680 in 1899. The fisheries are of considerable importance. At Tenby, Newland, and Milford (almost entirely the last two) 448,449 cwt. of fish valued at £381,610 was landed in 1899.

See *A Historical Tour through Pembrokeshire.* London, 1811. —TOMBS. *Concerning Pembrokeshire.* Haverfordwest, 1863.—The guide-books to South Wales. (T. F. H.)

Pembroke, a municipal and contributory parliamentary borough of Pembrokeshire, Wales, in the Pembroke and Haverfordwest district of boroughs, 272 miles west of London by rail. The dock has a length of 404 feet, with a depth on sill, at high water ordinary spring tides, of 25 feet. Population (1881), 14,156; (1891), 14,978; (1901), 15,853.

Pembroke, a town of Ontario, Canada, capital of Renfrew county, 74 miles west-north-west of Ottawa by rail, on the south shore of Allumette Lake, and on the Canadian Pacific and Canada Atlantic railways. It is the seat of a Roman Catholic bishop, and contains saw, grist, and woollen mills, axe factory, &c. The Muskrat river, which flows through the town, affords excellent water-power. Population (1881), 2820; (1891), 4401; (1901), 5156.

Penang. See PRINCE OF WALES ISLAND.

Penarth, a seaport, urban district (1894), and railway station in the Southern parliamentary division of Glamorganshire, Wales, on the river Taff, opposite Cardiff. The town is rapidly spreading. Gardens have been laid out along the cliff, numerous villas built in the western district, and a promenade and landing-pier opened, with a length of 630 feet. The chief buildings of modern erection are an Established church (1891) and an intermediate and technical school (1894). Three miles to the west is Dinas Powis Castle. Penarth dock, which cost £775,000 and comprised 17½ acres, was extended in 1884 at a cost of £250,000, and now covers 23 acres. It is 2900 feet in length, has a minimum depth of 26 feet, and is furnished with every convenience for facilitating the export of coal, of which from 20,000 to 30,000 tons can be stored in the sidings near by. The trade of the dock in one year totalled a tonnage of 3,454,964, and a still further extension is contemplated. Penarth harbour (55 acres) and basin (3 acres) have a minimum depth of 20 feet. A considerable import trade is carried on at the Penarth-Ely tidal harbour, mainly through coasting vessels. Commodious store-houses have been erected there; also tanks to hold about 6000 tons of oil. Population (1881), 6228; (1891), 12,424; (1901), 14,227.

Pender, Sir John (1816–1896), was born in the Vale of Leven, Scotland, on 10th September 1816, and, after attending school in Glasgow, entered on a successful business career in that city and in Manchester. His name is chiefly known in connexion with submarine cables. He was one of the 345 contributors who each risked a thousand pounds in the transatlantic cable in 1857, and when, after many disappointments, the Atlantic Cable Company was ruined by the loss of the 1865 cable, he did not lose faith in submarine telegraphy, but formed the Anglo-American Telegraph Company to continue the work. His faith, however, was not generally shared, and it was not till he had given his personal guarantee for payment to the amount of a quarter of a million that the makers would undertake the manufacture of a new cable. But in the end he was justified, and telegraphic communication with America became a commercial success. Subsequently he fostered cable enterprise in all parts of the world—to the Mediterranean, India and China, Australia and Africa—with the result that at the time of his death, which occurred in London on 7th July 1896, he controlled companies having a capital of 15 millions sterling and owning 73,640 nautical miles of cable.

Pennsylvania, a central eastern state of the American Union. The area is 45,215 square miles (44,985 land and 230 water), with a mean elevation of 1100 feet. The distribution of this area in altitude is as follows:—

Elevation.	Area.
0 to 100 feet	600 square miles
100 to 500 ,,	5,550 ,,
500 to 1000 ,,	12,700 ,,
1000 to 1500 ,,	15,900 ,,
1500 to 2000 ,,	8,215 ,,
2000 to 3000 ,,	2,300 ,,

The first two elevations are in the south-eastern end of the state, and represent Philadelphia and the adjacent region. The third, largest in the western end of the state, is a continuation of the southern Ohio plain, and includes Pittsburg. The third and fourth are two coal tracts. The fifth is a central plateau, whose population, the largest at this elevation of any state but Colorado, is drawn thither by the oil wells. The sixth is a mountain region. The state is also rudely divided between the Delaware valley, 11,000 square miles, the Susquehanna, 24,000 square miles, and the Monongahela and Allegheny, 18,000 square miles. The census of 1890 showed a total population of 5,258,014, of whom 2,666,331 were males and 2,591,683 females; 4,412,294 were native-born, and 845,720 were foreign-born. The negroes numbered 107,596. Of the male population over 16 years of age 1,602,153, or 89·95 per cent., and of the female population 311,296, or 14·88 per cent., were engaged in different occupations. Owing to legislation requiring school attendance and forbidding employment under twelve, a decided decrease occurred between 1880 and 1890 in the number of children employed. The families were 1,061,626, and dwellings 999,364; 5·26 persons to a dwelling and 4·95 to a family. The number of persons to a family has fallen, from 1850 to 1890, from 5·66 to 4·95, and the persons to a dwelling from 5·99 to 5·26. The decrease in persons to a family is apparently still in progress with accelerated rapidity. While the general population increased, from 1880 to 1890, 22·77 per cent., the number of children under five in 1880 was 552,174, and in 1890, 477,591, a decrease of 74,583, or 13·48 per cent. According to the census of 1900, the population of the state was 6,302,115, an increase for the decade of 1,044,101, or 19·9 per cent. The average number to the square mile had increased to 140·1, as compared with 116·9 in 1890. The males numbered 3,204,541, the females, 3,097,574; the native-born, 5,316,865; the foreign-born, 985,250; the negroes, 156,845. The proportion of foreign-born has for a long period varied within narrow limits, having been 13·12 per cent. in 1850, 16·08 per cent. in 1890, and 15·6 in 1900. The foreign-born take the place of an equal number of native-born who have moved west. The proportion of Germans has always been large, being estimated at one-half in 1750.

State and Local Government.—To the executive, legislature, and judiciary provided by the constitution of 1874, legislation has added commissioners of insurance (1872), banking (1891), a department of agriculture (1876), a factory inspector (1893) and mine inspectors (1891–93); a board of health (1885), board of charities, with a lunacy committee (1883), fishery commission (1873), and game commission (1895); also boards and other lesser commissions to manage the lands, parks, soldier and orphan asylums, public buildings, and other state properties. Each commission has its body of special statutes, and collectively they constitute an important part of the development of state administration. A superior court between the common pleas and supreme court has been added (1897). The exercise of suffrage, conferred on male citizens over twenty-one years old, has been regulated by the adoption of the Australian ballot (1893–97), and by a series of laws (1881, 1883, 1897) imposing penalties for false voting and providing for the judicial determination of nominations by party organizations. The two leading parties have, under these laws, become strongly organized, with clearly-defined membership, rules, and elections, whose choice is usually decisive of the final result for the state and most of the counties in it. Stringent provisions forbid special legislation, particularly legislation for corporate or municipal purposes. The constitution, by prohibiting special municipal legislation, made necessary the adoption of general charters for the cities of the state. For charter purposes these are divided into first-class cities (over 600,000: Philadelphia alone), second-class (over 100,000 and less than 600,000: first Pittsburg, and later Allegheny and Scranton), and third-class (all below 100,000, comprising all the cities of the state but the four named). The three classes of charters are substantially the same. They provide for a mayor, elected, with wide executive powers, who appoints and removes the heads of city police, public works and charities, and lower officers, such appointments being subject, except in the case of lower officials, to the confirmation of the upper branch of the municipal legislature. The city legislature, which consists of two branches elected by districts, levies all taxes, votes all appropriations, and through standing committees exercises a close supervision over public works. In 1901 the Legislature placed the government of Pittsburg and Scranton temporarily in the hands of officers appointed by the governor. Education and the parks in first-class cities are in the hands of a separate body, appointed by judges, which submits estimates to and receives appropriations from the city council. In second and third class cities the schools are in the hands of an appointed board. Any local population over 300, not within a city, can, on application to a court of quarter sessions, receive a charter as a borough, electing a chief burgess, a council of five, and two poor trustees. Such a body can, by taxation, supply drainage, water, and light within its area, and can provide for its police and poor, but in small boroughs little use is made of these powers. The remainder of the area is divided into townships, whose officers have lesser power, collecting taxes for roads, the poor, &c., but cannot issue bonds. The right to issue bonded indebtedness for municipalities and boroughs is limited to 7 per cent. of the assessed valuation in the former and 1 per cent. in the latter. Bonds to the amount of 2 per cent. of the assessed valuation can be issued by the officers of a municipality. A larger amount must be authorized at a regular election, and this authorization must be repeated when such issue has been redeemed by the sinking fund required by law. The total local debt of the state was reduced under this plan from $93,318,474 in 1880 to $66,973,065 in 1890.

The population of the state has been distributed at each census under these five forms of local government:—

	1880.	1890.	1900.
Cities, first-class	847,170	1,046,964	1,293,697
,, second-class	156,389	343,904	553,538
,, third-class	430,792	522,095	700,540
Boroughs over 4000 population	224,172	444,744	670,462
Townships and smaller boroughs	2,624,368	2,900,307	3,083,878
Total	4,282,891	5,258,014	6,302,115

Finances.—The receipts and expenditures in the whole state, including state, county, municipal, and local governments, were in 1890: receipts, $49,859,913, and expenditures, $45,589,937. Of these receipts, $36,111,124 was derived from the direct taxation of real and personal property. The true valuation for the state, as determined by the census of 1890, in gross and per capita of this property, has been as follows, the figures being corrected and differing from the assessment of county officials:—

	1870.	1880.	1890.
Total	$3,806,340,112	$4,942,000,000	$6,190,746,550
Per caput	1,081	1,154	1,177

The assessed valuation amounted in 1890 to $2,659,796,909, of which $2,042,016,599 was realty and $617,780,310 personalty. In 1899 the aggregate was $3,027,649,299; in 1850, $492,898,829. The census returns of this assessed valuation in realty have been:—

	1870.	1880.	1890.
Total	$1,071,680,934	$1,540,007,957	$2,042,016,599
Per caput	373.38	427.93	494.29

Philadelphia raises two-thirds of its income from direct taxation, lesser cities a larger proportion. The state receives one-tenth of its income from this source, the rest from the taxation of corporations. Of the gross expenditures for public purposes in 1890, $5,512,128 was disbursed by the state. Of the remainder, amounting to $40,077,809, over one-third or $15,430,983 was expended by five cities of 50,000 or more in population. For school education $12,828,645 was dispensed. The per capita expenditure for all purposes was $8.67 through the state, but this was made up of a per capita expenditure of $13.90 in five cities and of $6.54 in the remainder of the state. The aggregate receipts of state and all local taxation in 1899 were: state, $15,158,462; local, $55,808,585—a total of $70,967,047. Nearly one-third of this aggregate, or $21,733,586, was raised by Philadelphia. In the decade state revenue had more than doubled, and local taxation increased 32 per cent. The local expenditures have grown by tolerably steady increments from the settlement of the state, the best example being in Philadelphia. The expenditures of the state government are the creation of the 19th century. Cut off by the Federal Government from customs revenue and by its own system of local finance from a direct land or property tax, the state government was forced to create a source of revenue for itself, and this did not develop to a point which met its necessities until the growth of corporations had provided a field of taxation independent of customs on the one side and realty or personal taxation on the other. Of the total state revenue in 1899, viz., $15,158,462, $8,617,343 was derived from taxes on corporations, $2,764,258 from taxes on personal property, and the remainder from a great variety of small taxes. Of the state expenditures in 1899, $15,063,467, over one-half, or $8,301,562, was returned to local agencies for disbursement, of which $5,871,984 was for schools, $2,360,308 from the personal tax was for the use of counties, and $69,270 from fire insurance taxes was for fire departments. With one-half of its taxation the state government therefore supports the executive, legislature, numerous commissions, penitentiaries ($122,907), insane asylums ($882,478), and various charitable corporations, which in 1899 received grants amounting to $1,278,594. The other half aids local government, the grant for education meeting all the expenses of the public schools in many rural districts.

History.—In 1882 and in 1892 the continuous election of Republican candidates as governor was broken by the election of Robert E. Pattison, his majority being due in one case to the presence of two Republican candidates, and in the other to a wide change of votes from the Republican to the Democratic party. Both elections were part of a continuous protest by a small but energetic body, variously designated, in favour of administrative reform, and against the increasing control of party and political action by individuals—a control due in great measure to the growth through custom and law of a stricter and more systematic organization. Industrial disputes, both as to the rate of wages and the recognition of a union, led, on 6th July 1892, to the Homestead steel strike over the employment of non-union workers by Carnegie and Company, in which several persons on both sides were killed, and the riot was only suppressed by the presence of state militia on 1st October. A coal strike, on 10th September 1897, led to a collision between deputy-sheriffs and a mob at Lattimer, in which twenty persons were killed. Another and still more serious strike, with riots, occurred in the coal-mining region in the summer of 1902. The Johnstown flood, 31st May 1889, in the Conemaugh valley, swept away the town and 3500 lives, though only 1440 bodies were recovered. No estimate of the property loss was possible. The fund disbursed by the relief fund commission was $2,899,727.

Education.—The legal system of public tax-supported education has remained unchanged since 1880, but its development only became possible when the constitution of 1874 changed the varying appropriations of the legislature in aid of local grants into a mandatory appropriation of at least $1,000,000 annually.

		Schools.	Teachers.	Students.
Common	1872	15,999	18,368	975,753
	1898	14,666	28,080	1,173,082
Normal	1872	11	140	2,191
	1898	15	359	10,656
Secondary	1872	44	272	5,015
	1898	292	1,022	27,082
High schools	1872	...	...	...
	1898	427	1,878	35,700
Colleges	1872	22	293	1,625
	1898	30	544	6,203
Law schools	1872	3	3	62
	1898	3	36	488
Medical schools	1872	5	50	942
	1898	6	227	2,415
Dental schools	1872	2	13	63
	1898	5	91	1,387
Pharmacy schools	1872	1	3	239
	1898	2	13	501

This sum has been as high as $5,500,000, though reduced in 1899 to $5,000,000. The amount levied by local taxation for educational purposes in 1880 was $5,634,072. In 1899–1900 this amount was $14,700,512. The state had therefore increased its appropriation 450 per cent., and local taxation 168 per cent., during a period in which the children in attendance had increased from 937,310 to 1,151,880, or 22·89 per cent., and the average attendance from 601,627 to 854,640, or 40·37 per cent. The estimated growth of population in the same period, taking the growth in previous decades, was 42·82. The best comparative view of the educational progress of the state is offered by the reports of the U.S. Bureau of Education, from which the foregoing table is compiled. The common schools, of which the high schools are a part, are wholly supported by taxation; the normal schools are partly dependent on state grants and partly on fees; the remaining schools are all conducted by private bodies, though appropriations are made from time to time by the state in aid of higher education. Illiterates, unable to read and write, have for thirty years been almost an unchanged fraction of the population, an indication that the education offered by the state and by private enterprise had reached all but that fraction which could be educated only under a compulsory system. Provision for a yearly count of school children and fines for non-attendance were first arranged for in 1897, and enforced only in the largest cities. Another decade will be needed to decide whether this measure and policy can deal with what has hitherto been a proportion whose reduction has been slow. Illiterates were in 1870, 8·5 per cent. of those over ten years of age; in 1880, 7·12; in 1890, 6·78; and in 1900, 6·1. Of this illiterate population one-half was in each census of foreign birth, the illiterate proportion of the foreign population, over ten years of age, 191,706, or 19·9 per cent., being ninefold, and of the small coloured population 20,298, or 15·3 per cent., fourteenfold that of the illiterate proportion of native white population, 87,372, or 2·3 per cent. The problem of complete elementary education turns on reaching this fraction. As this can be done only by a compulsory system, the great increase in expenditure has been attended by no increase in relative attendance. In 1900 the male illiterates of 21 years of age and over numbered 139,982. Of these 41,324 were native-born and 98,658 were foreign-born.

Crime and Charity.—From 1880 to 1898, 93 persons were executed for murder in the first degree. The prison population in 1898 was 7603, as compared with 4623 in 1880. The proportion of convicts had risen from 1 to 1555 inhabitants to 1 to 1272. Two juvenile reformatories had 835 inmates in 1881, and 1567 in 1898, an increase about twice that of the population. Insane patients in 1898 were 10,565, of whom 672 were in private institutions. In 1886 the same institutions had 5923. County almshouses had in 1881, 8566 inmates, including pauper insane, and in 1898, 11,722. In addition, in 1898, 22,187 persons received outdoor relief. Four deaf and dumb institutions held in 1898, 815 inmates; two for the blind, 266; and two for the feeble-minded, 1487. Hospitals had 6477 inmates, and "homes," for the most part for children and the aged, 16,080. These institutions receive yearly appropriations from the state aggregating about $1,500,000.

Communications.—The general railway system, complete as to main lines in 1880, consists of the Pennsylvania, whose trunk line occupies the middle of the state and crosses it by repeated branches, and the Reading, which reticulates the anthracite coal region, while the trunk lines of other states cross portions of the state. A railway mileage of 5500 in 1880 in the state had increased to 10,330 in 1900. The capital shares and debt, funded and floating, of railways in whole or in part in the state had risen within these years from $1,030,683,638 to $2,310,968,116, divided nearly equally between capital shares and debt. Gross receipts rose from $133,945,771 to $377,825,660, and expenses from $75,815,377 to $334,570,957, reducing the balance from $58,130,394 to $43,254,703, though the capital had doubled and the tonnage advanced from 111,348,416 to 400,548,087. While the Pennsylvania, with 3385 miles in the state, with an east and west traffic, and with an ownership of profitable lines outside of the state amounting to 6644 miles, has maintained a credit and prosperity unequalled, the Reading, 961 miles in and 39 out of the state, has thrice been in the hands of receivers. The street car lines of the state have a mileage of 1493, and a total capitalization of $242,628,019. Their present cost, all having been re-equipped with electric power since 1885, is $197,161,214, principally represented by the capital of operating companies, $147,570,893, $103,122,319 shares and $31,309,425 bonds. The remaining sum in the total capital represents for the most part the franchises of corporations formerly working the lines by horse-power. These lines have 5864 cars, employ 12,680 persons, and in 1899 carried 473,313,258 passengers. About 80 telephone companies operate telephone lines in the state. Telegraph facilities are furnished by inter-state lines, of which the Western Union is the largest. Three canal companies manage canals, now almost unused, 293 miles long.

Forestry.—The territory composing the state began with an exceptional wealth of forest, the conifers of the north and the deciduous trees of the south meeting within its limits. They contain 35 genera, and over 80 species of indigenous trees, of which

78 have economic value, or nearly as many as the entire continent of Europe, whose number Asa Gray estimates as 33 genera and 85 species. Nearly one-third of the state's area in 1896, 9,099,817 acres out of 28,937,600, was returned by assessors as woodland—much being scrub-oak and brush, but all abandoned to wood growth or but partly cleared. There has probably never been a time when nearly one-third of its area was not so overgrown with trees, large or small, as not to be open to cultivation, though the share of this in timber is not over a quarter of the area of the state. In its original condition, a yield of hemlock (spruce) of 30,000 feet board measure to the acre, or of white pine of 50,000 feet board measure, was usual. The Delaware, Allegheny, and Susquehanna were successively lumber centres. In 1880 the lumber product was $22,457,359, only exceeded by Michigan ($52,449,928). In 1890 this product was $27,772,834, and that of Michigan $73,484,306. Local statistics of the yield were not preserved, but at Williamsport, the last great lumbering centre, in the seven years 1873–80 the pine yield was 7,395,455 logs and 1,266,608,045 feet board measure. The yield of the four Delaware river counties was estimated, prior to exhaustion, at 12,000,000,000 feet board measure of pine. In 1897 the state forester, Dr J. T. Rothrock, reported white pine at 500,000,000 feet; spruce, 70,000,000; and hemlock, 5,000,000,000. By the close of the ninth decade of the 19th century exhaustion was seen to be near. In the eastern fifth of the state only 12 per cent. of the area was under timber; in the elevated west, 28 per cent.; and in the valleys of the east and west, 24 per cent. Over a sixth of the area of the state is at an elevation of 1500 to 2000 feet, and a broad belt 2000 to 3000 feet high is economically unfit for any cultivation but forestry, having a mean annual temperature of 40° to 45° F., a climate similar to that of northern New England. Forest fires yearly sweep broad areas of this region, which would otherwise reforest. In 1880, 685,738 acres were burned, with a loss of $3,043,723. During the decade ending with 1890 the annual loss was estimated at $1,000,000. In 1896 it was $557,056, in 1897, $394,327, and in 1898, $53,345. This reduction is believed to be due to legislation for reforesting the state. Penn, in his regulations, provided that one acre in four of woodland should be preserved. This wise provision was altogether neglected, and desultory statutes in regard to fires, the first in 1735, were the only legislation for the preservation of timber. In 1860, 1870, and 1879 statutes more stringent were formed to prevent fires. In 1887 a yearly bounty of 45 cents an acre was offered for timber; in 1893 a state forestry commission was established; and in 1897 Acts were passed for fire-wardens, providing means for detecting forest fires, for forest reserves, and for the state purchase of waste land sold for taxes, of which about 2300 square miles are yearly sold, usually land from which the timber has been stripped. Forest reserves of 40,000 acres each have been (1900) bought on the head-waters of the Delaware in Pike and Monroe counties, in Clinton, Cameron, and Center counties on the Susquehanna, and on the Allegheny.

Agriculture.—Of the total area of the state, only one-half has ever been reduced to cultivation in improved farm lands. This reached its maximum in 1880 in 213,542 farms of 19,791,341 acres, 13,423,007 improved and 6,368,334 unimproved. In 1900 the farms were 224,248, of 19,371,015 acres, 13,209,183 acres improved and 6,161,832 unimproved, employing 331,119 persons, 30,007 more than in 1880. The change measures the increase of lands used as woodland for collieries, and for industrial purposes. Tanneries in 1892 held 749,017 acres of bark lands, valued at $11,383,920. The growth of paper and other industries constantly turns farm lands near the margin of cultivation to other purposes. The valuation of farm lands was in 1870, $1,119,786,853 (gold at 15 per cent. premium); in 1890 it was $1,062,939,846; and in 1900 was $1,051,629,173. From 1870 to 1900 the selling value of farm lands in the eastern and centre parts of the state fell about one-third, many failing under foreclosure to reach their mortgage value. In the decade 1880–90 the farms cultivated by owners fell from 168,220 to 162,219, but rose again in 1900 to 165,982. Of the area under cultivation, one-third, 4,738,194 acres, in 1899 was under cereals and 3,269,441 acres under hay, producing 4,020,388 tons. Over one-half the farm area is devoted to these crops, whose yield has been stationary since 1880 (the increase from 1850 to 1899 keeping pace with acreage) and in 1899 the crop was: Indian corn, 51,869,780 bushels; wheat, 20,632,680; and oats, 37,242,810. The great change in the agriculture of the state is in sheep—1,749,301 in 1870 and 959,483 in 1900. Milch cows have in part taken their place—706,437 in 1870; 943,773 in 1900. Tobacco is the largest special crop—in 1899, 27,760 acres, 41,502,620 ℔.

Manufactures.—Pre-eminence in iron and steel industries made Pennsylvania the leading manufacturing state up to 1890. The relative increase of textiles and lesser industries has advanced other states, but in 1890, with 39,339 establishments, a capital of $991,243,115, and an output of $1,331,794,901, one-third in iron, and 620,562 persons employed, Pennsylvania was exceeded only by New York. In 1900 it still ranked as the second manufacturing state, having 52,185 establishments, with $1,551,548,712 of capital, employing 733,834 hands, and with a product valued at $1,834,790,860. The percentage of increase in the value of the product for the preceding decade was 37·8. In 1850 Pennsylvania had approximately one-sixth of the manufacturing capital and product of the country, and in 1900 over one-seventh of each, so that its relative position has been fairly maintained.

The following table shows the leading industries and the value of the product in 1890 and 1900:—

Industry.	1890.	1900.
Iron and steel . . .	$264,571,624	$434,445,200
Foundry and machine-shop products	67,587,025	127,292,440
Leather	49,931,716	55,615,009
Cars and repairs by railway companies . . .	28,769,728	43,065,171
Flouring and grist mill products	39,478,076	36,639,423
Printing and publishing .	34,408,493	36,455,629
Sugar and molasses refining .	46,599,754	36,163,817
Lumber products . . .	29,087,920	35,749,965
Petroleum refining . .	18,498,777	34,977,706
Liquors	22,698,423	34,520,358
Tobacco	23,387,910	33,355,932
Silk and silk goods . .	19,357,546	31,072,926
Cotton goods . . .	18,431,773	25,447,697
Woollen goods . . .	29,878,010	25,389,344
Slaughtering and meat-packing	21,991,604	25,238,772

Other important industries were men's clothing, newspapers and periodicals, carpets and rugs, worsted goods, coke, glass, and hosiery and knitted goods.

Mineral Products.—The petroleum, coal, coke, and iron deposits of the state, after standing almost alone to 1880, entered during the following 20 years on a competition whose results were apparent in labour disturbances and a reduction of profits on previously invested capital. In 1880 the production of petroleum, 26,027,631 barrels, was practically that of the country. In 1898 the Pennsylvania field yielded 15,948,464 barrels, 28·83 per cent. of the entire yield of 55,364,233 barrels. In natural gas the state yield in 1895, valued at $4,500,000, was nearly that of the whole country. In 1898 the Pennsylvania product was valued at $6,806,742, or 44·12 per cent. of all the states. In 1880 the bituminous coal mined in the state, 26,229,031 short tons, was 61·28 per cent. of the total. In 1898 a yield of 65,165,133 tons was but 39·49 per cent. of the entire product. The anthracite coal, which nearly doubled from 1870 to 1880 (1870, 15,596,257 tons; 1880, 28,612,575), under this competition made but about the same advance in the next 18 years, reaching, in 1898, 53,382,644 tons. The coke yield, 1880, 2,821,384 tons, 84·72 per cent. of the total, rose to 10,715,302 tons in 1898, but sank to 66·97 per cent. of the whole American yield. Iron ore in 1880, 1,820,561 long tons, was 20·59 per cent. of the total product, and in 1898, 1,773,082 tons, 3·98 per cent. of the entire ore output of the United States. Cheap fuel and high skill, however, maintained the iron supremacy of the state. In 1870 the state yield of pig iron, 1,836,808 tons, was 50·32 per cent. of the total for the country, and in 1899 it was 6,558,878 tons, or 48·23 per cent., never having been less than 46 per cent. in the interval, coke taking the place of anthracite and Lake Superior of local ores. Bessemer steel, 1899, 4,473,493 tons, was 54·42 per cent., a slightly larger proportion than a decade before. Rolled steel and iron in all forms in 1873, 835,584 tons, was 42·63 per cent., in 1898, 4,622,770 tons, 54·32 per cent. of all rolled in the United States. In 1901 the pig iron produced in the state was 7,343,257 tons; the bituminous coal, 80,914,236 tons; and the anthracite coal, 59,905,951 tons. In stone, the state's product in 1880 was $1,944,208, 10·62 per cent. of the total, and in 1898, $5,993,616, or 15·60 per cent. This was due to the increase in slate, $2,421,756, 1898, 64·29 per cent. of the total, the state product having trebled since 1880, when it raised 56·83 per cent. of all. Clay products, 1898, $9,642,098, were 13·47 per cent. of the total. The Portland cement yield, 221,000 barrels, then 65·91 per cent. of the total, increased to, 1898, 2,095,114 barrels, but sank to 26·30 per cent. of all produced. (T. W*.)

Pennsylvania, University of.—The University of Pennsylvania, situated at Philadelphia, Pa., had its beginning in 1740, and was incorporated under its present name in 1791. In 1850 it had 22 instructors and 586 students; in 1880, 97 instructors and 972 students; in 1890, 180 instructors and 1579 students; in 1900 it had 260 instructors and 2673 students. The student body represented 41 states of the Union and 30 foreign countries. The university property consisted (1901) of 57 acres, on which are 32 buildings. Of these only 4 existed prior to 1880, and 20 were erected between 1890 and 1900. The buildings and equipments were valued at $6,455,218, of which $4,965,261 had been expended since 1890. For the year 1901 the expenditure for educational purposes was $716,380. The undergraduate (college) courses are in arts, sciences, finance and economy, and music. There are graduate (philosophy) courses; schools of law, medicine, dentistry, veterinary medicine, hygiene; hospitals of medicine and surgery, and of veterinary surgery; a school for nurses; a general museum of science and art, especially archæological; a special institute of anatomy and biology; an astronomical observatory; a general and some special libraries. Athletics and physical education are under careful official supervision, and a large athletic field is provided. There are a students' club house, a dining hall, and a system of dormitory houses of the latest hygienic construction, and several substantial fraternity houses. (See also EDUCATION and UNIVERSITIES.) (C. C. H*.)

Penn Yan, a village of New York, U.S.A., capital of Yates county, at the foot of Keuka Lake, on the Northern Central and the Fall Brook railways, west of the central part of the state, at an altitude of 750 feet. It is in the grape-growing region of central New York, for which it serves as a shipping point. Population (1880), 3475; (1890), 4254; (1900), 4650, of whom 449 were foreign-born and 67 negroes.

Penryn, a municipal borough (since 1216), parliamentary borough, and market town, in the Truro parliamentary division of Cornwall, England, situated on an arm of Falmouth harbour, 2 miles north-west of Falmouth, on the Great Western Railway. The borough returned two members to Parliament until 1885, when the number was reduced to one. A Wesleyan chapel was built in 1891. Granite, which is extensively quarried in the county, is dressed and polished here; chemical and bone manure is also manufactured, and there are engineering works and an iron foundry. Population (1881), 3466; (1891), 3256; (1901), 3190.

Pensacola, a city and seaport of Florida, U.S.A., capital of Escambia county, on Pensacola Bay, in the western part of the state. The harbour is excellent, with 24 feet of water at the entrance, and the city has an extensive export commerce, consisting largely of lumber, fruit, vegetables, and cotton. It has two railways, the Louisville and Nashville, and the Pensacola, Alabama, and Tennessee. Its street plan is regular, it has a good water-supply and sewer system, and varied manufactures. Population (1890), 11,750; (1900), 17,747, of whom 1105 were foreign-born and 8561 negroes.

Pensions (*United States*).—The American "Pension Fund" is so singular a feature of the national budget, that it is desirable to give here an account of the different classes of allowances which are granted.

Old war pensions.

In the United States allowances for services in wars prior to 4th March 1861 are called "old war" pensions, and may be divided into three classes, viz., (1) invalid pensions, based upon wounds or injuries received, or disease contracted in the course of duty, (2) "service" pensions, and (3) land bounties, both granted for service irrespective of injuries.

The first provision made by Congress for pensions was a resolution passed 26th August 1776, promising invalid pensions to officers and men of the army or navy who lost a limb or were otherwise disabled in the Revolutionary war, at a rate equal to half of their monthly pay as officers or soldiers during life or continuance of the disability, those not totally disabled to receive an adequate monthly pension not to exceed half of their pay. Then followed various Acts of Congress enlarging the provisions for invalid pensions and extending them to those who had been in the war of 1812, and to the widows and children of those who died in the war or from wounds received in the war. The Act of 3rd May 1846 provided for the prosecution of the war with Mexico and for pensioning those volunteers wounded or otherwise disabled in service. Other Acts were subsequently passed making further provision for pension on account of service in the Mexican war. The first general law granting "service" pensions was not passed until 18th March 1818, thirty-five years after the termination of the war of the American Revolution. Its beneficiaries were required to be in indigent circumstances and in need of assistance from their country. Two years later Congress became alarmed by reason of the large number of claims filed (about 8000), and enacted what was known as the "Alarm Act," requiring each applicant for pension and each pensioner on the rolls to furnish a schedule of his whole estate and income, clothing and bedding excepted. Many pensioners were dropped who were possessed of as much as $150 worth of property. Numerous Acts were, however, passed from time to time liberalizing the law or dealing more generously with the survivors of the Revolution. Service pensions were not granted to widows of the soldiers of this war until 1836, and then only for a period of five years and on condition that the marriage of the soldier was prior to his last service, and that the soldier's service was not less than six months. In 1853, seventy years after the close of the war, the limitation as to the time of marriage was removed. The rolls in 1901 contained nine pensions based upon service in the Revolutionary war. The first law granting service pensions on account of the war of 1812 was passed in 1871, fifty-six years after the close of the war. This Act required sixty days' service. Widows were not pensionable unless the marriage to the soldier had taken place prior to the treaty of peace of 15th February 1815. On 9th March 1878, sixty-three years after the war, an Act was passed reducing the requisite period of service to fourteen days and removing the limitations as to date of marriage. In 1901 the pension rolls contained the names of one survivor and 1527 widows of this war. Service pensions were provided for those who served in the Black Hawk war, Creek war, Cherokee disturbances, and the Seminole war (1832 to 1842), on 27th July 1892, fifty years after the period embraced in the Act: they were granted to those who had served for thirty days and were honourably discharged, and to their widows. In 1901 there were 1086 survivors and 3479 widows pensioned under this Act. Service pensions were granted to the survivors of the war with Mexico by an Act passed 29th January 1887, thirty-nine years after the Guadeloupe-Hidalgo treaty. The pensions were granted to those who were honourably discharged, and to their widows, for service of sixty days, if sixty-two years of age, or disabled or dependent. This law was liberalized by the Acts of 5th January 1893 and 23rd April 1900, increasing from $8 to $12 per month the pension to survivors who are totally disabled and destitute. In 1901 the pension rolls contained the names of 7568 survivors and 8109 widows on account of service in the Mexican war. To give title to bounty land, service must have been for at least fourteen days or in a battle prior to 3rd March 1855; and if in the navy or regular army, must have been in some war in which the United States was engaged. Bounty land warrants are issued for 160 acres, and over 70,000,000 acres have been granted under the different Bounty Land Acts.

Civil War pensions.

For services rendered in the War of the Rebellion (1861–65) in the army or navy of the United States, or in their various branches, the law provided two distinct systems of pensioning—(1) the general laws, granting pensions for wounds or injuries received, or disease contracted in service in the line of duty, the pensions ranging from $6 to $100 per month; and (2) the so-called Dependent Pension Act, granting pensions for permanent disabilities regardless of the time and manner of their origin, provided they were not the result of vicious habits, the pensions ranging from $6 to $12 per month. What is known as the general law for disabilities incurred in service and in the course of duty was constituted in the Act of 14th July 1862 as amended by the Act of 3rd March 1873. Under its provisions the following classes of persons are entitled to benefit, viz., any officer of the army, including regulars, volunteers, and militia, or any officer in the navy or marine corps, or any enlisted man, however employed, in the military or naval service of the United States, or in its marine corps, whether regularly mustered or not; any master serving on a gunboat, or any pilot, engineer, sailor, or other person not regularly mustered, serving upon any gunboat or war-vessel of the United States; any acting assistant or contract surgeon; any provost-marshal, deputy provost-marshal, or enrolling officer; subject to the several conditions in each particular case prescribed in the law. This law also embraces in its provisions the following classes, each class being subject to certain specified conditions, viz., widows, children under sixteen years of age, dependent parents, and brothers and sisters. This Act has been the subject of numerous amendments along more liberal lines. As an illustration a case may be cited where a soldier lost both hands in the service in the course of duty, and was discharged in 1862. He is entitled to a pension of $8 per month from the date of his discharge. Under subsequent Acts he is entitled to $25 per month from 4th July 1864; $31.25 from 4th June 1872; $50 from 4th June 1874; $72 from 17th June 1878, and $100 from 12th February 1889.

Under the general law a widow or dependent relative cannot be pensioned unless the cause of the soldier's death originated in service in the line of duty; if it is so shown, a widow may be pensioned whether she is rich or poor. Upon the death or remarriage of the widow the minor children of the soldier under the age of sixteen years are entitled to pension. If the soldier died of causes due to his service, and left no widow or minor children, his other relatives become entitled, if dependent, in the following order, viz.: First, the mother; secondly, the father; thirdly, orphan sisters and brothers under sixteen years of age, who shall be pensioned jointly. In 1901 the number of invalids pensioned under the general law was 301,230, and the number of widows and dependent relatives was 90,851.

The so-called Dependent Pension Act is based upon an Act of Congress approved 27th June 1890, which was amended on 9th May 1900. Properly speaking, it may be called "dependent" only as regards widows and parents. The main conditions as to the soldier or sailor are, ninety days' service, an honourable discharge, and a permanent disability from disease or otherwise, not the result of his own vicious habits, to such an extent as to render him unable to maintain himself by manual labour. The rates of pension under this Act are $6, $8, $10, and $12 per month. Widows become entitled under this law if they married the soldier or sailor prior to 27th June 1890, provided they are without means of support other than their daily labour, and an actual net income not exceeding $250 per year, and have not remarried. Claims of children under sixteen years of age are governed by the same conditions as apply to claims of widows, except that their dependence is presumed, and need not be shown by evidence. If a minor child is insane, idiotic, or otherwise physically or mentally helpless, the pension continues during the life of said child or during the period of disability. In 1901 there were 438,114 invalids on the rolls, and 145,111 widows and dependents. All women employed by competent authority as nurses during the War of the Rebellion for six months or more, who are unable to earn a support, are granted a pension of $12 per month by an Act of 5th August 1892. In 1901 the pension rolls contained the names of 650 pensioners under this Act.

Other benefits.

In addition to pensions, the United States Government grants the following gratuities:—*First:* If a soldier lost a limb in the service, or as a result of his service in line of duty, he is furnished with an artificial limb free of cost every three years, or commutation therefor, and transportation to and from a place where he shall select the artificial limb. *Second:* An honourably discharged soldier or sailor is given preference for appointment to places of trust and profit, and preference for retention in all civil service positions. *Third:* There are nine National Soldiers' Homes situated at convenient and healthy points in different parts of the country, where comfortable quarters, clothing, medical attendance, library, and amusements of different kinds are provided free of all expense; Government providing the soldiers free transportation to the home, continuing payments of pension while they are members of the home, and increasing the same as disabilities increase. *Fourth:* There are twenty-nine homes maintained by the different states, which are similar in their purpose to the National Homes, the sum of $100 per year being paid by the general Government for each inmate. Many of these state homes also provide for the wives and children of the inmates, so that they need not be separated while they are members of such home. *Fifth:* Schools are established by the different states for the maintenance and education of soldiers' orphans until they attain the age of sixteen years.

Amount paid for pensions.

From the close of the Civil War in 1865 to 1901 the Government of the United States paid to its pensioners the sum of $2,666,904,589. The payments for the fiscal year ended 30th June 1901 were $138,531,483. Over $17,000,000 has been paid to surgeons for making medical examinations of pensioners and applicants for pensions. The amount paid to pensioners under the so-called Dependent Pensions Act is over $600,000,000. The total amount paid for pensions from 1st July 1790 to 30th June 1865 was $96,445,444, making a total disbursement for pensions from 1790 to 1901 of $2,763,350,033. No other nation or government in all time has dealt so liberally with its defenders.

The appropriations for the support of the National Homes for 1900 amounted to $3,783,450, and appropriation for artificial limbs to $549,275. The money appropriated by Congress for the payment of pensions is disbursed by eighteen pension agents established in different parts of the country. Pensions are paid quarterly, and the agencies are divided into three classes, one of which pays on the 4th of every month. (H. C. E.)

Penza, a government of east central Russia, south of Nijni-Novgorod, with an area of 14,997 square miles. Population (1881), 1,356,600; (1897), 1,491,215, of whom 767,391 were women, and 137,560 lived in towns. It is divided into ten districts, the chief towns of which are Penza, Gorodische (3973), Insar (4264), Kerensk (4006), Krasnoslobodsk (7378), Mokshany (10,072), Narovchat (4695), Nijni Lomoff (9984), Saransk (13,743), Chembar (5335). The schools, chiefly owing to the efforts of the *zemstvo* (provincial council), are comparatively good; school farms and gardens have increased. More than one-sixth of the area is still under forests (1,661,900 acres in 1898, as against 2,564,400 acres in 1869). More than one-half (4,955,000 acres) is owned by the village communities, while 3,482,000 acres are in the hands of private owners. No less than 3,381,100 acres were under cereals in 1900, and 263,700 acres under roots, flax, tobacco, &c. The annual average yield of the crops in 1895–99 was: rye, 11,263,000 cwt.; wheat, 484,000; oats, 4,007,000. Total crop of cereals, 17,811,000 cwt.; potatoes, 5,676,000 cwt. Grain and flour are considerable exports. The local authorities have established depots for the sale of improved agricultural machinery, the use of which is rapidly spreading among the peasants. There are also several agricultural and horticultural schools, and two model dairy-farms. Cattle-breeding and especially horse-breeding are comparatively flourishing, there being (1896) 352,500 horses, 270,130 horned cattle, 945,500 sheep, and 200,900 pigs in the government. The peasants are relatively well provided with cattle, there being 112 horses, 86 horned cattle, and 255 sheep to every 100 households. Bees are kept in large numbers. Factories afford employment to only about 14,000 persons (annual returns about £1,000,000). Spirits, oils, matches, paper, and timber are the principal manufactures.

Penza, the capital of the above province, 440 miles by rail south-east of Moscow. It has four lyceums for boys and girls, one *real-schule*, several technical schools (railway, gardening, and drawing, the last with a fine art gallery), five public libraries, a museum of antiquities, a theatre, and ten hospitals. There is a considerable trade in grain, spirits, and timber. Population (1897), 61,851.

Penzance, a municipal borough, seaport, and market town in the St Ives parliamentary division of Cornwall, England, at the head of Mounts Bay, 26 miles west-south-west of Truro by rail. The spacious new dock was completed in 1887. The harbour has a total area of 24 acres, with 12 to 16 feet depth of water; and there are a floating dock and a graving dock. Modern erections are public baths, swimming baths, mining and science schools, a free library, and a convalescent home. The West Cornwall Infirmary has been extended. Penzance became a meteorological station in 1893. In 1900 the registered shipping totalled 53 vessels of 6615 tons. In the same year the port was entered by 1476 vessels of 229,608 tons and cleared by 1424 vessels of 220,877 tons. The whole value of the trade was £71,205, about three-fourths of this being for imports. Area, 472 acres. Population (1881), 12,409; (1891), 12,432; (1901), 13,123.

Peoria, a city of Illinois, U.S.A., capital of Peoria county, on the Illinois river, north-west of the centre of the state, at an altitude of 459 feet. Most of the city is built on a terrace above the river, whence it spreads to the bluff at the back, on which is a fine residential quarter. Its street plan is regular, and it is divided into seven wards. Its water-works are owned by the city, and it has a good sewerage system. Its streets are well paved, mainly with brick. Peoria is in a fertile agricultural region, and is one of the great grain markets of the Mississippi valley. It is the centre of no fewer than thirteen railways, which, with the river, here navigable, give it a large commerce. In 1900 it contained 871 manufacturing establishments, with a total capital of $27,971,613, employing 8022 hands. The products were valued at $48,871,596. These were extremely varied, but over one-half, or $26,792,354, were distilled liquors. The city contains, moreover, several large grain elevators. The assessed valuation of real and personal property was in 1900 placed at the extremely low estimate of $9,353,906, the net debt of the city was $779,685, and the rate of taxation was $89.10 per $1000. Population (1890), 41,024; (1900), 56,100, of whom 8945 were foreign-born and 1402 negroes.

Pepper, William (1843–1898), American physician, was born in Philadelphia, 21st August 1843. He was educated at the University of Pennsylvania, graduating from the academic department in 1862 and from the medical department in 1864. In 1868 he became lecturer on morbid anatomy in the same institution, and in 1870 lecturer on clinical medicine. From 1876 to 1887 he was professor of clinical medicine, and in 1887 succeeded Dr Stillé as professor of theory and practice of medicine. He was elected provost of the university in 1881, resigning that position in 1894. For his services as medical director of the Centennial Exposition in 1876 he received the decoration of knight commander of the order of St Olaf from the king of Sweden. He founded the *Medical Times*, and was editor of that journal in 1870–71. Among the members of his profession he was known particularly for his contributions to the literature on the subject of the theory and practice of medicine, and the *System of Medicine* which he edited in 1885–86 became one of the standard text-books in America. He contributed to the medical and scientific journals of the day, including "Trephining in Cerebral Disease," 1871; "Local Treatment in Pulmonary Cavities," 1874; "Catarrhal Irrigation," 1881; "Epilepsy," 1883; and "Higher Medical Education: the True Interest of the Public and the Profession." He died 28th July 1898. (E. H. W.)

Pêrak. See MALAY STATES (FEDERATED).

Pereda, José María de (1834-——), one of the most distinguished of Spanish novelists, was born at Polanco near Santander in 1834. He was educated at Santander grammar school, whence he went to Madrid, where he studied engineering with the vague purpose of entering the artillery corps. Abandoning this design after three years' trial, he returned home and began his literary career by contributing articles to a local journal, *La Abeja Montañesa* in 1859. He also wrote much in a weekly paper, *El Tío Cayetán*, and in 1864 he collected his sketches under the title of *Escenas Montañesas*. These studies of local life and manners gained Pereda a considerable reputation in his province, but they failed to please the general public. Their originality, their total lack of sentimentalism, and their powerful realism were unacceptable novelties, and a popular novelist of the period, Antonio de Trueba, rebuked the author for his pessimistic view of life. Pereda fought against the revolution of 1868 in *El Tío Cayetán*, writing the newspaper almost single-handed. His articles against the revolutionists were more widely read than his *Ensayos dramáticos* (1869), and in 1871 he was elected as the Carlist deputy for Cabórniga. In this same year he published a second series of *Escenas Montañesas;* and in 1876 appeared *Bocetos al temple*, three tales, in one of which the author describes his disenchanting political experiences. The *Tipos trashumantes* belongs to the year 1877, as does *El Buey suelto*, which is intended as a reply to the thesis of Balzac's work, *Les petites misères de la vie conjugale.* More and more pessimistic as to the political future of his country, Pereda takes occasion in *Don González de la Gonzalera* (1878) to ridicule the revolution as he had seen it at work, and to pour scorn upon the *nouveaux riches* who exploited Liberalism for their personal ends. Two novels by his friend Pérez Galdós, *Doña Perfecta* and *Gloria*, drew from Pereda a reply, *De tal palo tal astilla* (1879), in which he endeavours to show that tolerance in religious matters is disastrous alike to nations and to individuals. The *Esbozos y Rasguños* (1881) is of lighter material, and is less attractive than *El Sabor de la Tierruca* (1882), a striking piece of landscape which won immediate appreciation. New ground was broken in *Pedro Sánchez* (1883), where Pereda leaves his native province to portray the disillusion of a sincere enthusiast who has plunged into the political life of the capital. The book was a dangerous experiment, upon which Pereda ventured with much hesitation; but the result has justified his boldness, for, though *Pedro Sánchez* is not actually his best work, it would suffice to make the reputation of any writer. Pereda's masterpiece is *Sotileza* (1884), a vigorous rendering of marine life by an artist who perceives and admires the daily heroisms of his fisher-folk. It has often been alleged against the author that he confines himself to provincial life, to lowly personages and to unrefined subjects, and no doubt an anxiety to clear himself from this absurd reproach led him to attempt a description of society at the capital in *La Montálvez* (1888). If not an absolute failure, *La Montálvez* is certainly the least interesting of his performances. In *La Puchera* (1889) he returned to the marine subjects which he knows and loves best. Again, in *Peñas arriba* (1895), the love of country life is manifested in the masterly contrast between the healthy, moral labour of the fields and the corrupt, squalid life of cities. Pereda belongs to the native realistic school of Spain, which, founded by the unknown author of *Lazarillo de Tormes*, was continued by Mateo Alemán, by Cervantes, by Quevedo, by Castillo Solórzano, and many others. With the single exception of Cervantes, however, the picaresque writers are almost entirely wanting in the spirit of generous sympathy and tenderness which constitutes a great part of Pereda's charm. His realism is purely Spanish, as remote from M. Zola's moroseness as it is remote from the graceful sentimentality of Pierre Loti. Few writers in any country possess the virile temperament of Pereda, and, with the single exception of Tolstoi, none keeps a moral end more steadily in view. This didactic tendency unquestionably injures his effects. Moreover, his grim satire occasionally degenerates into somewhat truculent caricature, and the excessive use of dialect and technical terms (which has caused the author to supply *Sotileza* with a brief vocabulary) is a grave artistic blemish. But he sees, knows, understands character; he creates not only types, but living personages, such as Andrés, Cleto, and Muergo in *Sotileza*, as Pedro Juan and Pilara in *La Puchera;* and he personifies the tumult and calm of the sea with more power than Victor Hugo displayed in *Les Travailleurs de la Mer*. His descriptive powers are of the highest order, and his style, pure of all affectations and embellishments, is of singular force and suppleness. The statutes of the Spanish Academy, which require members to reside in Madrid, were specially suspended in his favour. The compliment was no more than Pereda deserved, for, with all his limitations, he is as original a genius as Spain has produced during the 19th century.

Pérez Galdós, Benito (1845-——), was born at Las Palmas, in the Canary Islands, in 1845. In 1863 he was sent to Madrid to study law, drifted into literature, and was speedily recognized as one of the most promising recruits on the Liberal side. Shortly after the revolution of 1868 he abandoned journalism, and employed fiction as the vehicle for propagating advanced opinions. His first novel, *La Fontana de Oro*, was printed in 1871, and later in the same year appeared *El Audaz;* from the very beginning Pérez Galdós was copious. The reception given to these early essays encouraged the writer to adopt novel-writing as a profession. He had already determined upon his scheme—and he proceeded with incredible labour to prepare himself for the task before him—of producing in the "Episodios Nacionales" a series which might compare with the "Comédie Humaine." Old charters, old letters, old newspapers were collected by him with the minuteness of a German archivist; no novelist was ever more thoroughly equipped as regards the details of his period. *Trafalgar*, the first volume of the "Episodios Nacionales," appeared in 1879; the remaining books of this first series are entitled *La Cort de Carlos IV.*, *El 19 de Marzo y el 2 de Mayo*, *Bailén*, *Napoleón en Chamartín*, *Zaragoza*, *Gerona*, *Cádiz*, *Juan Martín el Empecinado*, and *La Batalla de Arpiles*. As the names suffice to show, the author's aim is to write the national epic of the 19th century in prose; and he so greatly succeeded that, long before the first series ended in 1881, he took rank among the foremost novelists of his time. A second series of "Episodios Nacionales," beginning with *El Equipaje del Rey José* and ending with a tenth volume, *Un Faccioso más y Algunas Frailes Menos*, was brought to a close in 1883, and is, like its predecessor, a monument of industry and exact knowledge, of realism and romantic conception. A third series of "Episodios Nacionales" now in progress will raise the total to thirty volumes. In fecundity and in the power of creating characters, Pérez Galdós vies with Balzac. Parallel with this immense achievement in historical fiction, Pérez Galdós has published a collection of romances dealing with contemporary life, its social problems and religious difficulties. Of these the best known, and perhaps the best, are *Doña Perfecta* (1876); *Gloria* (1877); *La Familia de Leon Roch* (1878); *Marianela* (1878); *Fortunata y Jacinta* (1887); and *Ángel Guerra* (1891). Nor does this exhaust his prodigious activity. Besides adapting several of his novels for stage purposes, he has written original dramas such as *La Loca de la Casa* (1893), and *San Quintín* (1894). As experiments these plays are peculiarly interesting; but the very diffuse, exuberant genius of Pérez Galdós can scarcely accommodate itself to the narrow convention of the theatrical form, and his incessant preoccupation with politico-social theories is a very serious blemish upon his art. This defect, though present, is less obvious in his novels; yet the rapidity with which these are produced—four yearly—naturally affects their style. Still, when all allowances are made, it must be admitted that in Pérez Galdós Spain possesses a genuinely national novelist of extraordinary talent, a fertile inventor of types, and a most happy humorist, who in his eccentrics and oddities is scarcely inferior to Dickens. He is a member of the Spanish Academy and is a deputy in the Cortes; but it is solely as the romancer that his name is familiar wherever Spanish is spoken.

Périgueux, chief town of the department of Dordogne, France, 297 miles south-south-west of Paris, on the railway from Bordeaux to Lyons and the river Isle, on the left bank of which is the suburb of Barris. The large seminary, rebuilt 1887–89, is one of the finest in France. Périgueux is said to be the most important market in France for young pigs. Excellent building stone is quarried. Population (1881), 22,331; (1901), 28,875.

Periodicals.—The history of the origin and development of periodicals (apart from newspapers) in all languages down to 1884 is traced in the article on the subject in vol. xviii. of this Encyclopædia (ninth edition). Since that date the number of periodicals in every country, especially in Great Britain and the United States, has increased enormously, and the tendency has been to specialize in every direction. All professions and trades have not only their general class-periodicals, but every section has its special review or magazine. There were 7 cycling periodicals published in Great Britain in 1884; in 1902 there were 16, besides 5 for motors and motoring. There were 15 insurance and 18 medical periodicals in 1884; in 1902 they numbered 33 and 47. Cheap periodicals appealing to a class of readers hitherto unprovided for, such as *Tit-Bits* (1881) and *Answers* (1888), and profusely illustrated magazines like the *Strand* (1891) and *Pearson's* (1896), which owe much to process-printing from photographs, have multiplied. Most of these publications do not preserve literary matter of permanent value, but the high-class reviews and the archæological, artistic, and scientific magazines contain a great mass of valuable facts, so that general and special indexes have become necessary to all literary workers. The *Edinburgh* and *Quarterly Reviews*, the *Revue des Deux Mondes*, the *Revue Historique*, *Deutsche Rundschau*, and others issue from time to time general indexes of their contents, while the periodical literature of special departments of study and research are noted in the various *Jahresberichte* published in Germany, and indexed monthly in such English and American magazines as the *Engineering Magazine*, the *Geographical Journal*, *English Historical Review*, *American Historical Review*, *Economic Journal* (for political economy), *Library Journal* and *Library Association Record* (for bibliography), and the *Educational Review.* There are also annual indexes, such as those in the *Zoological Record* and the *Annales de Géographie.*

The most complete collection of periodicals in all languages ever brought together is that preserved in the British Museum, and the excerpt from the printed catalogue of the library, entitled *Periodical Publications* (London, 1899–1900, 6 parts folio, with index), includes journals, reviews, magazines, and other works issued periodically, with the exception of transactions and proceedings of learned societies and of British and colonial newspapers later than 1700. The titles of these periodicals, which number about 23,000, are arranged under the town or place of their publication. The collection is very complete as regards Great Britain and Ireland, less perfect as regards the British colonies and the United States, and it includes the leading periodicals belonging to every other country in the world. An examination of the catalogue shows that about 3840 were published since 1880, many, of course, being of an ephemeral nature. Arranged geographically, these fall into the following divisions:—UNITED KINGDOM: England (1956), Wales (26), Scotland (106), Ireland (30); total, 2118. BRITISH COLONIES AND POSSESSIONS: Europe (22), Asia, including India (120), Africa, including Cape Colony (81), America (11), Canada (37), Australia (63), New Zealand (20); total, 354. EUROPE: Austria (72), Belgium (37), Bulgaria (5), Denmark (23), France (312), Germany (258), Greece (9), Holland (32), Italy (133), Portugal (15), Russia (39), Spain (37), Sweden and Norway (21), Switzerland (30), Turkey (2); total, 1025. ASIA: China (16), Japan (6), other countries (21); total, 43. AFRICA: Egypt (6), other countries (5): total, 11. NORTH AMERICA: United States (260), other countries (4); total, 264. SOUTH AMERICA: Argentine (6), Brazil (4), other countries (15); total, 25.

The magazines published in the United Kingdom number 2486 (Mitchell's *Newspaper Press Directory,* 1902). In 1884 the London monthlies were 699, and the quarterlies 129. In 1902 they numbered 1010 and 215 (May's *British and Irish Press Guide,* 1884, and Willing's *Press Guide,* 1902).

It is difficult sometimes to define a magazine or review as distinguished from a newspaper or a trade or professional journal, but the following is a representative list, omitting publications of societies, of existing British, American, French, German, Italian, and Spanish periodicals founded since 1880:—

BRITISH.—*Ancestor* (1902); *Anglican Church Magazine* (1886); *Anglo-Catholic* (1899); *Anglo-Saxon Review* (1899); *Annals of Botany* (1887); *Annals of Surgery* (1885); *Answers* (1888); *Antiquary* (1888); *Architects' Magazine* (1900); *Architectural Review* (1896); *Archives of Surgery* (1889); *Artist* (1880); *Author* (1890); *Babylonian and Oriental Record* (1887); *Baconiana* (1886); *Badminton Magazine* (1895); *Bankers' Journal* (1889); *Beekeepers' Record* (1883); *Bill Poster* (1887); *Bimetallist* (1895); *Black and White* (1891); *Board of Trade Journal* (1886); *Bookman* (1891); *Book-Prices Current* (1887); *Books of To-Day and Books of To-Morrow* (1894); *British Dental Journal* (1898); *British Empire Review* (1899); *British Gynæcological Journal* (1885); *British Journal of Dermatology* (1888); *Broadway* (1899); *Builders' Journal* (1895); *Cabinet Maker* (1880); *Camera Magazine* (1901); *Canadian Gazette* (1883); *Candid Friend* (1901); *Caxton Magazine* (1901); *Century Guild Hobby Horse* (1893); *Chamber of Commerce Journal* (1882); *Chimes* (1896); *Classical Review* (1887); *Connoisseur* (1901); *Cosmopolitan* (1886); *Country Life* (1894); *Economic Journal* (1891); *Economic Review* (1891); *Educational Review* (1890); *Engineering Magazine* (1881); *English Historical Review* (1886); *English Illustrated Magazine* (1883); *Feilden's Magazine* (1898); *Folklore* (1888); *Gardener* (1892); *Genealogical Magazine* (1897); *Geographical Journal* (1893); *Harmsworth Magazine* (1898); *Harper's Magazine,* English edition (1880); *Hibernia* (1897); *Home Counties Magazine* (1895); *Idler* (1892); *Imperial and Asiatic Quarterly Review* (1886); *Index of Archæological Papers* (1891); *Index to the Periodical Literature of the World* (1890); *International Journal of Ethics* (1889); *Investors' Review* (1889); *Jewish Quarterly Review* (1888); *Journal of Balneology and Climatology* (1897); *Journal of Hellenic Studies* (1881); *Journal of Hygiene* (1901); *Journal of Indian Art* (1886); *Journal of Laryngology* (1887); *Journal of Malacology* (1892); *Journal of Obstetrics* (1902); *Journal of Pathology* (1892); *Journal of Physical Therapeutics* (1900); *Journal of State Medicine* (1892); *Journal of the Board of Agriculture* (1896); *King* (1899); *Lady's Magazine* (1901); *Lady's Realm* (1896); *Laryngoscope* (1893); *Law Notes* (1882); *Law Quarterly Review* (1885); *Legal Literature* (1899); *Library* (1889); *Library Assistant* (1898); *Library Association Record* (1899); *Library World* (1898); *Literary Gazette* (1898); *Literature* (1897; combined with *Academy,* 1901); *Longman's Magazine* (1882); *M'Clure's Magazine,* English edition (1894); *Medical Magazine* (1892); *Medical World* (1896); *Metaphysical Magazine* (1896); *Modern Language Quarterly* (1897); *Monthly Magazine of Fiction* (1885); *Monthly Review* (1900); *Moring's Quarterly* (1896); *Motor Car World* (1899); *Munsey's Magazine* (1900); *Museums Journal* (1901); *Musical News* (1891); *National Review* (1883); *Nature Notes* (1890); *New Ireland Review* (1894); *New Liberal Review* (1901); *Onlooker* (1900); *Open Court* (1887); *Ophthalmic Review* (1881); *Optician* (1891); *Outlook* (1898); *Page's Magazine* (1901); *Pall Mall Magazine* (1893); *Patents* (1895); *Pearson's Magazine* (1896); *Pearson's Weekly* (1890); *Philatelic Journal* (1901); *Physical Review* (1893); *Pick-me-up* (1888); *Pilot* (1900); *Playgoer* (1901); *Positivist Review* (1895); *Quarterly Medical Index* (1900); *Quarterly Medical Journal* (1890); *Railway Engineer* (1880); *Reporters' Magazine* (1880); *Review of Reviews* (1890); *Royal Magazine* (1898); *St George* (1898); *St Martin's-le-Grand* (1890); *Sandow's Magazine* (1898); *Scandinavian* (1881); *Science Abstracts* (1898); *Science Siftings* (1891); *Scientific Roll* (1880); *Scribner's Magazine,* English edition (1887); *Secretary's Journal* (1893); *Sketch* (1893); *Smart Set,* English edition (1901); *Something to Read* (1881); *Speaker* (1890); *Sphere* (1900); *Stage* (1880); *Strand Magazine* (1891); *Studio* (1893); *Sunday Strand* (1899); *Tatler* (1901); *Temple Magazine* (1896); *Tit-Bits* (1881); *To-Day* (1893); *Travel* (1896); *Twentieth Century* (1900); *Universal Magazine* (1900); *Wide World Magazine* (1898); *Windsor Magazine* (1895); *Young Man* (1887); *Young Woman* (1892); *Zoophilist* (1881).

AMERICAN.—*Alienist and Neurologist* (1880); *American Amateur Photographer* (1888); *American Book Lore* (1898); *American Geologist* (1888); *American Engineer* (1893; commenced as *Railroad and Engineering Journal,* 1887); *American Journal of Archæology* (1885); *American Jewish Year Book* (1899); *American Journal of Philology* (1880); *American Journal of Psychology* (1887); *American Journal of Semitic Languages* (1893; commenced as *Hebraica,* 1884); *American Journal of Sociology; Annual of the Universal Medical Sciences* (1888); *Annual Literary Index* (1892); *Arena* (1889); *Astrophysical Journal* (1895; commenced as *Sidereal Messenger,* 1882); *Biblical World; Bibliographer* (1902); *Book Chat* (1886); *Bookman* (1895); *Book Lover; British American* (1887); *Cassier's Magazine* (1891); *Chapbook* (1894); *Chatauquan* (1880); *Christian Science Journal* (1896); *Churchman* (1893); *Collector* (1887); *Cosmopolitan* (1886); *Critic* (1881); *Educational Review* (1891); *Electricity* (1891); *Engineering and Mining Journal* (1893); *Esoteric* (1888); *Forum* (1886); *Gunton's Magazine of American Economics* (1896; commenced as *Social Economist,* 1891); *Federal Reporter* (1880); *Harvard Law Review* (1894); *Humanitarian* (1892); *Intelligence* (1897; commenced as *Metaphysical Magazine,* 1895); *Journal of Morphology* (1887); *Journal of Political Economy* (1892); *Journal of Practical Metaphysics* (1896); *Journal of U.S. Artillery* (1891); *Kipling Note Book* (1899); *Ladies' Home Journal* (1882); *Library Notes* (1886); *Literary News* (1880); *McClure's Magazine* (1893); *Mazama* (1897); *Medico-Legal Journal* (1882); *Modern Language Notes* (1886); *Monist* (1890); *Municipal Affairs* (1897); *Nautilus* (1889); *New Church Review* (1894); *New Science Review* (1894); *New York Genealogical and Biographical Record; New World* (1892); *Notes on New Books* (1890); *Open Court* (1887); *Pediatrics* (1896); *Philosophical Review* (1892); *Photo American Review* (1891); *Poet Lore* (1889); *Popular Astronomy* (1893); *Præco Latinus; Presbyterian and Reformed Review* (1890); *Psychological Review* (1894); *Quarterly Journal of Economics; Records of the Past; Ring Record* (1896); *Science* (1883); *Scribner's Magazine* (1887); *Select Notes* (1895); *Sewanee Review* (1892); *Statistician and Economist* (1893; commenced as *McCarty's Annual Statistician,* 1884); *Street Railway Gazette* (1886); *Terrestrial Magnetism* (1896); *Virginia Magazine; West American Scientist* (1885); *Woman's Journal; Yale Review* (1892).

FRENCH.—*Aérophile* (1893); *Ami des Monuments* (1887); *Annales de Droit Commercial* (1887); *Annales Économiques* (founded as *La France Commerciale* in 1885); *Annales de Géographie* (1891); *Annales de l'École Libre des Sciences Politiques* (1886); *Annales du Midi* (1889); *Annales des Sciences Psychiques* (1891); *Anthropologie* (1890); *Archives de Biologie; Archives de* *l'Anthropologie Criminelle; Annales de Neurologie* (1880); *Les Arts* (1902); *Botaniste* (1888); *Bulletin Critique* (1882); *Bulletin de Géographie Historique; Bulletin de Numismatique* (1891); *Bulletin des Musées* (1890); *Bulletin des Sommaires des Journaux* (1888); *Cocarde* (1888); *Diatomiste* (1890); *Le Droit d'Auteur* (Bern, 1888); *Éclairage Électrique* (1894); *Électricien* (1881); *Études Religieuses; France Noire* (1894); *Génie Civil* (1880); *Grande Dame* (1893); *Hermine* (1889); *Initiation* (1888); *Intermédiaire des Mathématiciens* (1894); *Intransigéant* (1880); *Journal de Botanique* (1887); *Justice* (1880); *La Lecture* (1887); *Lotus Bleu* (1890); *Manuscrit* (1894); *Minerva* (1902); *Mouvement Géographique* (Brussels, 1884); *Moyen Age* (1885); *Nouvelle Revue Rétrospective* (1894); *Orient* (1889); *Politique Coloniale* (1892); *Question Sociale* (Brussels, 1893); *Réforme Sociale* (1881); *Renaissance Latine* (1902); *Répertoire des Ventes* (1894); *Révolution Française* (1881); *Revue Africaine; Revue Albanaise* (Brussels, 1897); *Revue Algérienne; Revue Anglo-Romaine* (1895); *Revue Biblique* (1892); *Revue Blanche* (1891, new series); *Revue d'Art Dramatique* (1886); *Revue d'Assyriologie* (1884); *Revue de Cavalerie* (1885); *Revue de Chirurgie* (1881); *Revue d'Économie Politique* (1887); *Revue de l'Art Chrétien; Revue de l'Art Ancien et Moderne* (1897); *Revue de l'Histoire des Religions* (1880); *Revue de l'Orient Latin* (1893); *Revue de l'Univ. de Bruxelles* (1895); *Revue de Mathématiques spéciales* (1890); *Revue de Médecine* (1881); *Revue de Métaphysique* (1893); *Revue de Paris* (1894); *Revue des Bibliothèques* (1891); *Revue du Clergé Français* (1894); *Revue du Droit Public* (1894); *Revue du Génie Militaire* (1887); *Revue du Monde Latin* (1883; now published as *Le Monde Latin et le Monde Slave*); *Revue Française de l'Étranger* (1885); *Revue Générale de Botanique* (1889); *Revue Hispanique* (1894); *Revue Historique de l'Ouest* (1885); *Revue Illustrée* (1886); *Revue Indépendante* (1882); *Revue Internationale de Sociologie* (1893); *Revue Pédagogique* (1882); *Revue Politique et Parlementaire* (1894); *Revue Sémitique* (1893); *Revue Socialiste* (1885); *Science Sociale* (1886); *Sciences Populaires* (1886); *Semaine Médicale* (1884); *La Société Nouvelle* (Brussels, 1885).

GERMAN.—*Academische Monatshefte* (Stuttgart, 1884); *Afrika* (1894); *Allgemeiner Anzeiger f. Buchbindereien* (1885); *Allgemeine Deutsche Universitätszeitung* (1887); *Die Arbeiter-Versorgung* (1884); *Annuaire Généalogique par H. R. Hiort Lorenzen* (1882); *Archiv f. latein. Peripatus.—Peripatus is a genus of animals belonging to the air-breathing division of the phylum Arthropoda. It differs, however, from all other Arthropoda in such important respects that a special class, equivalent in rank to the old-established Arthropod classes, has been created for its sole occupancy. This class has been named the Prototracheata or Onychophora, and may be most appropriately placed in the system in the neighbourhood of the Myriapoda, though it must not be forgotten that it differs from the Myriapoda more than the Myriapoda differ from other Arthropoda, and that in some respects it presents features which recall the segmented worms (Annelida). The genus has a wide distribution (see later), but it has not been found in Europe or in North America. There is but little variety of structure in the genus, and the species are limited in number. They live beneath the bark of trees, in the crevices of rock and of rotten stumps of trees, and beneath stones. They require a moist atmosphere, and are exceedingly susceptible to drought. They avoid light, and are therefore rarely seen. They move slowly, picking their course by means of their antennæ. When irritated they eject with considerable force the contents of their slime reservoirs by means of the sudden contraction of the muscular body-wall. The slime, which appears to be harmless, is extremely sticky, but it easily comes away from the skin of the animal itself. Locomotion is effected by means of the legs, with the body fully extended. Hutton describes his specimens as sucking the juices of flies, which they had stuck down with their slime, and they have been observed in captivity to devour the entrails which have been removed from their fellows, and to eat raw sheep's liver. They move their mouths in a suctorial manner, tearing the food with their jaws. They have the power of extruding their jaws from the mouth, and of working them alternately backwards and forwards. They are viviparous; the young are fully formed at birth, and differ from the adult only in size and colour. The mother does not appear to pay any special attention to her offspring, which wander away and get their own living. It has lately been stated that some of the Australian species are normally oviparous, but this has not been fully proved. Sexual differences are not strongly marked, and are sometimes absent. There does not appear to be any true copulation. In some species the male deposits small oval spermatophores indiscriminately on any part of the body of the female. It seems probable that in such cases the spermatozoa make their way from the adherent spermatophore through the body-wall into the body, and so by traversing the tissues reach the ovary. In other species which possess *receptacula seminis* it is probable that fertilization is effected once only in early life before any ova pass into the uterus.

External Features.—The anterior part of the body may be called the head, though it is not sharply marked off from the rest of the body (Fig. 1). The head carries three pairs of appendages, a pair of simple eyes, and a ventrally-placed mouth. The body is elongated and vermiform; it bears a number of paired appendages, each terminating in a pair of claws, and all very much alike. The number varies in the different species. The anus is always at the posterior end of the body, and the generative opening is on the ventral surface, just in front of the anus; it may be between the legs of the penultimate pair, or between the legs of the last pair, or it may be subterminal. The colour varies considerably in the different species, and even in different individuals of the same species. The skin has a velvety appearance, and is thrown into a number of transverse ridges, along which

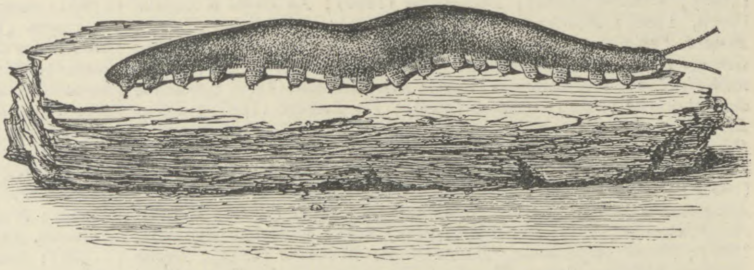

FIG. 1.—*Peripatus capensis*, drawn from life. Life size. (*After Sedgwick.*)

wart-like papillæ are placed. These papillæ, which are found everywhere, are the *primary* papillæ; they are covered with small, scale-like projections called *secondary* papillæ, and are specially developed on the dorsal surface, less so on the ventral. Each papilla carries at its extremity a well-marked spine. Among the primary papillæ smaller *accessory* papillæ are sometimes present.

The appendages of the head are the antennæ, the jaws, and the oral papillæ. The mouth is at the hinder end of a depression called the buccal cavity, and is surrounded by an annular tumid lip, raised into papilliform ridges and bearing a few spines (Fig. 2). Within the buccal cavity are the two jaws. They are short, stump-like, muscular structures, armed at their free extremities by a pair of cutting blades or claws, and are placed one on each side of the mouth. In the median line of the buccal cavity in front is placed a thick muscular protuberance, which may be called the tongue, though attached to the dorsal instead of to the ventral wall of the mouth (Fig. 2). The tongue bears a row of small, chitinous teeth. The jaw-claws (Figs. 3 and 4), which resemble in all essential points the claws borne by the feet, and, like these, are thickenings of the cuticle, are sickle-shaped. They have their convex edge directed forwards, and their concave, or cutting edge, turned backwards. The inner cutting plate (Fig. 3) usually bears a number of cutting teeth. The oral papillæ are placed at the sides of the head (Fig. 2). The ducts of the slime-glands open at their free end. They possess two main rings of projecting tissue,

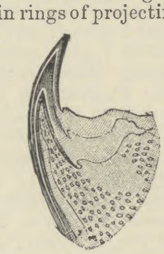

FIG. 4.—Outer jaw-claw of *P. capensis*. (*After Balfour.*)

and their extremities bear papillæ irregularly arranged. The ambulatory appendages vary in number. There are seventeen pairs in *P. capensis* and eighteen in *P. Balfouri*, while in *P. jamaicensis* the number varies from twenty-nine to forty-three. They consist of two main divisions, which we may call the leg and the foot (Fig. 5). The leg (*l*) has the form of a truncated cone, the broad end of which is attached to the ventro-lateral wall of the body, of which it is a prolongation. It is marked by a number of rings of papillæ placed transversely to its long axis, the dorsal of which are pigmented like the dorsal surface of the body, and the ventral like the ventral surface. At the narrow distal end of the leg there are on the ventral surface three or four (rarely five) spiniferous pads, each of which is continued dorsally into a row of papillæ. The foot is attached to the distal end of the leg. It is slightly narrower at its attached extremity than at its free end. It bears two sickle-shaped claws, and at its distal end three (rarely four) papillæ. The part of the foot which carries the claws is especially retractile, and is generally found more or less telescoped into the proximal part. The legs of the fourth and fifth pairs differ from the others in the fact that the third pad (counting from the distal end of the leg) carries the opening of the enlarged nephridia of these segments. In some species certain of the legs bear on their ventral sides furrows with tumid lips and lined by smooth non-tuberculate epithelium; they are called coxal organs, and it appears that they can be everted. The males are generally rather smaller and less numerous than the females. In those species in which the number of legs varies the male has a smaller number of legs than the female.

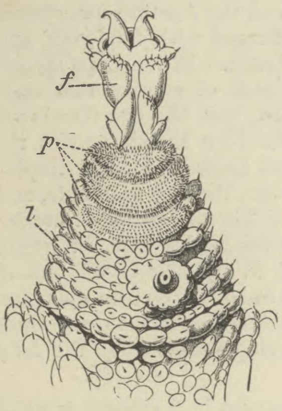

FIG. 5.—Ventral view of last leg of a male *P. capensis*. (*After Sedgwick.*) *f*, foot; *l*, leg; *p*, spiniferous pads. The white papilla on the proximal part of this leg is characteristic of the male of this species.

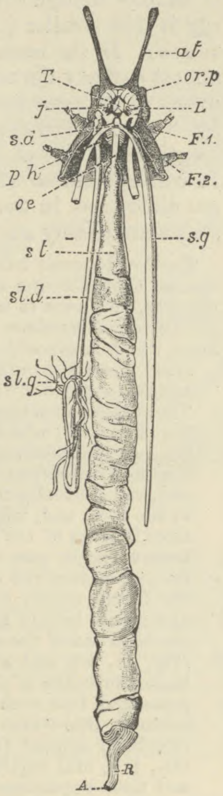

FIG. 6.—*Peripatus capensis* dissected so as to show the alimentary canal, slime glands, and salivary glands. (*After Balfour.*) The dissection is viewed from the ventral side, and the lips (*L*) have been cut through in the middle line behind and pulled outwards so as to expose the jaws (*j*), which have been turned outwards, and the tongue (*T*) bearing a median row of chitinous teeth, which branches behind into two. The muscular pharynx, extending back into the space between the first and second pairs of legs, is followed by a short tubular œsophagus. The latter opens into the large stomach with plicated walls, extending almost to the hind end of the animal. The stomach at its point of junction with the rectum presents an S-shaped ventro-dorsal curve. *A*, Anus; *at*, antenna; *F.1*, *F.2*, first and second feet; *j*, jaws; *L*, lips; *oe*, œsophagus; *or.p*, oral papilla; *ph*, pharynx; *R*, rectum; *s.d*, salivary duct; *s.g*, salivary gland; *sl.d*, slime reservoir; *sl.g*, portion of tubules of slime gland; *st*, stomach; *T*, tongue in roof of mouth.

Breeding.—As already stated, *Peripatus* is viviparous. The Australasian species come nearest to laying eggs, inasmuch as the eggs are large, full of yolk, and enclosed in a shell; but development normally takes place in the uterus, though, abnormally, incompletely developed eggs are extruded. The uterus always contains several young, which are usually at different stages of development and are born at different times of the year. In most of the African species, however, the embryos of the uterus are almost of the same age and are born at a definite season. The young of *P. capensis* are born in April and May. They are almost colourless at birth, excepting the antennæ, which are green, and their length is 10 to 15 mm. A large female will produce thirty to forty young in one year. The period of gestation is thirteen months, that is to say, the ova pass into the oviducts about one month before the young of the preceding year are born.

Anatomy.—The alimentary canal (Fig. 6). The buccal cavity, as explained above, is a secondary formation around the true mouth, which is at its dorsal posterior end. It contains the tongue and the jaws, which have already been described, and into the hind end of it there open ventrally by a median opening the salivary glands. The mouth leads into a muscular pharynx, which is connected by a short œsophagus with the stomach. The stomach forms by far the largest part of the alimentary canal. It is a dilated soft-walled tube, and leads behind into the short narrow rectum, which opens at the anus. There are no glands opening into the alimentary canal. The central nervous system, the anterior part of which is shown in Fig. 7, is described in the ninth edition of this work (see vol. xvii. p. 116).

The cuticle is a thin layer, of which the spines, jaws, and claws are special developments. Its surface is not, however, smooth, but is everywhere, with the exception of the perioral region, raised into minute secondary papillæ, which in most instances bear at their free extremity a somewhat prominent spine. The epidermis, placed immediately within the cuticle, is composed of a single row of cells. The pigment which gives the characteristic colour to the skin is deposited in the protoplasm of the outer ends of the cells in the form of small granules. Beneath the epidermis is a thin cutis, which is followed by the muscular layers (external circular and internal longitudinal). The muscular fibres of the jaws are transversely striated, the other muscles are unstriated.

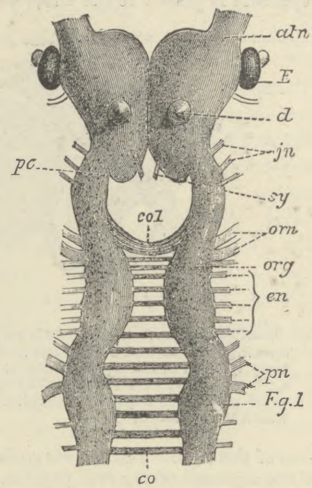

FIG. 7.—Brain and anterior part of the ventral nerve-cords of *Peripatus capensis* enlarged and viewed from the ventral surface. (*After Balfour.*) *atn*, antennary nerves; *co*, commissures between ventral cords; *d*, ventral appendages of brain; *E*, eye; *en*, nerves passing outwards from ventral cord; *F.g.*1, ganglionic enlargements from which nerves to feet pass off; *jn*, nerves to jaws; *org*, ganglionic enlargement from which nerves to oral papillæ pass off; *orn*, nerves to oral papillæ; *pc*, posterior lobe of brain; *pn*, nerves to feet; *sy*, sympathetic nerves.

The apertures of the tracheal system are placed in the depressions between the papillæ or ridges of the skin. Each of them leads into a tube, which may be called the tracheal pit (Fig. 8); the walls of this are formed of epithelial cells, bounded towards the lumen of the pit by a very delicate cuticular membrane continuous with the cuticle covering the surface of the body. Internally it expands in the transverse plane, and from the expanded portion the tracheal tubes arise in diverging bundles. The tracheæ are minute tubes exhibiting a faint transverse striation which is probably the indication of a spiral fibre. They appear to branch, but only exceptionally. The tracheal apertures are diffused over the surface of the body, but are especially developed in certain regions.

FIG. 8.—Section through a tracheal pit and diverging bundles of tracheal tubes taken transversely to the long axis of the body. (*After Balfour.*) *tr*, tracheæ, showing rudimentary spiral fibre; *tr.c*, cells resembling those lining the tracheal pits, which occur at intervals along the course of the tracheæ; *tr.o*, tracheal stigma; *tr.p*, tracheal pit.

The vascular system consists of a dorsal tubular heart with paired ostia leading into it from the pericardium, of the pericardium, and the various other divisions of the perivisceral cavity (Fig. 12, D). As in all Arthropoda, the perivisceral cavity is a hæmocœle; *i.e.*, contains blood, and forms part of the vascular system. It is divided by septa into chambers (Fig. 12, D), of which the most important are the central chamber containing the alimentary canal and the dorsal chamber or pericardium. Nephridia are present in all the legs. In all of them (except the first three) the following parts may be recognized (Fig. 9): (1) a vesicular portion (*s*) opening to the exterior on the ventral surface of the legs by a narrow passage (*s.d*); (2) a coiled portion, which is again subdivided into several sections (*s.c*); (3) a section with closely-packed nuclei ending by a somewhat enlarged opening (*p.f*); (4) the terminal portion, which consists of a thin-walled vesicle. The nephridia of the first three pairs of legs are smaller than the rest, consisting only of a vesicle and duct. The fourth and fifth pairs are larger than those behind, and are in other respects peculiar; for instance, they open on the third pad (counting from the distal end of the leg), and the external vesicular portion is not dilated. The external opening of the other nephridia is placed at the outer end of a transverse groove at the

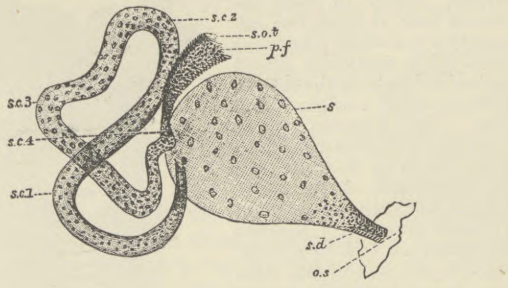

FIG. 9.—Nephridium from the ninth pair of legs of *P. capensis*. *o.s*, external opening of segmental organ; *p.f*, internal opening of nephridium into the body cavity (lateral compartment); *s*, vesicle of segmental organ; *s.c.*1, *s.c.*2, *s.c.*3, *s.c.*4, successive regions of coiled portion of nephridium; *s.o.t*, third portion of nephridium broken off at *p.f* from the internal vesicle, which is not shown.

base of the legs. The salivary glands are the modified nephridia of the segment of the oral papillæ.

The male generative organs (Fig. 10) consist of a pair of testes (*te*), a pair of seminal vesicles (*v*), vasa deferentia (*v.d*), and acces-

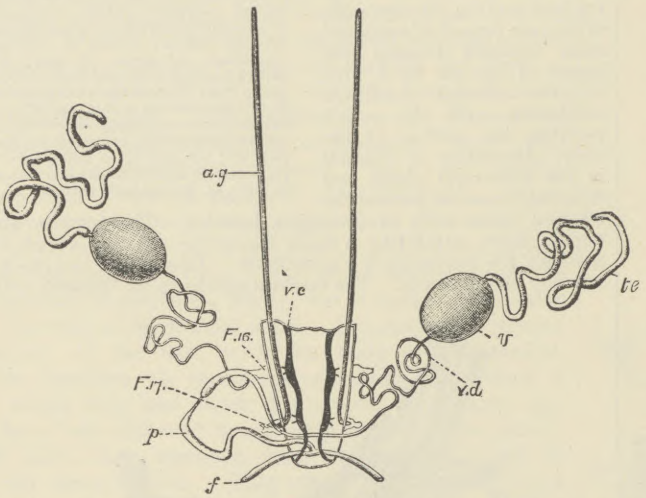

FIG. 10.—Male generative organs of *Peripatus capensis*, dorsal view. sory glandular tubules (*f*). All the above parts lie in the central compartment of the body cavity. The ovaries consist of a pair of tubes closely applied together, and continued posteriorly into the oviducts. Each oviduct, after a short course, becomes dilated into the uterus. The two uteri join behind and open to the exterior by a median opening. The ovaries always contain spermatozoa, some of which project through the ovarian wall into the body cavity. Spermatozoa are not found in the uterus and oviducts, and it appears probable, as we have said, that they reach the ovary directly by boring through the skin and traversing the body cavity. In all the species except the African species there is a globular receptaculum seminis opening by two short ducts close together into the oviduct, and in the neotropical species there is in addition a small receptaculum ovorum, with extremely thin walls, opening into the oviduct by a short duct just in front of the receptaculum seminis. The epithelium of the latter structure is clothed with actively moving cilia. There appear to be present in most, if not all, of the legs some accessory glandular structures opening just externally to the nephridia. They are called the crural glands.

Development.—Peripatus is found in Africa, in Australasia, in South America and the West Indies, in New Britain, and in the Malay Peninsula and Sumatra. The species found in these various localities are closely similar in their anatomical characters, the principal differences relating to the structure of the female generative organs and to the number of the legs. They, however, differ in the most striking manner in the structure of the ovum and the early development. In all the Australasian species the egg is large and heavily charged with food-yolk, and is surrounded by a tough membrane. In the Cape species the eggs are smaller, though still of considerable size; the yolk is much less developed, and the egg membrane is thinner though dense. In the New Britain species the egg is still smaller (·1 mm.), and there is a large trophic vesicle. In the neotropical species the egg is minute, and almost entirely devoid of yolk. The unsegmented uterine ovum of *P. novæ zealandiæ* measures 1·5 mm. in length by ·8 mm. in breadth; that of *P. capensis* is ·56 mm. in length; and that of *P. trinidadensis* ·04 mm. in diameter. In correspondence with these differences in the ovum there are differences in the early development, though the later stages are closely similar.

The development has been worked out in *P. capensis*, to which species the following description refers. The segmentation is peculiar, and leads to the formation of a solid gastrula, consisting of a cortex of ectoderm nuclei surrounding a central endodermal mass, which is exposed at one point—the blastopore. The enteron arises as a space in the endoderm, and an opacity—the primitive streak—appears at the hind end of the blastopore (Fig. 11, B). The elongation of the embryo is accompanied by an elongation of the blastopore, which soon becomes dumb-bell shaped (Fig. 11, C). At the same time the mesoblastic somites (embryonic segments of mesoderm) make their appearance in pairs at the hind end, and gradually travel forwards on each side of the blastopore to the front end, where the somites of the anterior pair soon meet in front of the blastopore (Fig. 11, D). Meanwhile the narrow middle part of the blastopore has closed by a fusion of its lips, so that the blastopore is represented by two openings, the future mouth and anus. A primitive groove makes its appearance behind the blastopore (Fig. 11, D). At this stage the hind end of the body becomes curved ventrally into a spiral (Fig. 11, E), and at the same time the appendages appear as hollow processes of the body-wall, a mesoblastic somite being prolonged into each of them. The first to appear are the antennæ, into which the præoral somites are prolonged. The remainder appear from before backwards in regular order, viz., jaw, oral papillæ, legs 1–17. The full number of somites and their appendages is not, however, completed until a later stage. The nervous system is formed as an annular thickening of ectoderm passing in front of the mouth and behind the anus, and lying on each side of the blastopore along the lines of the somites. The præoral part of this thickening, which gives rise to the cerebral ganglia, becomes pitted inwards on each side (Fig. 11, F, *c.g*). These pits are eventually closed, and form the hollow ventral appendages of the supra-pharyngeal ganglia of the adult (Fig. 7, *d*). The lips are formed as folds of the side wall of the body, extending from the præoral lobes to just behind the jaw (Fig. 11, F, *L*). They enclose the jaws (*j*), mouth (*M*), and opening of the salivary

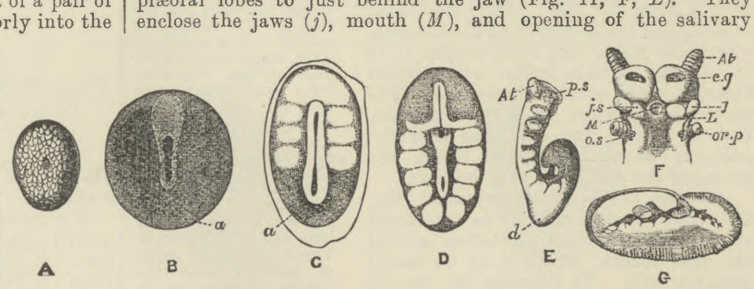

FIG. 11.—A series of embryos of *P. capensis*. The hind end of embryos B, C, D is uppermost in the figures, the primitive streak is the white patch behind the blastopore. (*After Sedgwick.*) A, Gastrula stage, ventral view, showing blastopore. B, Older gastrula stage, ventral view, showing elongated blastopore and primitive streak. C, Ventral view of embryo with three pairs of mesoblastic somites, dumb-bell shaped blastopore and primitive streak. D, Ventral view of embryo, in which the blastopore has completely closed in its middle portion. The anterior pair of somites have moved to the front end of the body. E, side view of later embryo. *At*, antenna; *d*, dorsal projection; *p.s*, præoral somite. F, Ventral view of head of embryo, intermediate between E and G. *At*, antennae; *c.g*, cerebral groove; *j*, jaws; *j.s*, swelling at base of jaws; *L*, lips; *M*, mouth; *or.p*, oral papillae; *o.s*, opening of salivary gland. G, side view of older embryo.

glands (*o.s*), and so give rise to the buccal cavity. The embryo has now lost its spiral curvature, and becomes completely doubled upon itself, the hind end being in contact with the mouth (Fig. 11, G). It remains in this position until birth. The just-born young are from 10 to 15 mm. in length, and have green antennæ, but the rest of the body is either quite white or of a reddish colour. This red colour differs from the colour of the adult in being soluble in spirit. The mesoblastic somites are paired sacs formed from the anterior lateral portions of the primitive streak (Fig. 11, C). As they are formed they become placed in pairs on each side of the blastopore. The somites of the first pair eventually obtain a position entirely in front of the blastopore (Fig. 11, D). They form the somites of the præoral lobes. The full complement of somites is acquired at about the stage of Fig. 11, E. The relations of the mesoblastic somites is shown in Fig. 12, A, which represents a transverse section taken between the mouth and anus of an embryo of the stage of Fig. 11, D. The history of these somites is an exceedingly interesting one, and may be described shortly as follows: They divide into two parts—a ventral part, which extends into the appendage, and a dorsal part (Fig. 12, B). Each of the ventral parts acquires an opening to the exterior, just outside the nerve-cord, and becomes entirely transformed into a nephridium (Fig. 12, D, 2′). The dorsal part shifts dorsalwards and diminishes relatively in size (Fig. 12, C). Its fate differs in the different parts of the body. In the anterior somites it dwindles and disappears, but in the posterior part it unites with the dorsal divisions of contiguous somites of the same side, and forms a tube—the generative tube (Fig. 12, D, 2). The last section of this tube retains its connexion with the ventral portion of the somite, and so acquires an external opening, which is at first lateral, but soon shifts to the middle line, and fuses with its fellow, to form the single generative opening. The præoral somite develops the rudiment of a nephridium, but eventually entirely disappears. The jaw somite also disappears; the oral papilla somite forms ventrally the salivary glands, which are thus serially homologous with nephridia. The various divisions of the perivisceral cavity develop as a series of spaces between the ectoderm and endoderm, and later in the mesoderm. The mesoderm seems to be formed entirely from the proliferation of the cells of the mesoblastic somites. It thus appears that in *Peripatus* the cœlom does not develop a perivisceral portion, but gives rise only to the renal and reproductive organs.

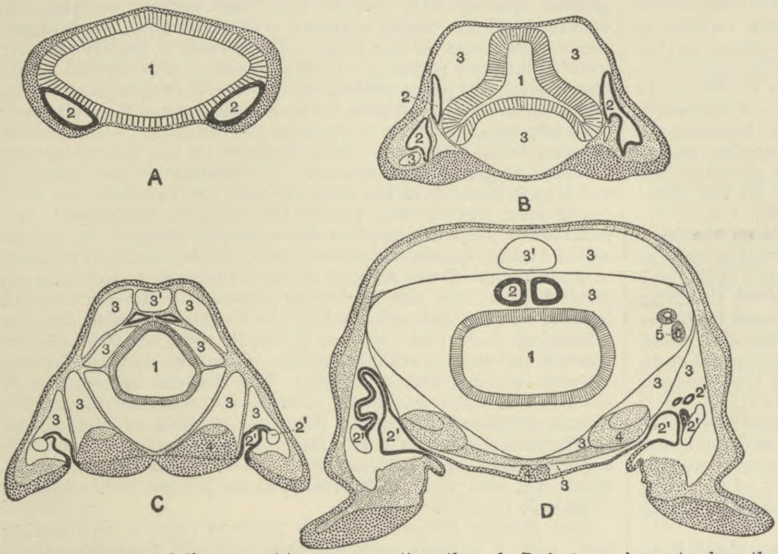

FIG. 12.—A series of diagrams of transverse sections through *Peripatus* embryos to show the relations of the cœlom at successive stages. (*After Sedgwick.*) A, Early stage; no trace of the vascular space; endoderm and ectoderm in contact. B, Endoderm has separated from the dorsal and ventral ectoderm. The somite is represented as having divided on the left side into a dorsal and ventral portion. C, The hæmocœle (3) has become divided up into a number of spaces, the arrangement of which is unimportant. The dorsal part of the somite has travelled dorsalwards, and now constitutes a small space (triangular in section) just dorsal to the gut. The ventral portion (2) has assumed a tubular character, and has acquired an external opening. The internal vesicle is already indicated, and is shown in the diagram by the thinner black line; 1, gut; 2, somite; 2′, nephridial part of cœlom; 3, hæmocœle; 3′, part of hæmocœle which will form the heart—the part of the hæmocœle on each side of this will form the pericardium; 4, nerve-cord; 5, slime glands. D represents the conditions at the time of birth. The cœlom is represented as surrounded by a thick black line, except in the part which forms the internal vesicle of the nephridium.

The genus *Peripatus* was established in 1826 by Guilding, who first obtained specimens of it from St Vincent in the Antilles. He regarded it as a Mollusc, being no doubt deceived by the slug-like appearance given by the antennæ. Specimens were subsequently obtained from other parts of the neotropical region, and from South Africa and Australia, and the animal was variously assigned by the zoologists of the day to the Annelida and Myriapoda. Its true place in the system, as a primitive member of the group Arthropoda, was first established in 1874 by Moseley, who discovered the tracheæ. *Peripatus* is an Arthropod, as shown by (1) the presence of appendages modified as jaws; (2) the presence of paired lateral ostia perforating the wall of the heart and putting its cavity in communication with the pericardium; (3) the presence of a vascular body cavity and pericardium (hæmocœlic body cavity); (4) absence of a perivisceral section of the cœlom. Finally, the tracheæ, though not characteristic of all the classes of the Arthropoda, are found nowhere outside that group, and constitute a very important additional reason for uniting *Peripatus* with it. *Peripatus*, though indubitably an Arthropod, differs in such important respects from all the old-established Arthropod classes, that a special class, equivalent in rank to the others, and called Prototracheata or Onychophora, has had, as we have seen, to be created for its sole occupancy. This unlikeness to other Arthropoda is mainly due to the Annelidan affinities which it presents, but in part to the presence of the following peculiar features: (1) the number and diffusion of the tracheal apertures; (2) the restriction of the jaws to a single pair; (3) the disposition of the generative organs; (4) the texture of the skin; and (5) the simplicity and similarity of all the segments of the body behind the head. The Annelidan affinities are superficially indicated in so marked a manner by the thinness of the cuticle, the dermo-muscular body-wall, the hollow appendages, that, as already stated, many of the earlier zoologists who examined *Peripatus* placed it among the segmented worms; and the discovery that there is some solid morphological basis for this determination constitutes one of the most interesting points of the recent work on the genus. The Annelidan features are: (1) the paired nephridia in every segment of the body behind the first two (Saenger, Balfour); (2) the presence of cilia in the generative tracts (Gaffron). It is true that neither of these features is absolutely distinctive of the Annelida, but when taken in conjunction with the Annelidan disposition of the chief systems of organs, viz., the central nervous system, and the main vascular trunk or heart, they may be considered as indicating affinities in that direction.

SYNOPSIS OF SPECIES.

PERIPATUS (Guilding). Soft-bodied vermiform animals, with one pair of ringed antennæ, one pair of jaws, one pair of oral papillæ, and a varying number of claw-bearing ambulatory legs. Dorsal surface arched and more darkly pigmented than the flat ventral surface. Skin transversely ridged and beset by wart-like spiniferous papillæ. Mouth anterior, ventral; anus posterior, terminal. Generative opening single, median, ventral, and posterior. One pair of simple eyes. Brain large, with two ventral hollow appendages; ventral cords widely divaricated, without distinct ganglia. Alimentary canal simple, uncoiled. Segmentally arranged paired nephridia are present. Body cavity is continuous with the vascular system, and does not communicate with the paired nephridia. Heart tubular, with paired ostia. Respiration by means of tracheæ. Diœcious; males smaller and generally less numerous than females. Generative glands tubular, continuous with the ducts. Viviparous. Young born fully developed. Distribution: Africa (Cape Colony, Natal, and the Gaboon), New Zealand, Australia and Tasmania, New Britain, South and Central America and the West Indies, the Malay Peninsula [and in Sumatra ?].

The genus *Peripatus*, so far as adult conformation is concerned, is a very homogeneous one. It is true, as was pointed out by

Sedgwick, that the species from the same part of the world resemble one another more closely than they do species from other regions, but recent researches have shown that the line between them cannot be so sharply drawn as was at first supposed, and it is certainly not desirable in the present state of our knowledge to divide them into generic or subgeneric groups, as has been done by some zoologists. (The following genera have been proposed: *Peripatus* for the neotropical species, *Peripatoides* for the Australasian, *Peripatopsis* and *Opisthopatus* for the African, *Paraperipatus* for the New Britain, *Eoperipatus* for the Malayan species, and *Ooperipatus* for the supposed oviparous species of Australia and New Zealand.) The colour is highly variable in species from all regions; it is perhaps more constant in the species from the neotropical region than in those from elsewhere. The number of legs tends to be variable whenever it exceeds 19 prægenital pairs; when the number is less than that, it is usually, though not always, constant. More constant points of difference are the form of the jaws, the position of the generative orifice, the presence of a receptaculum seminis and a receptaculum ovorum, the arrangement of the primary papillæ on the distal end of the feet, and above all the early development.

South African Species.—With three spinous pads on the legs, and feet with two primary papillæ on the anterior side and one on the posterior side; outer jaw with one minor tooth at the base of the main tooth, inner jaw with no interval between the large tooth and the series of small ones; last fully-developed leg of the male with enlarged crural gland opening on a large papilla placed on its ventral surface; coxal organs absent; the nephridial openings of the 4th and 5th pairs of legs are placed in the proximal spinous pad. Genital opening subterminal, behind the last pair of fully developed legs; oviduct without receptacula seminis or receptacula ovorum; the terminal unpaired portion of vas deferens short. Ova of considerable size, but with only a small quantity of yolk. The embryos in the uterus are all nearly of the same age, except for a month or two before birth, when two broods overlap.

The following species are aberrant in respect of these characters: *Peripatus* (*Opisthopatus*) *cinctipes* Purcell (Cape Colony and Natal) presents a few Australasian features; there is a small receptaculum seminis on each oviduct, some of the legs are provided with well-developed coxal organs, the feet have one anterior, one posterior, and one dorsal papilla, and the successive difference in the ages of the embryos in the uterus, though nothing like that found in the neotropical species, is slightly greater than that found in other investigated African species. Several pairs of legs in the middle region of the body are provided with enlarged crural glands which open on a large papilla. Male with four accessory glands, opening on each side of and behind the genital aperture. *P. tholloni* Bouvier (equatorial West Africa [Gaboon]) shows some neotropical features; there are 24 to 25 pairs of legs, the genital opening is between the penultimate legs, and though there are only three spinous pads, the nephridial openings of the 4th and 5th legs are proximal to the 3rd pad, coxal organs are present, and the jaws are of the neotropical type; the oviducts have receptacula seminis. The following South African species may be mentioned: *P. capensis* (Grube), with 17 (rarely 18) pairs of claw-bearing legs; *P. Balfouri* (Sedgw.) with 18 (rarely 19) pairs; *P. Moseleyi* (Wood-M.), with 20 to 24 pairs.

Australasian Species.—With 14, 15, or 16 pairs of claw-bearing ambulatory legs, with three spinous pads on the legs, and nephridial opening of the 4th and 5th legs on the proximal pad; feet with one anterior, one posterior, and one dorsal primary papilla; inner jaw without diastema, outer with or without a minor tooth. Last leg of the male with or without a large white papilla on its ventral surface for the opening of a gland, and marked papillæ for the crural glands are sometimes present on other legs of the male; well-developed coxal glands absent. Genital opening between the legs of the last pair; oviducts with receptacula seminis, without receptacula ovorum; the terminal portion of the vas deferens long and complicated; the accessory male glands open between the genital aperture and the anus, near the latter. Ova large and heavily charged with yolk, and provided with a stoutish shell. The uterus appears to contain embryos of different ages. Specimens are recorded from West Australia, Queensland, New South Wales, Victoria, and New Zealand. The Australasian species are in some confusion. The number of claw-bearing legs varies from 14 to 16 pairs, but the number most often found is 15. Whether the number varies in the same species is not clear. There appears to be evidence that some species are occasionally or normally oviparous, and in the supposed oviparous species the oviduct opens at the end of a papilla called from its supposed function an ovipositor, but the oviparity has not yet been certainly proved as a normal occurrence. Among the species described may be mentioned *P. Leuckarti* (Saenger), *P. insignis* (Dendy), *P. oviparus* (Dendy), *P. viridimaculatus* (Dendy), *P. novæ zealandiæ* (Hutton), but it is by no means certain that future research will maintain these. Mr J. J. Fletcher, indeed, is of opinion that the Australian forms are all varieties of one species, *P. Leuckarti*.

Neotropical Species.—With 3 to 5 spinous pads on the legs, nephridial opening of the 4th and 5th legs usually proximal to the 3rd pad, and feet either with two primary papillæ on the anterior side and one on the posterior, or with two on the anterior and two on the posterior; outer jaw with small minor tooth or teeth at the base of the main tooth, inner jaw with diastema. A variable number of posterior legs of the males anterior to the genital opening with one or two large papillæ carrying the openings of the crural glands; well-developed coxal organs present on most of the legs. The primary papillæ usually divided into two portions. Genital opening between the legs of the penultimate pair; oviduct provided with receptacula seminis and ovorum; unpaired part of vas deferens long and complicated; accessory organs of male opening at the sides of the anus. Ova minute, with little food-yolk; embryos in the uterus at very different stages of development. The number of legs usually if not always variable in the same species; the usual number is 28 to 32 pairs, but in some species 40 to 43 pairs are found. The neotropical species appear to fall into two groups: (1) the so-called Andean species, viz., those which inhabit the high plateaux or Pacific slope of the Andes; in these there are 4 (sometimes 5) pedal papillæ, and the nephridial openings of the 4th and 5th legs are on the third pad; and (2) the Caribbean species, viz., the remaining neotropical species, in which there are 3 papillæ on the foot and the nephridial openings of the 4th and 5th legs are between the 3rd and 4th pads. The Andean species are *P. eisenii* (Wh.), *P. tuberculatus* (Bouv.), *P. Lankesteri* (Bouv.), *P. quitensis* (Schm.), *P. Corradi* (Cam.), *P. Cameranoi* (Bouv.), and *P. Balzani* (Cam.). Of the remaining species, which are the majority, may be mentioned *P. Edwardsii* (Blanch), *P. jamaicensis* (Gr. and Cock.), *P. trinidadensis* (Sedgw.), *P. torquatus* (Ken.), *P. im Thurmi* (Scl.).

New Britain Peripatus.—With 22 to 24 pairs of claw-bearing legs, with 3 spinous pads on the legs, and nephridial openings of legs 4 and 5 (sometimes of 6 also) on the proximal pad; feet with one primary papilla on the anterior, one on the posterior side, and one on the dorsal side (median or submedian); outer jaw with a minor tooth, inner jaw without diastema; crural glands absent; well-developed coxal organs absent. Genital opening subterminal behind the last pair of legs; oviduct with receptaculum seminis without recept. ovorum; unpaired part of vas deferens very short; accessory glands two, opening medianly and dorsally. Ova small, ·1 mm. in diameter, with little yolk, and the embryos provided with large trophic vesicles (Willey). Embryos in the uterus of very different ages, and probably born all the year round. One species only known, *P. novæ britanniæ* (Willey).

Sumatran Peripatus.—Peripatus with 24 pairs of ambulatory legs, and 4 spinous pads on the legs. The primary papillæ of the neotropical character with conical bases. Generative opening between the legs of the penultimate pair. Feet with only two papillæ. Single species. *P. sumatranus* (Sedgw.). The existence of this species is doubtful.

Peripatus from the Malay Peninsula.—With 23 to 25 pairs of claw-bearing legs, 4 spinous pads on the legs, and nephridial openings of legs 4 and 5 in the middle of the proximal pad or on its proximal side; feet with two primary papillæ, one anterior and one posterior; outer jaw with 2, inner jaw with 2 or 3 minor teeth at the base of the main tooth, separated by a diastema from the row of small teeth; crural glands present in the male only, in the two pairs of legs preceding the generative opening; coxal glands present. Genital opening between the penultimate legs; oviduct with receptacula seminis and ovorum; unpaired part of vas deferens long; male accessory glands two, opening medianly between the legs of the last pair. Ova large, with much yolk and thick membrane, like those of Australasian species; embryos with slit-like blastopore and of very different ages in the same uterus, probably born all the year round. The species are *P. Weldoni* (Evans), *P. Horsti* (Evans), and *P. Butleri* (Evans). It will thus be seen that the Malay species, while resembling the neotropical species in the generative organs, differ from these in many features of the legs and feet, in the important characters furnished by the size and structure of the ovum, and by their early development.

Perityphlitis. See APPENDICITIS.

Perkin, William Henry (1838-——), English chemist, was born in London on 12th March 1838. From an early age he determined to adopt chemistry as his profession, although his father, who was a builder, would have preferred him to be an architect. Attending the City of London School—one of the few which at that time included natural science in its curriculum—he devoted all his spare time to chemistry, and on leaving, in 1853, entered the Royal College of Chemistry, then under the direction of A. W. Hofmann, in whose own research laboratory he was in the course of a year or two promoted to be an assistant. Devoting his evenings to private investigations in a rough laboratory fitted up at his home, Perkin was fired by some remarks of Hofmann's to undertake the artificial production of quinine. In this attempt he was unsuccessful, but the observations he made in the course of his experiments induced him, early in 1856, to try the effect of treating aniline sulphate with bichromate of potash. The result was a black precipitate, which he found to contain the colouring matter subsequently known as aniline blue or mauve. He lost no time in introducing this substance to the notice of Messrs Pullar, the well-known dyers, and they expressed a favourable opinion of it, if only it should not prove too expensive in use. Thus encouraged, he took out a patent for his process, and leaving the College of Chemistry, a boy of eighteen, he proceeded, with the aid of his father and brother, to erect works at Greenford Green, near Harrow, for the manufacture of the newly-discovered colouring matter. Various preliminary difficulties were encountered, not only in designing suitable plant, but also in obtaining supplies of raw materials; but these were successfully overcome, and by the end of 1857 the works were in operation. That date may therefore be reckoned as that of the foundation of the coal-tar colour industry, which has since attained such important dimensions—in Germany, however, rather than in England, the country where it originated. The further difficulties of finding methods of successfully dyeing with the material were also grappled with, and it soon came into wide use, first for dyeing silk in London, and then for calico-printing in Scotland. Dr Perkin also had a large share in the introduction of artificial alizarin, the red dye of the madder root. Graebe and Liebermann in 1868 prepared that substance synthetically from anthracene, but their process was not practicable on a large scale, and it was left to him to patent a method that was commercially valuable. This he did in 1869, thus securing for the Greenford Green works a monopoly of alizarin manufacture for several years. About the same time he also carried out a series of investigations into kindred substances, such as anthrapurpurin. About 1874 he abandoned the manufacture of coal-tar colours, and devoted himself exclusively to research in pure chemistry, which, however, he had by no means neglected even while his attention was occupied with the practical problems of manufacture; and among the discoveries he made in this field was that of the reaction known by his name, depending on the condensation of aldehydes with fatty acids. Later still he engaged in the study of the relations between chemical constitution and rotation of the plane of polarization in a magnetic field, and enunciated a law expressing the variation of such rotation in bodies belonging to homologous series. For this work he was in 1889 awarded a Davy medal by the Royal Society, which ten years previously had bestowed upon him a Royal medal in recognition of his investigations in the coal-tar colours. The Chemical Society, of which he became secretary in 1869 and president in 1883, presented him with its Longstaff medal in 1889, and in 1890 he received the Albert medal of the Society of Arts. His eldest son, William Henry Perkin, junior, who was born at Sudbury, near Harrow, on 17th June 1860, and was educated at the City of London School, the Royal College of Science, and the Universities of Würzburg and Munich, became professor of chemistry at the Heriot-Watt College, Edinburgh, in 1887, and professor of organic chemistry at Owens College, Manchester, in 1892.

Perm, a government of East Russia, on both slopes of the Ural Mountains, with an area of 128,211 square miles. Population (1881), 2,520,100; (1897), 3,003,208, of whom 1,552,551 were women, and 176,255 urban. The immense majority of this population are peasants (2,604,207 in 1896), and according to religion they were distributed as follows: Greek Orthodox 2,566,475, Nonconformists 250,361, Mussulmans 141,294, pagans 19,464, Catholics 1510, Jews 1154, and Lutherans 841, leaving 22,119 as nondescript. Agriculture is carried on everywhere, but in the north and north-west the crops are insufficient for the population. Nearly 8,000,000 acres, *i.e.*, 9·5 per cent. of the total area, are under cereals—chiefly rye, oats, barley, and wheat in the south—the average annual yield of the crops in 1895–99 being: rye, 9,424,000 cwt.; wheat, 6,179,000; oats, 11,358,000; barley, 2,862,000; various, 734,000; and potatoes, 2,878,000 cwt. Bees are kept in large numbers. Cattle-breeding is active, especially among the Bashkirs, there being in the province more than 1,200,000 horned cattle, 1,200,000 sheep, and 900,000 horses. Various domestic trades are carried on in the villages, and several new industries, such as the manufacture of agricultural machinery, have sprung up. Mining is developing steadily, but slowly. The iron-works employ some 194,360 workers (11,850 in the Crown works), and their aggregate output in 1898 was: pig iron, 9,568,000 cwt.; iron, 3,902,000 cwt.; steel, 2,366,300 cwt.; metal goods, 700,000 cwt.; copper, 40,000 cwt.; of a total estimated value of 56,320,000 roubles. There were also 16,160 persons engaged in the working of gold and platinum, the annual production of gold being valued at £487,000, and of platinum at £240,800; coal and coke (7,233,000 cwt.), salt (5,930,000 cwt.), asbestos (30,000 cwt.), iron chromates (240,000 cwt.), and sulphates (323,800 cwt.). In 1897, 1090 factories employed 9835 workers, producing goods to the annual value of £2,200,000; and 12,475 workshops employed 37,000 workers, whose production was valued at £5,240,000 annually. The government is intersected by a railway from Perm eastwards across the Urals, and thence southwards along the eastern slope of the Urals to Ekaterinburg, Chelyabinsk (main Siberian trunk line), and Tyumeñ; also by a railway from Perm to Kotlas, at the head of the northern Dvina. Of schools the province had, in 1896, 827 (65,740 pupils) under the Ministry of Public Instruction, and 782 (31,475 pupils) Church primary schools. There are also several mining schools, and 115 village schools have school-farms or gardens attached to them. The Perm *zemstvo* is one of the most active in Russia in promoting the spread of education and agricultural knowledge among the peasants.

The province is divided into 12 districts, the chief towns of which are, in Europe, Perm (45,403), Kungur (14,324), Krasnoufimsk (6427), Okhansk (1896), Osa (5176), Solikamsk (4069), and Tcherdyn (3662); and in Asia, Ekaterinburg (55,488), Irbit (20,064), Kamyshloff (8064), Shadrinsk (11,686), and Verkhoturiye (3178). The chief iron-works forming important towns are: Nijne-Taghilsk (30,000), Neviansk (16,066), Kyshtym (12,331), Revdinsk (9914), Upper and Lower Turinsk (10,795), Bogoslovsk (4510), Suksunsk (3130), Nyazepetrovsk, Verkh-Iset, Nijne-Iset, and Verkhne-Tagilsk. The chief salt-works are at Usolie (7785).

Perm, the capital of the above province, had in 1897 a population of 45,403, as compared with 32,350 in 1879. It has several scientific institutions (the Ural Society of Natural Sciences, Archives Committee, Technical Society), a scientific museum, a theatre, and various philanthropic institutions. Its industries develop but slowly, the chief works being shipbuilding yards, tanneries, chemical works, and rope works, their total annual production being valued at £300,000. Its river port is visited every year by more than 1160 vessels (nearly 150,000 tons, and £350,000 worth of goods being imported, and nearly as much exported), and its connexion by rail with Vyatka and Kotlas, now completed, will probably make it a port for the export of Siberian grain and raw produce to Archangelsk.

Pernambuco, an Atlantic state of Brazil, situated between 7° and 10° 40′ S. and 34° 45′ and 42° 10′ W. Area, 49,625 square miles. It is bounded on the E. by the Atlantic, on the N. by the states of Parahyba and Ceará, on the W. by Piauhy and Bahia, on the S. by Alagoas. Population (1872), 841,539; (1890), 1,101,539. The capital, Recife, and the islands of S. Antonio, S. José, and Boa Vista, are known by the name of Pernambuco, and have a population of 190,000. The total trade was valued at £5,848,360 in 1900—imports, £2,748,360; exports, £3,100,000 (sugar, £1,850,000; cotton, £750,000; and rum, skins, and minor exports, £500,000). Amongst the chief towns in the state are Bezerros, Bom Jardim, Brejo da Madre de Deus, Cabo, Caruarú, Escada, Garanhuns, Gloria de Goitá, Goyana (10,000 inhabitants), Olinda, Rio Formoso (8000 inhabitants). Railways connect Recife with Goyana, Timbaúba, Limoeiro, Caruarú, Palmares, &c. Total length of lines, 186 miles.

Perovsk, formerly Ak-mechet, a fortress of Kokand, and later Fort Perovskiy, a district town of Russian Central Asia, province of Syr-Daria, on the right bank of the navigable Syr-Daria river, 357 miles north-west of the Tashkent railway station. It carries on a considerable trade in cattle. Population (1897), 4662.

Perpignan, chief town of the department of Pyrénées-Orientales, 525 miles south-south-east of Paris, on the railway from Narbonne to the Spanish frontier. A monument to the soldiers who fell in the war of 1870–71 has been erected. Perpignan is the seat of the superior tribunal of the republic of Andorra. Population (1881), 21,895; (1891), 25,167; (1901), 32,950.

Perry, a city of Oklahoma, U.S.A., capital of Noble county, in the north-eastern part of the territory, on the Atchison, Topeka, and Santa Fé Railway. It is regularly laid out on a level site, contains a U.S. Land Office, and has a large trade, as it is the supply-point for a wide range of country. It was settled in 1893. Population (1900), 3351, of whom 127 were foreign-born and 399 negroes.

Perry. See Cider.

Perryville, a town of Boyle county, Kentucky, U.S.A., near the centre of the state. It is famous as the scene of a sharp battle on 8th October 1862, between the retreating forces of General Bragg and the Union forces under General Buell. General Bragg had entered Kentucky, hoping to secure the addition of that state to the Confederacy. His plan, however, was frustrated by General Buell, and he was obliged to retreat into Tennessee. The Union losses were heavy, and the Confederates were allowed to continue their retreat, taking with them a large waggon-train of provisions. Population (1900), 431.

PERSIA.

I. Geography and Statistics.

Since the publication of the ninth edition of the *Encyclopædia Britannica* the labours of many travellers and explorers have materially added to our knowledge of the geography of Persia, but as regards the salient physical features of the country there is little to add.

Mountains.—The Persians have no special names for the great ranges. Mountains and valleys are known only by local names which frequently cover but a few miles. Even the name Elburz, which European geographers apply to the chains and ranges that extend for a length of over 500 miles from Azerbáiján in the west to Khorassan (Khorasán) in the east, stands with the Persians only for the 60 or 70 miles of mountains north and north-east of Teherán (Tehran), including the cone of Demavend; and, as its meaning, "high mountain" (Zend, *Hara-berezaiti*), implies, it probably stood in ancient times for many other high mountains as well. The great central range, which extends, almost unbroken, for nearly 800 miles from Azerbáiján in the north-west to Baluchistan in the south-east, may aptly be called the *Central Range*. It has many peaks of 9000 to 10,000 feet in height, and some of its summits rise to an elevation of 11,000 feet, and near Kermán of nearly 13,000 feet (Kúh-i-Júpár). The valleys and plains west of the central range, as for instance those of Mahallát, Jóshekán, Isfáhán, Sírján, have an elevation of 5000 to 6500 feet; those within the range, as Jásp, Ardahál, Só, Páríz, are about 1000 feet higher; and those east of it slope from an elevation of

5000 to 6000 feet down to the depressions of the central plateau which, east of Kom, are not more than 2600 feet and east of Kermán 1500 to 1700 feet above the sea-level. Some of the ranges west of the Central Range, which form the highlands of Kurdistán, Luristán, Bakhtiári, and Fars, and are parallel to it, end near the Persian Gulf; others follow the central range, and take a direction to the east at some point between Kermán and the sea on the western frontier of Baluchistan. Some of these western ranges rise to considerable elevations; those forming the Turko-Persian frontier west of the lake of Urmia have peaks 11,000 feet in height, while the Sahand, east of the lake and south of Tabriz, has an elevation of 12,000 feet. Farther south, the Takht-i-Bilkís, in the Afshár district, rises to 11,200 feet, the Elvend (ancient Orontes), near Hamadán, to 11,600. The Shuturun Kúh, south of Burújird, is over 11,000 feet in height, the Sháhán Kúh, Kúh-i-Gerra, Zardeh Kúh and Kúh-i-Kuran (by some writers called Kúh-i-Rang), all in the Bakhtiári country west of Isfáhán, are 12,800 to 13,000 feet in height; and the Kúh-i-Diná (by some writers wrongly called Kúh-i-Dínár) has an elevation of over 14,000 feet. Still farther south, towards Kermán, there are several peaks (Bíd-Khún, Lálehzár, Sháh-Kúh, Jamálbáriz, &c.) which rise to an elevation of 13,000 feet or more, and the Kúh-i-Hazár, south of Kermán, is 14,700 feet in height. Commencing near Ardabíl in Azerbáiján, where the cone of Savalan rises to an elevation of 15,792 feet (Russian trigonometrical survey), and ending in Khorasán, the great Elburz range presents on its southern, or inward, face a more or less abrupt scarp rising above immense gravel slopes, and reaches in some of its summits a height of nearly 13,000 feet; and the peak of Demavend, north-west of Teherán, has a height of at least 18,000 feet. There are several important ranges in Khorasán, and one of them, the Binalúd, west of Meshed and north of Nishápúr, has several peaks of 11,000 to 12,000 feet in height. In south-eastern Persia the Kúh-i-Basmán, a dormant volcano, 11,000 to 12,000 feet in height, in the Basmán district, and the Kúh-i-Taftán, *i.e.*, the hot, or burning mountain (also called Kúh-i-Núshádar from the "sal ammoniac," *núshádar*, found on its slopes), an active triple-peaked volcano in the Sarhad district and 12,681 feet in height (Capt. Jennings) are notable features.

Geology.—Since Mr W. T. Blanford's sketch of the geology of Persia was written (see *Ency. Brit.*, 9th edit., xviii. pp. 621–622) several travellers and explorers have gathered much valuable information, but no writer of note has as yet combined the new information into a general survey, and Mr Blanford's sketch is still the only trustworthy one. The following short sketch of the geology of the country between Teherán and Isfáhán, including a part of the Elburz, is given in the author's *Eastern Persian Irák* (London, 1896):—

"The part of the Elburz in the neighbourhood of Teherán is composed of a few granitoid and schistose rocks, sedimentary rocks of various ages from Devonian to Miocene, and volcanic rocks of various periods. There is no central axis of crystalline rocks, and Palæozoic rocks are very sparsely represented. In the Lár district, north-east of Teherán, are some Old Red Sandstone strata and Carboniferous limes with *Fuselina;* and at Hív, north-west of Teherán, there is a thin layer of Carboniferous limestone with *Productus.* Jurassic rocks form most of the southern slopes, and immediately under them, in Liassic formations, most of the coal which supplies Teherán is obtained. Between the Palæozoic and Liassic strata occur some rocks which have been classed as Triadic, although no fossils were found in them to prove it; and some of the volcanic rocks and tuffs which enter into the composition of the Elburz also seem to belong to the Triadic period. Cretaceous rocks with hippurites run out from the Elburz and form a ridge south-east of Teherán. Some of the volcanic rocks of the Elburz belong to the Miocene age, but the trachytic Demavend, raised up at the southern end of the Caspian depression, is probably post-Tertiary. The hills parallel to the Elburz, and between it and the central range, form a zone of trachytic rocks and tuffs and other volcanic formations associated with Cretaceous limes, sandstones, shales, and newer Tertiary formations. The hills south of Hív, and south-west of Teherán as far as Savah, are composed of volcanic rocks—dolerites, quartz-porphyries, andesites, rhyolites—and of Cretaceous limes without fossils, Eocene limes with corals, Miocene sandstones, limes with *Echinidæ* and *Pecten*, and Miocene gypsiferous strata and conglomerates. Most of the ridges between Teherán and Kom are composed of trachytic and gypsiferous formations. Near Hawz-i-Sultan, Cretaceous limes and sandstones rest on trachytic rocks. The Siah Kúh, south-east of Teherán, is composed of trachytes and green trachytic tuffs of the Cretaceous period, underlying limes and sandstones of the lower Miocene and Miocene gypsiferous formations of variegated marls, salt, and gypsum. The hills through which the "Caspian Gates" (Sarderreh Pass) east of Teherán lead also belong to the gypsiferous formation. The great central range possesses a distinct axis of crystalline rocks and granite, and granitoid formations form a great zone or band extending from Azerbáiján to Kermán. Volcanic formations, mostly of the Cretaceous period, occupy an extensive area, and are associated with Cretaceous and Tertiary beds, which generally rest on old rocks. Between Kom and Isfáhán we see black slates and massive Cretaceous limes interstratified with diorites, andesites, trachytes, and other volcanic formations of the same age, resting on granites, syenites, and tonalites which occasionally pass into gneissose and schistose rocks. The hills of the Isfáhán valley are composed of Cretaceous limes resting on black slates and shaly limestones. On the outer edges of the central range, particularly towards the east, Miocene formations, principally of the gypsiferous series, and resting on crystalline schists and dolerites, andesites and trachytes, abound. South-east of Natanz, and towards Naïn, the schists are broken through by basalts, and south of the Isfáhán–Naïn road the Gavkhání depression, which takes up the Isfáhán river, is in the gypsiferous series resting on trachytes. The rocks composing the hills parallel to and east of the central range are similar to those of the central range, and comprise Cretaceous and Miocene formations resting on gneiss, granite, and volcanic rocks."

From this sketch it will be seen that the Palæozoic rocks are rare, but that, from the Trias upwards, nearly all the principal formations are represented. The Miocene salt formation, "the gypsiferous series" of Loftus, covers vast extents of ground. During the Cretaceous period, when much volcanic action took place, the central desert of Persia was a sea; but the Miocene salt formation, which is so largely represented in inner Persia, is completely wanting on the Caspian side of the Elburz, proving that the Elburz range must already then have been a dividing wall between the Caspian depression and inner Persia. The greatest changes probably took place at the end of the Miocene, or perhaps during the Pliocene period, and the volcanic forces acted most at those places which offered the least resistance—as, for instance, all along the precipitous inner sides of the ranges and towards the depressions of central Persia. During the post-Tertiary period, when the hills and valleys were very much as they are now, Demavend was formed; and then also the immense recent, or sub-recent, accumulations of gravel, pebbles, and boulders, which form gentle inclines from the base of the hills down to the alluvial flats and fill up with long slopes the broad valleys opening into the plains, were deposited from the detritus of the hills. The lowest portion of these accumulations consist of fine alluvial loam, shifting sands, and sometimes swamp or marsh; then follows the gravel, first fine, then getting coarser as one ascends. The most remarkable gravel slopes are that south of Káshán and that on which the city of Teherán is situated. The former extends from Gebrábád, at the foot of the Kúhrúd hills, to Káshán, a distance of about 12 miles, and the latter from the foot of the Elburz to five or six miles south of Teherán, a distance of 16 miles. The depth of these deposits must be great: a well bored at Teherán, 10 miles away from the base of the hills, had not reached the end of the gravel at a depth of over 500 feet.

Rivers.—Three rivers, *Kizil Uzain*, *Atrak*, and *Gurgán*, are mentioned in the ninth edition (p. 620), as belonging essentially to Persia in reference to the Caspian watershed, but there is a fourth, the *Herház*, which, though not important in length of course or drainage, also, like the *Kizil Uzain*, breaks through the Elburz range from the inner southern scarp to the north. It rises on the slopes of the *Kasíl Kúh*, a peak 12,000 feet in height within the Elburz and about 25 miles north of Teherán, flows in an easterly direction through the Lár plateau, where it is known as the Lár river, and takes up several affluents; turns to the north-east at the foot of Demavend, leaving that mountain to the left, and flows due north past Amol to the Caspian. Its length is about 120 miles. The late Sir Oliver St John estimated the drainage of the rivers which have no outlet to the sea, and form inland salt lakes and swamps (kavírs) at 380,000 square miles, including the drainage into the lake of Urmia, which he estimated at 20,000 miles. There are fourteen rivers which flow into the lake of Urmia:

Ají Chái, Sáfí Chái, Murdí Chái, and Jaghatú from the east, the Tatává (Tataú) from the south, and nine smaller rivers from the west. During heavy rains and at the end of winter, when the snows on the hills melt, thousands of streams, mostly nameless, flow from all directions into the innumerable depressions of inner Persia, or help to swell the perennial rivers which have no outlet to the sea. These latter are few in number, and some of them barely suffice for purposes of agricultural irrigation, and in summer dwindle down to small rills. The perennial streams which help to form the kavírs (salt swamps) east of Kom and Káshán are the Hableh-rúd, rising east of Demavend, the Jájrúd, rising north of Teherán, the Kend and Kerej rivers, rising north-west of Teherán, the Shúreh-rúd (also called Abhar-rúd), rising near Sultaníeh on the road between Kazvín and Tabriz, and the Kara-sú, which rises near Hamadán and is joined by the Zarín-rúd (also known as Dó-áb), the Rezá Chái (also called Mazdakán-rúd), the Jehrúd river and the Kom-rúd. The river of Isfahán, Zendeh-rud, *i.e.*, "the great river" (from Persian *zendeh* [Pehleví, *zendek*], great), but now generally known as Záyendeh-rúd, *i.e.*, "the life-giving river," flows into the Gavkháni or Gavkháneh swamp, east of Isfáhán. In Fars the *Kur* with its affluents forms the lake of Bákhtegán (also known as lake of Nairíz), and is, in its lower course, generally called Bandámír (made famous by Thomas Moore) from the band (dam) constructed by the Amír (prince) Azud-ed-dowleh in the 10th century. ("Note on the Kur River in Fars," *Proc. Royal Geogr. Soc.*, London, 1891.) With regard to the rivers which flow into the Persian Gulf and the Indian Ocean, St John, after mentioning the Shatt-el-Arab, Jerráhi, and Táb, states that "after this, not a single stream *unfordable at all seasons* bars the passage of the traveller along the coast till he reaches the Indus, eighteen degrees of longitude to the east and five degrees of latitude farther south, a stretch of riverless waste perhaps unequalled save on the neighbouring shores of Arabia and the Red Sea" (*Eastern Persia*, i. 8). There are, however, many streams which though fordable at most seasons (some of them are often quite dry) are quite unfordable during the rains. Two of these may be mentioned here, viz., the Mánd, erroneously mentioned as *Mira* in the ninth edition (p. 620), and the Mínáb, which St John (*loc. cit.* p. 9) considered as being "of far more importance than the maps would lead the observer to suppose." The former, after a run of over 300 miles from its sources in the hills west of Shiráz, debouches at Khor-i-Ziáret, about 60 miles south of Bushire. It is mentioned by the old Arab and Persian geographers as the Sitakán (in some MSS. misspelt Sakkán), and is the Sitakos of Arrian and the Sitioganus of Pliny. In its upper course it is now known as the Kara-aghach (Wych-elm) river (cf. "Notes on the River Mand in Southern Persia," *Royal Geogr. Soc.*, London, December 1883). The Mínáb has two outlets into the Persian Gulf, one the Khor-i-Mínáb, a salt-water creek into which the river overflows during the rains, about 30 miles east of Bander Abbási, the other the true Mínáb, at Khágún, some miles south of the creek. It rises in the hills about 100 miles north of Bander Abbási, and has a considerable drainage. Its bed near the town of Mínáb (15 miles from the coast) is nearly a mile in width, and during the rains the water covers the whole bed, rendering it quite unfordable. During ordinary weather, in March 1884, the water flowing past the town was 100 yards in width and 2 feet deep (Preece, *Proc. Royal Geogr. Soc.*, January 1885). In ordinary seasons very little water of the river runs in its original bed, being diverted into canals, &c. The creek, the Anamis of Nearchus, is navigable nearly all through the year as far as Shahbander, the custom-house, about 7 miles inland, for vessels of 20 tons burden.

Climate.—Since the paragraphs "rainfall and winds" and "climate" in the article PERSIA of the ninth edition were written (pp. 621, 623), many meteorological observations have been taken at various places in and near Persia, and much additional information can now be given. For the rainfall on the watershed of the Persian Gulf we have two places of observation, Bushire and Jask; at the former place it is a little in excess of that of inner Persia, while at the latter place it is very much less. The rainfall on the Caspian watershed greatly exceeds that of inner Persia; at Astrábád and Ashúrada, in the south-eastern corner of the Caspian, it is about 50 per cent. more; and at Resht and Lenkoran, in the south-western corner, it is four and five times that of the adjoining districts across the ridges to the south. With the exception of the Caspian watershed and that of the Urmia basin, the country has probably in no part a yearly rainfall exceeding 13 to 14 inches, and throughout the greater part of central and south-eastern Persia the yearly rainfall probably does not exceed 6 inches. The following mean values of the rainfall at Teherán have been derived from observations taken by Dr Tcherepnine during the years 1884–87 (Symons's *Monthly Meteorological Mag.*, November 1893) and by the writer during the years 1892–99:—

	Jan.	Feb.	Mar.	April.	May.	June.	
Mean	in. 2·00	in. 1·69	in. 2·09	in. 1·55	in. ·49	in. ·12	Total for Year. in. 10·71
	July.	Aug.	Sept.	Oct.	Nov.	Dec.	
	in. ·03	in. ·04	in. ·05	in. ·30	in. 1·10	in. 1·25	

Good harvests depend on the rainfall from October to April, and on an amount of snow sufficient to cover the crops during frosts. During normal winters in Teherán and surrounding districts the rainfall amounts to 9 or 10 inches, with 3 to 4 of snow, but in the winter 1898–99 it was only 5½ inches, with only 1 inch of snow; and in 1899–1900 the harvests were in consequence exceptionally bad, and large quantities of wheat and flour had to be brought from the provinces and even from Russia at high freights, causing the price of bread at Teherán to rise 200 per cent. The following table, which has been compiled from the latest available information, shows the mean annual rainfall in inches at fifteen stations in and near Persia:—

Station.	Lat. N.	Long. E.	Altitude.	Period of Observations.	Year.	Authority
			Feet.	Years.		
Lenkoran	38° 46′	48° 51′	−60	28¼	46·82	Supan.[1]
Resht	37° 17′	49° 35′	−50	2	56·45	British Consul.[2]
Ashúrada	36° 54′	53° 55′	−80	19	17·17	Supan.[1]
Astarábád	36° 51′	54° 25′	−40	7	16·28	Symons.[3]
Meshed	36° 17′	59° 36′	3180	6	6·43	British Consul.[4]
Quetta	30° 11′	67° 3′	5500	19	10·09	Supan.[1]
Kelat	28° 53′	66° 28′	6500	15	8·98	"
Maskat	23° 29′	58° 33′	..	3	6·13	"
Jask	25° 39′	57° 46′	..	10	3·24	English Telegraph.[5]
Bushire	28° 59′	50° 49′	..	19	13·36	Supan.[1]
Isfáhán	32° 37′	51° 40′	5370	6	3·23	English Telegraph.[5]
Teherán	35° 41′	51° 25′	3810	12	10·71	The writer.
Urmia (Sair)	37° 28′	45° 8′	6225	1	21·51	Symons.[3]
Baghdad	33° 19′	44° 26′	..	7	10·59	Supan.[1]
Merv	37° 35′	61° 50′	700	1	6·36	Symons.[3]

The figures for Meshed and Isfáhán do not give the total rainfall at those places, because the observers have measured only the falls of rain and neglected those of snow. The mean annual rainfall of Meshed and Isfáhán, as given in the table, is therefore considerably less than what it ought to be, and would no doubt, if the falls of snow were added, amount to quite as much as that of Teherán, or 10 to 11 inches instead of 6½ and 3¼ as given in the table. Among the prevailing winds should be noted the dry and warm wind which comes down from the snowy Elburz to Gilán in December and January, and much resembles the foehn of the Alps (Dr Tholozan, "Sur les vents du Nord de la Perse et sur le foehn du Guilan," *Comptes Rendus*, Acad. d. Sciences, March 1882). Observations for temperature have been taken for many years at the stations of the Indo-European Telegraph and for a few years at the British consulate in Meshed, and the monthly and annual means shown in the table on the following page have been derived from the indications of maximum and minimum thermometers in degrees Fahrenheit.

Very few hygrometrical observations have been taken, and only those of the British Residency at Bushire are more or less trustworthy, and have been regularly registered for a number of years. In inner Persia the air is exceptionally dry, and in many districts polished steel may be exposed in the open during a great part of the year without becoming tarnished. Along the shores of the Caspian, particularly in Gilán and Mázandarán, and of the Persian Gulf from the mouth of the Shatt-el-Arab down to Bander Abbási, the air during a great part of the year contains much moisture—dry- and wet-bulb thermometers at times indicating the same temperature—and at nights there are heavy falls of dew. In Gilán and Mázandarán the air contains much moisture up to considerable elevations and as far as 30 to 40 miles away from the sea; but along the Persian Gulf, where vegetation is very scanty, stations only a few miles away from the coast and not more than 20 or 30 feet above the sea-level have a comparatively dry climate.

Dehbíd [4]	27	30	38	45	57	65	69	65	61	52	43	36	49·0	91	−19	110
Shiráz [5]	48	47	55	63	73	80	85	81	76	67	55	49	65·0	113	21	92
Kazerún [6]	51	50	52	67	84	93	95	94	87	79	70	56	73·2	110	36	74
Borazjún [7]	55	57	66	80	94	97	100	99	92	83	72	64	80·0	117	48	69
Bushire	58	60	65	74	82	86	90	90	87	80	71	62	75·4	109	41	68

Frequently when the temperature in the shade at Bushire is not more than 85° or 90°, and the great humidity of the air causes much bodily discomfort, life is almost pleasant 12 or 20 miles inland with a temperature of over 100°.

Area and Population.—In 1880, when a great part of the northern and the whole of the eastern and western frontiers were not defined, the area of Persia was estimated at 1,647,070 square kilometres, or 635,934 square miles ("Die Bevölkerung der Erde," *Pet. Mitt.* Erg. Heft. 69, p. 28). Since then the northern and eastern frontiers have been demarcated, but the Turco-Persian frontier, from Mount Ararat in the north to Muhamrah in the south, a distance of 700 miles, is still an undefined line lying within a border-strip of from 20 to 40 miles in width, and the area has been estimated at 628,000 square miles. In 1881 the writer estimated the population of Persia at 7,653,600; 1,963,800 urban, 3,780,000 rural, and 1,909,800 wandering ("Bevölkerung der Erde," p. 28; ninth edit. *Ency. Brit.*, p. 628); and, allowing for an increase of about 1 per cent. per annum, the population for 1900 may be estimated at 9 to 9¼ millions. E. Lorini (*La Persia economica contemporanea*, Roma, 1900, p. 378) estimates it at 9,333,000. No statistics whatever being kept, nothing precise is known of the movement of the population. During the 'eighties many Persian subjects emigrated, and a number of Persian villages were deserted and fell to ruins; since then a small immigration has set in and new villages have been founded. In some districts the population increases very slowly, perhaps only ½ per cent. per annum; in others the increase exceeds 1½ per cent. and even reaches 2 per cent. Persians say that the females exceed the males by 10 to 20 per cent., but wherever the present writer has been able to obtain trustworthy information, he found the excess to be less than 2 per cent. Of the deaths in any place the only check obtainable is from the public body-washers, but many corpses are buried without the aid of the *public* body-washers; and the population of the place not being accurately known, the number of deaths, however correct, is useless for statistical purposes. Medical men have stated that the number of deaths, in times when there are no epidemics, amounts to 19 or 20 per thousand, and the number of births to 25 to 40 per thousand.

The prices of the staple articles of food and all necessaries of life have risen considerably since 1880, and, particularly in the large cities, are now very high. As salaries and wages have not increased at the same rate, many of the upper classes and officials are not so well off as formerly. By dismissing their servants in order to reduce expenditure, they have thrown great numbers of men out of employ, while many labourers and workmen are living very poorly and often suffer want. Tradesmen are less affected, because they can sell the articles which they manufacture at values which are more in proportion with the increased prices of food. In 1880 a labourer earning 25 krans, or £1 sterling a month, could afford to keep a family; by 1901, in krans, he earned double what he did then, but his wage, expressed in sterling, was the same, and wherever the prices of food have risen more than his wages he could not afford to keep a family. In many districts and cities the number of births is therefore reduced, while at the same time the mortality, in consequence of bad and often insufficient food, is considerably increased.

Constitution and Government. — The government of Persia is an absolute monarchy, and resembles in its principal features that of the Ottoman empire, with the exception, however, that the monarch is not the religious head of the community. His powers over his subjects and their property are absolute, but only in so far as they are not opposed to the *shar'*, or "divine law," which consists of the doctrines of the Mahommedan religion, as laid down in the Koran, the oral commentaries and sayings of the Prophet, and the interpretations of the same by his successors and the high priesthood. The government is, therefore, much like that of the French monarchy until a few centuries ago, viz., on the principle of the old Roman "quod principi placuit, legis habet vigorem," with the restriction, as the French lawyer Beaumanoir has it, "pourvu qu'il ne soit pas fet *contre Dieu*, ne contre bonnes meurs, car s'il le feroit, ne le devroient pas si souget soufrir."

The form of government as it now exists is admirably described by Lord Curzon of Kedleston in *Persia and the Persian Question.* "The language," says that author, "in which the Shah addresses his subjects and is addressed by them, recalls the proud tone in which an Artaxerxes or Darius spoke to his tributary millions, and which may still be read in the graven record of rock-wall and tomb. He remains the *Shâhanshâh*,[8] or 'King of Kings'; the *Zill Ullah*, or 'Shadow of God'; the *Kibleh Alam*, or 'Centre of the Universe'; 'Exalted like the planet Saturn; Well of Science; Footpath of Heaven; Sublime Sovereign, whose standard is the Sun, whose splendour is that of the Firmament; Monarch of armies numerous as the Stars.' Still would the Persian subject endorse the precept of Sadi, that 'The vice approved by the king becomes a virtue; to seek opposite counsel is to embrue one's hands in his own blood.' The march of time has imposed upon him neither religious council nor secular council, neither *ulema* nor senate. Elective and representative institutions have not yet intruded their irreverent features. No written check exists upon the royal prerogative.

"And yet the power of the Persian king by no means corresponds to its arrogant definition, nor is it now equal to what it once was. In the first place, the Shah is no longer the religious head even of the *Shiah* community of the Mussulman world. At no time have the sovereigns of Persia enjoyed the spiritual supremacy that was conceded to the caliphs of Baghdad and that is still claimed for the sultan of Constantinople. But the Sefavi monarchs, by virtue of their descent from a famous saint, who was himself a *Seyid*, or descendant of Ali, the son-in-law of the Prophet, were invested with a semi-sacred character, to which

[8] We see this title in its old Persian form, *Khsháyathiya Khsháyathiy*, in the cuneiform inscriptions; as Βασιλέως Βασιλεῶν on the coins of the Arsacides, and as the Pehlevi *Malkán Malká* on the coins and in the inscriptions of the Sassanians. With the Mahommedan conquest of Persia and the fall of the Sassanians the title was abolished; it was in use for a short time during the 10th century, having been granted to Shah Ismail Samáni by the Caliph Motadhid A.D. 900; it appeared again on coins of Nadir Shah, 1736–47, and was assumed by the present dynasty, the Kajárs, in 1799.

alone can we attribute the passiveness with which, for a whole century, their subjects submitted to the rule of a succession of capricious and dissolute drunkards. Chardin says that they were regarded as vicars and successors of the *Imams;* and Kaempfer records that the water in which they had washed was deemed holy, and was eagerly sought after as a cure for all complaints. No such pretensions, however, have been made, or could be made, on behalf of any subsequent dynasty; least of all on behalf of a family like the Kajárs, of Turkish extraction. The Shah of Persia, therefore, must be dissociated from any claims of personal sanctity, and both the scope and limitations of his prerogative must be sought on purely secular grounds.

"Besides the respect for the religious teachers and law, there are many other restraints upon the Shah's powers. Regard for established usage has been found a stronger deterrent. So long as the revenue is collected and robbery is suppressed, the complete assertion of the royal power is not, in hazardous cases, too rigorously pressed. In other words, political expediency acts as a further deterrent. But, strongest of all, in the case of the reigning monarch, and of great interest as proving the extent to which Persia has been drawn into the vortex of civilized states, is the deterrent of foreign opinion, which, in the absence of any indigenous public opinion worthy of the name, has taken its place, and has operated as a safeguard for which the Persian people are probably quite without gratitude, and of which they are, as may be suspected, wholly unaware. It may safely be predicted that any extravagant or savage exercise of the royal prerogative, such as has been a familiar incident in the Persian history of the past, will rarely occur, if at all, in the future, and that in any case it will prove an exceptional instead of a normal feature of government. This remarkable change is to be attributed to the permanent presence of foreign ministers and to the electric telegraph."

In the task of government the Shah is assisted by the *Sadr Azam* ("Grand Vizír"), a number of *vizírs*, ministers, or heads of departments somewhat on European lines, and a "grand council of state," composed of some ministers and other members nominated by the Shah himself as occasion may require. Many of the "ministers" would be considered in Europe merely as chiefs of departments of a ministry, as, for instance, the minister for Crown buildings, that for Crown domains, the minister of ceremonies, those for arsenals, army accounts, &c.; also an accumulation of several offices without any connexion between their functions, in the hands of a single person, has frequently been a characteristic departure from the European model. The ministers are not responsible to the Crown in a way that ministers of a European Government are; they rarely take any initiative, and generally refer their affairs to the Grand Vizír or to the Shah for final decision. This irresponsibility on the part of the ministers, and the system of referring all affairs, even unimportant ones, to the head of the State, makes the Shah, whenever the office of Grand Vizír is vacant—which has frequently happened — one of the hardest-worked sovereigns in the world, and the post of Grand Vizír is anything but a sinecure.

The official *Sálnámeh* ("Year-book") for 1899 enumerates twenty-seven *vizírs* (ministers), but only some of them are consulted on affairs of State. The departments that have a *vizír* at their head are the following: Court, Ceremonies, Shah's secretarial department, Interior, Correspondence between Court and Governors, Revenue accounts and budget, Finance, Treasury, Outstanding accounts, Foreign Affairs, War, Army accounts, Military stores, Arsenals, Justice, Commerce, Mines and industries, Agriculture and Crown domains, Crown buildings, Public Works, Public Instruction, Telegraphs, Posts, Mint, Religious endowments and pensions, Customs, Press. In addition to these twenty-seven *vizírs* with portfolios, there are some titulary *vizírs* at Court, like *Vizír i Huzúr i Humayún* (Minister of the Imperial Presence), *Vizír i makhsús* (Extraordinary Minister), &c., and a number in the provinces assisting the governors in the same way as the Grand Vizír assists the Shah.

Political and Administrative Divisions.—The empire of Persia, officially known as *Mamálik i Mahrúseh i Irán*, "the protected kingdoms of Persia," is divided into a number of provinces, which, when large, and containing important sub-provinces and districts, are called *mamlikat*, "kingdom," when smaller, *viláyat* and *ayálat*, and are ruled by governor-generals and governors appointed by and directly responsible to the Crown. These provinces are further divided into sub-provinces, *viláyats*, districts, sub-districts, and parishes, *bulúk*, *nahíyeh*, *mahál*, and towns, cities, parishes, and villages, *shehr*, *kassábeh*, *mahalleh*, *dih*, which are ruled by lieutenant-governors and other functionaries appointed by and responsible to the governors. The administrative system of Persia is practically the same as it was in ancient times when the empire of the *Sháhansháh*, the "Great King," βασιλεύς μέγας of the Arsacides, was divided into a number of provinces ruled by satraps, or governors, who were responsible for the due payment of the tributes and taxes. All governors are called *hákim*, or *hukmrán*, but those of large provinces generally have the title of *váli*, and sometimes *firmán-firmá*. A governor of a small district is a *zábit;* a deputy-governor is called *náib el hukúmeh*, or *naïb el ayáleh;* an administrative division is a *kalamró*, or *hukúmat*. Until recently the principal governorships were conferred upon the Shah's sons, brothers, uncles, and other near relatives, but now many of them are held by men who have little if any connexion with the royal family. Also, the governors are now, as a rule, resident in their provinces instead of being absentees at the capital.

Every town has a mayor, or chief magistrate, called *beglerbegi*, "lord of lords," *kalántar*, "the greater" (same as mayor), and sometimes *dárogha*, "overseer," or chief of police; every ward or parish, *mahalleh*, of a town and every village has a head-man called *ked-khodá*, "house-lord." These officers are responsible to the governor for the collection of the taxes and the orderly state of their towns, parishes, and villages. In the important provinces and sub-provinces the governors are assisted by a man of experience, to whom the accounts and details of the government are entrusted. This person, called *vizír*, or *píshkár*, is often nominated by the Shah, and his functions in the provincial government are similar to those of the Grand Vizír in the central government, and comprise very extended administrative powers, including at times the command of the military forces in his province. Among the nomads a different system of titles prevails, the chiefs who are responsible for the taxes and the orderly conduct of their tribes and clans being known as *ilkháni*, *ilbegi* (both meaning "tribe-lord," but the latter being considered an inferior title to the former), *khán*, *raïs*, *amír*, *mír*, *shaikh*, *tushmál*, &c.

The governors and chiefs, excepting those possessing hereditary rights, are frequently changed; appointments are for one year only and are sometimes renewed, but it does not often occur that an official holds the same government for longer than that period, while it happens rarely that a province is governed by the same person for two or three years. This was not so formerly, when not infrequently an official, generally a near relation of the Shah, held the same governorship for five, ten, or even more years. The governorship of the province of Azerbáïján is an exception, and has, under the now reigning dynasty, always been held by the *valiahd*, "heir-apparent," or "Crown Prince."

The political divisions of Persia, provinces, sub-provinces, districts, &c., ruled by *hákims* number over 200 (cf. the statement in Nöldeke's *Geschichte des Artachšîr Pâpakân*, "after Alexander's death there were in Irán 240 local governors"), but the administrative divisions, *hukúmat*, or *kalamró*, with governors appointed by the Crown and responsible to it for the revenues, have been under fifty for sixty-five years or more. In 1840 there were twenty-nine administrative divisions, in 1868 twenty-two, in 1875 twenty-nine, in 1884 nineteen, in 1890 forty-six, and in 1900 thirty-five.

Mamlikats.—1. Azerbáïján; 2. Fárs; 3. Khorasán; 4. Kermán and Baluchistan; 5. Gilán and Tálish.

Viláyats.—1. Teherán; 2. Isfáhán; 3. Nishápúr; 4. Kermánsháh, and frontier (Turkish); 5. Kurdistán; 6. Gerrús; 7. Astrábád and Gurgán; 8. Mázandarán; 9. Irák, Kamareh, Gulpáigan, and Khunsár; 10. Luristán and Burújird; 11. Yezd; 12. Kazvín; 13. Maláyir, Túsirkán, and Nehávand; 14. Hamadán; 15. Kashán; 16. Khamseh; 17. Kharkán; 18. Sháhrúd and Bostám; 19. Semnán and Damghhán; 20. Kom; 21. Sáveh, Zerend and Sháhsevèn-i-Baghdádí; 22. Arabistán and Bakhtiarí; 23. Fírúzkúh; 24. Demavend; 25. Nátanz; 26. Kangáver; 27. Khár; 28. Jóshekán; 29. Tálikán; 30. Tárom 'uliá.

Justice.—By the theory of a Mahommedan State there should be no other courts of justice except those established for the administration of the *shar'*, the "divine, or written law," but in Persia there is another judicature, which is called *'urf* and represents the "customary," or "known and unwritten law." This *'urf* may be considered an emanation of the supreme temporal authorities subordinate to the Shah, while the *shar'* is interpreted and administered by the ecclesiastical authorities, the *'ulemá*, or clergy. Justice, therefore, is administered by the Shah and his representatives according to one law and by the clergy according to another, but necessarily the decisions of the former must not be opposed to the fundamental doctrines of Islám. On the other hand, it frequently happens that decisions by the ecclesiastical authorities are not in accordance with the views, or wishes, of the authorities administering the *'urf*, and much friction between the two authorities, leading sometimes to serious disorders, ensues, but generally ends in favour of the clergy. The Shah's representatives for the administration of justice are the governors and other officers already mentioned. The officials charged with the administration of justice according to the *shar'* are judges, called *shaikh-ul-islám* and *kázi* (*kadhi*, *kadi* of Arabs and Turks), members of the clergy appointed by the Government and receiving a fixed salary, but at present some cities are without regular appointed judges and the title of *kázi* is almost obsolete; decisions according to the *shar'* are given by all members of the clergy, ranging from ignorant *mullás* of little villages and cantons to learned *mujtahids* of the great cities. A judgment given by a lower member of the ecclesiastical hierarchy is not always executed, for, if the parties to the suit are dissatisfied with the judgment, they may appeal to a priest who stands higher in public estimation, or one of the parties may induce a higher authority by bribery to quash the judgment of the first. Unfortunately, many members of the clergy are corrupt, but the *mujtahids*, as a rule, are honest and entirely trustworthy. The functions of the representatives of the *shar'* are now limited to civil cases, while all criminal cases are referred to the *'urf*, which, however, also takes cognizance of civil disputes, should the parties desire it.

In criminal cases the dispensation of justice is always summary, and, when the offence is small, the whole procedure, including the examination of witnesses and criminal, as well as the decision and the punishment, a bastinado, is a matter of some minutes. For commercial cases, not paying a bill in time, bankruptcies, &c., a kind of jurisdiction is exercised by the Minister of Commerce, or a board of merchants, but the decisions of the minister, or those of the board, are rarely final. In Teherán the board of merchants is presided over by the *malik ut tujjár*, "King of Merchants," in the provincial cities by a person called *malik amín*, and *muín* of merchants.

After his second journey to L rope in 1878 the late Shah desired to organize a police for the whole of Persia on the European system, but this intention was not carried out in its entirety, and only a small body of police, whose services were confined to the capital and its immediate neighbourhood, was created in 1879. Its strength is 60 mounted policemen and 190 foot, with 11 superior and 40 subaltern officers. There are also 280 men for cleaning streets. Two battalions of infantry have been attached to the police department, and the whole force is under the "Minister of Police."

There is also a "Tribunal of the Ministry for Foreign Affairs," presided over at Teherán by an official of the Foreign Office, and in the provincial cities by the *kárguzárs*, "agents," of that department. The functions of this tribunal are to inquire into and judge differences and suits between Persian subjects and foreigners, and it is stipulated in the treaty of Turkmanchaï, which is the basis of all existing treaties between Persia and other countries, that "such differences and suits shall only be examined and judgment given in the presence of the dragoman of the mission or consulate (of the foreign subject), and that, once judicially concluded, such suits shall not give cause to a second inquiry. If, however, circumstances should be of a nature to require a second inquiry, it shall not take place without previous notice given to the minister, or the chargé d'affaires, or the consul, and in this case the business shall only be proceeded with at the supreme chancery of the Shah at Tabriz or Teherán, likewise in the presence of a dragoman of the mission, or of the consulate." (Article vii.)

A foreign subject implicated in a criminal suit cannot be pursued or molested in any way unless there exist full proofs of his having taken part in the crime imputed to him, and should he be duly convicted of the crime, he is handed over to his legation, which either sends him back to his own country to undergo the punishment established by law, or, according to more recent usage, punishes him in Persia by fine, imprisonment, &c. In this respect the powers of the foreign representatives in Persia, now numbering ten (Great Britain, Russia, France, Turkey, Austria-Hungary, Germany, United States of America, Italy, Belgium, and the Netherlands) vary considerably, some having the power of condemning a criminal to death, while others cannot do more than fine and imprison for short periods. Suits, civil and criminal, between foreign subjects are altogether out of Persian jurisdiction, and are judged by the representatives of the foreign powers accredited to Persia.

In 1889, after the late Shah's return from his third visit to Europe, the Council of State was instructed to compile a code of law for the regulation of justice. A beginning was made by ordering the translation of the Code Napoléon, the Indian Mahommedan code, and the Code Napoléon as modified for Algeria; but, as Lord Curzon says, "one more excellent scheme went into the waste-paper basket, and one more stone had to be added to the cairn of abortive reforms so conscientiously piled by Nássir-ed-dín Shah."

Religion.—About 8,000,000 of the population are Mahommedans of the Shía'h faith, and 800,000 or 900,000, principally Kurds in north-western Persia, are said to belong to the other great branch of Islám, the Sunni, which differs from the former in religious doctrine and historical belief, and is the State religion of the Turkish empire and other Mahommedan countries. Other religions are represented in Persia by about 80,000 to 90,000 Christians (Armenians, Nestorians, Greek Orthodox and Roman Catholics, Protestants), 36,000 Jews, and 9000 Zoroastrians.

Society in Persia, being based almost exclusively on religious law, is much as it was in Biblical times among the Jews, with this difference, however, that there exists no sacerdotal caste. In Persia any person capable of reading the Koran and interpreting its laws may act as a priest (*mullá*), and as soon as such a priest becomes known for his just interpretation of the *shar'* and his superior knowledge of the traditions and articles of faith, he becomes a *mujtahid*, literally meaning "one who strives" (to acquire knowledge), and is a chief priest. The *mullás* are referred to in questions concerning religious law, hold religious assemblies, preach in mosques, teach in colleges, and are appointed by the Government as judges, head-preachers, &c. Thus the dignitaries, whose character seems to us specially a religious one, are in reality doctors, or expounders and interpreters of the law, and officiating ministers charged with the ordinary accomplishment of certain ceremonies, which every other Mussulman, "true believer," has an equal right to fulfil. Formerly there were only four or five *mujtahids* in Persia, now there are many, sometimes several in one city—Teherán, for instance, has ten; but there are only a few whose decisions are accepted as final and without appeal. The highest authority of all is vested in the *mujtahid* who resides at Kerbela, or Najaf, near Baghdad, and is considered by many *Shía'hs* as the vice-regent of the Prophet and representative of the *imám*. The Shah and the Government have no voice whatever in the matter of appointing *mullás* or *mujtahids*, but frequently appoint *shaikhs-ul-islám* and *kazis*, and occasionally chief priests of mosques that receive important subsidies out of Government funds. The chief priest of the principal mosque of a city, the *masjid i jámi'*, is called *imám i juma'h*, and he, or a representative appointed by him, reads the *Khutbeh*, "Friday oration," and also preaches. The reader of the *Khutbeh* is also called *khatib*. The leader of the prayers in a mosque is the *pishnamáz*, and the crier to prayers is the *mu'azzin*. Many priests are appointed guardians of shrines and tombs of members of the Prophet's family (*imáms* and *imámzádehs*) and are responsible for the proper administration of the property and funds with which the establishments are endowed. Some shrines possess much landed property with considerable revenues. The guardian of a shrine is called *mutavali*, or, if the shrine is an important one with much property and many attendants, *mutavali-báshi*, and is not necessarily an ecclesiastic; for instance, the guardianship of the great shrine of Imám Reza in Meshed is generally given to a high court functionary or minister as a reward for long services to the State. A *mutavali* of a great shrine like that at Meshed is a very important personage, frequently equalling, or even surpassing, the governor in influence. He has on his staff a large number of priests, and other officials and attendants as secretaries, accountants, librarians, treasurers, inspectors, guards, doorkeepers, &c. The important shrines and their precincts afford inviolable sanctuary, or *bast*, to any malefactor who succeeds in entering them. In the precincts of a great shrine a malefactor finds a safe refuge from his pursuers and is lodged and fed, and from the security of his retreat he can arrange the ransom which is to purchase his immunity when he comes out.

Formerly all cases, civil and criminal, were referred to the clergy, and until the 17th century the clergy were subordinate to a kind of chief pontiff, named *sadr-us-sudár*, who possessed a very extended jurisdiction, nominated the judges, and managed all the religious endowments of the mosques, colleges, shrines, &c. Shah Safí (1629–1642), in order to diminish the influence of the clergy, appointed two such pontiffs, one for the court and nobility, the other for the people. Nádir Shah (1736–1747) abolished these offices altogether, and seized most of the endowments of the ecclesiastical establishments in order to pay his troops, and, the lands appropriated by him not having been restored, the clergy have never regained the power they once possessed.

Many members of the clergy, particularly those of the higher ranks, have very liberal ideas and are in favour of progress and reforms so long as they are not against the *shar'*, or divine law; but, unfortunately, they form the minority.

The *Armenians* of Persia, in so far as regards their ecclesiastical state, are divided into the two dioceses of Azerbáïján and Isfáhán, and, since the late troubles in Turkey, which caused many to take refuge in Persia, are said to number over 50,000. About three-fifths of this number belong to the diocese of Azerbáïján, with a bishop at Tabriz, and reside in the cities of Tabriz, Khoï, Selmás, Urmia, and Marágha, and in about thirty villages close to the north-western frontier; the other two-fifths, under the diocese of Isfáhán, with a bishop in Julfa, reside in Teherán, Hamadán, Julfa, Shiráz, Bushire, Resht, Enzeli, and other towns, and in some villages in the districts of Chahár Mahál,Ferídan, Barbarúd, Kamareh, Kazáz, Kharakán, &c. Many Persian Armenians are engaged in trade and commerce, and some of their merchants dispose of much capital, but the bulk live on the proceeds of agriculture and are poor.

The *Nestorians*, or Chaldeans, in Persia, all living in cities and villages close to the Turkish frontier, numbered about 25,000 to 30,000, but many of them, some say half, together with two or three bishops, recently went over to the Greek Orthodox (Russian) Church, in consequence of the unsatisfactory protection afforded them by their patriarch, who resides in Mosul. These latter are now cared for by an archimandrite of Russian nationality and some Russian priests.

The *Greek Orthodox Catholics* are represented by Russians, who reside in northern Persia; they have a church at the Russian legation in Teherán, and another at the Russian consulate in Tabriz.

The *Roman Catholics* in Persia, Europeans and natives (mostly Armenians), number about three or four thousand, and have churches in Teherán, Julfa, and Azerbáïján, served by members of the French Lazarist Mission. They also have some orphanages, schools, and medical dispensaries, under the care of Sisters of Charity of St Vincent de Paul.

The *Protestants*, Europeans and natives (converted Armenians and Nestorians), number about 6500. The religious missions ministering to their spiritual welfare are :—

1. The Board of Foreign Missions of the Presbyterian Church in the United States of America, which has four establishments in Persia: Urmia since 1835, Teherán since 1872, Tabriz since 1873, and Hamadán since 1880. The establishments of Tabriz and Urmia form the Western Persia Mission, those of Teherán and Hamadán the Eastern Persia Mission. The former mission has 37 churches, with 800 communicants, 150 schools with 3800 pupils, 2 hospitals and 4 dispensaries; the latter 4 churches with 200 communicants, 10 schools with 580 pupils, 1 hospital and 4 dispensaries.

2. The Church Missionary Society, established in Persia since 1869. It has at Julfa (near Isfáhán) a church with 146 communicants, 3 schools with 478 pupils (258 boys, 220 girls), 2 hospitals and 3 dispensaries; in Yezd a dispensary; in Karmán a school with 16 pupils. The establishment of the Church Missionary Society is under the care of a bishop, who resides at Julfa and is under the bishop of London.

3. The Anglican Mission, which was established by Dr Benson, archbishop of Canterbury, and has its work among the Nestorians in Azerbáïján.

4. The London Society for promoting Christianity among the Jews, which was established at Teherán in 1876, and at Isfáhán and Hamadán in 1889. It has in Teherán a church with 10 communicants and a school with 20 pupils, at Isfáhán a school with 95 pupils, and at Hamadán a small school (number of pupils not stated).

5. The British and Foreign Bible Society, which was represented at Isfáhán since 1878, and is at present looked after by the Church Missionary Society.

The *Jews* in Persia number about 36,000, and are found in nearly all cities of the country, but communities with synagogues and priests exist only in the larger cities like Teherán, Isfáhán, Yezd, Shiraz, Hamadán, &c.

The *Zoroastrians*, commonly called "gabrs," numbering about 9000, reside principally in the cities and villages of Yezd and Kermán, and only three or four hundred live in Teherán, Kashán, Isfáhán, and Shiraz, some engaged in trade and commerce, but most of them employed in agricultural work and gardening. Their interests are attended to by a delegate who is appointed by the Bombay Parsis and resides at Teherán.

The non-Mussulman Persian subjects, particularly those in the provinces, were formerly much persecuted, but since 1873, when the late Shah returned to Persia from his first journey to Europe, they have been treated more liberally, and the central authorities do their utmost to prevent their being persecuted or injustice being done to them. In cities where many non-Mussulman subjects reside, a special official is appointed to protect them; and the Ministry of Justice has a special section, now directed by a gentleman who was educated in England, to look after them and see that they are protected against fanaticism and injustice.

Instruction.—Primary schools, *maktab* (where Persian and a little Arabic, sufficient for reading the Koran, and sometimes also a little arithmetic, are taught to boys between the ages of seven and twelve), are very numerous, there being one in many villages which have a population of not more than forty or fifty families. These schools are private establishments, receive no aid from the State, and are not under any supervision whatever, and in consequence many teachers are inefficient, children are frequently improperly treated, and schoolrooms are often highly insanitary. The payment for tuition is very small, varying from fourpence or fivepence to tenpence a month for each child. Colleges, *madrasah* (where young men are instructed, fed, and frequently also lodged gratuitously), exist in nearly every town. Most of them are attached to mosques, and all are supported by religious endowments. The teachers are members of the clergy, and receive fixed salaries out of the college funds, and the education is practically the same as it was in similar establishments many centuries ago. The students are instructed in Arabic and Persian literature, religion, interpretation of the Koran, Mussulman law, logic, rhetoric, philosophy, and other subjects necessary for admittance to the clergy, for doctors of law, &c., while modern sciences are neglected. Families who have means and do not desire their children to become members of the clergy, employ private tutors, and several have latterly obtained the services of English and French professors to educate their children, while others send their boys to schools in England, France, Germany, and Russia. At the beginning of the late Nassir-ed-din Shah's reign, a public school on the lines of a French *lycée* was opened in Teherán, principally with the object of educating officers for the army, but also of introducing a knowledge of Western science and languages, and a ministry of public instruction was created at the same time. Military and civilian teachers were obtained from Europe, and the State granted a large sum of money for the support of the establishment. The tuition is gratuitous, and the pupils are clothed and partly fed at Government expense. Some years later a similar school, but on a much smaller scale, was opened in Tabriz. After a time the annual grant for the support of these two schools was reduced, and during the ten years 1890–1900 amounted to only £5000. The average number of pupils was about 250, and until the beginning of 1899 these two schools were the only establishments under the supervision of the Minister of Public Instruction. Soon after his accession in 1896 the Shah expressed a desire that something more should be done for public instruction, and in the following year a number of Persian notables formed a committee, subscribed considerable sums of money, and opened some schools in Teherán and other places in the beginning of 1898. A year later the new schools, until then private establishments, were placed under the Minister of Public Instruction. The new schools at Teherán have from 1000 to 1400 pupils. Much has been and is being done for education by the Armenians and the Protestant and Roman Catholic Missions in Persia, but Mussulmans only rarely attend their schools. The Alliance Israélite has also opened a school in Teherán. In 1899 the American Protestant Mission had 160 schools with 4380 pupils, the English Protestant Missions had 5 schools with 579 pupils, the Roman Catholic Mission (Lazaristes) had 3 schools with 400 pupils, and the Armenians had 4 schools and 646 pupils. All these schools are supported by voluntary subscriptions and donations, and instruct both boys and girls.

Finance.—The fixed revenues of Persia are derived from (1) regular taxation (*máliát*) composed of taxes on lands, flocks, herds, shopkeepers, artisans, and trade; (2) revenues from Crown lands; (3) customs; (4) rents and leases of State monopolies. There is also a kind of irregular revenue derived from public requisitions, presents, fines, confiscations, &c., nowadays not producing much. The land tax, which varies much according to localities, is paid in money and kind, and should amount on an average to about 25 per cent. of the yield of the soil. The taxation on flocks and herds exists either as a supplementary method of land taxation, or as a contribution of a certain sum per animal, and the tax on shopkeepers, artisans, and trades sometimes takes the form of a poll-tax, sometimes that of an impost on the profits of the trades. The revenue from Crown lands consists of a certain proportion of the produce, and also varies much according to localities. The customs are composed of a uniform *ad valorem* duty of 5 per cent. upon merchandise exported and imported by foreign subjects, as stipulated by the treaty concluded between Russia and Persia at Turkmancháï in 1828, and of a duty varying from $1\frac{1}{2}$ to 8 per cent. upon merchandise exported or imported by Persian subjects. Until March 1899 all the customs were farmed out, but since then an attempt has been made to organize them on European principles, with the help of Belgian officials, beginning with the two provinces of Azerbáïján and Kermánsháh, and, the attempt having been successful, other provinces have now been taken in hand, and it is hoped that the farm system, so far as concerns the customs, may be entirely done away with. It is also intended to introduce other reforms, either by establishing a uniform *ad valorem* duty of 5 per cent. upon the merchandise of both Persian and foreign subjects, or, with the assent of Russia, abolishing the 5 per cent. duty fixed by the Turkmancháï treaty and establishing an equitable tariff. The revenues from rents and leases of State monopolies are derived from the proceeds of various establishments, institutions, concessions, &c., leased out by the Government, as, for instance, posts, telegraphs, mines, mint, forests, banks, fisheries, factories, &c., and now amount to about £110,000 per annum.

The total revenue of Persia, from all sources, amounted in 1876 to 58,700,000 krans, in 1884 to 50,800,000, in 1890 to 60,000,000; it is now about 70,000,000 krans. This would seem to show a steady increase, but when we consider that the value of the kran in 1876 was nearly $8\frac{9}{10}$d., and has fallen in consequence of the great depreciation of silver to only $4\frac{4}{5}$d., the total revenue really decreased from £1,950,000 in 1876 to £1,400,000 in 1900. Out of the actual total revenue £350,000 is represented by customs and £110,000 by rents and leases of State monopolies, leaving £940,000 for máliát and revenues of Crown lands. In 1876 the two latter items amounted to about £1,600,000, while the two former were only £350,000 instead of £460,000 in 1900. While the prices in krans of agricultural produce, and hence the profits of the landowners, and the wages and profits of artisans and tradesmen, were in 1900 more than double what they were in 1876, the máliát, the backbone of the revenue, has hardly increased at all, being 47,000,000 krans (£940,000) against 43,200,000 krans (£1,600,000) in 1876, and showing a decrease of over 40 per cent. in sterling money. A new assessment of the máliát, based upon the present value of the produce of lands and actual profits of artisans and tradesmen, has frequently been spoken of, and Government, aided by a strong Minister of the Interior and an able Minister of Finance, ought to have no difficulty in raising the máliát to its proper level and the total revenues of the country to about two millions sterling. Until a few years ago the yearly expenditure was less than the yearly income, and every year a surplus found its way into the Shah's treasury, but lately, on account of the small máliát, the revenues have not been sufficient to cover the expenditure, and many payments have fallen in arrear in spite of large disbursements out of the reserve in the Treasury.

In May 1892 the Persian Government concluded a contract with the Imperial Bank of Persia, established by British royal charter in 1889, for a loan of £500,000 at 6 per cent., repayable in the course of forty years, and guaranteed by the customs of Fars and the Persian Gulf ports. The produce of this loan served for the payment of an indemnity to the Imperial Tobacco Corporation, which began in 1890 and had to cease its operations in January 1892. In January 1900 the Persian Government, in order to pay the arrears and start afresh with a clear balance-sheet, contracted a new loan, this time through the Banque des Prêts de Perse, a Russian institution connected with the Russian State Bank, and established in 1890. This loan was for $22\frac{1}{2}$ million roubles (£2,400,000) at 5 per cent. interest, guaranteed by all the Persian customs with the exception of those of Fars and the Persian Gulf ports, and repayable in the course of seventy-five years. In the contract, which was signed at St Petersburg at the end of January 1900, the Persian Government undertook to redeem all its former foreign obligations (the 1892 loan) out of the proceeds of the new loan, and not to contract any other foreign loan before the redemption of the new loan without the consent of the Russian bank. The loan was at $86\frac{3}{8}$, less $1\frac{3}{8}$ for commission and charges, the Persian Government thus receiving 85 per cent. of the nominal capital, or £2,040,000. The bonds enjoy the full guarantee of the Russian Government. The yearly charge for interest and amortization, about £124,000, is to be paid in two half-yearly instalments, and in the event of default the Russian bank will have the right to exercise effective control of the customs with a maximum number of twenty-five European employés. When the contract for the new loan was concluded, the liabilities of the Persian Government for the balance of the 1892 loan (about £435,000), temporary loans from various banks, arrears of pays and salaries, and other debts, amounted to over £1,500,000, so that not much margin was left.

Defence.—Lord Curzon says that the Persian army, nominally 200,000 men strong, has an effective force of 30,000 men actually serving with the colours. Persia had no regular army until 1807, when some regiments of regular infantry (*sarbáz*) were embodied and drilled by the first French military mission to Persia under General Gardane. Since then seven other military missions (two British, two French, two Austrian, and one Russian) have come to Persia at the request of the Persian Government, and many officers and non-commissioned officers, and even civilians, of various nationalities, as Spanish, Italian, French, Bavarian, Austrian, Prussian, British, Danish, and Bulgarian, have been engaged as army instructors. The last serious attempt to reorganize the Persian army was made in 1879, when the second Austrian mission, composed of a colonel, a major, ten captains and lieutenants, and a bandmaster, formed the "Austrian Corps" of seven new battalions of 800 men each. A relic of the Austrian régime still survives in a number of Persians who were drilled by the Austrians as officers of the new battalions. These new battalions were in 1882 disbanded and resolved into the territorial elements from which they had sprung. The Russian mission of 1879 has been the most successful, and the so-called "Cossack Brigade" which it formed has always been and is now commanded by Russian officers. The strength of the brigade is now being raised to about 1500 men, and it will cost £50,000 per annum. The total annual expenditure for the army amounts to about a third, or a little more, of the total revenues of the Government.

The Persian Government possesses three steamers, and no other vessels. These are the *Persepolis*, registered tonnage 600, 450 h.p., built at Bremerhaven in 1884, armed with one 8·5 and three 7·5 centimetre steel Krupp guns, and stationed in the Persian Gulf; the *Susa*, tonnage 36, 30 h.p., built at Bremerhaven in 1884, and stationed on the river Karun; the *Nassir-ed-dín*, a yacht of about 120 tons, presented by the emperor of Russia, and stationed at Enzeli, the port of Resht. The annual expenditure for the navy is about £3500.

Minerals and Mining.—Persia possesses considerable mineral riches, but the absence of cheap and easy means of transport, and the scarcity of fuel and water which prevails almost everywhere, make any exploitation on a large and remunerative scale impossible, and the various attempts which have been made in Persia to work mines with European capital and under European superintendence have been financially unsuccessful. Deposits of rich ores of copper, lead, iron, manganese, zinc, nickel, cobalt, &c., abound; but either the distance from the deposits to the nearest shipping port is so great that the freight to the port exceeds the price of the ore on the European market, or the difficulty of obtaining fuel and water raises the cost of reducing the ore to more than the price of the metal imported from abroad. The result is that the Persian mining industry is very small. A few mines are worked by natives in a primitive, systemless manner, and without any great outlay of capital—the value of the plant in some mines the writer has visited not being more than twenty pounds. There are turquoise mines near Nishápúr (for description of mines, manner of working, &c., see A. Houtum-Schindler, *Report on the Turquoise Mines in Khorasán*, F. O. Reports 1884, and "Die Gegend zwischen Sabzwar und Meschhed," *Jahrbuch, k. k. geol. R. A. Wien*, vol. xxxvi.;

also E. Tielze, *Verhandl. k. k. geol. R. A.*, 1884, 93); several copper mines in Khorasán, Semnán, Azerbäiján, and Kermán; some of lead, two considerably argentiferous, in Khorasán, Túdarvár (near Semnán), Angúrán, Afshár (both west of Zenján), and Kermán; two of iron at Masúlah in Gílán and Núr in Mázandarán; two of orpiment in Afshár and near Urmia; one of cobalt at Kamsar (near Kashán); one of alum in Tarom (near Kazvín); and a number of coal in the Lár district, north-east of Teherán, and at Hív and Abyek, north-west of Teherán. There are also many quarries of rock-salt, gypsum, lime, and some of marble, alabaster, soapstone, &c. The annual revenue of the Government from the leases, rents, and royalties of mines does not amount to more than £15,000, and about £6000 of this amount is derived from the turquoise mines near Nishápúr. As the rents and royalties, excepting those on the turquoise mines, amount to about one-fifth of the net proceeds, it may be estimated that the value of the annual output does not exceed £50,000, while the intrinsic value of the ores, particularly those of lead, iron, cobalt, and nickel, which have not yet been touched, can be estimated at millions. There are also some very rich coal seams in eastern Persia, far away on the fringe of the desert, and under existing conditions quite valueless. The richest deposits of nickel, cobalt, and antimony ores are also situated in localities where there is little water and the nearest useful fuel some hundred miles away. Auriferous alluvial strata have been discovered in various localities, but everywhere the scarcity of water has been a bar to their being exploited with profit. A rich naphtha-bearing zone stretches from the Luristán hills near Kermánsháh on the north down to the Persian Gulf in the south. Competent engineers and specialists have declared that borings in the Bakhtiari hills, west of Shushter, would give excellent results, but the difficult hilly country and the total absence of roads, as well as the antipathy of the inhabitants of the district, would make the transport and establishment of the necessary plant a most difficult matter.

Agriculture.—Wheat, barley, and rice are grown in all districts, the two former up to considerable altitudes (8000 feet), the last wherever the water-supply is abundant, and in inner Persia generally along rivers; and all three are largely exported. The most important rice-growing districts which produce more than they require for local consumption and supply other districts, or export great quantities, are Astrábád, Mázandarán, Gilán, Verámín (near Teherán), Lenján (near Isfáhán), and some localities in Fars and Azerbaïján. Peas, beans, lentils, gram, maize, millet, are also universally cultivated, and exported in not inconsiderable quantities from the Persian Gulf ports to India and the Arabian coast. The Persian fruit is excellent and abundant, and large quantities, principally dried and called *khushkbár* (dry fruit), as quinces, peaches, apricots, plums (of several kinds), raisins, figs, almonds, pistachios, walnuts, and dates (the last only from the south), as well as oranges (only from the Caspian provinces), are exported. Nothing is being done to improve the vine, and the Persian wines, until recently of world-wide reputation, are yearly getting thinner and poorer. The phylloxera has done much damage. Cotton is largely grown, principally in the central districts and Khorasán, and some qualities are excellent and command high prices in the European markets. 12,490 tons of raw cotton, valued at £384,013, were exported to Russia in 1897. Good hemp grows wild in Mázandarán. Tobacco of two kinds, one the *tumbakú* (*Nicotiana persica*, Lindl.), for water pipes, the other the *tutun* (*Nicotiana rustica*, L.), for ordinary pipes and cigarettes, is much cultivated. The tumbakú for export is chiefly produced in the central districts round about Isfáhán and near Kashán, while the tumbakú of Shiráz, Fessa, and Daráb in Fars, considered the best in Persia, is not much appreciated abroad. Tutun is cultivated in Azerbäiján, near Urmia and other places near the Turkish frontier, in Kurdistán, and, since 1875, in the district of Resht in Gilán. The cultivation of poppy for opium has greatly increased since 1880, and it is estimated that the annual produce of opium now amounts to over 1000 tons, of which about two-fifths is consumed and smoked in the country. The principal opium-producing districts are those of Shiráz, Isfáhán, Yezd, Kermán, Khorasán, Burújird, and Kermánsháh. The value of the silk produced in Persia in the 'sixties was £1,000,000 per annum, and decreased in consequence of silk-worm disease to £30,000 in 1890. The quantity produced is now again increasing, and its yearly value is estimated at £350,000. Of oil-yielding plants the castor-oil plant, sesame, linseed, olive are cultivated, the last only in a small district south of and near Resht. Very little oil is exported. The potato, not yet a staple article of food, tomatoes, celery, cauliflower, artichokes, and other vegetables are now much more grown than formerly, chiefly in consequence of the great influx of Europeans, who are the principal consumers, during recent years. Horticulture has much improved, the Shah and several princes and nobles retaining European gardeners, and some gardens at Teherán have shows of flowers vying with the prettiest in Europe. Horses, mules, and donkeys, formerly exported in great numbers, are at present not very abundant, and their prices have risen much since 1880. Some nomad tribes who owned many brood mares, and yearly sold hundreds of horses, now hardly possess sufficient animals for their own requirements. The scarcity of animals, as well as the dearness of fodder, is one of the causes of the dearness of transport, and freights have risen on the most frequented roads from 3d. per ton-mile in 1880 to 10d., and even 13d., per ton-mile now.

The following table shows the average prices of staple articles of food and necessaries at Teherán as they were in 1880 and in April 1900, and their apparent and real increases per cent. in local currency and sterling:—

	Average Price, 1880.			Price in April 1900.			Increase per cent.	
	Local currency.	Sterling. 1 kran = 9d.		Local currency.	Sterling. 1 kran = 4⅘d.		Apparent.	Real.
	krans.	s.	d.	krans.	s.	d.		
Wheat, per kharvár (649 lb)	30	22	6	255	102	0	750	353
Barley ,,	20	15	0	160	64	0	700	327
Rice ,,	75	56	3	400	160	0	433	184
Charcoal ,,	30	22	6	87·50	35	0	192	55
Coal ,,	16	12	0	50	20	0	212	66
Firewood ,,	12	9	0	28	11	2⅘	133	24
Bread, per mann (6½ lb)	·40	0	3⅗	2	0	9⅗	400	162
Mutton ,,	1·60	1	2⅖	7	2	9⅗	337	133
Beef ,,	1·20	0	10⅘	4	1	7⅕	233	77
Cheese ,,	2·00	1	6	6	2	4⅘	200	60
Milk ,,	·50	0	4½	2	0	9⅗	300	113
Clarified butter ,,	3·00	2	3	12	4	9⅗	300	113
Water melons ,,	·10	0	$\frac{9}{10}$	·60	0	$2\frac{9}{10}$	500	222 } season 1899.
Sweet melons ,,	·30	0	$2\frac{7}{10}$	2	0	9⅗	566	255 } season 1899.
Grapes ,,	·10	0	$\frac{9}{10}$	1·20	0	5¾	1100	539 } season 1899.
Eggs (per 100)	2·00	1	6	9	3	7⅕	350	140

At the lowest estimate it may be said for all Persia, that while wages since 1880 have risen in the proportion of 5 to 10, the prices of staple articles of food have gone up from 5 to 11.

Forests and Timber.—Timber from the forests of Mázandarán and Gilán has been a valuable article of export for many years, and since about 1870 large quantities of boxwood have also been exported thence; in some years the value of the timber and boxwood exported has exceeded £50,000. This value represented about 200,000 box trees and quite as many others. Much timber is also used for charcoal-burning, and occasionally large parts of forest are burned by the people in order to obtain clearings for the cultivation of rice. The destruction of the forests by timber-cutters and charcoal-burners has been allowed to go on unchecked, no plantations have been laid out, and nothing has been done for forest conservation. Indiscriminate cutting has occasionally been confined within certain bounds, but such restrictions were generally either of short duration or made for the convenience and profit of local governors. The oak forests of Kurdistán, Luristán, and the Bakhtiari district are also being rapidly thinned, and the time is not far distant when there will be no traces left unless the Government create a forest department with proper regulations and bye-laws. A small step in the right direction was made in 1900 by engaging the services of an official of the Prussian forest department, but unfortunately, beyond sending him to inspect the Mázandarán forests belonging to the Crown, and employing him to lay out a small plantation in the Jájrúd valley, east of Teherán, nothing was done. The monopoly for cutting and exporting the timber of the Mázandarán forests is leased to a Greek firm established at Baku, and the rent has been paid in advance for some years. Boxwood has become scarce. There are many kinds of good timber-yielding trees, the best known being alder (*Alnus glutinosa*, Wild., *A. barbata*, *A. cordifolia*, Ten.), ash (*Fraxinus excelsior*, L.), beech (*Fagus sylvatica*), elm (*Ulmus campestris*, *U. effusa*, *U. pedunculata*), wych-elm (*Ulmus montana*), hornbeam (*Carpinus betulus*, L.), juniper (*Juniperus excelsa*, *J. communis*, *J. sabina*), maple (*Acer insigne*, Boiss., *A. campestre*, *A. pseudo-platanus*, L.), oak (*Quercus ballota*, *Q. castaneæfolia*, *Q. sessifloria*, *Q. pedunculata*), walnut, nettle tree (*Celtis australis*, L.), Siberian elm (*Zelkova crenata*, Spach.), and various kinds of poplar. Pipe-sticks, from the wild cherry tree, are exported to Turkey. Considerable quantities of gums, exudations of various plants, drugs, and dyes, some of them produced only in Persia, are gathered and exported.

Fisheries.—Along the shores of the Persian Gulf fish is a staple food, but the Crown derives no revenue from the fisheries there. The fisheries of the Caspian littoral were leased to a Russian firm about 1870 at an annual rent of £16,000, and most of the fish goes to Russia. The fish principally caught are the *ag-máhí* (dog-fish); sturgeon (*Acipenser huso*), which gives the caviare; the *summ* (sheat-fish), or silure (*Silurus glanis*); and the *Azád-máhí*, a kind of salmon (*Salmo sylvaticus*). In inner Persia fish are scarce. There are a few carp and roach in the canals, and salmon-trout and mud-trout abound in some mountain streams.

Manufactures.—Of the articles mentioned under this head in the ninth edition (p. 625) only carpets, shawls, woollen and cotton fabrics, and silk stuffs are of importance. Carpets may be divided into three categories: (1) *Kálí*, with a pile, and cut like plush; (2) *gilím*, smooth; (3) *nimads*, felts. Only the two first are exported. The *Kálí* and its smaller sizes, called *Kálícheh* (in Europe, rugs), are chiefly made in Ferahan, Sultánábád (Irák), Khorasán, Yezd, Kermán, and among the nomad tribes of southern Persia. From the two first-mentioned localities, where two British firms have been established for many years, great quantities, valued in some years at £100,000, find their way to European and American markets, while rugs to the value of £30,000 per annum are exported from the Persian Gulf ports. Of the second kind, *gilím* (used in Europe for curtains, hangings, and chair-covers), considerable quantities are exported from Shushter and Kurdistán. Shawls are manufactured in Kermán and Meshed, and form an article of export, principally to Turkey; and some of Kermán are quite equal to good Cashmere shawls. Woollen fabrics are manufactured in many districts, but are not exported. Coarse cotton-stuffs, chiefly *kerbás*, are manufactured in nearly all districts, but not exported; but cottons, called *kalamkár*, which are Manchester goods that have been block-printed in colours, find their way from Isfáhán and Komisheh to foreign markets. Of the great quantities of silk fabrics manufactured in Persia, principally in Khorasán, Kashán, and Yezd, only a small part is exported to Turkey and Afghanistan. In the environs of Kashán and in Fars, chiefly near Maimand, much rose-water is made, and a considerable quantity of it is exported by way of Bushire to India and Java. Attempts have been made to start manufactures, supported by foreign capital and conducted by foreigners, but nearly all have resulted in loss. In 1879 the Persian Government was induced to spend £30,000 on the erection of a gas factory in Teherán, but work was soon stopped for want of good coal. A few years later a Persian bought the factory and plant for £10,000, and made them over in 1891 to the Compagnie Générale pour l'Éclairage et le Chauffage en Perse, which, after bringing out much additional plant, and wasting much capital in trying for some years in vain to make good and cheap gas out of bad and dear coal, closed the factory. In 1891 another Belgian company, Société anonyme des verreries nationales de Perse, opened a glass factory in Teherán, but the difficulty of obtaining the raw material cheaply and in large quantities was too great to make it a paying concern, and the factory had to be closed. A third Belgian company, Société anonyme pour la fabrication du sucre en Perse, with a large capital, then came to Persia, erected a magnificent factory with the best and most modern machinery obtainable, and began making beetroot sugar in the winter of 1895. But, like the gas and glass companies, it found the cost of the raw material and the incidental expenses too great, and ceased its operations in 1899.

Commerce.—The total annual value of the exports and imports may safely be estimated at ten million pounds sterling. The estimated value of the imports and exports is arrived at by considering the amounts received by the Government from the farmers of the customs as equivalent to 4 per cent. of the value of the imports and exports, and allowing 20 per cent. as profits of the farmers. The following table, compiled from the *Statesman's Year-Book*, shows the farm-money received by the Government at intervals for the years 1879 to 1899, the estimated amounts paid annually for customs, and the estimated value of the imports and exports, obtained by taking the average of the duty at 4 per cent. *ad valorem.*

Year.	Farm money received by Government.		Rate of exchange for the year.	Estimated totals of customs paid. Farm money + 20 per cent.	Estimated value of imports and exports, average duty taken at 4 per cent. *ad valorem.*
	tomans.	£	krs. = £1.	£	£
1879–1880	606,400	219,500	27⅝	263,400	6,585,000
1889–1890	800,000	242,724	33	290,908	7,272,700
1895–1896	1,250,000	250,000	50	300,000	7,500,000
1896–1897	1,250,000	250,000	50	300,000	7,500,000
1897–1898	1,500,000	300,000	50	360,000	9,000,000
1898–1899	1,500,000	300,000	50	360,000	9,000,000
1899–1900	1,750,000	350,000	50	420,000	10,500,000

As has been already stated (see "Finance," *supra*), the customs department is being reorganized, the farm system has been abolished in two provinces since March 1899, and the result has been highly satisfactory; the new system is to be introduced into all the provinces. The new administration estimated the net receipts for 1900–01 at about £400,000; but in this amount were included the transit dues levied in the interior and the gate dues (octroi) levied in all principal towns, amounting to about £50,000; these should be deducted from the total receipts, and the remainder (£350,000) would then represent the amount of customs received on imports and exports. Calculating the customs at a little less than 3½ per cent., the total value of the imports and exports would amount to £9,500,000 or £10,000,000, which may safely be taken as within the mark, while the value of the imports and exports may be put down at not less than £7,500,000 to £8,000,000 for 1879 to 1892, and since then at not less than £8,500,000 to £9,000,000.

The export and import trade may be considered, in relation to the frontiers, under four heads:—

(*a*) *Northern Frontier.*—This extends for a length of about 1300 miles from near Maku in the west to the Afghan frontier in the east, and comprises the Perso-Transcaucasian frontier, with Julfa and Astara as principal stations, the southern Caspian shore, with the principal ports Enzeli (Resht), Meshhed-i-Sar (Barfurúsh), and Bander Gez (Astrábád), and the Perso-Transcaspian frontier, with a carriageable road crossing it north-west of Meshed between Kúchan and Askábád, and an easy road from Meshed eastwards, *viâ* Serrekhs, to Turkistan. For the exports and imports on this frontier the Russian custom-house returns give trustworthy figures, and show that their value exceeded £3,500,000 in 1897.

(*b*) *Western Frontier.*—For the trade on this frontier—a line of about 750 miles from Maku in the north to Muhamrah in the south—the only returns trustworthy as to quantities, but frequently understating values, are those made at Trebizond for the merchandise which passes that port in transit to and from Persia. Of the great trade on the Kermánsháh–Baghdad road and numerous other roads crossing the frontier there are no returns. The value of transit trade at Trebizond to and from Persia, in thousands of pounds sterling, is shown in the following table:—

Year.	Exports.	Imports.	Total.
1885	235	821	1056
1890	312	665	977
1895	212	683	895
1896	189	577	766
1897	216	555	771
1898	208	550	758

Allowing for the understatement of the values of the imports by the Trebizond route, and adding the value of the trade on the Kermánsháh–Baghdad route, estimated in 1898 at a minimum value of £750,000, and that of the lively trade which is carried on between Persia and Asiatic Turkey by many other routes, which may be estimated at a minimum of £250,000, a total value not far short of £2,000,000 is arrived at for the exports and imports by way of the western frontier, and more than one-third of this is in British hands.

(*c*) *Southern Frontier.*—This is formed by a coast-line of about 1100 miles in length from Muhamrah in the west to British Baluchistan in the east. The export and import trade passes through Muhamrah, Bushire, Lingah, Bander Abbási, and many smaller ports, but only the first four are mentioned in the consular reports. Many of the figures given in these reports are based on information which has been obtained from custom-house officials, and do not give the true values of the exports and imports. The value of exports from and imports into Persia by way of Persian Gulf ports, according to British consular reports, in thousands of pounds sterling is shown in the following table:—

Year.	Exports.					Imports.					Total value of exports and imports, four ports.
	Muhamrah.	Bushire.	Lingah.	Abbási.	Total.	Muhamrah.	Bushire.	Lingah.	Abbási.	Total.	
1890	58	720	592	348	1718	146	1268	665	409	2488	4206

1900	115	710	470	103	1398	282	1323	501	339	2445	3843

In order to arrive at the value of the total trade on the southern frontier, there should be added to the values given in this table a certain percentage for understated values of exports and imports at the four ports and a considerable sum for the trade of the small ports which are not mentioned in the consular reports. The value of the total trade on the southern frontier will then no doubt be found to exceed £4,000,000.

The trade at the four Gulf ports was distributed mainly as follows in 1900:—

Countries.	Imports from.	Exports to.	Countries.	Imports from.	Exports to.
United Kingdom	£788,114	£163,716	Persian ports	£438,059	£346,449
India . . .	1,034,824	745,142	Arab coast .	189,424	207,061
France . .	119,712	7,664	Muskat .	45,467	28,780
Turkey . .	125,112	192,172	Bahrein .	7,516	19,830
China . .	35,920	318,611	Egypt . .	5,289	37,975

(*d*) *Eastern Frontier.*—Of the trade on this frontier, which separates Persia from Afghanistan and British Baluchistan and has a length of about 900 miles, there are also no complete returns, and only since 1892 the British consular reports show the value of the trade between Meshed and Afghanistan as obtained from Persian officials, and quite recently that of the trade on the Quetta–Núshki–Sistan–Meshed road. The value of the exports and imports between Meshed and Afghanistan was £18,000 in 1892; £23,000 in 1893 and also in 1894; £24,000 in 1895; £21,000 in 1896; and £29,000 in 1897. The value of the exports and imports over the eastern frontier probably much exceeds £100,000 per annum.

From the figures given in the above tables the value of the exports and imports at the present time may be estimated as follows:—

	Exports.	Imports.	Total exports and imports.	Proportion exports to imports.
Northern frontier	£2,000,000	£1,800,000	£3,800,000	100 : 90
Western ,,	900,000	1,100,000	2,000,000	100 : 122
Southern ,,	1,500,000	2,500,000	4,000,000	100 : 166
Eastern ,,	50,000	50,000	100,000	100 : 100
Total .	£4,450,000	£5,450,000	£9,900,000	

According to this estimate, the proportion of exports to imports for all Persia would be 100 : 111, but Lorini (*Persia Economica*, &c., pp. 320–321) thinks that the balance of trade is in favour of Persia.

What are the chief imports and exports in the various districts will be seen from the table in the next column and the paragraph which succeeds it. At the four Gulf ports the trade in 1900 was mainly in the following articles:—

Imports.	Value in pounds sterling, 1900.	Exports.	Value in pounds sterling, 1900.
Cottons . .	697,760	Opium . .	348,310
Pearls . .	244,274	Pearls . .	727,447
Tea . . .	196,191	Grain . .	89,982
Dates . . .	44,916	Fruits . .	85,551
Woollens . .	31,277	Mother of pearl .	25,388
Sugar . . .	207,997	Carpets, &c. .	77,057
Wheat and flour .	336,482	Timber . .	28,175
Copper, &c. .	57,038	Dates . . .	27,916
Indigo . .	49,997	Tobacco . .	28,175
Coffee . . .	37,742	Gums . . .	68,919
Specie . .	490,516	Specie . .	368,387

The prohibition against the importation of arms and ammunition that has been in existence since 1881 is only spasmodically enforced, and in 1897 they found their way through the Gulf ports to the value of £132,018; the import in 1898 was *nil*.

From the Gulf ports, excluding Muhamrah, wheat to the value of £84,100 was exported in 1898. At Tabriz in the year 1898–99 the total imports were valued at £682,330, including Manchester shirtings and printed cottons, £376,000; sugar from Russia, £81,600; tea from India, £68,800; cloth and woollen goods from Europe, £57,200; silk stuffs and velvets from France and Germany, £55,400; and haberdashery from Germany and Austria, £28,000. The exports amounted to £219,930, including dried fruits (raisins and almonds), £72,000; carpets, £50,000 (but trustworthy private information makes it £85,000); shawls, £20,000; and native silk, £14,000. In the Resht district in 1896 the imports *viâ* Baku were valued at £842,655, and included sugar, £614,311; tissues, £81,400; silk-worm seed, £67,200; bar silver, £30,000; and petroleum, £15,000. The exports to Russia *viâ* Baku amounted to £365,342, amongst them being rice, £177,220; fruits, £42,350; raw cotton, £40,740; and tea, £31,890. The export of silk of all kinds from Resht, principally *viâ* Kermánsháh–Baghdad, hardly any going to Russia, was valued at £116,280 in 1898. From the Caspian littoral the export of fish to Russia in 1897 was £84,427. Along the whole northern frontier the import of cotton goods from Russia in 1898 was £520,000 (in 1897, £420,452); of glassware in 1897, £32,061; of sailcloth, £26,043; of china, £21,030; the export of rice in 1897 amounted to £336,489; of dried fruit, to £443,902; of cotton, to £360,114; and of live stock, to £58,930. The trade of Khorasán through Meshed in 1896–97 was: imports from India by Bombay and Bander Abbási, £89,547; from Russian territory, £92,547; through Turkey, £19,740; from Afghanistan, £6206: exports to India, £19,681; to Russian territory, £80,320; to Afghanistan, £15,073.

Shipping and Navigation.—Shipping under the Persian flag is restricted to vessels belonging to the Persian Gulf ports. Some of the larger craft, which are called *baglah*, and vary from 50 to 300 tons, carry merchandise to and from Bombay, the Malabar coast, Zanzibar, &c.; while the smaller vessels, called *bagarah*, and mostly under 20 tons, are employed in the coasting trade and the pearl-fisheries on the Arabian coast. No returns as to the number and tonnage of the native craft are available, but it is estimated that the four principal ports and the many smaller ones (as Mashúr, Hindián, Zaidín, Dílum, Ríg, Kongún, Táherí, Kishm, Hormuz, &c.) possess at least 100 *baglahs* and several hundred *bagarahs*, besides a large number of small boats. The following figures from British consular reports show the total and British shipping in thousands of tons (including both entrances and clearances) at the four principal Persian Gulf ports in 1891 and 1898:—

Port.	1891.				1898.			
	Total Tonnage.		British Tonnage.		Total Tonnage.		British Tonnage.	
	Entered.	Cleared.	Entered.	Cleared.	Entered.	Cleared.	Entered.	Cleared.
Bushire . . .	152	151	148	148	112	97	99	85
Lingah . . .	208	219	167	181	125	76	102	58
Abbási . . .	95	90	86	83	87	86	79	79
Muhamrah . .	76	79	71	74	100	82	91	74
Total . .	531	539	472	486	424	341	371	296

As most of the pearls obtained on the Arabian coast of the Gulf are brought to and exported from Lingah, that port has more native shipping than the others. It will be found from the figures in the last table that the British shipping amounted to 93·3 per cent. of the whole shipping at Muhamrah, to 90·2 per cent. at Bushire, to 78·9 per cent. at Lingah, and to 90·5 per cent. at Bander Abbási, or to 88·2 per cent. of the *total shipping* at the four ports. The percentage of foreign shipping other than

British is very small in the Persian Gulf. All the shipping on the Caspian is under the Russian flag[1] and no returns of arrivals and departures of vessels at the Persian ports exist, but seeing that the value of the merchandise, most of it bulky, exported and imported from and into the Persian ports of Resht, Meshed-i-Sar, and Bander-i-Gez, and the Russian port of Astara, which supplies a great part of Azerbáiján, exceeds £2,000,000, the shipping must be very considerable. Russian statistics for 1897 give for Astara 77 vessels (76 steamers) with an aggregate of 43,101 tons entered, and 272 vessels (240 steamers) with 88,011 tons cleared. The British consul at Resht, in his report dated 3rd March 1893, reports 49 steamers with an aggregate tonnage of 16,702 as plying between the Russian and Persian ports of the Caspian; but he omitted several steamers then already plying, and many more have been added since. Two or three flat-bottomed sailing vessels navigate the lake of Urmia in north-western Persia, carrying merchandise, principally agricultural produce, from the western and south-western shores to the eastern for the supply of Tabriz. The navigation is a State monopoly, and leased out for £250 per annum.

Internal Communications.—1. *Roads.*—Mr A. Hotz, head of a commercial firm long established in Persia, wrote in a paper communicated to the Society of Arts and published in the society's *Journal* of 10th March 1899: "If we consider the present means of conveyance, it is indeed astounding that a country of about 636,000 square miles, without navigable rivers, but inhabited by 9,000,000 people who are remarkable for their intelligence and industry, should have to carry on its foreign trade and local traffic along mule tracks, the like of which are hardly to be met with in any other part of the world, however backward. The passes between the Gulf ports and the Persian plateau are in the same condition as Herodotus described them and as they were found by Marco Polo and his innumerable successors." With the exception of four short roads, having an aggregate length of less than 800 miles, all the roads of the country are as Nature has made them—in other words, mere mule tracks, carriageable in the plains and during the dry season, but totally unfit for continuous wheeled traffic during all seasons, and in the hilly districts often so difficult as to cause much damage to goods and the animals carrying them.[2] The four exceptions are:—(1) Resht–Kazvín–Teherán, 227 miles; (2) Teherán–Kom–Sultánábád, 160 miles; (3) Meshed–Kúchán–Askábád, 150 miles, 30 of which on Russian territory; (4) Isfáhán–Ahváz, 280 miles. The first of these roads consists of two sections: Resht–Kazvín, 135 miles, and Kazvín–Teherán, 92 miles. The first section was constructed in 1897–99 by a Russian company, in virtue of a concession which the Persian Government granted in 1893; and the second section was constructed in 1878–79 by the Persian Government at a cost of about £20,000, ceded to the concessionnaire of the first section in 1896, and repaired and partly reconstructed by the Russian company in 1898–99. Both sections were officially opened to traffic in August 1899. The capital of the company is 3,200,000 roubles (£341,330), of which 1,700,000 is in shares taken by the public, and 1,500,000 in debentures taken by the Russian Government, which also guarantees 5 per cent. on the shares. About two-thirds of the capital has been expended on construction. The company's income is derived from tolls levied on vehicles and animals using the road. These tolls are at present very high, but will be reduced by 15 per cent. in 1904, and by another 10 per cent. five years later. If all the trade between Russia and Teherán were to pass over this road, the tolls would no doubt pay a fair dividend on the capital, but quite 40 per cent. of it goes by way of the Teherán–Meshed-i-Sar route, which is much shorter and has no tolls.

The second road, Teherán–Kom–Sultánábád, 160 miles, also consists of two sections: the first, Teherán–Kom, 92 miles, the other, Kom–Sultánábád, 68 miles. The first section was constructed by the Persian Government in 1883 at a cost of about £12,000, purchased by the Imperial Bank of Persia in 1890 for £10,000, and reconstructed at a cost of about £45,000. The second section formed part of the "Ahváz road concession" which was obtained by the Imperial Bank of Persia in 1890 with the object of connecting Teherán with Ahváz on the Karun by a direct cart-road *viâ* Sultánábád, Burujird, Khorremabad (Luristán), Dizful, and Shushter.

[1] By article v. of the treaty of Gulistan of 1813, confirmed by article viii. of the treaty of Turkmancháí of 1828, it was declared that Russia alone should have the right of maintaining vessels of war on the Caspian, and that no other Power should fly the military flag on that sea; and by a decision of the Council of the Russian empire, published on the 24th November 1869, the establishment of companies for the navigation of the Caspian, except by Russian subjects, and the purchase of shares of such companies by foreigners were prohibited. (*State Papers*, vol. lxiii. 925.)

[2] There are a few miles of roads in the immediate neighbourhood of Teherán leading from the city to royal palaces, but not of any commercial importance.

The third cart-road, Meshed–Askábád, 120 miles to the Persian frontier, was constructed by the Persian Government in 1889–92 in accordance with article v. of the Khorasán Boundary Convention between Russia and Persia of December 1881. The Persian section cost £13,000.

The fourth road, Isfáhán–Ahváz, 280 miles, is the old mule track provided with some bridges, and improved by freeing it of boulders and stones, &c., at a total cost of £5500. The concession for this road was obtained in 1897 by the Bakhtiari chiefs, the necessary capital being advanced by an English firm at 6 per cent. interest, and revenues being derived from tolls levied on animals passing with loads.

2. *Railways.*—Persia possesses only 8 miles of railway and 6½ miles of tramway, both run by a Belgian company. The railway consists of a single line, one-metre gauge, from Teherán to Shah-abdul-Azím, south of Teherán, and of two branch lines which connect the main line with some limestone quarries in the hills south-east of the city. The tramway also is a single line of one-metre gauge, and runs through some of the principal streets of Teherán. The length of the main railway line is 5½ miles, that of the branches 2½. The main line was opened in 1888, the branches were constructed in 1893, and the tramway started in 1889. The capital now invested in this enterprise, and largely subscribed for by Russian capitalists, amounts to £320,000. There are also ordinary shares to the amount of £200,000 put down in the company's annual balance-sheets as of no value. The general opinion is that if Russian capitalists had not been interested in the enterprise the company would have liquidated long ago. (On railways in Persia, the many concessions granted by the Persian Government, and only one having a result, chapter xviii. of Lord CURZON's *Persia* [vol. i. pp. 613–639], and on the Belgian enterprise, LORINI's *La Persia Economica* [pp. 157–158] may be read with great advantage.)

Posts.—Down to 1874 the postal system was in the hands of an official called *chapárchí báshí*, who was the head farmer of the post, or *chapárs*, and letters and small parcels were conveyed by him and his agents at high and arbitrary rates and without any responsibility. The establishment of a regular post was one of the results of the late Shah's first visit to Europe (1873). Two officials of the Austrian postal department having been engaged in 1874, an experiment of a post office upon European lines was made in the following year with a postal delivery in the capital and some of the neighbouring villages where the European legations have their summer quarters. In the beginning of 1876 a regular weekly post was established between Teherán, Tabriz, and Julfa (Russo-Persian frontier), and Resht. Other lines, connecting all the principal cities with the capital, were opened shortly afterwards, and on 1st September 1877 Persia joined the International Postal Union with the rates of 2½d. per ½ oz. for letters, 1d. for post-cards, ½d. per 2 oz. for newspapers, &c., between Persia and any Union country. The inland rates were a little less. There are now between Persia and foreign countries a bi-weekly service *viâ* Russia (Resht–Baku, Tabriz–Tiflis) and a weekly service *viâ* India (Bushire–Bombay). On the inland lines, with the exception of that between Teherán and Tabriz, the service is weekly. There are reported to be ninety-seven post offices. Statistics as to the number of letters, post-cards, newspapers, &c., conveyed are kept but not published; and since 1885, when a liberal-minded director communicated those for the year 1884–85 to the present writer, no others, although many times promised, have been obtained. In the year 1884–85 there were conveyed 1,368,835 letters, 2050 post-cards, 7455 samples, and 173,995 parcels, having a value of £304,720; and the receipts exceeded the expenditure by £466. Since then the traffic has much increased, and the excess of receipts over expenditure in the year 1898–99 was reported to have been £10,000, but is probably more than that, for the minister of posts has farmed the department for £12,000 per annum. Under the most favourable conditions letters from London *viâ* Russia are delivered at Tabriz in 14 days, at Teherán in 16, at Isfáhán in 20, at Meshed in 25, and at Shiraz in 26 days; and *viâ* India, at Bushire in 26 days, at Shiráz in 31, at Isfáhán in 36, and at Teherán in 40 days; but during winter, when the roads are heavy or snowed up, or the mail steamers on the Caspian on account of bad weather cannot land the mails, the times of transmission are much increased, and sometimes letters between London and Teherán take forty days. In the interior the mails are conveyed on horseback, and, being packed in badly-made soft leather bags, are frequently damaged through careless packing and wet. The first Persian postage stamps were issued in 1875 and roughly printed in Persia. Since then there have been many issues, and specimens of the early ones are much valued by stamp collectors. (For information on the postal system of Persia, see G. RIEDERER, *Aus Persien*, Vienna, 1882; FR. SCHUELLER, *Die Persische Post und die Postwerthzeichen von Persien*, Vienna, 1893.)

Telegraphs.—The first line of telegraphs—from Teherán to Sultanieh, about 160 miles on the road to Tabriz—was constructed in 1859. In the following year it was continued to Tabriz, and in 1863 to Julfa on the Russian frontier. With the object of establishing a direct telegraphic communication between England and India, by connecting the European and Indian systems by a land line through Persia from Baghdad—then the most easterly Turkish telegraphic station—to Bushire and by a cable from Bushire eastwards, a telegraphic convention was concluded in the same year between the British and Persian Governments, and a one-wire line on wooden posts from the Turkish frontier, near Baghdad, to Bushire *viâ* Kermánsháh, Hamadán, Teherán, Isfáhán, and Shiráz, was constructed at the cost and under the supervision of the British Government. In 1865 a new convention, providing for a second wire, was concluded, and for some years messages between Europe and India were transmitted either *viâ* Constantinople, Baghdad, Teherán, Bushire, or *viâ* Russia, Tiflis, Tabriz, Teherán, Bushire. An alternative line between Baghdad and India was created by the construction of a land line to Fao, at the head of the Persian Gulf, and the laying of a cable thence to Bushire. The service was very inefficient, and messages between England and India took several days and sometimes weeks to reach their destination, and besides, "the staff in no case was competent, there was hopeless confusion of dates arising from the different calendars recognized, and the mutilation of messages consequent upon the frequent translations and retranslations by ignorant clerks into English, French, Dutch, German, Italian, Greek, Bulgarian, Wallachian, Servian, Russian, Turkish, and Armenian, reduced the patrons of the various lines to a state bordering upon frenzy" (Curzon, *Persia*, ii. 610). In 1869 Messrs Siemens of Berlin, in virtue of concessions obtained in the year before and later disposed of to the Indo-European Telegraph Company, Limited—who also took over Reuter's cable from Lowestoft to Emden (274 knots)—constructed a two-wire line on iron posts through Germany and Russia, and in Persia from Julfa to Teherán. This line was opened 31st January 1870. The British Government then handed the Baghdad–Teherán section, which had become unnecessary for international through traffic between Europe and India, over to the Persian Government, and changed its Teherán–Bushire line into one of two wires on iron posts. In 1873, according to a convention signed December 1872, and renewed concessions to the company, a third wire was added to the line, and there is now a three-wire line on iron posts (415 miles Indo-European Telegraph Company, 675 miles Indian Government) from Julfa to Bushire. It is worked throughout by an English staff, and may be considered one of the finest and most efficient lines in the world. From Bushire messages go by cable (laid in 1864) to Jask, and thence either by cable or by land to Karachi, Bombay, &c. The telegraphic convention between the British and Persian Governments has again been renewed, and is in force until 1925; and the concessions to the company were prolonged to the same year by the Russian Government in March 1900. In addition to these lines, Persia possesses about 3700 miles of single-wire lines on wooden poles, belonging to the Persian Government and worked by a Persian staff; the Teherán-Meshed line, however, is looked after by an English inspector, and since 1885 the Indian Government has allowed a sum not exceeding 20,000 rupees per annum for its maintenance. The minister of telegraphs has the Persian lines in farm for £6000 per annum, and no statistics are published. Statistics of the traffic on the Indo-European line are given in the administration reports of the Indo-European Telegraph Department, published by Government, and from them the figures in the following table have been obtained:—

Year.	Traffic over Lines between London and Karachi.	Earnings in thousands of Pounds.		Net Profits of the Government Dept.	
	Number of Messages transmitted.	Government Department.	Indo-Europ. Telegraph Co.	Total amount. Rupees.	Percentage on Capital Outlay.
1887–88	83,031	74	100	198,381	1·75
1892–93	117,500	84	116	437,668	3·80
1895–96	140,401	102	138	852,631	7·42
1896–97	148,274	101	138	713,030	6·17
1897–98	146,988	106	145	758,172	6·57
1898–99	147,592	105	144	697,303	6·03

Banking.—It was only in 1888 that a European bank (the New Oriental Bank Corporation, Limited) established itself in Persia and modern ideas of banking were introduced into the country. Until then the banking was done by the native money-changers (*sarráfs*) and some merchants—foreign and native—who did the banking operations connected with their business, and occasionally undertook special outside transactions when they considered them sufficiently remunerative. In 1889 the Shah granted a concession to Baron Julius de Reuter for the formation of a State bank with the exclusive right of issuing bank-notes—not exceeding £800,000 without special assent of the Persian Government—on the basis of the local currency, the silver kran. With the title of "The Imperial Bank of Persia" the bank was formed in the autumn of the same year, and incorporated by royal charter granted by Queen Victoria and dated 2nd September 1889. The authorized capital was four millions sterling, but the bank started with a capital of one million, and began its business in Persia in October 1889. In April 1890 it took over the Persian business of the New Oriental Bank Corporation, soon afterwards opened branches and agencies at the principal towns, and issued notes in the same year. During the first two years the bank remitted the greater part of its capital to Persia at the then prevailing exchange, and received for every pound sterling 32 to 34 krans; but in consequence of the great fall in silver in 1893 and 1894, the exchange rose to 50 krans per pound sterling and more, and the bank's capital employed in Persia being reduced in value by more than one-third—100 krans, which at the beginning represented £3, then being worth only £2 or less—the original capital of one million sterling was reduced to £650,000 in December 1894. The bank has made steady progress in spite of innumerable difficulties, and paid a fair dividend to its shareholders.[1]

In the same year, 1889, the Shah granted a concession to Jaques de Poliakov of St Petersburg for the establishment of a "Loan Bank," or, as the original concession said, "Mont de Piété," with exclusive rights of holding public auctions. A company was formed in the same year and started business at Teherán in 1890 as the "Banque des Prêts de Perse." After confining its operations for some years to ordinary pawnbroking, without profits, it obtained the aid of the Russian State Bank, acquired large premises in Teherán, made advances to the Persian Government (since 1898), and in January 1900 financed the loan of £2,400,000 to Persia (see "Finance," *supra*). It has opened branches at Tabriz and Resht.

There is also established at Teherán a branch of the Russian "Banque de Commerce de Moscou," and various Armenian firms, one with branches at many places in Persia and Russia, do banking business, while various European firms at Tabriz, Teherán, Isfáhán, Shiráz, and Bushire facilitate remittances between Europe and Persia.

The chief business of the native *sarráfs* (money-changers, bankers, &c.) is to discount bills at high rates, hardly ever less than 12 per cent., and remit money from place to place in Persia for a commission amounting to from 1 to 5, or even 6 per cent. on each transaction; and in spite of the European banks giving lower rates of discount and remitting money at par, the majority of the people and mercantile classes still deal with the natives. For advances with good security a native *sarráf* charges at least 12 per cent. interest per annum; as the security diminishes in value the rate of interest increases, and transactions at 10 per cent. a month, or more than 120 per cent. per annum, are not infrequent. A Persian who obtains an advance of money at less than 12 per cent. considers that he gets money "for nothing."

The monetary unit is the kran, a silver coin, formerly weighing 28 nakhods (88 grains), then reduced to 26 nakhods (77 grains), and now weighing only 24 nakhods (71 grains) or somewhat less. Before the new coinage came into use (1877) the proportion of pure silver was from 92 to 95 per cent.; subsequently the proportion was for some time 90 per cent.; now it is about 89½ per cent. In consequence of this depreciation of the coinage and the fall in the price of silver, the value of the kran is now only about half what it was in 1874. In that year it was worth a franc, the exchange being 25 to the pound sterling; in 1898–99 the average exchange for a £1 bill to London was 50 krans, which gives the value of 1 kran as 4⅘d. Taking this value of the kran, the values of the various nickel and silver coins in circulation work out as—

Nickel Coins.		Silver Coins.	
Shâhî = 2 pûl . .	0·24d.	Five shâhîs = ¼ kran .	1·20d.
Two shâhîs = 4 pûl .	0·48d.	Ten shâhîs = ½ kran .	2·40d.
		One krân = 20 shahîs = 40 pûl . .	4·80d.
		Two krans . .	9·60d.

In 1899 from 80 to 83 copper shâhîs (weighing about ⅛ lb) were being given for one silver kran. This was owing to the

[1] In his paper on "Banking in Persia" (*Journal of the Institute of Bankers*, 1891), Mr Joseph Rabino pointed out the great difficulties which make the easy distribution of funds—that is, the providing them when and where required—a matter of impossibility in Persia, and gives this fact as the reason why the Imperial Bank of Persia has local issues of notes, payable at the issuing branches only, "for, in a country like Persia, where movements of specie are so costly, slow, and difficult as to become impracticable except on a small scale, the danger of issuing notes payable at more than one place is obvious."

depreciation of the copper coinage from 1896 onwards, consequent upon there being an excess of coinage due to the excessive quantities formerly put in circulation from the mint. Accordingly the Government in 1900 replaced the copper by a nickel coinage. Gold coins are the $\frac{1}{4}$ toman, $\frac{1}{2}$ toman, 1 toman, 2, 5, and 10 tomans. The nominal value of the toman is 10 krans (4s.), but as there are very few gold pieces in circulation, its actual value is now about $16\frac{1}{2}$ krans (6s. $7\frac{1}{2}$d.). Accounts are reckoned in dinârs, an imaginary coin, $\frac{1}{10000}$ of a toman of 10 krans. 1000 dinârs thus equal 1 kran, and 50 dinârs 1 shâhî.

The unit of weight is the miskâl (71 grains), subdivided into 24 nakhods (2·96 grains), a nakhod being further subdivided into 4 gandum (·74 grains). Larger weights, again, are the sîr (16 miskâls) and the abbási, wakkeh, or kervânkeh (5 sîr). Most articles are bought and sold by a weight called batman, or man, of which there are several kinds, the principal being—

Man-i-Tabriz=8 abbásis	= 640 miskâls	= 6·49 lb
Man-i-Noh abbási=9 abbásis	= 720 ,,	= 7·30 ,,
Man-i-Kohneh (the old man)	=1000 ,,	= 10·14 ,,
Man-i-Shâh=2 Tabriz mans	=1280 ,,	= 12·98 ,,
Man-i-Rey=4 ,, ,,	=2560 ,,	= 25·96 ,,
Man-i-Bander abbási	= 840 ,,	= 8·52 ,,
Man-i-Hâshemî=16 mans of	720 ,,	=116·80 ,,

Corn, straw, coal, &c., are sold by kharvâr=100 Tabriz mans =649 lb.

The unit of measure is the zar or gez, of which, as in the case of the man, there are several variants. 40·95 inches is the most common length for the zar, but in Azerbáiján the length is 44·09 inches. Long distances are calculated in farsakhs, a farsakh being equal to 6000 zar. Probably the zar in this measure =40·95 inches, which makes the farsakh 3·87 miles, but the other length of the zar is sometimes used, when the farsakh becomes 4·17 miles. Areas are measured in jerîbs of from 1000 to 1066 square zar of 40·95 inches, the surface unit thus being from 1294 to 1379 square yards.

II. Recent History (1884–1901).

The history of Persia in the ninth edition of this Encyclopædia closed with the statement that in 1884 two steamers for the Persian Government were in course of construction, and that the Karun river was to be opened up to Ahváz, and a carriageable road constructed connecting that place with Teherán. Already in 1865 the Shah had mooted the idea of a Persian naval flotilla in the Persian Gulf, to consist of two or three steamers manned by Arabs and commanded by English naval officers; but the idea was discountenanced by the British Government, to whom it was known that the project really concealed aggressive designs upon the independence of the islands and pearl fisheries of Bahrein (Curzon, *Persia*, ii. 294). Fifteen or sixteen years later it was repeatedly pointed out to the authorities that the revenues from the customs of the Persian Gulf would be much increased if control were exercised at all the ports, particularly the small ones where smuggling was being carried on on a large scale, and in 1883 the Shah decided upon the acquisition of four or five steamers, one to be purchased yearly, and instructed the late Ali Kuli Khan, Mukhber-ed-dowleh, minister of telegraphs, to obtain designs and estimates from British and German firms. The tender of a well-known German firm at Bremerhaven was finally accepted, and one of the minister's sons then residing in Berlin made the necessary contracts for the first steamer. Sir Ronald Thomson, the British representative in Persia, having at the same time induced the Shah to consider the advantages to Persia of opening the Karun river and connecting it with Teherán by a carriageable road, a small river steamer for controlling the shipping on the Karun was ordered as well, and the construction of the road was decided upon. The two steamers were completed in January 1885 at a cost of £32,000, and despatched with German officers and crew to the Persian Gulf (as has been already mentioned). One, the *Persepolis*, an iron schooner-rigged screw steamer, has a registered tonnage of 600, engines of 450 h.p., and a maximum speed of 10 knots; the other, the *Susa*, now on the Karun above Ahváz, is a screw steam launch, with a tonnage of 36, engines of 30 h.p., and speed of 6 knots, and was sent out in sections on the *Persepolis* and put together at Muhamrah in 1885. The *Persepolis* has an armament of one $8\frac{1}{2}$ and three $7\frac{1}{2}$ centimetre Krupp steel guns, and forty old-system Mauser rifles. One of the $7\frac{1}{2}$ centimetre guns was originally on the *Susa*, but transferred to the *Persepolis* in 1886. When the steamers were ready to do the work they had been intended for, the farmer, or farmers, of the Gulf customs raised difficulties and objected to pay the cost of maintaining the *Persepolis*; the governor of Muhamrah would not allow any interference with what he considered his hereditary rights of the shipping monopoly on the Karun, and the objects for which the steamers had been brought were not attained. The *Persepolis* remained idle at Bushire, and the *Susa* was tied up in the Failieh creek, near Muhamrah. The annual cost of maintenance of the two vessels, merely for salaries and wages of officers and crew and expenses of necessary painting, oiling, and scrubbing, amounted to £3500, a large item in the small revenue of Persia, and the Shah wisely desisted from buying more steamers. The scheme of opening the Karun and of constructing a carriageable road from Ahváz to Teherán was also abandoned.

The control of the Persian Gulf.

Frequent interruptions occurred on the telegraph line between Teherán and Meshed in 1885, at the time of the "Panjdeh incident," when the Russians were advancing towards Afghanistan and Sir Peter Lumsden was on the Afghan frontier; and since (often for many days at a time) no news could be obtained, Sir Ronald Thomson concluded an agreement, still in force, with the Persian Government by which the line is kept in working order by an English inspector, the Indian Government paying a share not exceeding 20,000 rupees per annum of the cost of maintenance, and an English signaller is stationed at Meshed. Shortly afterwards Sir Ronald Thomson left Persia (he died 15th November 1888), and Mr (afterwards Sir) Arthur Nicolson was appointed chargé d'affaires. During the latter's tenure of office an agreement was concluded between the Persian and British Governments regarding the British telegraph settlement at Jask, and the telegraph conventions of 1868 and 1872, relative to telegraphic communication between Europe and India through Persia, in force until 1st January 1895, were prolonged until 31st January 1905 by two conventions dated 3rd July 1887. Since then these conventions have been prolonged to 1925. (See "Telegraphs," *supra*.)

Ayúb Khan, son of Shír Ali of Afghanistan, who had taken refuge in Persia in October 1881, and was kept interned in Teherán under an agreement, concluded 17th April 1884, between Great Britain and Persia, with a pension of £8000 per annum from the British Government, escaped on the 14th of August 1887. After a futile attempt to enter Afghan territory and raise a revolt against the Amir Abdur Rahman, he gave himself up to the British consul-general at Meshed in the beginning of November, and was sent under escort to the Turkish frontier and thence *viâ* Baghdad to India. Yahya Khan, Mushir-ed-dowleh, the Persian minister for foreign affairs (died 1892), who was supposed to have connived at Ayúb Khan's escape in order to please his Russian friends, was dismissed from office.

In December 1887 Sir Henry Drummond Wolff was appointed minister to Persia. The appointment greatly pleased the Persian court, and the Shah lent a willing ear to his advocacy for the development of trade and commerce, construction of roads, abolition of various restrictions hampering Persian merchants, &c. The Shah soon afterwards (26th May 1888) issued a proclamation assuring freedom of life and property to all his subjects, and (30th October) declared the Karun river open to international navigation up to Ahváz. At about the same time he appointed Amin-es-Sultán, who had been prime minister since 1884, Grand Vizír (Sadr Azam). In the same year (25th June) the first railway in Persia, a small line of $5\frac{1}{2}$ miles from Teherán to Shah-abdul-Azím, was opened under the auspices of a Belgian company in virtue of a concession granted two years before. A few months later (30th January 1889) Baron Julius de Reuter, in consideration of giving up the rights which he held by his concession obtained in 1873, became, as has been already stated, the owner of a concession for the formation of a Persian State Bank, with exclusive rights of issuing bank-notes and working the mines of iron, copper, lead, mercury, coal, petroleum, manganese, borax, and asbestos in Persia. Russia now insisted upon what she considered a corresponding advantage; and Prince Dolgorouki, the Russian minister, obtained in February 1889 a document from the Shah which gave to Russia the refusal of any railway concession in Persia for a period of five years. The Persian State Bank was established by British royal charter, dated 2nd September 1889, and started business in Persia (23rd October) as the "Imperial Bank of Persia." The railway agreement with Russia was changed in November 1890 into one interdicting all railways whatsoever in Persia, and is still in force.

Shah's visit to Europe, 1889.

In April 1889 the Shah set out upon his third voyage to Europe. After a visit to the principal courts, including a stay of a month in England, where he was accompanied by Sir Henry Drummond Wolff, he returned to his capital (20th October). Sir Henry returned to Persia soon afterwards, and in March of the following year the Persian Government granted another important concession, that of a tobacco monopoly, to British capitalists. In the autumn bad health obliged the British minister to leave Persia. It was during his stay in England that the Shah, for two or three days without his Grand Vizír, who was mourning for the death of his brother, listened to bad advice and granted a concession for the monopoly of lotteries in Persia to a Persian subject. The latter ceded the concession to a British syndicate for £40,000. Very soon afterwards the Shah was made aware of the evil results of this monopoly, and withdrew the concession, but the syndicate did not get the money paid for it returned. This unfortunate affair had the effect of greatly discrediting Persia on the London Stock Exchange for a long time. The concession for the tobacco monopoly was taken up by the Imperial Tobacco Corporation (1891). The corporation encountered opposition fostered by the clergy, and after a serious riot at Teherán (4th January 1892) the Persian Government withdrew the concession and agreed to pay an indemnity of £500,000 (5th April 1892). In order to pay this amount Persia contracted the 6 per cent. loan of £500,000 through the Imperial Bank of Persia, which was redeemed in 1900 out of the proceeds of the Russian 5 per cent. loan of that year. (For details of the tobacco concession and an account of the events which led to its withdrawal, see E. Lorini, *La Persia Economica*, Rome, 1900, pp. 164-169; and Dr Feuvrier, *Trois ans à la Cour de Perse*, Paris, 1899, chap. v., the latter ascribing the failure of the tobacco monopoly to Russian intrigue.)

In November 1889 Malcolm Khan, Nizam-el-Mulk, who had been Persian representative to the court of Great Britain since October 1872, was recalled, and Mirza Muhammad Ali Khan, consul-general at Tiflis, was appointed in his stead, arriving in London the following March, and later receiving the title Ala-es-Saltaneh. In 1890 the scheme of a carriageable road from Teherán to Ahváz was taken up again; the Imperial Bank of Persia obtained a concession, and work of construction was begun in the same year, and continued until 1893. In this year, too, the mining rights of the Imperial Bank of Persia were ceded to the Persian Bank Mining Rights Corporation, and a number of engineers were sent out to Persia. The total absence of easy means of communication, the high rates of transport, and the scarcity of fuel and water in the mineral districts made profitable operations impossible, and the corporation liquidated in 1894, after having expended a large sum of money. The work of the corporation proved that without cheap means of transport no mining operations on a large scale in Persia can be undertaken with profit.

Kate Greenfield case.

Great excitement was caused in the summer of 1891 by the report that an English girl, Kate Greenfield, had been forcibly carried away from her mother's house at Tabriz by a Kurd. The British authorities demanded the girl's restitution from the Persian Government. The Kurd, a Turkish subject, refused to give up the girl, and took her to Saújbulagh, where he and a number of wild tribesmen entrenched themselves, and threatened to resist any attempt on the part of the Persians to recover her. The Turkish authorities protected him, and serious complications were imminent; but finally an interview between the girl and the British agent was arranged, and the matter was promptly settled by her declaring that she had left her mother's house of her own accord, and was the wife of the Kurd. It also became known that she was the daughter of a British-protected Hungarian named Grünfeld, who had died some years since, and an American lady of Tabriz.

Sir Frank Lascelles, who had been appointed minister to Persia in July, arrived at Teherán in the late autumn of 1891. In the following year Persia had a visitation of cholera. The epidemic entered Persia from the East, made many victims, and travelled as far as western Persia. In Teherán the mortality rose for several days to over 1000 a day, and in the city and surrounding villages the number of fatal cases exceeded 28,000, or about 8 per cent. of the population. In 1893 the epidemic appeared again, but in a milder form. In June 1893, by a convention ratified a month later at Peterhof, Persia ceded to Russia the small but very fertile and strategically important district of Firúzeh and the adjacent lands between Baba Durmaz and Lutfábád on the northern frontier of Khorasán, and received in exchange the important village of Hissár and a strip of desert ground near Abbasábád on the frontier of Azerbáiján, which had become Russian territory in 1828, according to the treaty of Turkmanchaï.

French archæological concession.

Sir Frank Lascelles left Persia in the early part of 1894, and was succeeded by Sir Mortimer Durand, who was appointed in July and arrived in Teherán in November. In the following year the Shah, by a firman dated 12th May, gave the exclusive right of exploring ancient sites in Persia to the French Government, with the stipulation that one-half of the discovered antiquities, excepting those of gold and silver and precious stones, should belong to the French Government, which also had the preferential right of acquiring by purchase the other half and any of the other antiquities which the Persian Government might wish to dispose of. The period for which this valuable concession is to remain in force is not mentioned in the firman, and is in consequence considered unlimited. In 1897 the French Government granted the necessary funds, and M. J. de Morgan, who had been on a scientific mission in Persia some years before and later distinguished himself as head of the archæological department in Egypt, was appointed chief of a mission to Persia, and, assisted by an efficient staff, began work at Susa in December. Operations have been continued until now, and so far confined to Susa and southern Persia, but according to recent information the sphere of operations is to be greatly extended, and more than 400 ancient sites are to be explored.

Assassination of the Shah, 1896.

On 1st May 1896 Nássir-ed-dín Shah was assassinated while paying his devotions at the holy shrine of Shah-abdul-Azím, a few miles from Teherán. Five days later he would have entered the fiftieth (lunar) year of his reign, and great preparations for duly celebrating the jubilee had been made throughout the country. The assassin was a small tradesman of Kermán named Mirza Reza, who had resided a short time in Constantinople and there acquired revolutionary and anarchist ideas from Kemál-ed-dín, the so-called Afghan sheikh, who, after having been very kindly treated by the Shah, preached revolution and anarchy at Teherán, fled to Europe, visited London, and finally took up his residence in Constantinople. Kemál-ed-dín was a native of Hamadán and a Persian subject, and as the assassin repeatedly stated that he was the sheikh's emissary and had acted by his orders, the Persian Government demanded the extradition of Kemál from the Porte; but during the protracted negotiations which followed he died. Mirza Reza was hanged 12th August 1896. There were few troubles in the country when the news of the Shah's death became known. The capital and most cities and districts were kept in order by the excellent measures taken by the Grand Vizír and the governors, and serious rioting arose only in Shiráz and Fars, where some persons lost their lives and a number of caravans were looted. European firms who had lost goods during these troubles were afterwards indemnified by the Persian Government. The new Shah, Muzaffar-ed-dín (born 25th March 1853), then governor-general of Azerbáiján, residing at Tabriz, was enthroned there on the day of his father's death, and proceeded a few days later, accompanied by the British and Russian consuls, to Teherán, where he arrived 8th June.

Currency difficulties.

An excessive copper coinage during the past three or four years had caused much distress among the lower classes since the beginning of the year, and the small trade was almost paralysed. Also the price of meat, particularly in the Teherán district, had been extraordinarily high for some months, and was now quite prohibitive to the poorer classes. Immediately after his accession the Shah was made aware of these facts, and decreed that the coining of copper money should cease and the excess of the copper coinage be withdrawn from circulation. An arrangement was concluded with the Imperial Bank of Persia by which that institution advanced the required money and bought up the copper coinage at the rates current in the various cities until its circulating value became 25 shâhîs equal to 1 kran. In order to reduce the price of meat, the meat tax, which had existed since ancient times, was abolished. The Imperial Bank of Persia, which had already advanced a large sum of money, and thereby greatly facilitated the Shah's early departure from Tabriz and enabled the Grand Vizír at Teherán to carry on the government, cheerfully accepted the arrangement, and started buying up the copper coinage at all its branches and agencies. The nominal value of the copper money was 20 shâhîs equal to 1 kran, but in some places the copper money circulated at the rate of 80 shâhîs to the kran, less than its intrinsic value; at other places the rates varied between 70 and 25 shâhîs, and the average circulating value in all Persia was over 40. If Government had been able to buy up the excess at 40 and reissue it gradually after a time at its nominal value when the people required it, the loss would have been small. But although the transport of copper money from place to place had been strictly prohibited, dishonest officials found means to traffic in copper money on their own account, and by buying it where it was cheap and forwarding it to cities where it was dear, the bank bought it at high rates, thus rendering the arrangement for a speedy withdrawal of the excess at small cost to Government futile. It was only in 1899 that the distress caused by the excessive copper coinage ceased, and then only at very great loss to Government. The well-intentioned abolition of the tax on meat also had not the desired result, for by a system of "cornering" the price of meat rose to more than it was before.

In the autumn of 1896 Nizam-es-Saltaneh, governor of Arabistán, and his brother Saad-el-Mulk, governor of Luristán, displayed much unfriendliness of attitude towards the British Government, and were removed from their posts at the instance of Sir Mortimer Durand, the Persian Government at the same time giving a promise that neither should be employed anywhere in Persia for a period of five years. In 1898 the British Government consented to the removal of the prohibition against the elder brother's further employment, provided that a guarantee was given that he should never be employed in southern Persia or in any place where he might injure British trade. This was agreed to, and Nizam-es-Saltaneh became minister of justice and commerce in March, minister of finance in June, and chief administrator of Azerbáïján in May of the following year (1899).

Ministerial changes, 1896-98.

In the autumn of 1896 the Grand Vizír (Amin-es-Sultan) encountered much hostility from some members of the Shah's entourage and various high personages. Amin-ed-dowleh was appointed chief administrator (vizír) of Azerbáïján and sent to Tabriz. Shortly afterwards the Grand Vizír found it impossible to carry on his work, resigned, and retired to Kom (24th November), and the Shah formed a cabinet composed for the greater part of the leading members of the opposition to the Grand Vizír. After three months of the new régime affairs of State fell into arrears, and the most important department, that of the Interior, was completely disorganized. The public treasury was empty. The ministers of the cabinet would not act together, and as all shirked responsibility, every matter, large and small, was brought before the Shah, who accordingly recalled Amin-ed-dowleh from Tabriz (February 1897), and appointed him minister president (Raïs-i-Vuzara) and minister of the interior. In June Amin-ed-dowleh was made prime minister (*Vizír Azam*) and given more extended powers, and in August raised to the dignity of Grand Vizír (*Sadr Azam*). Several reforms were now taken in hand, with a view of reducing expenditure and increasing the revenue; but reducing expenditure meant the pensioning off or dismissal of crowds of functionaries, and this could not be done without paying arrears of salaries due to them. Nássir-el-Mulk was appointed minister of finance (February 1898), and made an attempt to introduce a simple system of accounts, establish a budget, reorganize the revenue department, make a new assessment of the land-tax, &c.; but resistance on the part of the officials rendered it abortive. Other attempts at reform shared the same fate, and only resulted in making Amin-ed-dowleh very unpopular.

In the latter part of 1897 Mr E. Graves, the inspector of the English telegraph line from Jask eastwards, was brutally murdered by Baluchis, and the agents of the Persian Government sent to seize the murderers were resisted by the tribes. A considerable district breaking out into open revolt, troops under the command of the governor-general of Kermán were despatched into Baluchistan. The port of Fannoch was taken in March 1898, and order was restored. One of the murderers was hanged at Jask (31st May).

Abortive negotiations for British loan in 1898.

Various attempts to obtain a foreign loan had been made during the previous year, but with the sole result of discrediting the Persian Government in Europe. In the beginning of 1898 the Shah's medical advisers strongly recommended a cure of mineral waters in Germany or France, and as his departure from Persia without paying the arrears to the army and to thousands of functionaries, or providing a sufficient sum for carrying on the Government during his absence, would have created grave discontent, serious negotiations for a loan were entered upon. It was estimated that £1,000,000 would be required to pay all debts, including the balance of the 1892 loan, and leave a surplus sufficient for carrying on the Government until the Shah's return. Some time before this the Shah had asked Sir Mortimer Durand to assist, and the Persian Government, now applying to London, expected that the required money would be obtained quickly on easy terms, and thus enable the Shah to proceed on his journey to Europe in April. London capitalists offered to float a loan for £1,250,000 at 5 per cent. and on the guarantee of the customs of Fars and the Persian Gulf ports, and to give £1,025,000, or 82 per cent. of the nominal capital, to the Persian Government. They stipulated for a kind of control over the custom-houses by placing their own agents as cashiers in them. This stipulation was agreed to in principle by the Grand Vizír, Amin-ed-dowleh, who in March, in order to meet some pressing demands on the treasury, borrowed £50,000 on the customs receipts of Kermánsháh and Bushire, and agreed to the lenders, the Imperial Bank of Persia's agents, being placed as cashiers in the custom-houses of both cities. He encountered, however, much opposition from the other ministers. Objections were also taken to the low rate of 82, particularly when it was ascertained that a rate of 86 could have been obtained if the claims of some members of the London Stock Exchange, who had lost money over the lottery concession of 1889, had not had to be satisfied in order to obtain the necessary official recognition of the loan by the Stock Exchange. Further negotiations ensued, and the Shah's visit to Europe was abandoned. The assistance of the British Government not being forthcoming, the Grand Vizír's position became more and more difficult, and on 5th June he had to resign. Muhsin Khan, Mushir-ed-dowleh, minister for foreign affairs, then became president of the cabinet, and continued the negotiations, but could not bring them to a successful issue. Moreover, the Persian Government, finding that the previous estimate of the money required for paying its debts was about 50 per cent. below the mark, now asked for double the amount offered by the London capitalists, without, however, proportionately increasing the guarantee. This disorganized all previous arrangements, and the negotiations for a London loan came to an end for a time at the end of July, leaving in the minds of the Persians the unfortunate impression that the British Government had done nothing to aid them.

On 9th July the former Grand Vizír, Amin-es-Sultan, was recalled from Kom, where he had resided since November 1896, arrived at Teherán three days later, and was reinstated as Grand Vizír on the 10th of August. His immense popularity, his friendly relations with the clergy, and some temporary advances from the banks, tided over difficulties for some time. The reform of the customs department was now (September 1898) taken up seriously, and the three Belgian custom-house officials who had been engaged by Amin-ed-dowleh in the beginning of the year were instructed to collect information and devise a scheme for the reorganization of the department and the abolition of the farm system. In March 1899 the custom-houses of the provinces of Azerbáïján and Kermánsháh were given over to the Belgians. The results of this step were so satisfactory that Government was induced to abolish the farm system and set up the new régime in the other provinces in March 1900, and a number of other Belgian custom-house officials were engaged.

In March 1899 a small Persian force took Bander Lingah, one of the Persian Gulf ports, and expelled the Arab sheikh, whose family had enjoyed a quasi-independence there for many generations. The loss of life was unimportant, and British gunboats were present to protect British subjects. The sheikh fled to the hills north of Lingah, obliging the Government to keep a garrison at the port.

Russian loan of 1900.

In September, when renewed negotiations for a loan from London were not appearing to progress favourably, and the long-thought-of visit to Europe was considered to be absolutely necessary in the following year, the Shah issued a firman authorizing the Russian Banque de Prêts de Perse to float a loan. Shortly after this it was said that the London capitalists were willing to lend £1,250,000 without insisting upon the objectionable control clause; but the proposal came too late, and on 30th January 1900, as we have already mentioned, an official announcement appeared at St Petersburg to the effect that the Russian Government had permitted the issue of a loan for 22½ million roubles (£2,400,000) at 5 per cent., guaranteed by all the customs receipts of Persia, excepting those for Fars and the Persian Gulf ports. Only in the event of any default of paying instalments and interests will the bank have the right of exercising control of the custom-houses. Persia received 85 per cent. of the nominal capital, and the Russian Government guarantees the bondholders. Without Government guarantee it is doubtful whether any financial institution would have lent money on such advantageous terms. Money was immediately remitted to Teherán, and nearly all the arrears were paid, while the balance of the 1892 London 6 per cent. loan was paid off by direct remittance to London. The paying off the arrears, and the fact that a large quantity of cash was put into circulation in consequence, greatly revived trade, which had been languishing for a long time, and much distress and discontent disappeared.

Shah's visits to Europe, 1900, 1902.

Sir Mortimer Durand left Teherán in the early spring, and proceeded to Europe on leave. On 12th April the Shah, accompanied by the Grand Vizír and a numerous suite, started on his voyage to Europe, principally to undergo a cure at Contrexéville, but also with the intention of visiting the courts of Russia, France, Great Britain, Belgium, Netherlands, Germany, Italy, Austria, and Turkey. The affairs of State during his absence were entrusted to a council of ministers, under the presidency of his second son, Malik Mansur Mirza, Shua-es-Sultaneh, who had made a long stay on the Continent the year before.

After a residence of a month at Contrexéville, the Shah proceeded (14th July) to St Petersburg, and thence to Paris (29th July), intending to go to London on 8th August. But on account of the mourning in which several courts were thrown through the deaths of the king of Italy (29th July) and the duke of Saxe-Coburg-Gotha (30th July), the visits to England, Germany, and Italy were abandoned. On 2nd August an anarchist made an attempt upon the Shah's life in Paris, and a week later he went to Belgium. In the middle of June serious bread riots, instigated, it was said, by persons opposed to the Grand Vizír with the Shah in Europe, occurred in Teherán; and to prevent a repetition of the disorders, some of the suspected ringleaders or instigators were expelled from the city. Sir Mortimer Durand having been given the post of ambassador to Spain, Sir Arthur Hardinge was appointed minister to Persia 12th August 1900.

In 1902 the Shah made another visit to Europe, and was welcomed by King Edward in England during August.

AUTHORITIES.—The works treating of Persia and written by European writers, or in a European language, beginning with Herodotus, number thousands. The following bibliography has been restricted to works published during the 19th century which have not been quoted in the foregoing text, and, as giving useful information, may be consulted with advantage. The list excludes historical works and articles and papers, many of great value, which have appeared in the transactions, proceedings, and journals of learned societies, in magazines, reviews, newspapers, &c., and comprises only a selection, not a large one, of the works published as books. An able summary of the voluminous literature on Persia is given by Lord CURZON in his *Persia and the Persian Question* (vol. i. pp. 15–25). Col. VALENTINE BAKER. *Clouds in the East.* London, 1873. —H. W. BELLEW. *From the Indus to the Tigris.* London, 1872.—S. G. W. BENJAMIN. *Persia and the Persians.* London, 1887.—H. Perth, or PERTHSHIRE, an inland county of Scotland, bounded on the N.W. and N. by Inverness, on the N.E. by Aberdeen, on the E. by Forfar, on the S.E. by the Firth of Tay and Fife, Kinross, and Clackmannan, on the S. and S.W. by Stirling, and on the W. by Argyll.

Area and Population.—The area of the county is 1,617,808 acres, or 2528 square miles, with a population in 1881 of 129,007, in 1891 of 126,199, and in 1901 of 123,262, of whom 58,007 were males and 65,255 females, the number of persons per square mile being 48, and of acres to a person 13·01. Between 1881 and 1891 the percentage of decrease in the population was 2·17, and between 1891 and 1901, 2·3. The following table gives the numbers of marriages, births, and deaths, with the number and percentage of illegitimate births, for 1880, 1890, and 1899:—

Year.	Marriages.	Births.	Deaths.	Illegitimate Births. No.	Illegitimate Births. Per cent.
1880	743	3612	2372	357	9·2
1890	695	2869	2359	252	8·8
1899	730	2925	1945	227	8·4

In addition to Perth (32,872), the only town with over 5000 inhabitants is Crieff (5208). In 1891 there were in Perthshire 2465 natives of England, 68 natives of Wales, 1745 natives of Ireland, and 106 foreigners.

Administration.—For parliamentary purposes the county is divided into an Eastern and a Western division. The city of Perth also returns a member to Parliament.

Education.—The total grant to higher-class schools for the year ended 31st March 1900 was over £1651. The total accommodation in elementary schools for the year ended 30th September 1899 was 27,310, the average attendance 16,510, and the average cost per scholar £2, 17s. 11¼d. The amount of rates received in 1898–99 was £31,219, and the average rate per £ on rateable value was at 6·87 in 1895–96, at 6·75 in 1896–97, and at 7·67 in 1897–98.

Agriculture.—Only a little more than one-fifth of the total area of the county is under cultivation, and of this nearly one-third is in permanent pasture, while in addition there are about 930,000 acres of hill pasturage, grazed partly by the native highland cattle, but mainly by sheep, in regard to the number of which Perthshire ranks, in Scotland, next to Argyll. Much of the old sheep pasturage is, however, now occupied by deer forests. Over 94,000 acres are under wood, and nearly 600 acres under orchards. Apples are grown chiefly in the Carse of Gowrie and the district of Menteith. Over 1000 acres are under small fruit. Since 1880 the acreage under corn crops has decreased by about one-sixth, the largest decrease being in the acreage under barley, which now occupies about one-sixth of the corn crop acreage, oats occupying nearly three-fourths, and wheat less than one-fourteenth. Nearly three-fourths of the green crop acreage is occupied by turnips, and less than one-third by potatoes. The following table gives the main divisions of the cultivated area at intervals from 1885:—

Year.	Total Area under Cultivation.	Corn Crops.	Green Crops.	Clover.	Permanent Pasture.	Fallow.
1885	345,136	99,902	47,963	103,533	91,623	2115
1890	349,818	94,826	45,865	118,683	87,735	2130
1895	337,227	89,474	44,294	98,265	103,284	1158
1899	338,737	87,514	43,394	99,918	105,745	986

The following table gives particulars regarding the live stock for the same years:—

Year.	Total Horses.	Total Cattle.	Cows or Heifers in Milk or in Calf.	Sheep	Pigs.
1885	13,249	82,631	19,857	713,191	8902
1890	12,843	79,848	19,459	735,178	9631
1895	13,917	74,861	18,202	707,661	8886
1899	12,183	73,097	17,830	710,933	7212

Industries and Trade.—The total number of persons employed in factories and workshops in 1897 was 12,198, as compared with 11,640 in 1896. Of these 4225 were employed in textile factories, flax, hemp, &c., chiefly coarse linens, in the several towns and villages, employing 2838. In non-textile factories 6258 persons were employed, 3402 of these in the print, bleach, and dye works for which the county town is famous. Of the 1715 persons employed in workshops, 1170 were employed in clothing industries. Handloom weaving is still carried on in many of the villages. In 1899 among the minerals raised were 55,009 tons of igneous rocks, 41,508 tons of sandstone, and 9371 tons of slate.

Perth, an ancient city, a royal and parliamentary (one member) burgh, and the county town of Perthshire, Scotland, on the river Tay, at the junction of several lines of the Caledonian and North British railways, 48 miles north-north-west of Edinburgh by rail. Dyeing retains its importance, and there are also glass, linen, wincey, and floorcloth manufactures, steam joinery works, and brick and tile works. There is an Episcopalian cathedral, to which in 1900 considerable additions were made in commemoration of Bishop Wordsworth. The Perth Academy is a higher-class school under the direction of the school board; and Sharp's Institution, besides satisfying the requirements of an organized science school, provides a course of instruction in classics, instrumental music, and gymnastics. In addition to the board schools other educational institutions are Stewart's Free School, the industrial school for girls, and the Fechney industrial school. A scheme of city improvements has been to a large extent (1901) carried out. It includes a fine new street from the North Inch to the South Inch; the erection of a new bridge—a steel structure with handsome freestone piers—between the old bridge and the railway bridge, and connecting South Street with the Dundee Road. Jubilee corporation swimming baths, with bowling greens, were erected in 1887 by public subscription; a handsome new post office was opened in 1898, and in the same year the Sandeman Public Library, founded by a bequest of £32,000 from the late Professor Sandeman of Owens College, Manchester. At the south end of the North Inch a granite column was erected in 1895 to commemorate the achievements of the 90th Light Infantry, now the second battalion Cameron Highlanders. Population (1881), 28,949; (1891), 29,899; (1901), 32,872.

Perth, the capital of West Australia, situated about 12 miles from the sea by rail, on the Swan river, which here widens out into a beautiful lake, one and a half miles long and one mile broad. The city has grown very rapidly since 1890. In 1891 the population was only 8447; in 1899 it was 35,000, of whom some 27,000 were within the limits of the city proper (2560 acres). There is communication by bridge and steam ferry with South Perth, on the opposite side of the river; to the north-west lie the adjoining and rapidly growing municipalities of Leederville and Subiaco. Outlying suburbs are Victoria Park, Burswood, Belmont, Claremont, Cottesloe, Peppermint Grove, and Bayswater. A Jubilee Victoria Public Library was opened in 1887, the Scots College in 1897, and the Mint, an imposing structure of considerable architectural merit, in 1899. An observatory is finely situated on a hill immediately west of the city, and there is a general museum. Chief among several reserves is the Perth Park Reserve, comprising over 1000 acres, now being cleared and laid out. The mean temperature is 64·9° F.; the lowest that has been recorded is 37·5°; and the maximum, an exceptional reading which was taken in 1878, 116·7°. The average rainfall is 33 inches

The municipal council consists of a mayor, elected annually by the whole body of municipal electors, and 15 councillors, representing 5 wards. In the Parliament of West Australia, for the meetings of which the city contains Legislative Council and Legislative Assembly chambers, Perth is represented by 3 members on the Council and 4 members in the Assembly. The total length of streets is 64 miles, of which in 1899 about 40 miles were properly formed and metalled. There are gas and electric lighting works, both as yet in the hands of companies. The water works, however, were acquired in 1896 by the central Government for £220,000; a further sum of £140,000 has been expended on them, and the main reservoir, in the Darling range, is capable of holding 200,000,000 gallons. It is proposed to construct another with a capacity of 1,554,452,000 gallons, and a new service reservoir within the city boundaries is also contemplated. At present Perth has no proper sewerage system, but a scheme of surface drainage is being carried out as a temporary relief, and a permanent system of sewerage has also been approved, which will involve an expenditure of some £350,000. There are three racecourses in the neighbourhood. Three daily papers are published.

Perth Amboy, a city and port of entry in Middlesex county, New Jersey, U.S.A., at the head of Raritan Bay, in the eastern part of the state. Its site is low and level and the street plan regular. It has an excellent harbour and a large commerce, and three railways, the Central of New Jersey, the Lehigh Valley, and the Pennsylvania, afford rail transportation. It contains terra-cotta works, machine works, iron foundries, petroleum refineries, and chemical works. Population (1880), 4808; (1890), 9512; (1900), 17,699, of whom 7978 were foreign-born and 89 negroes.

Peru, a country of South America, bounded on the W. by the Pacific Ocean, on the N. by Ecuador, on the E. by Brazil and Bolivia, and on the S. by Chile. The frontiers towards Ecuador and Bolivia are not yet defined, and the question as to the possession of the provinces of Tacna and Arica, which have been occupied by Chile since 1884, is still pending. According to the agreement between Peru and Chile, a popular vote should have decided in 1894 to which country these provinces should belong, but as a *modus operandi* acceptable to both parties could not be devised, the decision was deferred. On 16th April 1898 a convention for the purpose of carrying out the plebiscite was signed at Santiago, but two years later it was rejected by the Chilian Congress. According to Peruvian claims, the territory of the republic stretches from 1° 29′ to 19° 13′ S., and from 61° 55′ to 81° 20′ 40″ W. Generally speaking, the climate is healthy, though a few endemic diseases are found. The climate in some places, as, for instance, Piura and Jauja, has a curative effect on rheumatic, pulmonary, and other complaints.

Area and population.

The area of Peru, according to estimates published by the Geographical Society of Lima, covers 695,730 square miles. No census of the population has been taken since 1876, when the number of inhabitants was returned at 2,657,853, exclusive of uncivilized Indians, said to number about 350,000. In 1896 the Geographical Society of Lima estimated the population at 4,609,999. In the following table the areas of the 18 departments (including Tacna) and two provinces (Callao and Moquegua) and their population (census for 1876, and estimated for 1896) are set forth:—

	Area Square Miles.	Population.	
		Census, 1876.	Estimated, 1896.
Piura	16,824	135,502	213,909
Cajamarca	12,538	213,391	442,412
Amazonas	13,943	34,245	70,676
Loreto	288,456	61,125	100,596
Libertad	10,206	147,541	250,931
Ancachs	16,562	284,091	428,703
Lima	13,310	226,922	298,106
Callao	14	34,492	48,118
Huancavelica	9,251	104,155	223,796
Huánuco	14,024	78,856	145,309
Junin	23,347	209,871	394,393
Ica	8,718	60,111	90,962
Ayacucho	18,185	142,205	302,469
Cuzco	156,270	238,445	438,646
Puno	41,198	256,594	537,345
Arequipa	21,947	160,282	229,007
Moquegua	5,549	28,786	42,694
Apurimac	8,187	119,246	177,387
Lambayeque	4,614	85,984	124,091
Tacna	12,590	36,009	50,449
Total	695,733	2,657,853	4,609,999

Of the total population in the republic, 57 per cent. are estimated to be aborigines; 23 per cent. of mixed blood, white and Indian, or negro and Indian; the remaining 20 per cent. are the descendants of Spaniards, some 6000 to 8000 Europeans, 15,000 Chinese, and 800 Japanese. No accurate data concerning the movement of population throughout the various departments are collected by the national authorities, but the prevalent opinion is that little change has taken place in the number of inhabitants, any increase from births being counterbalanced by the heavy infantile mortality and the effects of alcoholism amongst adults. The immigration to Peru from Europe or elsewhere is on a very small scale, but no official statistics are kept. The number of Chinese is rapidly decreasing, there being a high death-rate and no immigration. The population of the city of Lima in 1897 was 100,144 (48,728 males and 51,416 females). In 1898 the number of marriages in the city was 405; births, 3885 (illegitimate, 2023); deaths, 4213. The population of the city of Callao, which in 1880 was 35,000, is now stated to be 48,118; that of Arequipa, 35,000; and of Cuzco, 30,000.

In Peru the Spanish spoken by the educated classes, though they have a strain of Indian blood, is less corrupted than in most of the South American republics. The Peruvians are, as a rule, courteous and hospitable, proud in spite of their poverty, and patriotic in disputes with foreign powers. The Roman Catholic Church still holds great power amongst them, although its political influence is not so apparent as in former days. Amongst the Indians, the great bulk of the inhabitants, civilization has made comparatively little progress. They have, with the exception of a few remote tribes, adopted Christianity, but in other respects they retain the habits of life practised by their Inca forefathers. Away from the principal towns they live by cultivating small patches of ground, spinning by hand the cloth they need for their simple dress and household purposes, and tending flocks of alpacas and llamas; they are content to acknowledge the authority of the locality. In many districts little Spanish is understood, in some none at all. The inhabitants of the higher valleys possess great power of endurance, and travel long distances over mountainous country with only coca leaf and the barest modicum of food for sustenance. Unfortunately, drunkenness is a common vice in the interior, and is increasing.

National character.

The political constitution is that of 1860. The legislative power is vested in a Senate of 48 members and Chamber of Deputies of 108 members. Members of both houses are chosen for six years, by indirect popular election, in such manner that one-third of the number retire every two years. The executive power is vested in a President, elected by popular vote for four years; with him are elected two Vice-Presidents. The retiring President cannot be elected for the next presidential term. There are six ministers of state—the heads of the departments of foreign relations; justice, worship, and public instruction; the interior and police; war and navy; finance and commerce; public works, industry and internal development.

Government.

Local Government.—The executive power is represented in each of the eighteen departments by a prefect, in each province by a sub-prefect, in each district by a governor, and in each town by a lieutenant-governor. The prefects and sub-prefects are appointed by the President of the Republic, the governors by the prefects, and the lieutenant-governors by the sub-prefects. Each department is governed by a junta or council elected by the provincial councils, each consisting of twelve or sixteen members, according to its importance, and of forty members in the case of Lima. The smaller town districts are under district councils of three members, one chosen by the people and two by the provincial council.

By the constitution the Roman Catholic religion is the religion of the State, and the public exercise of any other is prohibited. Practically, however, there is a certain amount of toleration, and there are Anglican churches and mission schools in Callao and Lima. The marriage disabilities of non-Catholics were modified by an Act of 1897 and by a presidential decree published in May 1899.

Religion and education.

Primary instruction is in charge of the municipal authorities, and though it is nominally compulsory between the ages of five and fifteen, little more than 10 per cent. of the children of school age are under instruction. In 1898 there were 1456 primary schools, with 1618 teachers and an attendance of 60,732. Of the schools, 1152 were official and 304 were private. Of the teachers, 349 were men and 450 were women certificated, while 799 were assistants. Of the children, 39,547 were boys and 21,185 were girls. The expenditure on primary education in 1897 was 476,889 soles, equivalent to about £47,000, equal to 9 soles 78 centavos for each pupil attending the public schools. There is a normal school for the training of women teachers, founded in 1878, and upon which the Government expended 118,560 soles between 1878 and 1897. For secondary education there are twenty-three national colleges in different parts of the republic, twenty-two being for the instruction of boys, and one at Cuzco for girls. In 1897 the number of students at these colleges was 1984, and the average attendance 1403, of whom 1186 passed satisfactory examinations. The number of their teachers was 163. The expenditure on the twenty-three colleges was 186,045 soles (£18,604), equal to 156 soles 86 centavos or about £15 for each student passing the examinations. For higher education there are four universities, at Lima, Arequipa, Cuzco, and Trujillo, granting degrees in theology, law, medicine, science, and literature. In 1897 there were 792 students, of whom 519 passed the requisite tests. The revenues of the four universities in the same year amounted to £20,670, and their expenditure to £20,770. Lima has a school of mines and civil engineering, and there are also military and naval schools. There is a free library in the capital, in addition to one at the university and another at the school of mines. In several of the larger towns there are high schools under the direction of English and German teachers.

Justice is administered by the Supreme Court at Lima, and by superior and minor courts in nine judicial districts. Complaints against the administration of justice, both civil and criminal, are frequently made. On 1st July 1899 the police force consisted of 1152 officers and men of the civil guard, and 1266 officers and men of the mounted gendarmerie.

Justice.

There are in Peru forty-eight charitable societies, formed chiefly for the support of thirty public hospitals within the republic. Their revenues are derived chiefly from lotteries. There is but one national lunatic asylum. There are French, Italian, and Chinese hospitals. Floating hospitals have been authorized at Callao.

Charity.

The army, as fixed by the budget voted in 1899, consists of six battalions of infantry, with a strength of 1940 men; two regiments of cavalry containing 250 men each; four squadrons of 125 men to furnish the presidential escort; and a regiment of mountain artillery of 510 men. Since 1896 a preparatory school has been established for the education of officers for the army and navy, and a military school has been founded at Chorrillos for the instruction of officers and non-commissioned officers of the army. This institution is under the supervision of instructors from the French army, sent out at the request of the Peruvian Government. The small-arm in use is the Männlicher rifle. The Peruvian navy consists of the cruisers *Lima* and *Constitution;* and the transports *Santa Rosa* and *Chalaco*. There are also some smaller vessels, of little practical value for defence.

Defence.

The revenue and expenditure, which, before the outbreak of the war with Chile in 1891, amounted each to about 15,000,000 soles (or £1,500,000) annually, have been as follows in recent years (the sole being taken at the uniform rate of 2 shillings):—

Finance.

Years.	Revenue.	Expenditure.
1887	£525,380	£492,490
1897	1,053,990	1,114,570
1900	1,311,987	1,272,990

For 1900 the sources of revenue and the branches of expenditure were as follows (10 soles = £1):—

Revenue.		Expenditure.	
Customs . .	£741,291	Finance . .	£333,541
Taxes . .	471,982	Army, navy .	304,366
Posts . .	28,144	Government .	378,969
Telegraphs .	5,215	Justice, &c. .	115,429
Various . .	65,355	Various . .	140,685
Total .	£1,311,987	Total .	£1,272,990

The revenue is derived mainly from customs and internal taxes on alcohol, tobacco, opium, and stamps. These taxes have been farmed out since 1896; and a new contract was made in 1900 with a syndicate specially formed for the purpose. Of the total amount collected, the syndicate retains £60,000 for the expenses of collection; of the balance, 94 per cent. goes to the Government and 6 per cent. to the syndicate. Other sources of revenue are a tax on real property and another on mining. The proceeds of the salt monopoly are, by law of 1896, set apart for the redemption of Tacna. The foreign debt, contracted in 1870 and 1872, amounted to £31,580,000, but on this amount no interest was paid after 1876. In 1889 the arrears had accumulated to £23,000,000, and in January 1890 the Government entered into an agreement with the bondholders whereby it was released from all responsibility for the loans. To the bondholders were ceded the State railways for sixty-six years, the remaining guano deposits, and certain mines and lands. The Government agreed to pay them for thirty-three years an annual subsidy of £80,000, secured on the Callao customs; while they undertook, among other responsibilities, the extension and improvement of the railway system. For the purpose of carrying out the terms of this contract a company, called the Peruvian Corporation, was constituted in 1890, the bondholders becoming stockholders in the company on exchanging their bonds for shares. (See below.)

The outstanding internal debt in 1899 consisted of:—

Description.	Soles.
Interest-bearing funded debt . . .	26,606,645
Non-interest-bearing debt	7,500,000
Floating debt	5,000,000
Miscellaneous claims on the treasury . .	9,500,000
Total . . .	48,606,645
	= £4,850,000

The rate of interest paid on the funded debt is 1 per cent. per annum, and the stock is quoted at 7 to 8 per cent. of the nominal value. The non-interest-bearing debt is amortized by tender by law at the rate of 20,000 soles monthly, but this provision has not been regularly attended to. This stock was quoted in 1899 at 3 to 4 per cent. of the nominal value.

Sugar-growing and manufacture have been important for many years, and a considerable extension of the industry took place during the period 1888 to 1898, so that in 1899 the area planted with cane exceeded 160,000 acres. In 1871 the sugar available for export was 4500 tons; in 1881, 80,000 tons; in 1891, 41,400 tons; and in 1901, 110,000 tons. The home consumption of sugar is estimated at 20,000 tons annually. The climate is exceptionally favourable

Industrial development.

for the sugar-planting industry, the labour difficulty being the great hindrance to a more rapid extension. The number of Chinese coolies employed on the plantations is rapidly diminishing; Japanese have been tried, but have proved deficient in strength, and they suffered severely from the climate. The sugar exports to Great Britain in three years were, in tons: 1898, 43,000; 1899, 21,200; 1900, 15,700; to the United States the quantities were: 1898, 14,200; 1899, 38,400; 1900, 57,800. The total value of sugar exported in 1899 was £1,010,351; in 1900, £1,455,842. Next in importance to sugar amongst agricultural products is cotton, both the fibre and seed being exported. The cotton grown in the department of Piura, where extensive works for irrigation are in progress, is of exceptionally good quality. The production was as follows during the specified years:—

Year.	Cotton Fibre.		Cotton Seed.	
	Quantity.	Value.	Quantity.	Value.
	Tons.	£	Tons.	£
1891	4765	105,800	1,695	15,610
1892	9837	322,520	11,378	22,760
1898	6712	247,000	3,322	9,970

In 1899 the exports of cotton fibre amounted to the value of £178,747; in 1900, £326,074. In 1898 the shipments of cotton-seed cake amounted to 1469 tons, valued at £2344. Four-fifths of the total cotton products exported are shipped to Great Britain. The production of rice shows a steady increase. In 1891, 1259 tons, valued at £15,000, were exported; in 1898 it was 4295 tons, valued at £63,350. The shipments of coca-leaf were 128 tons in 1891, 818 tons in 1896, and 406 tons in 1898. Cocoina to the amount of 9590 ℔, worth £65,200, was exported in 1898. In the same year cochineal to the value of £710 was exported, as compared with £3210 in 1896. For the cultivation of coffee many new plantations were formed a few years ago in the Chanchamayo, Pérené, and Paucartambo districts of central Peru. For this purpose the Peruvian Corporation granted land on easy terms, and lent other assistance to settlers, the Government also offering facilities to European immigrants. The result was an increase in production from 191 tons in 1891 to 1215 tons in 1899. Unfortunately, owing to the heavy cost of transport, the scarcity of labour, and the fall in the price of coffee, these enterprises have proved unsuccessful, and the plantations are being abandoned. The cultivation of cacao shows a marked increase. In 1891 the amount exported was 17 tons; in 1898 it reached 618 tons, valued at £34,840. But this industry is hindered by difficulties similar to those which have checked the development of coffee cultivation. The rubber industry promises an important development in the near future. The rubber trees are principally found near the affluents of the Amazon, extending from Iquitos southwards to the rivers Beni, Madre de Dios, and Madeira. Accurate information concerning the quantity collected cannot be obtained, as the greater portion of the product is conveyed to Brazilian ports and shipped as Brazilian. The export from Iquitos, by way of the Amazon, in 1884 was 540 tons; in 1894, 1294 tons; and in 1898, 1525 tons. Pastoral industry is confined to breeding cattle for home consumption, horses for local use, sheep and alpacas for food and wool, llamas for transport purposes, goats for skins and meat, and vicuñas for the hair and hides. No official statistics have been compiled in regard to the number of cattle; the supply is, however, barely sufficient to meet the local demand. The exportation of hides in 1898 was 2127 tons, valued at £83,110. In 1896 the shipments of wool were:—sheep wool, 2,698,000 ℔; alpaca, 2,888,000 ℔; vicuña, 9200 ℔. In the same year 559,000 ℔ of vicuña skins and 677,000 ℔ of goat skins were exported. In 1898 the total amount of all wools exported was 7,674,900 ℔, valued at £308,260. The home consumption of native wools is considerable, the Indian population making the bulk of the cloth they need for the ponchos and other rough clothing for general use in the interior. The principal centres of the wool industry are Arequipa and Cuzco. In the coast provinces there are extensive areas of extremely fertile land, which might be made available for agriculture by irrigation. For instance, in the provinces of Tumbes, Nepena, and elsewhere vast networks of old irrigation canals, made before the Spanish conquest, prove that irrigation was extensively employed by the inhabitants in the time of the Incas. And at the present day the little valley of Chicama, to the north of Trujillo, in which irrigation is to some extent practised, is a standing illustration of the fertility of these coast-lands when properly watered; there, 25,000 acres produce a crop of more than 40,000 tons of sugar annually.

Mining has made substantial progress, partly owing to comparative freedom from revolutionary disturbances, and partly in consequence of the rise in the price of copper. The total mineral output of the republic in 1900 was 32,929 tons, valued at £1,695,055. The Cerro de Pasco copper mines, which have been developed only since 1897, yielded in 1900, 5040 tons of bar copper and 11,700 tons of copper ore, the metal being carried a distance of 65 miles on llamas or donkeys to reach the nearest point of railway communication with the seaboard. Silver is found in greatest abundance in the maritime Andes, especially in the valleys of the Rio Santa, near Carhuaz, Huaraz, and Recuay. Cerro de Pasco is a great mining district, with over 360 silver mines open and at work. Farther south, at Yauli, there are 225 silver mines in operation. Still farther south, in the province of Huarochiri, there are 117; in Huancavelica and Castro Vireyna, 54; in Caylloma, 24; at Puno, over 50.

The official returns of precious metals and mineral ores exported in 1898 and 1899 are:—

Description.	1898. Value in Soles.	1899. Value in Soles.
Silver in bars and piña and mineral ores	9,481,213	10,667,010
Coined silver	482,365	379,940
Worked silver	439,807	11,160
Gold in coin and bars	41,500	6,460
Total	10,444,885	11,064,570
	=£1,044,490	=£1,106,450

The output of copper and copper ores in 1900 was valued at £619,260. Discoveries of rich quartz and placer mines in the Sandia and Carabaya districts occurred in 1896, and attempts were made to work these fields. The natural obstacles of climate and difficulties of transport have as yet prevented any great development in this direction. Deposits of borax, discovered in 1892 about 45 miles south-east of Arequipa, are worked by a British company, which exported in 1897, 11,850 tons, valued at £94,800; and in 1898, 7177 tons, valued at £57,420. Recent explorations have demonstrated that extensive beds of anthracite and bituminous coal exist in the province of Hualgayoc. Coal is found also in the districts of Huamachuco and Cerro de Pasco, where it is used for the mining establishments. Petroleum is found in considerable quantities in the department of Piura. The oil is extracted at Negritos, 6½ miles south-east of Talara. Some of the wells have been sunk to a depth of 900 feet. The kerosene is consumed in Peru, and a considerable quantity of crude oil is used as fuel by factories and other industrial undertakings.

Manufacturing industries are carried on on a small scale. "Panama" straw hats are made especially in the neighbourhood of Payta and Piura, but this industry is declining. In 1897 hats were exported to the value of £16,700; in 1898, of £10,600. About 2,000,000 gallons of spirits are produced annually from sugar-cane. Other manufactures (cotton, woollen, matches, soap, beer, cigars, &c.) have only local interest.

Commerce.—The foreign trade from 1891 to 1900 was as follows (10 soles=£1):—

Year.	Imports.	Exports.
1891	£1,700,133	£1,665,705
1894	1,174,470	1,495,860
1899	2,123,020	3,361,530
1900	2,317,000	4,498,000

In 1899 the chief imports and exports were:—

Imports.		Exports.	
Haberdashery	£798,860	Minerals	£1,066,700
Cottons	377,030	Sugar	1,010,350
Woollens	145,140	Wool	311,810
Furniture, &c.	132,450	Cotton	178,750
Provisions	238,100	Coffee	48,410
Drugs, &c.	92,770	Borax	61,100
Wines, &c.	36,590	Hides	78,340
		Cocaine	67,510

Of the imports in 1900, 46 per cent. were from Great Britain, 16 per cent. from Germany, 13 per cent. from the United States, and 4 per cent. from Chile. Of the exports, 47 per cent. went to Great Britain, 21 per cent. to the United States, 13 per cent. to Chile, and 11 per cent. to Germany.

Shipping.

The sea-borne trade passes mainly through the port of Callao. In 1901, 531 vessels of 755,461 tons entered and 537 of 753,334 tons cleared at that port. Of those entered, 232 of 393,483 tons, and of those cleared 233 of 393,358 tons were British. There entered also 959 small vessels aggregating 12,697 tons, and cleared 952 aggregating 12,951 tons. The ports of Peru are visited regularly by the vessels of the Pacific Steam Navigation Company, and by those of the Chilian Compañia Sud Americana de Vapores. The German "Kosmos" Company, and the "Gulf Line," a Glasgow company, also maintain communication with the Peruvian ports, and another line connects Callao with New York *viâ* Magellan Strait. In 1900 the merchant vessels belonging to Peru were 5 steamers of altogether 4253 tons, and 57 sailing vessels of 24,295 tons.

Roads are badly needed throughout the interior, although the Government is devoting some attention and money to the subject. Since 1896 communication has been opened up through the valley of Chanchamayo, by way of the river Pichis, to Puerto Bermudez, and thence to Iquitos by steamer. But "as a matter of fact it is still easier to reach Iquitos *viâ* New York and Pará, or *viâ* the Strait of Magellan and Pará, than by going across country."[1] A serviceable cart-road has also been made between Sicuani and Cuzco, through the productive provinces of Canchis and Quispicanchis. The total length of railways open to traffic in 1899 was 971 miles, the majority of the lines being held by the Peruvian Corporation. In 1899 there were within the republic 339 post offices, and the postal movement comprised the transmission of 7,481,207 letters and post-cards in the internal service and 1,830,649 in the external. The post office receipts amounted to £80,625, and the expenses to £80,150. The telegraph system in 1899 extended 2037 miles, of which 1438 with 52 offices were under the administration of the Government, and 599 miles in the hands of the Peruvian Corporation. Peru is placed in communication with the outside world by the submarine cables of the Central and South American Company and the West Coast of America Company. The length of telephone wires erected was 3000 miles in 1900, offices being established in all the principal towns for telephonic service in the vicinity.

Communications.

There are four commercial banks in Peru, with paid-up capital and reserve funds amounting in the aggregate to £568,560. A savings bank has also been established, with a paid-up capital of 96,070 soles; the deposits on 31st December 1900 amounted to 1,504,422 soles. The customary rate of interest for loans is 8 per cent. per annum on sound securities. For several years the currency was based on the value of the silver sol, 25 grammes in weight, and ·900 fine. By decree of 9th April 1897 the free coinage of silver was suspended, and the reimportation of Peruvian silver money was prohibited. On 11th December 1897 it was enacted that, pending the coinage of Peruvian gold, customs duties were payable in gold at the rate of 10 soles to £1 sterling in gold coin or in silver, with a surcharge to equal the difference in value. On 29th December 1897 a decree was issued authorizing the coinage of Peruvian gold pieces of 10 soles of the same weight and fineness as the £ sterling. A decree on 10th January 1898 described the new gold coin as 22 millimetres in diameter, ·916 fine, weighing 988 milligrammes, and containing 2 milligrammes of alloy. The name of libra is given to these pieces. The value of Peruvian gold coins minted, 1898–1901, was £218,726. In 1900–01 the rate of exchange was about 10 soles 20 cents. to the libra. The silver coins in circulation are the sol (actual value about 2s.); half-sol = 50 cents.; peseta = 20 cents.; real = 10 cents.; and half-real = 5 cents. There are also current copper coins for values of less than 5 cents. The French metric system is the official standard of weights and measures, but is not in general use. The ounce, 1·104 oz. avoirdupois; the libra, 1·014 ℔ avoirdupois; the quintal, 101·44 ℔ avoirdupois; the arroba, 25·36 ℔ avoirdupois, and of wine, 6·70 imperial gallons; the gallon, ·74 of an imperial gallon; the vara, ·927 yard; and the square vara, ·859 square yard, are all commonly employed.

Money and credit.

As a result of the Grace-Donoughmore contract with the Peruvian Government, the Peruvian Corporation was constituted in 1890 with the following capital:—ordinary shares, £9,000,000; 4 per cent. preference shares, £7,500,000, and power to issue £6,000,000 in 6 per cent. debentures: of the latter, a sum of £3,700,000 has been issued to provide working capital, to cover costs of railway extension, and to settle certain outstanding claims. The Peruvian Government found that the national resources were unequal to the payment of the annual subsidy of £80,000, and in 1893 the amount was reduced to £60,000, and shortly afterwards the payments ceased altogether. In consequence of the failure of the Government to meet its obligations, the Corporation was unable to build an additional 100 miles of railway agreed to in the original contract. The Government is also heavily indebted to the Corporation for the transport of troops and other expenses, and has no funds to discharge these liabilities. The revenues of the Corporation are derived from the earnings of the railways, the steamer traffic on Lake Titicaca, the transport of freight on the river Desaguadero, the sales of guano, and some other small incidental items. The net earnings in 1900–01 were £204,189. In 1896 the interest on the debentures was temporarily reduced to 3 per cent. per annum, higher rates of interest to be paid as the earnings of the Corporation permitted. The Corporation has spent large sums of money in the endeavour to colonize the land conceded to it in the Pérené district, but without achieving satisfactory results. Considerable shipments of guano have been made of recent years, the net income in 1900–01 being £57,441, but the deposits in possession of the Corporation are rapidly becoming exhausted. The hope of the Corporation lies in the development of traffic in the mineral districts and for this an extension of the existing railway system is necessary, especially in connexion with the Central Railway. The Peruvian Government dispute the right of the Corporation to work the mineral deposits at Cerro de Pasco, on the ground that the privilege originally conceded has now lapsed.

The Peruvian Corporation.

(W. W. R.; I. P. A. R.; C. E. A.)

Political History since 1880.—The victory of the Chilians over the combined forces of Peru and Bolivia at Tacna on 7th June 1880 marked the close of the second stage of the war which had broken out in April of 1879. In November 1880 the Chilians began to make preparations for the landing of an army to attack the Peruvian capital. A force of 25,000 men was concentrated at Tacna and Arica under the command of General Baquedano. These troops were embarked on transports and convoyed by Chilian warships to a point a little to the south of Callao, there disembarking on 21st December 1880. The Peruvians, meanwhile, had not been idle. After the crushing defeat at Arica, every effort was made to put Lima in an effectual state of defence. Under the direction of Señor Nicolas de Pierola, who had assumed dictatorial powers after the departure of General Prado to Europe, all the remaining strength of Peru was organized for resistance. The military command was confided to General Andrés Cáceres. Two lines of defence were planned to intercept the advance of the enemy from the seaboard, trenches being dug, the mud walls dividing the various farms loopholed, artillery mounted on all commanding positions, and large supplies of ammunition and stores collected to enable the defenders to sustain a lengthy siege. The Peruvian army at this juncture numbered 26,000 men of the line and 18,000 in the reserves. The defensive measures inspired great confidence, both Señor Pierola and General Cáceres considering the position of Lima practically impregnable. At daybreak on 13th January 1881 the Chilian attack began, and the action soon became general throughout the whole length of the Peruvian first line of defence. The Chilian troops carried the trenches at the point of the bayonet after repeated charges, and at mid-day the defenders were forced to fall back upon the second line of fortifications. In this engagement, known as the battle of Chorrillos, the Chilian loss was 800 killed and 2500 wounded; the Peruvian 5000 killed, 4000 wounded, and 2000 prisoners. On the following day an attempt was made by the diplomatic representatives of foreign Governments in Lima to negotiate peace, but it proved abortive. On 15th January at 2 P.M. the final struggle of the war, known as the battle of Miraflores, commenced, and continued for some four hours. The Chilians were again victorious, and carried the second line of defence, this success placing Lima completely at their mercy. When the fate of the day was no longer in doubt, Señor Pierola, General Cáceres, and such officers as could escape retired to the interior for the purpose of endeavouring to organize further resistance in the mountain districts. At the battle of Miraflores the Chilian losses were 500 killed and 1625 wounded, the Peruvian 3000, including killed and wounded. On 17th January a division of 4000 Chilian troops under command of General Saavedra entered Lima under instructions from the Chilian commander-in-chief to occupy the city and restore order within the municipal limits.

Desultory fighting was now maintained by the remnants of the Peruvian army in the interior, under direction of General Cáceres, against Chilian authority. An attempt was made to constitute a Government with Señor Calderon as President of the Republic and General Cáceres as first Vice-President. The negotiations between this nominal administration and the Chilian authorities for a treaty of peace proved futile, the Chilian occupation of Lima and the Peruvian seaboard continuing uninterruptedly until 1883. In that year Admiral Lynch, who had replaced General Baquedano in command of the Chilian forces after the taking of Lima, sent an expedition against the Peruvians under General Cáceres, and defeated the latter in the month of August. The Chilian authorities now began preparations for the evacuation of Lima, and to enable this measure to be effected a Peruvian administration was organized with the support of the Chilians. General Iglesias was nominated to the office of President of the Republic, and in October 1883 a treaty of peace, known as the treaty of Ancon, between Peru and Chile was signed. The army of occupation was withdrawn from Lima on 22nd October 1883, but a strong Chilian force was maintained at Chorrillos until July 1884, when the terms of the treaty were finally approved. The principal conditions imposed by Chile were the absolute cession by Peru of the province of Tarapacá, and the occupation for a period of ten years of the territories of Tacna and Arica, the ownership of these districts to be decided by a popular vote of the inhabitants of Tacna and Arica at the expiration of the period named. A further condition was enacted that an indemnity of 10,000,000 soles was to be paid by the country finally remaining in possession—a sum equal to about £1,000,000 to-day. The Peruvians in the interior refused to recognize the validity of the nomination of President Iglesias, and at once began active operations to overthrow his authority on the final departure of the Chilian troops. A series of skirmishes now took place between the men in the country under Cáceres and the supporters of the administration in Lima. Affairs continued in this unsettled state until the middle of 1885, Cáceres meanwhile steadily gaining many adherents to his side of the quarrel. In the latter part of 1885 President Iglesias found his position, after some severe fighting in Lima, impossible, and he abdicated his office, leaving the field clear for Cáceres and his friends to assume the administration of public affairs. Under the guidance of General Cáceres a *junta* was then formed to carry on the government until an election for the Presidency should be held and the Senate and Chamber of Deputies constituted. In the following year (1886) General Cáceres was elected President of the Republic for the usual term of four years. The task assumed by the new President was no sinecure. The disasters suffered in the war with Chile had thrown the country into absolute confusion from a political and administrative point of view. Gradually, however, order in the official departments was restored, and peaceful conditions were reconstituted throughout the republic.

The four years of office for which General Cáceres was elected passed in uneventful fashion, and in 1890 Señor Morales Bermudez was nominated to the Presidency, with Señor Solar and Señor Borgoño as first and second Vice-Presidents. Matters continued without alteration from the normal course until 1894, and in that year President Bermudez died suddenly a few months before the expiration of the period for which he had been chosen as President. General Cáceres, who was the power behind the scenes, brought influence to bear to secure the nomination of Vice-President Borgoño to act as chief of the executive for the unexpired portion of the term of the late President Bermudez. This action in regard to the nomination of Señor Borgoño was illegal and unconstitutional, and was bitterly resented by Vice-President Solar, who by right should have succeeded to the office. Armed resistance to the authority of President Borgoño was immediately organized in the south of Peru, the movement being supported by Señores Nicolas de Pierola, Billinghurst, Durand, and a number of influential Peruvians. In the month of August 1894 General Cáceres was again elected to fill the office of President, but the revolutionary movement set afoot against President Borgoño was continued against his successor, and rapidly gained ground. President Cáceres adopted energetic measures to suppress the outbreak: his efforts, however, proved unavailing, the close of 1894 finding the country districts in the power of the rebels and the authority of the legal Government confined to Lima and other principal cities held by strong garrisons. A concentration of the revolutionary forces was now made upon the city of Lima, and early in March 1895 the insurgents encamped near the outskirts of the town. On 17th, 18th, and 19th March severe fighting took place, ending in the defeat of the troops under General Cáceres. A suspension of hostilities was then brought about by the efforts of H.B.M. consul, Mr St John. The loss on both sides to the struggle during these two days was 2800 between killed and wounded. President Cáceres, finding his cause was lost, left the country, a provisional Government under Señor Candamo assuming the direction of public affairs. On 8th September 1895 Señor Pierola was declared to be duly elected as President of the Republic for the following four years. The Peruvians were now heartily tired of revolutionary disturbances, and the administration of President Pierola promised to be peaceful and advantageous to the country. In these circumstances it is not surprising that an insurrectionary outbreak in the district of Iquitos met with small sympathy, and was speedily crushed. In 1896 a reform of the electoral law was sanctioned. By the provisions of this Act an electoral committee was constituted, composed of nine members, two of these nominated by the Senate, two by the Chamber of Deputies, four by the Supreme Court, and one by the President with the consent of his ministers. To this committee was entrusted the task of the examination of all election returns, and of the proclamation of the names of successful candidates for seats in Congress. Another reform brought about by President Pierola was a measure introduced and sanctioned in 1897 for a modification of the marriage laws. Under the new Act marriages of non-Catholics solemnized by diplomatic or consular officers or by ministers of dissenting churches, if properly registered, are valid, and those solemnized before the passing of this Act were to be valid if registered before the end of 1899. Revolutionary troubles again disturbed the country in 1899, when the Presidency of Señor Pierola was drawing to a close. In consequence of dissensions amongst the members of the election committee constituted by the Act of 1896, the President ordered the suppression of this body. Seizing on this action as a pretext, a group of malcontents under the leadership of one Durand, a man who had been prominent in the revolution against General

Cáceres in 1894–95, conspired against the authorities and raised several armed bands, known locally as *montaneras*. Some skirmishes occurred between these insurgents and the Government troops, the latter generally obtaining the advantage in these encounters. In 1899 several of these armed bands were still at large in the mountainous districts, but they were not regarded as formidable antagonists by the authorities, nor was any great sympathy extended to them by the rural population. In September 1899 President Pierola vacated the Presidency in favour of Señor Romaña, who had been elected to the office as a popular candidate and without the exercise of any undue official influence. President Romaña was educated at Stonyhurst, in England, and was a civil engineer by profession. He was credited with the desire to help on the development of Peru without any political ambitions to serve either on his own behalf or on that of his friends.

The principal political problem before the Government of Peru at the opening of the 20th century was the question with Chile of the ownership of the territories of Tacna and Arica. The period of ten years originally agreed upon for the Chilian occupation of these provinces expired in 1894. At that date the peace of Peru was so seriously disturbed by internal troubles that the Government was quite unable to take active steps to bring about any solution of the matter. Since 1894 negotiations between the two Governments have been attempted from time to time, but without any satisfactory results. The question hinges to a great extent on the qualification necessary for the inhabitants to vote, in the event of a plebiscite being called to decide whether Chilian ownership be finally established, or the provinces revert to Peruvian sovereignty. Peru has proposed that only Peruvian residents shall be entitled to take part in a popular vote; Chile rejects this proposition, on the ground that all residents in the territories in question shall have a voice in the final decision. The agreement between Chile and Bolivia, by which the disputed provinces are to be handed over to the latter country if Chilian possession be recognized, is also a stumbling-block, a strong feeling existing among Peruvians against this proceeding. It is not so much the value of Tacna and Arica that makes the present difficulties in the way of a settlement as it is that the national pride of the Peruvians ill brooks the idea of permanently losing all claim to this section of country. The money, about £1,000,000, could probably be obtained to indemnify Chile if occasion for it arose.

The question of the delimitation of the frontier between Peru and the neighbouring republics of Ecuador, Colombia, and Brazil has also cropped up at intervals. A treaty was signed with Brazil as far back as 1876, by which certain physical features were accepted by both countries as the basis for the boundary, but nothing has been accomplished towards definitely surveying the proposed line of limits. In the case of Ecuador and Colombia a dispute arose in 1894 concerning the ownership of large tracts of uninhabited country in the vicinity of the head-waters of the Amazon and its tributaries. An agreement was proposed between Peru and Ecuador in connexion with the limits of the respective republics, but difficulties were created to prevent this proposal from becoming an accomplished fact by the pretensions put forward by Colombia. The latter state claimed sovereignty over the Napo and Marañon rivers on the grounds of the ecclesiastical jurisdiction exercised over this section of territory during the period of Spanish dominion, the Government of Colombia pretending that these ecclesiastical rights to which Colombia became entitled after her separation from the Spanish Crown carried also the right of absolute ownership. In a treaty signed by the three interested states in 1895 a compromise was effected by which Colombia withdrew a part of the claim advanced, and it was agreed that any further differences arising out of this frontier question should be submitted to the arbitration of the Spanish Crown. The boundaries had in 1902 not yet been surveyed. (C. E. A.)

Peru, a city of Lasalle county, Illinois, U.S.A., on the north bank of the Illinois river, and on the Chicago, Burlington, and Quincy and the Chicago, Rock Island, and Pacific railways, north of the centre of the state, at an altitude of 462 feet. It is built on the face and top of the river bluffs, with a regular plan, and is divided into five wards. It is in an agricultural and coal-mining region, and has large trade and varied manufactures. Population (1890), 5550; (1900), 6863, of whom 2095 were foreign-born.

Peru, a city of Indiana, U.S.A., capital of Miami county, on the Wabash river, the Wabash and Erie canal, and the Wabash and the Lake Erie and Western railways, north of the centre of the state, at an altitude of 649 feet. It is in an agricultural region, has considerable trade, and contains varied manufactures. Population (1880), 5280; (1890), 7028; (1900), 8463, of whom 737 were foreign-born and 67 negroes.

Pesaro, a town, episcopal see, and capital of the province of Pesaro and Urbino, the Marches, Italy, on the Adriatic coast, 37 miles by rail north-west of Ancona. The house in which Rossini was born now contains collections of paintings, pottery, and furniture. The Rocca Costanza is now used as a prison. Pesaro possesses a technical institute, an agricultural school, a school of the industrial arts, and a meteorological observatory; also a monument (1896) to the statesman and author, Mamiani delle Rovere (1799–1885), and a statue to Garibaldi (1891). The Foglia is crossed by an ancient Roman bridge. Pesaro is famous for its figs. Population (1881), 13,943; (1901), 25,115.

Pescadores.—A group of islands (called by the Japanese *Hôko tô*, or *Hôko Guntô*), lying 30 miles westward of Formosa, between 23° and 24° N. Flat and with unproductive soil, they are swept during one half of the year by violent north-east winds, and also lie full in the path of the numerous typhoons that rush up the Gulf of Formosa. The anchorage is at Makyû (Japanese, *Makun*). The islands number 48, have a coast-line of 98·67 miles, a total area of 85·50 miles, and a population of 51,719. Meteorological observations taken by the Japanese during a period of three years show that the annual average of tempestuous days is 237.

Pesháwar, a city of British India, giving its name to a district and division of the Punjab, the capital of the North-West Frontier Province. The city is 1165 feet above the sea, near the left bank of the river Bara, 11 miles from Jamrud, at the entrance of the Khaibar Pass; the railway station is 1588 miles north-west of Calcutta. Population (1881), 79,982; (1891), 84,191; municipal income (1897–98), Rs.1,97,509; death-rate (1897), 27 per thousand. The city proper is surrounded by a mud wall with sixteen gates. The suburbs contain gardens stocked with fine fruit-trees. Two miles west lie the cantonments, which accommodate a strong force of all arms. Pesháwar is the depot for trade with Afghanistan and central Asia, and has manufactures of scarves and cutlery. The water-supply is derived from the river Bara. The station of the Church Mission is called after Sir Herbert Edwardes. There are four high schools, nine printing-presses, and Hindu and Mahommedan religious associations. In May 1898 there was a very destructive fire.

The district of PESHÁWAR has an area of 2444 square miles; population (1881), 592,674; (1891), 703,768; (1901), 786,406; showing an increase of 19 per cent. between 1881 and 1891, and of 11·7 per cent. between 1891 and 1901, the increase having been continuous since 1868; average density, 322 persons per square mile. The land revenue and rates in 1897–98 were Rs.11,43,287, the incidence of assessment being Rs.0:13:3 per acre; cultivated area, 697,020 acres, of which 405,290 were irrigated, including 155,066 from Government canals; number of police, 1117; number of schools (1896–97), 297, attended by 7401 boys, being 9·3 per cent. of the boys of school-going age; death-rate (1897), 22·9 per thousand. The principal crops are wheat, barley, maize, millet, oil-seeds, with a little cotton and sugar-cane. In 1897–98 the Swat river canal irrigated 138,557 acres, and the net profits were Rs.1,41,184, being 3·5 per cent. on a capital outlay of just Rs.40,00,000. The North-Western Railway crosses the district from Attock, with its terminus at Pesháwar city, 47 miles. The Indus is navigable for 146 miles.

The division of PESHÁWAR consists of the three frontier districts of Hazara, Pesháwar, and Kohat. Total area, 8206 square miles; population (1891), 1,423,231; (1901), 1,715,248, showing an increase of 20·5 per cent.; average density, 209 persons per square mile.

Peterborough, an ancient city and parliamentary and municipal borough of Northamptonshire, on the river Nene, 76 miles north of London by rail. The choir of the cathedral was reopened in 1889 after being closed, for thorough restoration, for six years. During 1888–89 the lantern tower was rebuilt, the north and south transepts were underpinned, and three columns repaired in the choir. During 1889–90 the internal masonry of the nave, aisles, and western transepts was cleaned, and in 1895 the restoration of the west front and other parts was commenced. Great care has been exercised in preserving the many interesting discoveries made during the carrying out of this work—the most important being the site of the cruciform Saxon church, enclosed within a crypt under the south transept. A public library was established in 1893. The school of art, science, and technology in the minster precincts consists of nine class-rooms and two workshops. Certain free studentships are offered annually by examination, and the students numbered in 1898 about 300. On the outskirts extensive brick-works have grown up, their forest of stalks forming a remarkable feature in the landscape. The soke, or liberty, of Peterborough was in 1888 declared a separate administrative county from the remainder of Northamptonshire. Except for parliamentary and militia purposes, it is entirely independent. Population (1881), 21,228; (1891), 25,171; (1901), 30,870.

Peterborough, a town and port of entry of Ontario, Canada, and capital of the county of the same name, situated 70 miles north-east of Toronto, on the Otonabee river and the Grand Trunk and Canadian Pacific railways. The five falls of the Otonabee at this point, with a total descent of 50 feet, furnish power for a large number of manufacturing establishments, whilst its canalization as part of the Trent canal will give communication with Lake Ontario and Georgian Bay. The most important buildings are the post office, custom-house, hospital, and Young Men's Christian Association building. It has an electric railway, and contains manufactories of electrical machinery and supplies, iron and steel bridges, and agricultural implements, saw, flour, and woollen mills, and pork-packing establishments. Exports for 1898–99 were valued at $616,972, and imports, $697,467. Population (1881), 6812; (1891), 9717; (1901), 11,239.

Peterhead, a seaport, market town, and parliamentary burgh (Elgin group) of Aberdeenshire, Scotland, 33 miles by road north-north-east of Aberdeen. The harbour comprises three basins covering an area of 21 acres. In 1888, 590 vessels of 63,802 tons entered; 540 vessels of 62,066 tons in 1898. Exports (mostly herrings) were valued at £259,040 in 1888 and £156,250 in 1898 (228,307 barrels). The value of the fish landed at the port in 1899 was £117,467. There are three trawling companies employing six trawlers, and a steam herring fishing company has been formed. The Arctic seal and whale fishing is extinct. The harbour of refuge has been under construction by convict labour since 1886. New police buildings have been erected. There is an academy with an elementary department. Population (1881), 10,922; (1891), 12,195; (1901), 11,763.

Petermann, August Heinrich (1822–1878), German cartographer, was born at Bleicherode, near Nordhausen, on 18th April 1822. At the age of seventeen he entered the Geographical School of Art in Potsdam, and in 1845 proceeded to Edinburgh to assist Dr Keith Johnston in the production of an English edition of the *Physical Atlas* of Berghaus. In 1847 he came to London, and during the next seven years published a large number of maps, including an atlas of physical geography (with Thomas Milner), and an account of Barth's expedition to Central Africa, 1855, besides contributing a number of geographical articles to the *Encyclopædia Britannica* which was then appearing. In 1854 he became director of the Geographical Institute of Julius Perthes in Gotha, and editor of its well-known *Mitteilungen*. His diligent research and careful delineation did much towards elucidating the geography of the interior of Africa and of the North Polar regions, and he drew up the plans, descriptions, and maps of all the German expeditions to Africa and to the Poles in his time. His merits as a scientific cartographer were universally recognized, and most of the geographical societies of the world numbered him among their honorary members. The University of Göttingen conferred an honorary degree upon him, and Queen Victoria, at the suggestion of Chevalier Bunsen, appointed him Physical Geographer-Royal. Dr Petermann died by his own hand at Gotha, 25th September 1878. (G. F. B.)

Peters, Karl (1856–——), German colonial administrator, was born at Neuhaus on the Elbe on 27th September 1856, being the son of a Lutheran clergyman. He studied at Göttingen, Tübingen, and Berlin, and in 1879 was awarded a gold medal by the Berlin University for his "Frieden zu Venedig" ("Peace of Venice, 1178"). After visiting London to study English principles of colonization, he returned to Berlin, and promoted the German Colonization Society (Deutsche Kolonialverein). In the autumn of 1884 he proceeded to East Africa, and concluded in the name of his society treaties with the chiefs of Useguha, Nguru, Usagara, and Ukami. Returning to Europe early in 1885, he undertook the management of the German East Africa Company, which had obtained an imperial charter. In 1888 he undertook an expedition from the east coast of Africa for the relief of Emin Pasha. He reached Victoria Nyanza in 1889 after great hardships, and learned of the departure of Emin with Stanley's expedition. Hearing of the hostilities between the Christians and Mahommedans in Uganda, he went to the assistance of King Mwanga, with whom he concluded treaties in favour of Germany. These treaties were, however, annulled by the Anglo-German Convention of July 1890. On his return to Germany Peters was received with great honours, and in 1891 published an account of his expedition entitled *Die deutsche Emin-Pasha-Expedition*, which was translated into English. In 1891 he went out to East Africa as Imperial High Commissioner, assisted in determining the Anglo-German boundary, and founded a German station on Kilimanjaro. Returning to Germany in the following year, he was employed in the Colonial Office from 1893 to 1895. In 1896 he removed to London, where he occupied himself in forming the Dr Karl Peters Estates and Exploration Company. The company, which was registered on 11th July 1898, was formed to prospect certain regions in Central and South-Eastern Africa, and to acquire the right to locate 500 mining shares in the British South Africa Company's territory, the same number in the Mozambique Company's territory, and also in the Zambezi Company's territory. In the interests of the company Peters explored the Fura district and Macombe's country on the Zambezi, where in 1899 he discovered ruins of ancient cities and deserted gold mines. On his return in 1901 he brought out an account of his explorations, and settled in London as managing director of the company for South Africa. Besides the books already mentioned, and some smaller treatises, Peters has published a philosophic work entitled *Willenswelt und Weltwille* (1883), and a disquisition on early gold production entitled *Das Goldene Ophir Salomos* (1895), translated into English in 1898.

Petersburg, a city of Virginia, U.S.A., on the right bank of the Appomattox river, 12 miles from its mouth, at the head of navigation and at the foot of the falls. It was formerly in Chesterfield, Dinwiddie, and Prince George counties, but is now independent of county government. It is well laid out on the sloping river bank, is divided into six wards, and has an excellent water-supply by pumping. It is on the Atlantic Coast line, the Seaboard Air line, and the Norfolk and Western railways. It has in the falls a fine water-power, which is largely utilized in manufactures. In 1890 the city contained 271 manufacturing establishments with a total capital of $3,911,240, employing 5525 hands, and with a total product of $7,167,004. The principal article of manufacture was tobacco, the value of which was $2,900,000; other prominent industries were canning and the making of cotton goods and flour-milling. Petersburg is the seat of the Southern Female College, a non-sectarian institution, which had in 1899 twelve instructors and 100 students. Population (1890), 22,680; (1900), 21,810, of whom 269 were foreign-born and 10,751 negroes.

Petit-Quevilly, Le, town, arrondissement of Rouen, department of Seine-Inférieure, France, 2½ miles south-west of Rouen by rail, on the Seine. The chapel of St Bruyères represents a leper hospital founded by Henry II. of England. The principal industries are cotton spinning and weaving, dyeing, and the manufacture of cables, gear for machinery, gutta-percha goods, chemicals, soap, cartridges and safety matches for mines. Population (1881), 7181; (1901), 13,885. The commune of Le Grand-Quevilly had in 1901 a population of 1939.

Petőfi, Alexander (1823–1849), the greatest lyric poet of Hungary, was born at Kis-Körösö, Pest county, on New Year's Day, 1823. The family received its diploma of nobility from the Emperor Leopold in 1688, but the ultra-patriotic Alexander early changed the old family name, Petrovics, which pointed to a Croatian origin, into the purely Magyar form of Petőfi. The lad's early days were spent at Félegyház and Szabadszállás, the most Hungarian parts of Hungary, where he got most of his early education, including a good grounding in Latin. German he learnt subsequently at Pesth, and French he taught himself. He began writing verses in his twelfth year, while a student at the Aszód gymnasium, where he also displayed a strong predilection for the stage, to the disgust of his rigorous father, who formally disowned his son, early in 1839, for some trifling peccadillo, and whose tyrannical temper became downright furious when a series of misfortunes ruined him utterly in 1840. For the next three years Petőfi led the wretched life of a strolling player, except for a brief interval when, to escape starvation, he enlisted as a common soldier in an infantry regiment. During the greater part of 1842 we find him a student at the Calvinist College at Pápá, where he made the acquaintance of young Jókai, and wrote the poem "Borozó," which the great critic Bajza at once inserted in the leading literary review, the *Athenæum*, 22nd May 1842. In November of the same year the restless poet quitted Pápá to join another travelling troupe, playing on one occasion the Fool in *King Lear*, and after wandering all over Hungary and suffering incredible hardships, finally settled down at Pesth (1844), where for a time he supported himself by all sorts of literary hack-work. Nevertheless, in the midst of his worst privations he had read voraciously, and was at this time profoundly influenced by the dominant Romanticism of the day; while, through Tieck, he learnt to know and value the works of Shakespeare. His first volume of original poems was published in 1844 by the Society Nemzeti Kör, through the influence of the poet Vörösmarty, when every publisher had refused his MS., and the seventy-five florins which he got for it had become a matter of life or death to him. He now became a regular contributor to the leading papers of Pest, and was reconciled to his parents, whom he practically supported for the rest of their lives out of his literary earnings. His position, if not exactly brilliant, was now at least secure. The little volume published by the Nemzeti Kör was followed by the parody, *A Helység Kalapácsa* (1844); the romantic epic, *János Vitéz* (1844); *Ciprislombok Etelké Sirjáról*, a collection of passionate elegies over his lost love, Etelké Csapó (1845); *Uti Jegyzetek*, an imitation of Heine's *Reisebilder* (1845); *Szerelem Gyöngyei* (1845); *Felhök* (1846); *Szerelme ès házassága* (1846), and many other volumes. The first edition of his collected poems appeared in 1847. Petőfi was not yet twenty-five, and, despite the protests of the classicists, who regarded him with something of the cold dislike with which the Scottish reviewers regarded the Lake School, the best heads in Hungary, poets like Vörösmarty and critics like Szemere, already paid him the homage due to the prince of Magyar lyrical poets. The great public was enthusiastic on the same side, and posterity, too, has placed him among the immortals. Petőfi is as simple and genuine a poet of nature as Wordsworth or Christian Winther, and his erotics, inspired throughout by a noble idealism, have all Byron's force and fervour, though it is perhaps in his martial songs that Petőfi's essentially passionate and defiant genius asserts itself most triumphantly. On 8th September 1847 Petőfi married Julia Szendrey, who bore him a son. When the revolutionary war broke out, he espoused the tenets of the extreme democratic faction with a heat and recklessness which estranged many of his friends. He took an active part in the Transylvanian campaigns of the heroic Bem; rose by sheer valour to the rank of major; was slain at the battle of Segesvár (31st July 1849), and his body, which was never recovered, is supposed to have been buried in the common grave of the fallen honveds in the churchyard of Fehéregyház. The first complete edition of Petőfi's poems appeared in 1874. The best critical edition is that of Haras, 1894. There are numerous indifferent German translations.

See Ferenczi. *Petőfi Életrajza.*—Fischer. *Petőfi's Leben und Werke.* (R. N. B.)

Petoskey, a city of Emmet county, Michigan, U.S.A. It is in the north-west part of the lower peninsula on Lake Michigan. It is entered by the Pere Marquette and the Grand Rapids and Indiana railways. Population (1890), 2872; (1900), 5285, of whom 856 were foreign-born and 24 negroes.

Petra, a ruined site, in 30° 19′ N. and 35° 31′ E., lying east of Wady-el-Arabah, the great valley running from the Dead Sea to the Gulf of Akabah. Access has been easy since the occupation of the plateau of Moab and Edom by Turkish troops, and a complete survey of the ruins and site of the ancient town has been made by Dr Brünnow. Petra was built in a basin in the "Nubian" sandstone through which the Wádi Músá brook runs—entering it by a deep, narrow gorge, the Sík, and leaving it by another of somewhat similar character. The Roman road running northwards from Petra, over the Edomite plateau, can be traced almost throughout, and the actual approach to the town is not nearly so difficult as travellers entering it by the Sík have supposed. Petra was occupied by Baldwin I. of Jerusalem, and formed the second fief of the barony of Krak, under the title Château de la Vallée de Moyse, or Sela—the territory being called Li Vaux Moyse. It remained in the hands of the Franks until 1189, and in 1217 there was still a small monastery on Mount Hor. There are several remains of the Frank occupation. The Nabataean inscriptions found in recent years have been edited for the Corpus of Semitic Inscriptions by Euting. At el-Beidha and el-Barid, near Petra, the rock excavations are almost of equal interest.

A few details noticed by recent travellers will be found in the *Quarterly Statements* of the Pal. Exp. Fund for 1898 and 1900, and in the *Revue Biblique* for 1897. There is a good general description of the site and ruins in BAEDEKER-SOCIN'S *Handbook to Syria and Palestine.*

Petrie, William Matthew Flinders (1853-——), English Egyptologist, was born at Charlton on 3rd June 1853, being the son of William Petrie, C.E. His mother was the daughter of Captain Matthew Flinders, the Australian explorer. He took an early interest in archæological research, and between 1875 and 1880 was busily engaged in studying ancient British remains at Stonehenge and elsewhere; in 1880 he published his book on Stonehenge, with an account of his theories on this subject. He was also much interested in ancient weights and measures, and in 1875 published a work on *Inductive Metrology;* his profound knowledge of the history of weights and measures was afterwards shown in his article in the ninth edition of this Encyclopædia. In 1881 he began the series of surveys and excavations in Egypt with which his name is so prominently connected, beginning with the pyramids at Ghizeh, and following up his work there by excavations at the great temple at Tanis (1884), and discovering and exploring the long-lost Greek city of Naukratis in the Delta (1885), and the towns of Am and Daphnæ (1886), where he found important remains of the time when they were inhabited by the Pharaohs. Between 1888 and 1890 he was at work in the Fayum, opening up Hawara, Kahun, and Lachish; and in 1891 he discovered at Medum the earliest known temple. Much of this work was done in connexion with the Palestine Exploration Fund. By this time his reputation was established. He published in 1893 his *Ten Years' Diggings in Egypt*, was given the honorary degree of D.C.L. by Oxford, and was appointed Edwards Professor of Egyptology at University College, London. In this position he continued to do most valuable work, organizing collections and exhibitions, and lecturing in connexion with them, besides constantly adding by active research and excavation to a scientific knowledge of ancient Egypt. For an account of the results of his work, see EGYPTOLOGY. Here it is only possible to mention his discovery of ancient sculpture at the temple of Koptos (1894), his remarkable find of evidences of an unknown race of prehistoric Egyptians at Nagada (1895), his exploration of the six temples at Thebes (1896), and his discovery of traces of Libyan foreigners in Egypt during the 12th dynasty (1898). Professor Flinders Petrie has published many volumes dealing with his work.

Petrolea, a town and port of entry in Lambton county, Ontario, Canada, situated 42 miles west of London on Bear creek, an affluent of Sydenham river, and on the Grand Trunk and Michigan Central railways. It is in the midst of the oil region of Canada, and there are in the neighbourhood about 6000 producing wells, with an aggregate output of 20,000 barrels of crude oil per annum. Population (1881), 3465; (1891), 4357; (1901), 4135.

PETROLEUM.

I. INDUSTRY AND PRODUCTION.

DURING the period which has elapsed since the article PETROLEUM in the ninth edition of the *Encyclopædia Britannica* was published (in 1885), the petroleum industry has undergone remarkable expansion. Fresh sources of supply have assumed importance, new uses have developed, and very considerable improvements, with resulting economies, have been effected in the work of production of the crude oil, and still more in the methods adopted in the refining, transport, and distribution of the commercial products. The author of that article (a high authority) felt justified in devoting nearly the whole space allotted to his subject to a description of American petroleum, and did not consider it necessary to make more than a brief mention of the petroleum of Russia and other countries. Since that time the Russian petroleum industry has assumed an importance not inferior to that of the oil business of the United States; while in Java, Sumatra, and Borneo, in Burma and Assam, and in Galicia, Rumania, and Alsace, highly productive oil-fields have been opened up. The rapid growth of the Russian petroleum trade has unquestionably been mainly due to the circumstance that the residuum, for which at first it was difficult to obtain a market, has long since been found to be an excellent fuel, and has become the principal product. This virtual conversion of the business into a fuel industry has admitted of the marketing of the immense quantities of oil produced in Russia without interference with the sale of American petroleum. The present tendency is towards the creation of a number of more or less local industries, with the result that the world's supplies of petroleum, which at one time were contributed almost entirely by the United States, and more recently by that country and Russia, are being obtained from a gradually increasing number of centres.

That markets can be found for all the oil which can be produced in localities so situated geographically that the cost of transport is not prohibitive, is usually admitted, and indeed is scarcely open to doubt when the scope for increased employment of the various products is considered. So long as petroleum was chiefly of value as yielding an oil for burning in lamps, as a candle-making material, or as a lubricant for machinery, the fear of over-production was justifiable, for the growth of the trade in countries already using petroleum products for the purposes specified could not be very rapid, and new markets had to be sought in less civilized countries, where inferior illuminating agents and lubricating materials were in use. With the recognition, however, of the value of petroleum as liquid fuel, and as a source of gas for illuminating purposes, the whole complexion of the case became altered, and the industry at once assumed an extensive character, which, notwithstanding its vast aggregate volume, it had not previously possessed. The effect of this upon the Russian petroleum trade has already been mentioned, but it remains to be said that the substitution of petroleum for coal in gas-making has also been a prominent feature of the development which the industry as a whole has undergone in recent years. A very large proportion of the gas used as a source of light in the United States is water-gas, to which light-giving power is furnished by carburetting it with the gaseous products of petroleum, and already in Great Britain large quantities of petroleum distillate are similarly employed. Amongst other recent uses to which petroleum products are being put is that of furnishing power, through the agency of an internal-combustion motor similar to a gas engine, the most successful types of automobile vehicles for carrying light weights at high speed for long distances being furnished with petroleum-spirit motors. Oil engines, in which the ordinary petroleum burning oil is similarly used, are also now largely employed in rural districts where gas is not obtainable, or is comparatively costly. Apart from these modern features of the industry, there has been a steady progression in the world's consumption of petroleum, and especially in the substitution of mineral oils for animal and vegetable oils in the lubrication of machinery. To afford some idea of the present magnitude of the trade, it may be stated that a pipe 41 inches in diameter would be needed for the conveyance of the petroleum which the world is at present using, assuming a rate of flow of 3 feet a second; and that for the storage of a year's supply, a tank 929 feet in length, breadth, and height would be required.

Expansion of the industry.

The technology of the business has been marked by several important advances. The system of drilling the wells in the United States, which closely resembles the ancient method practised by the Chinese, has been improved only in points of detail, and has remained practically unaltered for many years. In Russia a different system, in which the drilling instruments are attached to iron rods instead of to a manila cable, is usually employed. The wells in the latter country, though of less depth than the majority of those in the United States, are of far larger diameter and are much more costly to bore. The productiveness of a Russian oil "fountain" is, however, enormously in excess of the average production of wells in America, though the flow is not, as a rule, long sustained. In the Russian and Rumanian oil-fields electric motors have been substituted to a considerable extent for steam engines, and in a few instances oil engines have been successfully introduced. From those wells in the Russian oil-fields which do not flow, it is customary to raise the oil by means of a cylindrical baler, the presence of sand in the oil interfering with the use of the ordinary lift-pump adopted in the United States. Recently a system of raising the oil by means of a stream of compressed air has been successfully tested in the Baku district, and seems likely to be largely employed. In the refining of petroleum the principal features of improvement have been, in Russia, the general introduction of the continuous system of distillation, which effects considerable economy in time, fuel, and labour; and in the United States, the successful treatment of crude oil containing sulphur compounds, whereby these impurities are practically eliminated, and a class of crude oil, which could not previously be advantageously worked, is rendered commercially valuable.

Recent advances.

Doubtless, however, the salient feature of advance has been the general adoption of the bulk system of transport and distribution. It is not many years since competent authorities expressed grave doubts as to the possibility of safely carrying petroleum in bulk across the Atlantic in stormy weather, and it must be admitted that the first experiments in this direction were not attended with hopeful results. The Russian petroleum trade was the first to benefit by the successful introduction of a system of marine transport of petroleum, the credit for which belongs to the brothers Nobel. Subsequently British shipbuilders, and notably the firm of Armstrong, Mitchell and Company, directed their attention to the construction of steamships suitable for this traffic, and at the present time the fleet of petroleum tank steamers is a large and very valuable one. These vessels sail regularly at frequent intervals from American and Russian ports, carrying cargoes of oil in bulk for the supply not only of the markets of Great Britain and the European continent, but also those of the East and elsewhere. Concurrently with this general introduction of marine transport in bulk, there has been a corresponding extension in the use of pipe lines, tank barges, tank railway waggons, and tank road waggons for distribution, so that much of the oil finds its way from the mouth of the well to the shop of the retailer, or even to the premises of the actual consumer, without having been put into any special package, such as the 40-gallon barrel or 4-gallon tin can in which it was formerly delivered; and this, as will be readily understood, results in a considerable saving of expense.

The closer study which has for some years been devoted to the geological features of petroliferous territories has resulted in the acquisition of more exact knowledge of the age and structure of the rock-formations concerned. This knowledge has been found of high practical value in enabling the expert to select favourable sites for boring operations, and it may be urged that no labour should be spared which may contribute to the completeness and accuracy of the available records. On all well-conducted petroleum properties it is now customary to note with care and precision the character of the strata perforated by the drill, so that a complete section may be prepared from the recorded data. In some cases the depths are stated with reference to sea-level instead of being taken from the surface, and it is much to be desired that this practice should become universal, as the correlation of the rapidly-accumulating data is thus simplified. There is scarcely any part of the globe which does not afford some trace of bitumen, in the gaseous, liquid, or solid state, and it is a common fallacy that petroleum is a comparatively rare substance, in the sense of occurring in only a few localities. On the other hand, while the areas in which it occurs in sufficient concentration, or in such quantity as to be of commercial value, are both fairly numerous and extensive, the discovery of petroleum in a given locality is not necessarily of industrial importance. There are few substances more widely distributed in nature, but the conditions requisite

Geological occurrence.

for the creation of a valuable store of the material exist only in a limited number of places. No definite connexion can be traced between the localities where it is known to occur and the present limits of sea and land, equally rich and equally scanty deposits being found in the hearts of continents and in the oceanic islands. Similarly, the tropics, the temperate and the polar circles are about equal in respect of their possession of bitumen, but it may be noted that the greater part of the known oil-bearing territory is north of the equator. Several writers have pointed out that the principal petroleum deposits of the world are intimately associated with the great mountain chains. It must not, however, be assumed that there is any necessary connexion between the origin of petroleum and the positions of the deposits in relation to the mountain ranges, the rational explanation of the intimate relation referred to being that it is usually in the neighbourhood of the mountains that the strata have, by the same changes as those which created the mountains and valleys, been thrown into a form suitable for the collection or concentration of the oil. The geographical distribution of petroleum affords most valuable evidence in relation to its origin. For a rare mineral special local conditions may be of paramount importance, but for a substance of almost world-wide occurrence, the theory of origin must harmonize with conditions that were either widespread simultaneously or of frequent recurrence in various places. We find that every one of the great divisions of geological time has produced some form of bitumen, and in the following table Mr W. H. Dalton has attempted to classify on this basis the various localities in which petroleum has been found in large or small quantities :—

Geological Periods.	Localities.
Quaternary .	Lancashire, Schleswig-Holstein, Red Sea, Mexico.
Pliocene .	Italy, Sumatra, Borneo, New Zealand.
Miocene .	Auvergne, Italy, Algeria, Egypt, Zante, Rumania, Austria, Caucasus, Persia, Turkestan, Assam, Burma, Eastern Archipelago (Java, Sumatra, Borneo, &c.), Japan, Alaska, California, Mexico, West Indies, New Zealand.
Oligocene .	Switzerland, Alsace, Galicia, Caucasus, Alaska, and other areas included under Eocene or Miocene by various authors.
Eocene .	Spain, Italy, Egypt, Turkey, Rumania, Austria, Caucasus, Baluchistan, Punjab, Assam, Burma, Eastern Archipelago, Utah, Texas, Mexico, New Zealand.
Cretaceous .	Switzerland, Hanover, Greece, California, Wyoming, Colorado, Athabasca, New Zealand.
Neocomian .	Spain, East France, Switzerland, Hanover, Austria, Rumania, Syria, Venezuela, West Indies, and other areas included under Cretaceous by various authors.
Jurassic .	England, Switzerland, Alsace, Hanover, Colorado, Mexico, Argentine Republic, and possibly other South American regions.
Triassic .	Alsace, Hanover, Punjab, China.
Permian .	Autun, Saxony.
Carboniferous .	Great Britain, South Russia, Central and Eastern United States, New Brunswick. Some of the deposits now assigned to the Carboniferous were formerly classified with the Devonian.
Devonian .	England, North Russia, Ontario.
Silurian .	East Canada, Central and Eastern United States, Newfoundland.
Cambrian .	British Columbia and Alberta (Kootenay Pass).
Archæan .	Sweden (bituminous gneiss of Nullaberg), East Canada (graphite).

It should be pointed out that the deposits which are of chief commercial importance occur in the older rocks (Carboniferous and Silurian) on the one hand, and in the comparatively new Tertiary formation on the other, the intermediate periods yielding but little, or at any rate far less abundantly.

Formation of Deposits.

The anticlinal or terrace structure which characterizes the principal oil-fields of the world is a most important factor in the accumulation of oil and gas. The anticlines, which have been formed by the slow contractile movements of the earth, usually occur as a series of broad low arches separated by synclines. They often extend for long distances, with great regularity, but are not infrequently crossed by subsidiary anticlines, which themselves play a not unimportant part in the aggregation of the oil. Owing to difference of density the oil and water present in the anticlines separate into two layers, the upper consisting of oil which fills the anticlines, while the water remains in the synclines. Any gas which may be present rises to the summits of the anticlines. When the slow folding of the strata is accompanied by a gradual local descent, a modified or "arrested" anticlinal structure, known as a "terrace," is produced, the upheaving action at that part being sufficient only to arrest the descent which would otherwise occur. The terraces may thus be regarded as flat and extended anticlines. They need not be horizontal, and sometimes have a dip of a few feet per mile, as in the case of the Ohio and Indiana oil-fields, where the dip varies from 1 to 10 feet. These slight differences in level, however, are found to have a most powerful effect in the direction already mentioned. Generally, it may be said that the strata from which the main supplies of oil and gas have been obtained in the United States are unusually unbroken, nearly horizontal, and but little disturbed. The importance of the anticlinal structure has been equally observed in the oil-fields of the Caucasus, the Carpathians, and elsewhere.

The formation of large deposits of petroleum is, however, dependent upon something more than we have yet considered. We may have the necessary deposit of organic matter, subjected to the requisite conditions to effect its conversion into petroleum, and we may have the anticlinal structure favouring the accumulation of the oil produced, but in addition we need a rock of sufficient porosity to serve as a reservoir for the oil, and above it an impervious stratum to preserve the oil from evaporation and oxidation, and from being displaced by water. The principal deposits which provide the necessary porosity for the storage of the oil are sandstones, conglomerates, and limestones. Shaly sandstones and slaty shales also serve as reservoir-rocks in a lesser degree. In the case of limestones, a natural porosity, such as is found in the coarsely crystalline varieties, or a certain amount of chemical change resulting in the formation of interspaces capable of receiving the oil, appears to be necessary for the formation of a true reservoir-rock. Such change is usually dolomitic, consisting in the conversion of the calcium carbonate forming the limestone into the double carbonate of calcium and magnesium known as "dolomite," which occupies less space than the unaltered limestone. It is therefore characterized by the production of such numerous spaces between the dolomite crystals that the rock becomes capable of retaining a large volume of oil. This dolomitic change appears to be capable of occurring only in the purer limestones. The Trenton limestone, for instance, is thus modified only where almost free from silica, the changed parts showing about 54 per cent. of calcium carbonate and 44 per cent. of magnesium carbonate. A large proportion of the Trenton limestone is too impure to permit of the change, and is destitute of oil and gas. Even in rich oil-fields the dolomite has only been formed in a small portion of the stratum. When followed northwards into Ohio and Indiana, the Trenton limestone is found to have become dolomitic through a small thickness only of its upper beds. The changed and unaltered portions occur at short intervals, but only the former contain the oil and gas. The change usually affects from 10 to 50, and in some cases 100 feet of the stratum, and has occurred along a line passing into Indiana through the principal oil and gas fields of Ohio. In addition to possessing a porous structure, the reservoir-rock must be entirely covered by an impervious layer, the commonest and most perfect cover being a fine-grained shale. The fractured character of the strata in central and eastern Pennsylvania may account for the absence of oil and gas in those districts. In oil-bearing territory the occurrence of a porous rock beneath a cover-rock usually results in the formation of an oil-field.

Oil and gas are often met with in drilled wells under great pressure, which is highest as a rule in the deepest wells. The closed pressure in the Trenton limestone in Ohio and Indiana is about 200–300 ℔ per square inch, although a much higher pressure has been registered in many wells. The gas wells of Pennsylvania indicate about double the pressure of those drilled in the Trenton limestone, 600–800 ℔ not being unusual, and even 1000 ℔ having been recorded. The extremely high pressure under which oil is met with in wells drilled in some parts of the Russian oil-fields is a matter of common knowledge, and a fountain or spouting well resulting therefrom is one of the "sights" of the country. A famous fountain in the Groznyi oil-field in the northern Caucasus, which began to flow in August 1895, was estimated to have thrown up during the first three days 1,200,000 poods (over 4,500,000 gallons, or about 18,500 tons) of oil a day. It flowed continuously, though in gradually diminishing quantity, for fifteen months, quickly destroying the derrick which had been erected; afterwards the flow became intermittent. In April 1897 there was still an occasional outburst of oil and gas.

The manner in which Nature created and put away in her storehouses the petroleum which is being lavishly poured out to-day is a subject of more than academic interest, since it is closely connected with the question of the permanence of the supplies. The various theories of origin may be broadly classified into two groups, one consisting of those which assign to the product an inorganic origin, and the other those which account for its production from animal or vegetable matter, or both. The latter group of theories are the more generally accepted, and the researches of Engler have furnished strong support to the view previously advanced by Höfer that the organic matter from which the petroleum was derived was, at any rate in many instances, animal rather than vegetable. To our knowledge of the chemical composition of petroleum no very striking or commercially important addition has been made within recent years, although from time to time interesting results have been announced which have thrown light upon the subject, and afforded confirmation of views previously based largely upon deduction.

Production of petroleum.

The "production" of petroleum by means of drilled wells in the United States was fully described in the article PETROLEUM in the ninth edition of the *Encyclopædia Britannica*. The system remains substantially unchanged to-day, but in consequence of the increased depth of the wells, extending in some districts to upwards of 3000 feet, heavier tools are commonly employed. In the method hitherto most largely adopted in drilling in the Russian oil-fields a percussion or "jumper" drill is also used, but the tools are suspended from the mechanism, which imparts to them a vertical reciprocating motion by means of screw-jointed iron rods instead of the manila cable which fulfils a similar purpose in the American system. Cable drilling is also practised to some extent in the Baku district, and as it is admittedly far more expeditious than drilling with rods, it is probable that it will be increasingly adopted, on account of the greater depth at which the oil has to be sought. Although the Russian oil wells are of less depth than most of those in the United States, they are of much greater diameter, and are therefore comparatively expensive, some of them costing as much as £5000. Owing to the high price of screwed artesian casing of large diameter, and the difficulty of handling it, riveted casing of iron plate is generally used, although it is not easy with such casing effectively to exclude water from the bore-hole. Recently, on some properties in the Russian oil-fields, artesian casing has been employed advantageously. The character of the strata and mode of occurrence of the oil necessitate the drilling of wells of large diameter in these fields; but even such wells frequently get choked when a fountain is struck, the soft sand and boulders of the oil-bearing formation being driven into the bore-hole by the immense pressure often exerted by the outflowing oil. The large diameter is also highly advantageous when the well has ceased to flow, for, owing to the great quantity of sand present in suspension, the oil cannot be raised with ordinary lift-pumps, as in the United States, and has to be brought to the surface by means of a baler (a long cylindrical vessel made of sheet iron, with a valve at the lower end): it is therefore obvious that the quantity of oil thus obtained in the course of a day would be but small unless the size of the well were such as to admit of the use of a baler of considerable diameter.

Some success has attended the trial in the Baku district of a method of raising the oil from the well by the use of compressed air. In this system, which has been for some time past employed in raising water, the compressed air is forced down a pipe of small diameter, fixed centrally in the well, and issues at the bottom through an outlet fitted with an inverted cone. The stream of air is thus made to impinge against the inner surface of the casing of the well, so as to fill the annular space, and in its upward rapid flow it carries the oil to the surface. It is found that oil can thus be raised far more rapidly than by baling, and as the air-lift system can be employed in a well of comparatively small diameter, it is possible that its general introduction may lead to a reduction in the diameter of the wells, especially in those parts of the territory in which fountains do not commonly occur. Electrical power has been substituted for steam power in both drilling and pumping by Messrs Nobel on their Russian petroleum properties, and by a Dutch company working in Rumania. This may prove to be one of the most important advances made in this branch of the industry. In Galicia, as in Russia, preference has, up to the present time, usually been given to the rod system of drilling, wooden rods, however, being in most instances employed. The rod system has also always been adopted in the Canadian oil-fields, and was, in fact, introduced into Galicia by Canadian drillers. Experts differ as to the relative merits of the cable and rod systems, and as very few drillers have had practical experience of both, it is difficult to get data for an effective comparison. It is asserted that the comparative rigidity of the rod is sometimes highly advantageous, but, on the other hand, it is admitted that the cable system is far more expeditious, especially in drilling at considerable depth, the disconnecting and reconnecting of the rods for the frequently recurring operation of "dressing" the bit and removing the detritus from the well involving much loss of time. In this connexion mention should be made of what is known as the water-flush system of drilling, which has been usefully employed on the Pechelbronn (Alsace) property and elsewhere. In this system tubular rods attached to a bit with a hollow shank and apertures above the cutting edge are used. The rods are connected with a force-pump by means of flexible tubing, and water is driven through them while the drilling is in progress. The water escapes through the orifices in the bit, and flows from the top of the casing, carrying away the detritus from the well. This method has been found successful where the strata are soft, and in such cases is inexpensive and rapid, but it is unsuitable for use in hard rock.

Attempts are being made to substitute a rotary "crown" borer for the percussion drill in sinking wells for petroleum. The instrument in question, which is known as the Calyx drill, is furnished with a steel-toothed cutter of annular form, by means of which the bulk of the rock to be removed is obtained in the form of a solid core, instead of being broken up. It is thus similar in action to the well-known diamond drill. With the Calyx drill good work has already been done in drilling for water; and as the study of the nature of the strata perforated by the drill is greatly facilitated by the preservation of a core, it is to be hoped that this form of drill may in the future find employment in the oil-field.

Refining.

The system of continuous distillation, to which brief reference has already been made as an important feature of the Russian petroleum refining business, was first adopted by Nobel Brothers. In the ordinary or intermittent system of distillation the crude oil is subjected in the still to gradually increased heat, with the object of separating or classifying the various hydrocarbons of which the crude oil is composed by taking advantage of their differences in volatility, and thus obtaining the desired commercial products. The crude oil, on being treated in this manner, first parts with the very volatile hydrocarbons forming the various descriptions of petroleum spirit (gasolene, benzene, &c.). As the temperature rises, the less volatile compounds, met with in commerce as kerosene, are removed, and at still higher temperatures lubricating oils and other products are obtained. The hydrocarbons, of course, leave the still in the form of vapour, but are brought back to the liquid state by being passed through a condenser. It will be evident that we have thus a means of effecting such division and subdivision of the crude oil as we may desire. In the continuous system of distillation, on the other hand, we have, instead of a single still with a progressive temperature, a series of stills heated to successively higher temperatures, which are carefully maintained, and the crude oil is caused to flow slowly and continuously through the whole series, being thus subjected to a steadily increasing heat while the temperature of the contents of each still remains practically constant. In this manner each still yields continuously a product of given volatility, corresponding with the temperature at which it is maintained, and from the series of stills a range of products is continuously obtained corresponding with that yielded by the intermittent system within the same limits of temperature. In this system the loss of time, waste of fuel, and injury to plant involved in the cooling down and re-heating of the stills and furnaces in the intermittent system are avoided. The continuous system is now employed at all the principal refineries in Russia, and is in use in Burma, Galicia, Java, and elsewhere. In the United States, on the other hand, it has not found favour, although considerable sums of money have been spent in attempts to introduce it.

For a second important improvement in refining, viz., the desulphurizing of oils containing sulphur compounds, the credit belongs to the Standard Oil Company. Two processes are employed, both based on the use of cupric oxide as a desulphurizer. In one of these the vapour passes from the still through a vessel containing cupric oxide, where the sulphur is separated as cuprous sulphide, and thence to the condenser. In this way the whole of the volatile constituents of the oil are subjected to the desulphurizing treatment. In the other method, which, in spite of its involving a double operation, is understood to be generally adopted, the petroleum spirit and kerosene distillates, obtained by the ordinary process of distillation, are redistilled with a large excess of finely divided cupric oxide in a still fitted with an agitator, by means of which the contents are kept actively stirred. From the cuprous sulphide the cupric oxide is recovered for further use by burning off the sulphur. The introduction of this process was of great commercial importance, since it rendered available, as a source of burning oil, the sulphuretted petroleum yielded by the prolific oil-fields of Ohio.

Transport and distribution.

In view of the large extent to which pipe lines are employed in the United States for the conveyance of crude petroleum, it has been a matter of surprise that, notwithstanding the admittedly inadequate transport facilities afforded by tank waggons on the Transcaucasian Railway, a pipe line has not been laid from Baku to Batum or some other port on the Black Sea. In the United States the refining business was many years ago largely transferred from the neighbourhood of the oil-fields to the Atlantic seaboard, the crude oil being pumped through pipe lines to the refineries in New York and Philadelphia, the guiding principle apparently being to refine the oil in a locality as near as possible to the point of shipment for export, or in a central position as regards consumption for the home trade. Two circumstances stood in the way of the adoption of a similar principle in Russia. One was that the revenue derived by the railway from the transport of petroleum products could not be spared, and the other that any considerable transference of the refining business from the shore of the Caspian Sea to that of the Black Sea would seriously diminish the value of the Baku refineries, many of which are establishments upon which very large sums of money have been expended. But now a pipe line for refined oil has been laid along a part of the 560 miles of railway from Baku to Batum, and this is to be extended so as to be available for the transport of refined oil from the Caspian to the Black Sea. The 8-inch pipe already completed extends from Michaelov to Batum, a distance of 140 miles, over the portion of the railway most subject to interruption of traffic by floods and snowstorms, and by employing it in conjunction with the railway tank waggons already in use, the carrying capacity of the railway will be largely increased.

The building of tank steamships for the marine transport of petroleum has steadily progressed, and every year sees important additions to a fleet of these vessels, which now number about 160, exclusive of the large number employed in the local trade in America and Russia. Increase in number has been accompanied by increase in tonnage of the individual vessels, some having a carrying capacity of as much as 10,000 tons. Concurrently there has been a corresponding increase in the number of tank barges, tank railway waggons, and tank road waggons employed in the distribution of the oil, as well as in the number and capacity of the tank storage installations.

Much difference of opinion exists as to what is a desirable minimum flash-point for oil intended to be burned in household lamps of the usual construction. Attention has been drawn to the number of deaths and cases of personal injury resulting from accidents with mineral oil lamps, and it has been contended that the remedy lies in a sufficient raising of the standard. Since the early days of the petroleum industry most civilized countries have prescribed by law a test of flashing-point or inflammability, designed in most cases primarily to afford a definition of oils for lighting purposes which may be safely stored without the adoption of special precautions. In the United Kingdom the limit has, for the purpose in question, been fixed by the legislature at 73° Fahr. by the present legal test (a form of "close test," devised by the late Sir Frederick Abel), which is the equivalent of the former standard of 100° Fahr. by the "open test." In Germany the law prescribes a close test of 21° C., equal to about 70° Fahr., whilst in Russia the standard is 28° C., equal to 84·4° Fahr., by the close test. In the United States various methods of testing and various minimum standards have been adopted. In Pennsylvania the prescribed limit is a "fire test" of 110° Fahr., equivalent to about 70° Fahr. close test, while in the state of New York it is 100° Fahr. close test. The subject of the testing of petroleum for legislative purposes, with which in later inquiries that of accidents with mineral oil lamps has been associated, has been investigated in Great Britain by committees of both branches of the legislature, and voluminous evidence has been taken. It has been strongly contended that the raising of the standard from 73° to 100° Fahr. would put an end to lamp accidents, but this view has been equally forcibly combated; and although the committee reported in 1898, by a narrow majority, in favour of such an alteration, no action has been taken upon the recommendation. The questions involved are in truth by no means simple. Obviously, the higher the flashing-point the "safer" the oil in one sense; but there are equally evident objections to a course which would to some extent reduce the available supply, and thus might lead to an increase in price or a deterioration in quality. Moreover, since lamp accidents have occurred with oil of a higher flash-point than 100° Fahr. Abel test, it cannot be held to be proved that the adoption of this standard would prevent such accidents. Apart from this, it does not appear to have been sufficiently borne in mind by the advocates of a high standard that the object of the Petroleum Acts passed in the United Kingdom has hitherto been to regulate storage. Petroleum spirit, "flashing" at zero Fahr., has always been obtainable for use as an illuminating agent, and, on the other hand, commercial enterprise has, without any legislative help, placed oils of high flashing-point at the disposal of those who prefer them. Moreover, if the legislature should, by putting difficulties in the way of the use in lamps of oil of the present legal test, lead to the creation of an impression that oil of, say, 100° Fahr. test can be safely used without the adoption of ordinary precautions, accidents with lamps would probably increase in number. It has been said by advocates of a higher test that with a safe oil any lamp is safe, but it may with equal truth be asserted that in a properly-constructed lamp used with reasonable care the ordinary oil of commerce is a safe illuminant.

Flash-point.

The report of the United States Geological Survey on the production of petroleum in the United States during the year 1899, compiled by Mr F. H. Oliphant, indicates that the most conspicuous features of the industry for the period in question were: (1) The total production was considerably in excess of that of the previous year; (2) there was a large increase in the number of wells completed in both the Appalachian and the Lima–Indiana oil-fields; (3) in south-eastern Ohio and in Texas there was a largely increased production; and (4) only about 7 per cent. of the total production was obtained outside the Appalachian and the Lima–Indiana fields. The Appalachian field embraces all the districts producing what is known as "Pennsylvania oil." It extends from Wellsville in New York state on the north-east, through western Pennsylvania into West Virginia, and includes a large portion of south-eastern Ohio. Its extension through Kentucky and Tennessee into northern Alabama has not been attended with any noteworthy developments. The total production in the Appalachian field for 1899 was 33,050,076 barrels, as compared with 31,711,857 barrels in 1898. The greatest increase was in south-eastern Ohio, where the output was more than doubled, and the greatest falling off was in Pennsylvania. The Lima–Indiana field includes the whole of Indiana and that portion of north-western Ohio in which Lima petroleum, found in the Trenton limestone, is produced. The production decreased from 20,321,323 barrels in 1898 to 20,225,356 barrels in 1899. The total production of crude petroleum in the United States during 1899 was 57,070,850 barrels (of 42 American gallons or about 35 imperial gallons), as compared with 55,364,233 barrels in 1898 and 60,475,516 barrels in 1897. The following is a tabular statement of the production in the various states for the years 1897, 1898, and 1899:—

American supply.

State.	Production.		
	Barrels.	Barrels.	Barrels.
	1897	1898	1899
New York	1,279,155	1,205,250	1,320,909
Pennsylvania	17,982,911	14,743,214	13,053,603
West Virginia	13,090,045	13,615,101	13,910,630
Ohio	21,560,515	18,738,708	21,142,108
Indiana	4,122,356	3,730,907	3,848,182
Kentucky	322	5,568	18,280
Missouri	19	10	132
Colorado	384,934	444,383	390,278
California	1,903,411	2,257,207	2,642,095
Texas	65,975	546,070	669,013
Indian Territory	625	0	0
Illinois	500	360	360
Wyoming	3,650	5,475	5,560
Kansas	81,098	71,980	69,700
	60,475,516	55,364,233	57,070,850

Much attention has been attracted by the rapid development of the Beaumont oil-field in Texas and the large yield of the "gushers" or spouting wells characteristic of what is known as the Spindle Top area. The oil, which will doubtless be used chiefly as fuel, is apparently obtainable in very large quantities at low cost, and having regard to the proximity of the field to the sea-board, the expense of transport is also small. The discovery of this new source of supply has led to renewed consideration of the advantages possessed by liquid fuel, and arrangements are being made on a large scale for the transport and distribution of the produce of the Beaumont field, principally with a view to its use as a substitute for coal. Oil-fields in various parts of the world which had been regarded as of minor importance have become more prominent, and much evidence has concurrently been furnished of the commercial value of other areas of petroliferous territory at present unworked.

The producing territory in the Baku district comprises the oil-fields of Balachani, Sabuntchi, Romany, Binagadi, and Bibi–Eibat, the aggregate area being under 10 square miles. The Balachani–Sabuntchi–Romany territory, and the adjacent district of Binagadi, are situated on the Apsheron Peninsula from 8 to 12 miles north-east and north of the town of Baku, while the Bibi–Eibat field lies 2 to 3 miles south of Baku. The production of these fields from 1897 to 1899 is shown in the following table:—

Russian supply.

District.	1897.	1898.	1899.
	Poods.[1]	Poods.	Poods.
Balachani . .	100,336,495	108,836,439	114,854,151
Sabuntchi . .	162,610,054	179,828,697	230,757,289
Romany . . .	96,266,133	100,523,699	98,581,782
Binagadi . .	197,462	227,730	213,386
Bibi-Eibat . .	62,514,479	96,526,783	80,840,807
	421,924,623	485,943,348	525,247,415

In the year 1893 attention was directed to the prolific character of the oil-bearing lands of Groznyi in the Terek district, about 300 miles north-east of Baku, and recent developments in this field point to the conclusion that the Groznyi oil-field will be a formidable rival to those at Baku. The production in the Groznyi district during the years 1897, 1898, and 1899 was as follows :—

1897	27,568,794 poods.
1898	17,716,899 ,,
1899	25,194,566 ,,

Petroleum also occurs in many other places in the Caucasus, in the Kuban district, in the Crimea, and at Petchora in the north of Russia, near the Ural Mountains.

Other sources of supply.

In Canada petroleum has been produced in large quantities for many years in the Enniskillen district in Lambton county, Ontario. The production for the year 1898 was 758,391 barrels (of 35 imperial gallons), and for 1899, 704,794. Petroleum is also reported to occur in the province of Quebec, near the extremity of the Gaspé Peninsula, and in the North-West Territories, in the district of Athabasca.

On the European continent there is a considerable production of petroleum in Galicia (Austria-Hungary), Rumania, and Alsace. The Galician oil-belt extends for a distance of about 220 miles along the northern slopes of the Carpathian Mountains, whilst the Rumanian deposits occupy the south-eastern and southern slopes of the southern Carpathians or Transylvanian Alps. The Galician oil-fields have been worked by means of drilled wells for many years, but it is only recently that those of Rumania have been similarly developed, petroleum having until within the past few years been obtained in the latter country by means of hand-dug wells. Owing to its favourable geographical position and to the successful results of recent borings, Rumania appears destined to assume a position of importance among petroleum-producing countries. The production of petroleum in Galicia during the year 1898 amounted to 330,451 metric tons, and in 1899 to 321,681 metric tons. In Rumania the production was about 240,000 tons in 1898 and about 300,000 tons in 1899. Much activity has been displayed in the drilling of wells in the Alsace oil-fields, and a profitable local industry has been created. In Italy the production of petroleum is small, but the oil, which is chiefly found in the Milan district, commands a high price.

The Eastern Archipelago (Java, Sumatra, Borneo, &c.) bids fair to rank before long among the chief sources of the oil-supply of the world. In Java there has been a large production for many years; in Sumatra the results which have attended the drilling operations in the Moeara Enim field and elsewhere have demonstrated the existence of a rich oil-bearing formation; and in Borneo the recent work of development, at Kotei, on the east coast of the island, on which much money has been expended, has already resulted in the discovery of abundant supplies of fuel oil, for the distribution of which arrangements are being made on a large scale. The petroleum industry of Japan exhibits steady growth, and has already reached considerable proportions, the output of crude oil, which for the year 1899 was reported to be 800,000 barrels, having increased so much that, according to estimate, it has almost doubled. Of this production the greater part was obtained in the province of Echigo. In Upper Burma British capital and energy have completely transformed the conditions which existed in the Yenangyaung oil-fields in the days of King Thibaw, when "Rangoon oil" (named after the port of shipment) was an unimportant article of commerce. The primitive hand-dug shafts have long been superseded by drilled wells, the produce of which is treated in a refinery provided with the most modern appliances, and an important industry has been created. In Assam an English company has met with similar success in boring operations, and has obtained a considerable production, for the treatment of which a refinery is in course of erection. Petroleum has been produced and refined in Peru in moderate quantities for many years, and has been found in Ecuador and Colombia. It also occurs in Algeria, on the Gold Coast, in Newfoundland, Alaska, the West Indies, New Zealand, and in other localities.

[1] 1 pood=36·1127 ℔ avoirdupois. In comparing the production of crude petroleum in Russia with the production of crude petroleum in the United States, 8 poods may be taken as the equivalent of the American "barrel" unit.

II. MINERAL OIL AS LIQUID FUEL.

The use of petroleum as fuel had long been recognized as a scientific possibility, and some attempts had been made to adopt it in practice upon a commercial scale, but the insufficiency, and still more the irregularity, of the supplies prevented it from coming into practical use to any important extent until recent discoveries of oil specially adapted by chemical composition for fuel purposes changed the aspect of the situation. These discoveries of special oil were made first in Borneo and later in Texas, and experience in treating the oils from both localities has shown that while not less adapted to produce kerosene or illuminating oil, they are better adapted to produce fuel oil than either the Russian or the Pennsylvanian products.

With regard to the chemical properties of petroleum, it is not necessary to say more in the present place than that the lighter and more volatile constituents, known commercially as naphtha and benzene, must be removed by distillation in order to leave a residue composed principally of hydrocarbons which, while containing the necessary carbon for combustion, shall be sufficiently free from volatile qualities to avoid premature ignition and consequent danger of explosion. Attempts have been made to use crude oil for fuel purposes, and these have had some success in the neighbourhood of the oil wells and under boilers of unusually good ventilation both as regards their chimneys and the surroundings of their stokeholds; but for reasons both of commerce and of safety it is not desirable to use crude oil where some distillation is possible. The more complete the process of distillation, and the consequent removal of the volatile constituents, the higher the flash-point, and the more turgid and viscous is the fuel resulting; and if the process is carried to an extreme, the residue or fuel becomes difficult to ignite by the ordinary process of spraying or atomizing mechanically at the moment immediately preceding combustion. The proportions which have been found to work efficiently in practice are as follows :—

Carbon	88·00 per cent.
Hydrogen	10·75 ,,
Oxygen	1·25 ,,
Total . .	100

The standards of safety for liquid fuel as determined by flash-point are not yet finally settled, and are changing from time to time. The British Admiralty require a flash-point of 270° Fahr., and to this high standard, and the consequent viscosity of the fuel used by vessels in the British fleet, may partly be attributed the low rate of combustion that has been found possible in them. The German Admiralty have fixed a flash-point of 187° Fahr., and have used oil of this standard with perfect safety, and at the same time with much higher measure of evaporative duty than has been attained in British war-vessels. In the British mercantile marine Lloyd's Register has permitted fuel with a flash-point as low as 150° Fahr. as a minimum, and no harm has resulted. The Board of Trade, the department of the Government which controls the safety of passenger vessels, has fixed a higher standard upon the basis of a minimum of 185°. In the case of locomotives the flash-point as a standard of safety is of less importance than in the case of stationary or marine boilers, because the storage is more open, and the ventilation, both of the storage tanks and the boilers during combustion, much more perfect than in any other class of steam boilers.

The process of refining by distillation is also necessary to reduce two impurities which greatly retard storage and combustion, *i.e.*, water and sulphur. Water is found in all crude petroleum as it issues from the wells, and sulphur exists in important quantities in oil from the Texas wells. Its removal was at first found very expensive, but there no longer exists difficulty in this respect, and large quantities of petroleum fuel practically free from sulphur are now regularly exported from Texas to New York and to Europe.

Water mixed with fuel is in intimate mechanical relation, and frequently so remains in considerable quantities even after the process of distillation. It is in fact so thoroughly mixed as to form an emulsion. The effect of feeding such a mixture into a furnace is extremely injurious, because the water must be decomposed chemically into its constituents, hydrogen and oxygen, thus absorbing a large quantity of heat which would otherwise be utilized for evaporation. Water also directly delays combustion by producing from the jet a long, dull, red flame instead of a short bright, white flame, and the process of combustion, which should take place by vaporization of the oil near the furnace mouth, is postponed and transferred to the upper part of the combustion-box, the tubes, and even the base of the chimney, producing loss of heat and injury to the boiler structure. The most effective means of ridding the fuel of this dangerous impurity is by heat and settlement. The coefficients of expansion of water and oil by heat are substantially different, and a moderate rise of temperature therefore separates the particles and precipitates the water, which is easily drawn off—leaving the oil available for use. The heating and precipitation are usually performed upon a patented system of settling tanks and heating apparatus known as the Flannery-Boyd system, which has proved itself indispensable for the successful use at sea of petroleum fuel.

Progress of liquid fuel.

The laboratory and mechanical use of petroleum for fuel has already been referred to, but it was not until the year 1870 that petroleum was applied upon a wider and commercial scale. In the course of distillation of Russian crude petroleum for the production of kerosene or lamp oil, large quantities of refuse were produced—known by the Russian name of *astatki*—and these were found an incumbrance, and useless for any commercial purpose. To a Russian oil-refiner gifted with mechanical instinct and the genius for invention occurred the idea of utilizing the waste product as fuel by spraying or atomizing it with steam, so that, the thick and sluggish fluid being broken up into particles, the air necessary for combustion could have free access to it. The earliest apparatus for this purpose was a simple piece of gas-tube, into which the thick oil was fed; by another connexion steam at high pressure was admitted to an inner and smaller tube, and, the end of the tube nearest to the furnace being open, the pressure of the steam blew the oil into the furnace, and by its velocity broke it up into spray. The apparatus worked with success from the first. Experience pointed out the proper proportionate sizes for the inlets of steam and oil, the proper pressure for the steam, and the proportionate sizes for the orifices of admission to the furnaces, as well as the sizes of air-openings and best arrangements of fire-bricks in the furnaces themselves; and what had been a waste product now became a by-product of great value. Practically all the steam power in South Russia, both for factories and navigation of the inland seas and rivers, is now raised from *astatki* fuel.

In the Far East, including Burma and parts of China and Japan, the use of liquid fuel spread rapidly during the years 1899, 1900, and 1901, owing entirely to the development of the Borneo oil-fields by the enterprise of Sir Marcus Samuel and the large British corporation known as the Shell Transport and Trading Company, of which he is the head. In the United States of America liquid fuel is not only used for practically the whole of the manufacturing and locomotive purposes of the state of Texas, but factories in New York, and a still larger number in California, are now discarding the use of coal and adopting petroleum, because it is more economical in its consumption and also more easily handled in transit, and saves nearly all the labour of stoking. So far the supplies for China and Japan have been exported from Borneo, but the discoveries of new oil-fields in California, said to be of a character specially adapted for fuel, have encouraged the belief that it may be possible to supply Chile and Peru and other South American countries, where coal is extremely expensive, with Californian fuel; and there are some who believe that it will ultimately find its way across the Pacific to Japan. There are believed to be large deposits in West Africa, but in the meantime the only sources of supply to those parts of Africa where manufacture is progressing, *i.e.*, South Africa and Egypt, are the oil-fields of Borneo and Texas, from which the import has well begun, from Texas to Alexandria *viâ* the Mediterranean, and from Borneo to Cape Town *viâ* Singapore.

In England, notwithstanding the fact that there exist the finest coal-fields in the world, there has been a surprising development of the use of petroleum as fuel. The Great Eastern Railway have adapted 120 locomotive engines to its use, and these are running with regularity and success both on express passenger and goods trains. The London, Brighton, and South Coast Railway are also commencing the adaptation of some of their locomotive engines, and they have recently entered into a contract for the delivery of a large quantity of Texas oil fuel. Several large firms of contractors and cement manufacturers, chiefly on the banks of the Thames, have made large purchases for future delivery, extending over as many as three years in some cases. The facts that the depôt for the reception of Texas oil fuel is at Thames Haven, and that coal is necessarily dearer in the south of England than in the coal-bearing parts of the country, suggest that the development of liquid fuel is more likely to continue in the neighbourhood of London than elsewhere in England.

The chief factors of economy are the greater calorific value of oil than coal (about 16 ℔ of water per ℔ of oil fuel evaporated from a temperature of 212° Fahr.), not only in laboratory practice, but in actual use on a large scale, and the saving of labour both in transit from the source of supply to the place of use and in the act of stoking the furnaces. The use of cranes, hand labour with shovels, waggons and locomotives, horses and carts, is unavoidable for the transit of coal; and labour to trim the coal, to stoke it when under combustion, and to handle the residual ashes, are all indispensable to steam-raising by coal. On the other hand, a system of pipes and pumps, and a limited quantity of skilled labour to manage them, is all that is necessary for the transit and combustion of petroleum fuel; and it is certain that even in England petroleum will find places which, from topographical and other circumstances, will

Economy of liquid fuel.

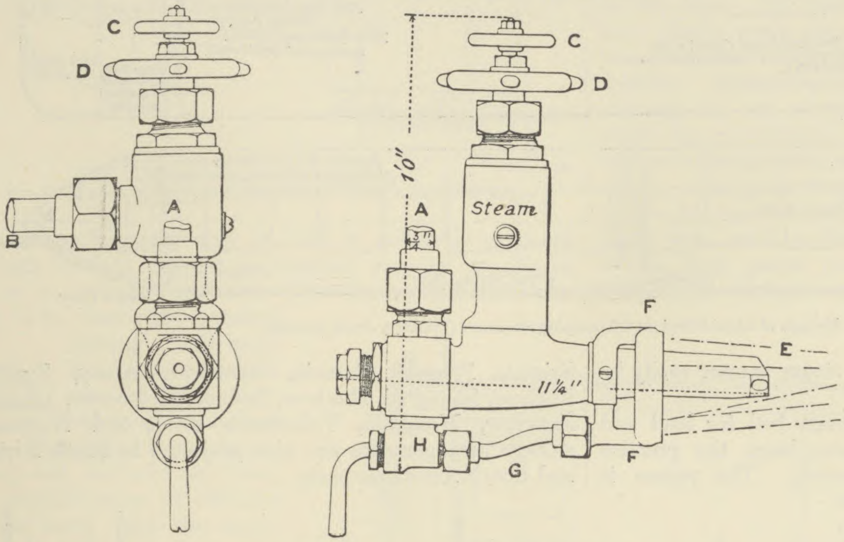

Fig. 1.—Holden Burner.

more economically use petroleum than coal as fuel for manufacturing purposes.

The theoretical calorific value of oil fuel is more nearly realized in practice than the theoretical calorific value of coal, because the facilities for complete combustion, due to the artificial admixture of the air by the atomizing process, are greater in the case of oil than coal, and for this reason, among others, the practical evaporative results are proportionately higher with liquid fuel. In some cases the work done in a steam engine by 2 tons of coal has been performed by 1 ton of oil fuel, but in others the proportions have been as 3 to 2, and these latter can be safely relied on in practice as a minimum. This saving, combined with the savings of labour and transit already explained, will in the near future make the use of liquid fuel compulsory, except in places so near to coal-fields that the cost of coal becomes sufficiently low to counterbalance the savings in weight of fuel consumed and in labour in handling it. In some locomotives on the Great Eastern Railway the consumption of oil and coal for the same development of horse-power has been as 17 ℔ oil is to 35 ℔ coal; all, however, have not realized so high a result.

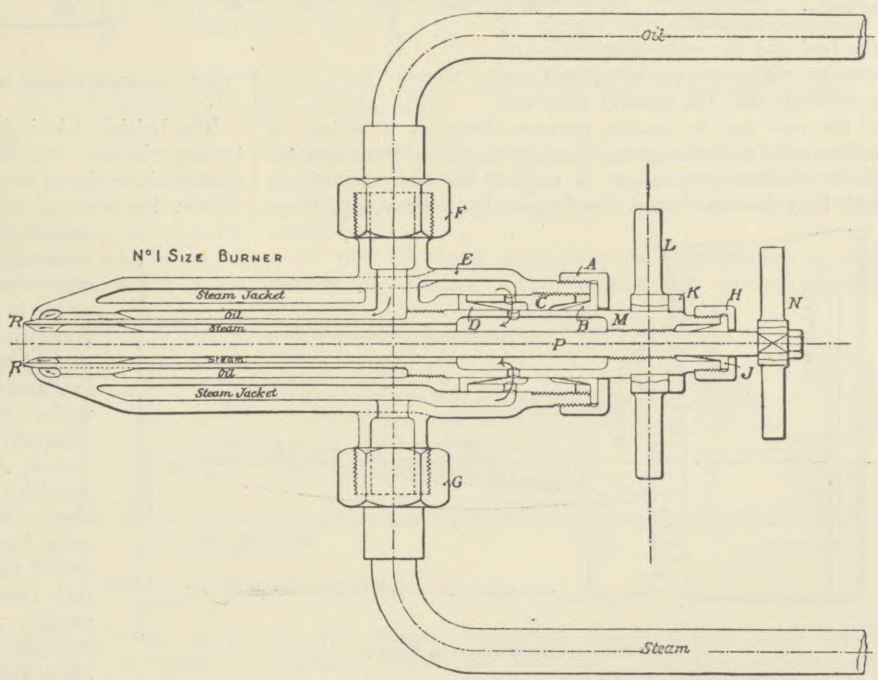

Fig. 2.—Rusden and Eeles Burner.

Liquid fuel in locomotives.

The mechanical apparatus for applying petroleum to steam-raising in locomotives is very simple. The space in the tender usually occupied by coal is closed up by steel-plating closely riveted and tested, so as to form a storage tank. From this tank a feed-pipe is led to a burner of the combined steam-and-oil type already indicated, and this burner is so arranged as to enter a short distance inside the furnace mouth. The ordinary fire-bars are covered with a thin layer of coal, which starts the ignition in the first place, and the whole apparatus is ready for work. The burner best adapted for locomotive practice is the Holden Burner shown in Fig. 1. The steam-pipe is connected at A, the oil-pipe at B, and the hand-wheels C and D are for the adjustment of the internal orifices according to the rate of combustion required. The nozzle E is directed towards the furnace, and the external ring FF, supplied by the small pipe G and the bye-pass valve H, projects a series of steam jets into the furnace, independent of the injections of atomized fuel, and so induces an artificial inrush of air for the promotion of combustion. This type of burner has also been tried on stationary boilers and on board ship. It works well, although the great consumption of steam by the supplementary ring is a difficulty at sea, where the

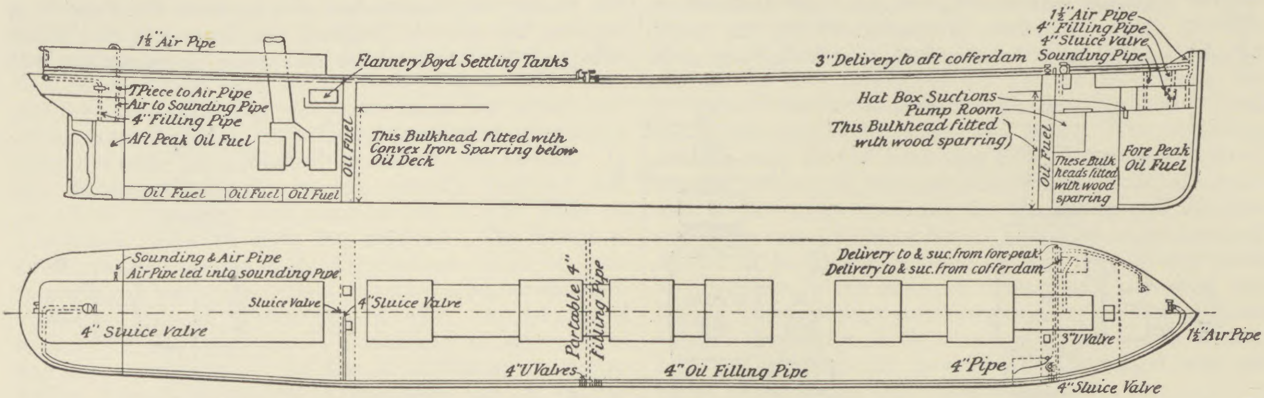

FIG. 3.—Storage of Liquid Fuel on Oil-carrying Steamers (Flannery-Boyd system).

water lost by the consumption of steam cannot easily be made up.

Although the application of the new fuel for land and locomotive boilers has already been large, the practice at sea has been far more extensive. The reason is chiefly to be found in the fact that although the sources of supply are at a distance from Great Britain, yet they are in countries to whose neighbourhood British steamships regularly trade, and in which British naval squadrons are regularly stationed, so that the advantages of adopting liquid fuel have been more immediate and the economy more direct. The certainty of continuous supply of the fuel and the wide distribution of storage stations have so altered the conditions that the general adoption of the new fuel for marine purposes becomes a matter of urgency for the statesman, the merchant, and the engineer. None of these can afford to neglect the new conditions, lest they be noted and acted upon by their competitors.

Liquid fuel at sea.

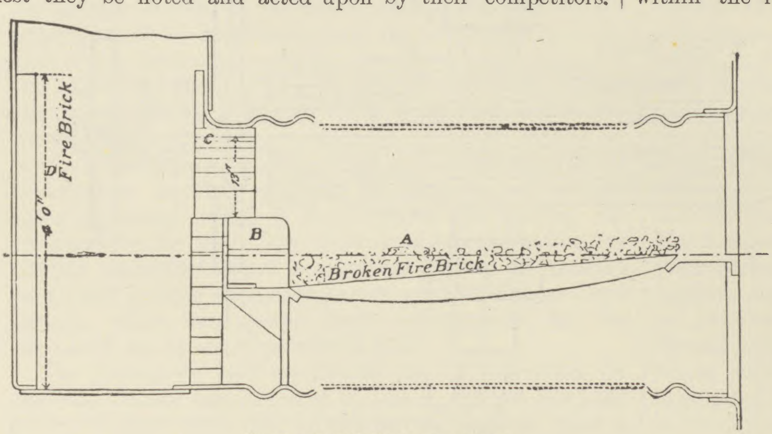

FIG. 4.—Installation on ss. *Trocas*.

Storage and supply now exist or will shortly be established in the following wide range of seaports :—London, Barrow, Southampton, Amsterdam, Copenhagen, New Orleans, Savannah, New York, Philadelphia, Singapore, Hong Kong, Madras, Colombo, Suez, Hamburg, Port Arthur, Texas, Rangoon, Calcutta, Bombay, Alexandria, Bangkok, Saigon, Penang, Batavia, Surabaya, Amoy, Swatow, Fuchow, Shanghai, Hankow, Sydney, Melbourne, Adelaide, Zanzibar, Mombasa, Yokohama, Kobe, and Nagasaki; storage arrangements are also projected in South African and South American ports.

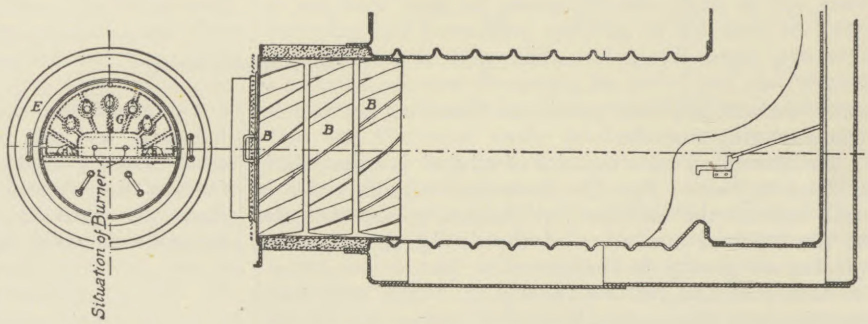

FIG. 5.—Details of Furnace, Meyer System.

The British Admiralty are proceeding with some vigour to experiment with liquid fuel at sea, and at the same time to investigate the possibility of supply from sources within the regions of the British Empire. There is an enormous supply of shale under the north-eastern counties of England, but no oil that can be pumped—still less oil with a pressure above it so as to "gush" like the wells in America—and the only source of liquid supply under the British flag appears to be in Burma. The Borneo fields are, however, under British control, and have been developed entirely by British capital. The Italian Admiralty have fitted several large warships with boiler apparatus to burn petroleum. The German Admiralty are regularly using liquid fuel on the China station. The Dutch navy have fitted coal fuel and liquid fuel furnaces in combination, so that the smaller powers required may be developed by coal alone, and the larger powers by supplementing coal fuel with oil fuel. The speeds of some vessels of the destroyer type have by this means been accelerated nearly two knots.

The questions which govern the use of fuel in warships are more largely those of strategy and fighting efficiency than economy of evaporation. Indeed, the cost of constructing and maintaining in fighting efficiency a modern warship is so great that the utmost use strategically must be obtained from the vessel, and in

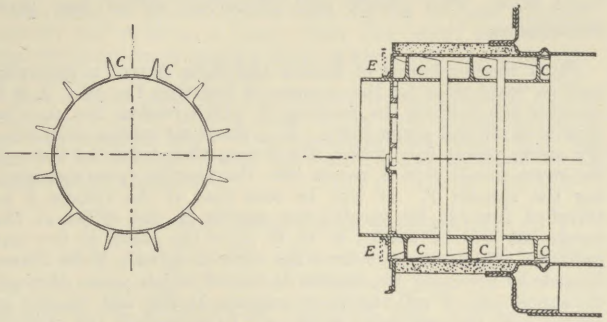

FIG. 6.—Details of Exterior Elongation of Furnace, Meyer System.

this comparison the cost of fuel is relatively so small an item that its increase or decrease may be considered almost a negligible quantity. The desideratum in a warship is to obtain the greatest fighting efficiency based on the thickest armour, the heaviest and most numerous guns, the highest maximum speed, and, last and not least, the greatest range of effective action based upon the maximum supplies of fuel, provisions, and other consumable stores that the ship can carry. Now, if by changing the type of fuel it be possible to reduce its weight by 30 per cent., and to abolish the stokers, who are usually more than half the ship's company, the weight saved will be represented not merely by the fuel, but by the consumable stores otherwise necessary for the stokers. Conversely, the radius of effective action of the ship will be doubled as regards consumable stores if the crew be halved, and will be increased by 50 per cent. if the same weight of fuel be carried in the form of liquid instead of coal. In space the gain by using oil fuel is still greater, and 36 cubic feet of oil as stored are equal in practical calorific value to 67 cubic feet of coal according to the allowance usual for ship's bunkering. On the other hand, coal has been relied upon, when placed in the side bunkers of unarmoured ships, as a protection against shot and shell, and this advantage, if it really exists, could not be claimed in regard to liquid fuel.

Advantages in warships.

Recent experiments in coaling warships at sea have not been very successful, as the least bad weather has prevented the safe transmission of coal bags from the collier to the ship. The same difficulty does not exist for oil fuel, which could be pumped through flexible tubing from one ship to the other even in comparatively rough weather. Smokelessness, so important a feature of sea strategy, has not always been attained by liquid fuel, but where the combustion is complete, by reason of suitable furnace arrangements and careful management, there is no smoke. The great drawback, however, to the use of liquid fuel in fast small vessels is the confined space allotted to the boilers, such confinement being unavoidable in view of the high power concentrated in a small hull. The British Admiralty's experiments, however, are gradually solving the problem, and the quantity of oil which can be consumed by forced draught in confined boilers now more nearly equals the quantity of coal consumed under similar conditions.

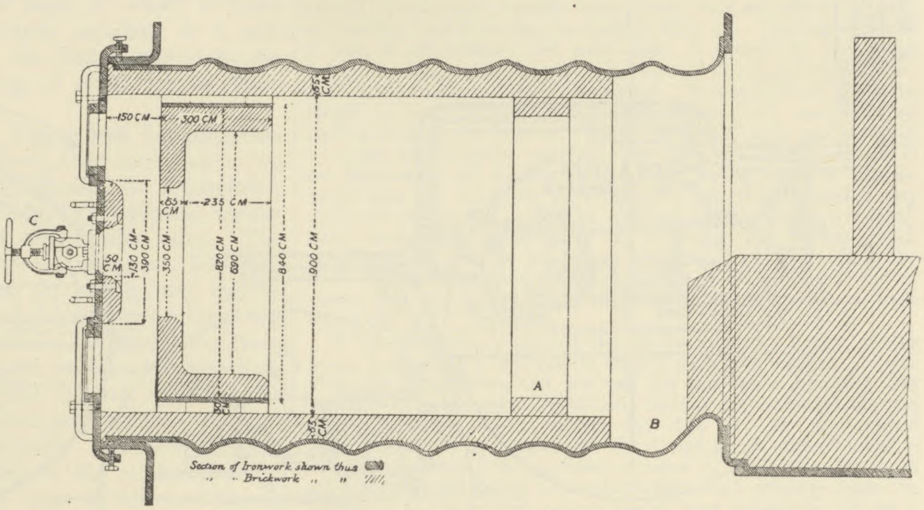

FIG. 7.—Furnace on ss. *Ferdinand Laeisz*. A, it is proposed to do away with this ring of brickwork as being useless; B, it is proposed to fill this space up, thus continuing lining of furnace to combustion chamber, and also to fit protection bricks in way of saddle plate.

In view of recent accusations of insufficiency of coal storage in foreign naval depots, by reason of the allegation that coal so stored quickly perishes, it is interesting to note that liquid fuel may be stored in tanks for an indefinite time without any deterioration whatever.

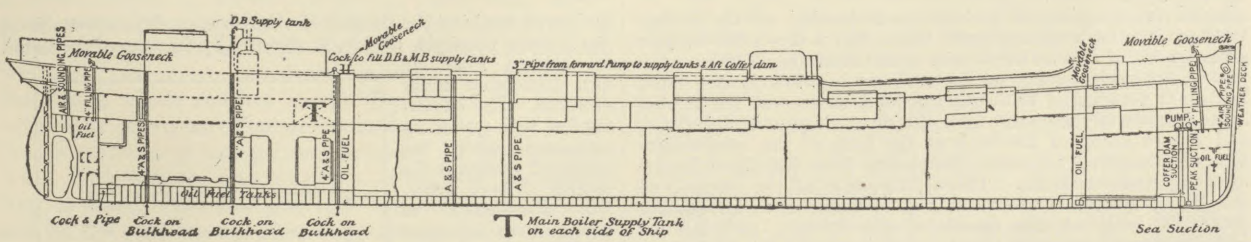

FIG. 8.—Fuel Tanks, &c., of ss. *Murex*.

In the case of merchant steamers large progress has also been made. The Shell Transport and Trading Company have twenty-one vessels successfully navigating in all parts of the world and using liquid fuel. The Hamburg-America Steam Navigation Co. have four large vessels similarly fitted for oil fuel, although differing in furnace arrangements, as will be hereafter described. One of the large American transatlantic lines is adopting liquid fuel, and French, German, Danish, and American mercantile vessels are also beginning to use it in considerable amounts.

Advantages in merchant ships.

In the case of very large passenger steamers, such as those of 20 knots and upwards in the Atlantic trade, the saving in cost of fuel is trifling compared with the advantage arising from the greater weight and space available for freight. Adopting a basis of 3 to 2 as between coal consumption and oil consumption, there is an increase of 1000 tons of dead weight cargo in a large Atlantic steamer, and a collateral gain of about 100,000 cubic feet of measurement cargo, by reason of the ordinary bunkers being left quite free, and the oil being stored in the double bottom spaces hitherto unutilized except for the purpose of water ballast. The cleanliness and saving of time from bunkering by the use of oil fuel is also an important factor in passenger ships, whilst considerable additional speed is obtainable. The cost of the installation, however, is very considerable, as it includes not only burners and pipes for the furnaces, but also the construction of oil-tight tanks, with pumps and numerous valves and pipe connexions.

Fig. 2 shows a burner of Rusden and Eeles' patent as generally used on board ships for the purpose of injecting the oil. A is a movable cap holding the packing B, which renders the annular spindle M oil and steam tight. E is the outer casing containing the steam jacket from which the steam, after being fed through the steam-supply pipe G, passes into the annular space surrounding the spindle P. It will be seen that if the spindle P be travelled inwards by turning the handle N, the orifice at the nozzle RR will be opened so as to allow the steam to flow out radially. If at the same time the annular spindle M be drawn inwards by revolving the handle L, the oil which passes through the supply pipe F will also have emission at RR, and, coming in contact with the outflowing steam, will be pulverized and sprayed into the furnace. Fig. 3 is a profile and plan of a steamer adapted for carrying oil in bulk, and showing all the storage arrangements for handling liquid fuel. Fig. 4 shows the interior arrangement of the boiler furnace of the steamship *Trocas*. A is broken fire-brick resting on the ordinary fire-bars, B is a brick bridge, C a casing of fire-brick intended to protect the riveted seam immediately above it from the direct impact of the flame, and D is a lining of fire-brick at the back of the combustion-box, also intended to protect the plating from the direct impact of the petroleum flame. The arrangement of the furnace on the Meyer system is shown in Fig. 5, where E is an annular projection built at the mouth of the furnace, and BB are spiral passages for heating the air before it passes into the furnace. Fig. 6 shows the rings CC and details of the casting which forms the projection or exterior elongation of the furnace. The brickwork arrangement adopted for the double-ended boilers on the Hamburg-America Steamship Company's *Ferdinand Laeisz* is represented in Fig. 7. The whole furnace is lined with fire-brick, and the burner is mounted upon a circular disc plate which covers the mouth of the furnace. The oil is injected not by steam pulverization, but by pressure due to a steam-pump. The oil is heated to about 60° C. before entering the pump, and further heated to 90° C. after leaving the pump. It is then filtered, and passes to the furnace injector C at about 30 pounds pressure; and its passage through this injector and the spiral passages of which it consists pulverizes the oil into spray, in which form it readily ignites on reaching the interior of the furnace. The injector is on the Körting principle, that is, it atomizes by fracture of the liquid oil arising from its own momentum under pressure. The advantage of this system as compared with the steam-jet system is the saving of fresh water, the abstraction of which is so injurious to the boiler by the formation of scale.

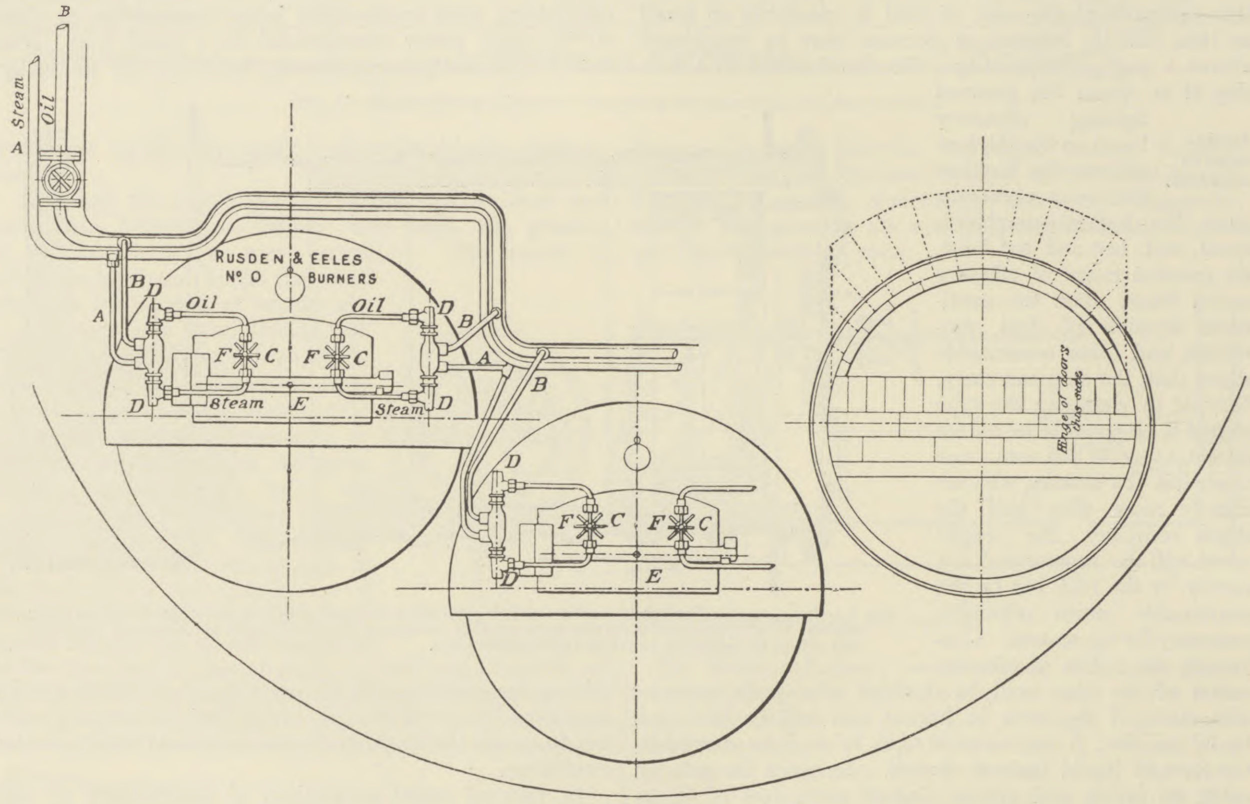

Fig. 9.—Furnace Gear of ss. *Murex*.

The general arrangement of the fuel tanks and filling pipes on the Shell Transport Company's ss. *Murex* is shown in Fig. 8; and Fig. 9 represents the furnace gear of the same vessel, A being the steam-pipe, B the oil-pipe, C the injector, D the swivel upon which the injector is hung so that it may be swung clear of the

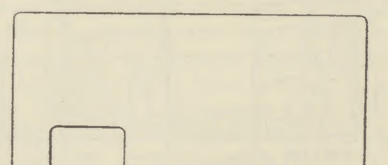

Fig. 10.—Section through Furnace of ss. *Murex*.

furnace, E the fire-door, and F the handle for adjusting the injector. In Fig 10, which represents a section of the furnace, H is a fire-brick pier, and K a fire-brick baffling bridge.

It is found in practice that to leave out the fire-bars ordinarily used for coal produces a better result with liquid fuel than the alternative system of keeping them in place and protecting them by a layer of broken fire-brick.

Boilers fitted upon all the above systems have been run for thousands of miles without trouble. In new construction it is desirable to give larger combustion chambers and longer and narrower boiler tubes than in the case of boilers intended for the combustion of coal alone. (F. F*.)

III. Mineral Oil as an Illuminant.

As early as 1781 the idea was mooted of burning naphtha, obtained by the distillation of coal at low temperatures, for illuminating purposes, and in 1820, when coal gas was struggling into prominence, light oils obtained by the distillation of coal tar were employed in the Holliday lamp, which is still to be found flourishing as the chief factor in illuminating the street barrow of the costermonger. In this lamp the coal naphtha is contained in a conical reservoir, from the apex of which it flows slowly down through a long metal capillary to a rose burner, which, heated up by the flame, vaporizes the naphtha, and thus feeds the ring of small jets of flame escaping from its circumference.

First use of petroleum as an illuminant.

It was in 1847 that James Young had his attention drawn to an exudation of petroleum that occurred in the Riddings Colliery at Alfreton, in Derbyshire, and found that he could by distillation obtain from it a lubricant of considerable value. The commercial success of this material, however, was accompanied by a failure of the supply, and, rightly imagining that as the oil had apparently come from the Coal Measure, it might be obtained by distillation from material of the same character, he commenced investigations in this direction, and in 1850 started distilling oils from a shale known as the "Bathgate mineral," in this way founding the Scotch oil industry. At first but little attention was paid to the fitness of the oil for burning purposes, although in the early days at Alfreton Young attempted to burn some of the lighter distillates in an Argand lamp, and later in a form of lamp which had been made many years before for the consumption of turpentine. About 1853, however, it was noticed that the lighter distillates were readily bought, and were being shipped to Hamburg and sent on to Germany, where lamps fitted for the consumption of the grades of oil now known as lamp oil were being made by Stohwasser of Berlin; and some of these lamps being imported, were afterwards manufactured in Great Britain by Messrs Laidlaw in Edinburgh, undergoing several improvements during the ensuing years.

In Pennsylvania in 1859 Colonel Drake's successful boring for petroleum caused the outbreak of oil fever in the States, which resulted in the flooding of the market with oil at prices never before deemed possible, and led to the introduction of lamps from Germany for its consumption. Although the first American patent for a petroleum lamp is dated 1859, that year saw forty other applications, and for the next twenty years they averaged about eighty a year.

The perfection of the mineral-oil lamp.

The English lamp-makers were not behind in their attempts to improve on the methods in use for producing the highest results from the various grades of oil, and in 1865 Messrs Hinks introduced the duplex burner, while later improvements made in various directions by Messrs Hinks, Silber, and Defries led to the high degree of perfection to be found in the lamps of to-day. Mineral oil for lamps as used in England at the present time may be defined as consisting of those portions of the distillate from shale oil or crude petroleum which have their flash-point above 73° F., and which are mobile enough to be fed by capillarity in sufficient quantity to the flame. The oil placed in the lamp reservoir is drawn up by the capillarity of the wick to the flame, and being there volatilized, is converted by the heat of the burning flame into a gaseous mixture of hydrogen and hydrocarbons, which is ultimately consumed by the oxygen of the air and converted into carbon dioxide and water vapour, the products of complete combustion.

In order to secure high illuminating power, together with a smokeless flame and only products of complete combustion, it is necessary to pay strict attention to several important factors. In the first place, the *wick* must be so arranged as to supply the right quantity of oil for gasification at the burner-head—the flame must be neither starved nor overfed: if the former is the case great loss of light is occasioned, while an excess of oil, by providing more hydrocarbons than the air-supply to the flame can completely burn, gives rise to smoke and products of incomplete combustion. The action of the wick depending on the capillary action of the microscopic tubes forming the cotton fibre, nothing but long-staple cotton of good quality should be employed; this should be spun into a coarse loose thread with as little twist in it as possible, and from this the wick is built up. Having obtained a wick of soft texture and loose plait, it should be well dried before the fire, and when put in position in the lamp must fill the wick-holder without being compressed. It should be of sufficient length to reach to the bottom of the oil reservoir and leave an inch or two on the bottom. Such a wick will suck up the oil in a regular and uniform way, provided that the level of the oil is not allowed to fall too low in the lamp, but it must be remembered that the wick acts as a filter for the oil, and that if any sediment be present it will be retained by and choke the capillaries upon which the action of the wick depends, so that a wick should not be used for too long a time. A good rule is that the wick should, when new, trail for 2 inches on the bottom of the oil vessel, and should be discarded when these 2 inches have been burnt off.

When the lamp is lighted the oil burns with a heavy, smoky flame, because it is not able to obtain sufficient oxygen to complete the combustion, and not only are soot flakes produced, but products of incomplete combustion, such as carbon monoxide and even petroleum vapour, escape into the air—the first-named highly injurious to health, and the second of an offensive odour. In order to supply the *necessary amount of air* to the flame, an artificial draught has to be created which shall impinge upon the bottom of the flame and sweep upwards over its surface, giving it rigidity, and by completing the combustion in a shorter period of time than could be done otherwise, increasing the calorific intensity and thus raising the carbon particles in the flame to a far higher incandescence so as to secure a greater illuminating power. This in practice has been done in two ways, first by drawing in the air by the up-suck of the heated and expanded products of combustion in a chimney fitted over the flame, and secondly by creating a draught from a small clockwork fan in the base of the lamp. It is necessary to break the initial rush of the draught: this is mostly effected by discs of perforated metal in the base of the burner, called *diffusers*, while the metal dome which surrounds and rises slightly above the wick-holder serves to deflect the air on to the flame. These arrangements also act to a certain extent as regenerators, the air passing over the heated metal surfaces being warmed before reaching the flame, whilst other contrivances, such as discs, cones, buttons, perforated tubes, inner air-tubes, &c., have from time to time been introduced with the object of increasing the illuminating power and completing the combustion.

The illuminating efficiency of modern oil lamps.

According to Dr Boverton Redwood, duplex burners which give a flame of 28 candle-power have an average oil consumption of 50 grains per candle per hour, while Argand flames of 38 candle-power consume about 45 grains of oil per candle per hour. These must, however, be regarded as the duties obtained from lamps of the best types, and in order to obtain information as to the efficiency of the lamps most extensively used in daily practice, a number of the most popular types were examined, using both American and Russian oil.

The results obtained are embodied in the table on the next page. The first thing that strikes one in this table is the apparent superiority of the American over Russian oil in the majority of the lamps employed, and there is no doubt that the bulk of the lamps on the market are constructed with the view of burning American or shale oil. A second interesting point is that with the flat-flame lamps the Russian oil is as good as the American. We have the authority of Dr Redwood, moreover, for the fact

American oil—Sp. gr. 0·7904 ; flash-point, 110° F. Russian oil—Sp. gr. 0·823 ; flash-point, 83° F.

that after prolonged burning the Russian oil, even in lamps least suited to it, gives highly improved results. Although the average consumption with these various forms of lamps is close upon 60 grains per candle with American oil, yet some of the burners are so manifestly wasteful that 50 grains per candle-power per hour is clearly the fairest basis to take for any calculation as to cost.

Products of combustion of oil and other illuminants. Candles, oil, and coal gas all emit the same products of complete combustion, viz., carbon dioxide and water vapour. The quantities of these compounds emitted from the different illuminants for every candle of light per hour will be seen from the following table :—

Illuminant.	Cubic Feet per Candle. Carbon Dioxide.	Water Vapour.
Sperm candle	0·41	0·41
Oil lamp	0·24	0·18
Gas—Flat flame	0·26	0·67
Argand	0·17	0·45
Regenerative	0·07	0·19
Incandescent	0·03	0·08

From these data it appears that if the sanitary condition of the air of a dwelling-room be measured by the amount of carbon dioxide present, as is usually done, candles are the most prejudicial to health and comfort, oil lamps less so, and gas least, an assumption which practical experience does not bear out, the discomfort and oppression felt being distinctly less in a room lighted by candles or oil than in one lighted by any of the older forms of gas-burner. The explanation of this is to be found in these facts :—First, where we illuminate a room with candles or oil we are contented with a less intense and more local light than when we are using gas, and in a room of ordinary size would be more likely to use a lamp or two candles placed near our book or plate than the far higher illumination we should demand if gas were employed. Secondly, the amount of water vapour given off during the combustion of gas is greater than in the case of the other illuminants, and water vapour absorbing radiant heat from the burning gas becomes heated, and, diffusing itself about the room, causes great oppression. Also the air, being highly charged with moisture, is unable to take up so rapidly the water vapour which is always evaporating from the surface of our skin, and in this way the functions of the body receive a slight check, resulting in a feeling of depression.

The amount of heat emitted by our illuminants is a matter of importance upon which little has been said, and which places a distinct limit upon the size and illuminating power of oil lamps. ***Heat emitted by oil flames.*** Taking the composition of lamp oil to be 86 per cent. carbon and 14 per cent. hydrogen, the relative amount of heat evolved from gas flames and oil lamps for every candle-power of illumination per hour will be—

Incandescent mantle	36

A very successful form of oil lamp for use in engineering is that type of lamp represented by the "Lucigen," ***Oil-spray lamps.*** "Doty," and "Wells" lights, in which the oil is forced from a reservoir by air-pressure through a spiral heated by the flame of the lamp, and the heated oil being then ejected partly as vapour and partly as spray, burns with a large and highly luminous flame. The great drawback to these devices is that a certain proportion of the oil spray escapes combustion and is deposited in the vicinity of the light. This form of lamp is often used for heating as well as lighting, and any one who saw the wonderful engineering work at the Forth Bridge in progress will remember the effective way in which the rivets needed for that colossal undertaking were heated in trays by lamps of this type at the spot where they were required. The great advantage of these lamps was that oils of but very little value could be employed, and the light obtained approximated to 750 candles per gallon of oil consumed. They may to a certain extent be looked upon as the forerunners of perhaps the most successful form of incandescent oil-burner.

As early as 1885 Mr Arthur Kitson attempted to make a burner for heating purposes on the foregoing principle, that is, by injecting oil under pressure from a fine tube into a chamber where it would be heated by the waste heat escaping from the flame below, ***Oil applied to incandescent lighting.*** the vapour so produced being made to issue from a small jet under the pressure caused by the initial air-pressure and the expansion in the gasifying tube. This jet of gas was then led into what was practically an atmospheric burner, and drew in with it sufficient air to cause its combustion with a non-luminous blue flame of great heating power. At the time when this was first done the Welsbach mantle had not yet reached the period of commercial utility, and attempts were made to use this flame for the generation of light by consuming it in a mantle of fine platinum gauze, which, although giving a very fine illuminating effect during the first few hours, very soon shared the fate of all platinum mantles—that is, carbonization of the platinum surface took place, and destroyed its power of light emissivity. It was not until 1897 that the perfecting of the Welsbach mantle enabled this method of consuming the oil to be employed. The Kitson lamp has given results which certainly ought to ensure its future success, the only drawback to it being that it needs a certain amount of intelligent care to keep it in good working order, but where this has been forthcoming the lamp has more than fulfilled the high expectations formed of it.

In this lamp as used for outside street lighting the oil reservoir is in the base of the pillar, and is made of steel in order to withstand very high pressures, so as to be absolutely safe under the conditions of ordinary use. In this reservoir the oil is by means of a small pump put under an air-pressure of 50 or 60 ℔, which forces it up through a small capillary tube to the burner-head. Here it passes through a small cross-tube containing filtering material, for removing any solid particles in it, and is then ejected through a small aperture into a lower cross tube placed immediately above the top of the mantle, the heat from which passing upwards causes vaporization and partial gasification of the oil. The mixed gas and vapour rush out under considerable pressure from a small aperture in the under side of the tube down what is practically an inverted Bunsen tube, through the holes in the side of which it draws in a sufficient amount of air to render the flame at the burner-head not only non-luminous but sufficiently oxidizing in its character as to prevent any deposition of carbon on the mantle. By the time the burner-head is reached, the gas is practically down to atmospheric pressure again, so that the wear and tear to the mantle are not excessive. The performances of this lamp have been most carefully studied, and experiments show that with a large single burner it is perfectly easy to obtain illuminating values of from 1000 to over 1200 candles, and that 1000 candle-power could with a large installation be readily obtained for 1d. per hour, a figure which makes this method of illumination only one-third the cost of electric arc lighting. The cost, however, must vary with the number of lamps employed. Where the installation is large enough to keep a man constantly employed, the labour item becomes reduced to a very small figure, but rises to an excessive degree when the number of lamps decreases.

Incandescent table lamps.

Oil gas and oil vapours differ from coal gas merely in the larger proportion and greater complexity of the hydrocarbon molecules present, and to render the oil flame available for incandescent lighting it is only necessary to cause the oil gas or vapour to become mixed with a sufficient proportion of air before it arrives at the point of combustion. A simple statement of this kind, however, gives no idea of the great difficulties which exist in bringing about so simple an end, as with gases so rich in hydrocarbons as those developed from oil it is excessively difficult to get the necessary air intimately and evenly mixed with the gas in sufficient proportion to bring about the desired result. If even coal gas be taken and mixed with 2·27 volumes of air, its luminosity is destroyed, but such a flame would be useless with the incandescent mantle, as if the non-luminous flame be superheated a certain proportion of its luminosity will reappear. When such a flame is used with a mantle the superheating effect of the mantle itself very quickly leads to the decomposition of the hydrocarbons and blackening of the mantle, which not only robs it of its light-giving powers, but also rapidly brings its life to a close. If, however, the proportion of air be increased, the appearance of the flame becomes considerably altered, and the hydrocarbon molecules being burnt up and so destroyed before impact with the heated surface of the mantle, all chance of blackening is avoided.

As soon as attempts began to be made to construct a satisfactory oil lamp which could be used with the incandescent mantle, this trouble showed itself to be a most serious one, as although it was comparatively easy so to regulate a circular-wicked flame fed by an excess of air as to make it non-luminous, the moment the mantle was put upon this, blackening quickly appeared, while when methods for obtaining a further air supply were devised, the difficulty of producing a flame which would burn for a considerable time without constant necessity for regulation proved a serious drawback. This has been the trouble which has militated against most of the incandescent oil lamps placed upon the market.

It soon became evident that if a wick were employed the difficulty of getting it perfectly symmetrical was a serious matter, and that it could only be utilized in drawing the oil up to a heating chamber where it could be volatilized to produce the oil gas, which on then being mixed with air would give the non-luminous flame. In the earlier forms of incandescent oil lamps the general idea was to suck the oil up by the capillarity of a circular wick to a point a short distance below the opening of the burner at which the flame was formed, and here the oil was vaporized or gasified by the heat of the head of the burner. An air supply was then drawn up through a tube passing through the centre of the wick-tube, while a second air current was so arranged as to discharge itself almost horizontally upon the burning gas below the cap, in this way giving a non-luminous and very hot flame, which if kept very carefully adjusted afforded excellent results with an incandescent mantle. It was an arrangement somewhat of this character that was introduced by the Welsbach Company. The lamps, however, required such careful attention, and were moreover so irregular in their performance, that they have never proved very successful. Many other forms have been suggested and have reached a certain degree of perfection, but have not so far attained sufficient regularity of action to make them commercial successes. One of the most successful was one devised by Herr Altmann, in which an ingenious arrangement caused the vaporization of oil and water by the heat of a little oil lamp in a lower and separate chamber, and the mixture of oil gas and steam was then burnt in a burner-head with a special arrangement of air supply, heating a mantle suspended above the burner-head.

The perfect petroleum incandescent lamp on any of these systems, however, has not yet been made, but the results that have been obtained show that when the right system has been found a very great increase in the amount of light developed from the petroleum may be expected. In the case of one lamp which was experimented with for some time it was easy to obtain 3500 candle hours per gallon of oil, or three times the amount of light obtainable from the oil when burnt under ordinary conditions.

Comparative cost of oil as an illuminant.

The cost of obtaining illuminating power of equal intensity from the various illuminating agents has been calculated, the basis of calculation in each case being the figure which practice shows to represent the average duty obtained from each. The following table gives the results:—

Cost of 1000 Candles of Light per Hour.

(V. B. L.)

Petrovsk, a district town and seaport of Russia, on the Caspian Sea, in the province of Daghestan, Transcaucasia, 180 miles by rail east of Vladikavkaz, and 235 miles from Baku. The fort has been abandoned, but the town has become a considerable seaport, the imports reaching 400,000 tons annually, and the exports 50,000 tons. There are naphtha wells, and the hot sulphur baths at Ah-Göl and Talga, close by, attract many visitors in summer. Population (1897), 9810.

Pettie, John (1839–1893), Scottish painter, was born at East Linton, Haddingtonshire, 17th March 1839, the son of Alexander and Alison Pettie. His first art work was done in the studio of Robert Frier, and while there he made several drawings for book illustration. At the age of seventeen he entered the Trustees' Academy in Edinburgh, working under Robert Scott Lauder with W. Q. Orchardson, J. MacWhirter, W. M'Taggart, Peter Graham, Tom Graham, and G. P. Chalmers. He first exhibited at the Royal Scottish Academy in 1858, the subject chosen being "The Prison Pet," following it in 1859 with a "Scene from the Fortunes of Nigel," and two portraits; and at the Royal Academy with "The Armourers" in 1860. The success of this work and of its successor, "What d'ye Lack, Madam?" in the following year, encouraged him to settle in London (1862), where he joined Orchardson. In 1866 he was elected an Associate of the Royal Academy, and in 1873 received full Academical honours in succession to Sir Edwin Landseer. His diploma picture was "Jacobites, 1745." Pettie was a hard and rapid worker, and, in his best days, a colourist of a high order and a brilliant executant. He was a successful portrait-painter, if not quite in the front rank; but he will always be better known for his subjects drawn from the romance of history, especially that of his native country. He was an accurate and charming draughtsman, with a capacity for the dramatic arrangement of a composition, and it is probable that his works of this class will always enjoy a very considerable popular vogue. In his early days he, along with many of his fellows, produced a certain amount of book illustration (see ILLUSTRATION). His connexion with *Good Words* began in 1861, and was continued during 1862 and 1863. In 1868 and 1869 wood-engravings after his drawings appeared in the *Sunday Magazine*. He also illustrated *The Postman's Bag* (with J. MacWhirter), Wordsworth's *Poetry for the Young* (Strahan, 1863); as well as contributing to *Pen and Pencil Pictures from the Poets* (Nimmo, 1866) and to *Touches of Nature by Eminent Artists* (Strahan, 1866). His principal paintings, in addition to those already mentioned, are "One of Cromwell's Divines" (1862); "The Trio," "The Tonsure," and "George Fox refusing to take the Oath" (1863); "The Drumhead Court-Martial" (1865); "An Arrest for Witchcraft" (1866); "Sir Hugh and Ralph in the Stocks," "A Visit to the Necromancer," "The Rehearsal," "John MacWhirter, Esq." (1871); "Terms to the Besieged" (1872); "The Flag of Truce" (1873); "A Scene in Hal o' the Wynd's Smithy" (1874); "The Sword and Dagger Fight" (1877, now belonging to the city of Aberdeen); "A Death Warrant" (1879); "Before his Peers" (1881); "Monmouth and James II." (1882); "The Vigil" (1884, in the Chantrey Collection at the National Gallery of British Art; see Plate); "Challenged" and "Sir Peter Teazle" (1885); "The Chieftain's Candlesticks" (1886); "The Traitor" (1889); and "The Ultimatum" (1892). Pettie died at Hastings on the 21st February 1893, at the age of fifty-four, and was buried in Paddington Cemetery. In 1894–95 a selection of his work was included in the Winter Exhibition of the Royal Academy.

See Sir WALTER ARMSTRONG's article in the *Dictionary of National Biography*.—W. MATTHEWS GILBERT in the *Art Journal*. (E. F. S.)

Pézenas, town and railway station, arrondissement of Béziers, department of Hérault, 26 miles in direct line west-south-west of Montpellier. The distilling of absinthe and other spirits, and the manufacture of distilling apparatus, casks, &c., are the principal industries. The commerce in cognac, spirits, and wines is so important that the prices current for these at the weekly sales are registered throughout the wine marts of France and Europe. A handsome monument of Molière, who lived here for several years, was erected in 1896. Population (1881), 6502; (1901), 6951.

Pfäffers. See RAGATZ.

Pfleiderer, Otto (1839–——), German Protestant theologian and philosopher, was born near Cannstadt in Würtemberg on 1st September 1839. From 1857 to 1861 he studied under Baur at Tübingen, and afterwards studied in England and Scotland. He then entered the Church, and for a short time held a pastorate at Heilbronn; but in 1875 he was called to the chair of systematic theology at Berlin, having made his name by a series of articles on New Testament criticism and Johannine and Pauline theology, which appeared in Hilgenfeld's *Zeitschrift für wissenschaftliche Theologie*, and by his *Paulinismus*, published in 1873. *Das Urchristentum* was published in 1887, and in 1890 *The Development of Theology since Kant, and its Progress in Great Britain since 1825*, which was written for publication in England. Kant's essay *Was ist Aufklärung?* is taken as the programme of the task to which German philosophy has devoted itself since his day. "The Influence of the Apostle Paul on Christianity" was the title of a course of Hibbert Lectures given in London in 1885. In 1894 he delivered the Gifford Lectures at Edinburgh, the subject being "The Philosophy and Development of Religion." In New Testament criticism Pfleiderer belongs to the critical school which has grown out of the impulse given by Baur. But, like other modern German theologians, he shows a greater disposition to compromise, and has none of the dogmatic narrowness that was at one time a characteristic of the German school. All his work shows a judicial tone of mind, and is remarkable for the charm of its style. Professor Pfleiderer's younger brother EDMUND (1842–1902) devoted himself to similar studies, and distinguished himself both in philosophy and theology. He too for a time held a post in the Church, and during the Franco-German war served as army chaplain, an experience described in his *Erlebnisse eines Feldgeistlichen* (1890). He was afterwards appointed professor of philosophy at Kiel, and in 1878 he was elected to the philosophical chair at Tübingen. He published works on Leibnitz, Empiricism and Scepticism in Hume's Philosophy, Modern Pessimism, Kantic Criticism, English Philosophy, Heraclitus of Ephesus, and many other subjects.

Pforzheim, a town of Germany, grand-duchy of Baden, on the outskirts of the Black Forest, 19 miles by rail south-east of Carlsruhe. It is a centre for the manufacture of gold and silver ornaments and jewellery. Amongst its public institutions may be mentioned a technical school, a hydropathic, a lunatic asylum, and a museum. Population (1885), 27,201; (1895), 33,345; (1900), 43,097.

Phaltan, a native state of India, in the Deccan division of Bombay, ranking as one of the Satara Jagirs. Area, 397 square miles; population (1891), 66,383; gross revenue (1897–98), Rs.2,29,425, of which Rs.14,810 was expended on public works; tribute, Rs.9600; number of police, 65; 33 schools, with 1355 pupils. The chief, whose title is desmukh, is a rajput by caste, tracing his descent to a grantee from a Delhi emperor in the 14th century. The town of PHALTAN is 37 miles north-east of Satara. Population (1891), 10,564; municipal revenue (1897–98), Rs.11,323.

Pharmacology.—Systematic writers on the subject differ considerably in the exact meaning which they attach to the term pharmacology (φάρμακον, a drug, λόγος, a discourse), some making it much more comprehensive than others. Binz, for instance, defines it as treating of the origin, nature, chemical and physical qualities, physiological actions, and therapeutical uses of drugs; in France and in Italy it is restricted to the mere description of medicines and their preparations, the action and uses of which as remedies are included in the term therapeutics. In the English-speaking countries of the world, and by the majority of German writers also, the meaning is now restricted to the study of the action of chemical substances (as apart from foods) on all kinds of animals, from bacteria up to man; it is, in fact, a comparative study of the action of chemical bodies on invertebrate and vertebrate animals, the ultimate aim being to obtain a wider and more accurate knowledge of remedial substances in relation to their practical

"THE VIGIL." By JOHN PETTIE.

(From a Photograph by W. A. Mansell and Co.)

application in the treatment of disease. This meaning of the word has now become fixed in the English language by use and wont. The term pharmaco-dynamics (φάρμακον, δύναμις, power), which is etymologically more correct, is often used as its equivalent, but it has never become widely adopted in the United Kingdom. Hitherto the study of pharmacological actions has been almost entirely confined to remedial agents, and especially to those in the different national pharmacopœias, but in many cases it has now been extended to substances which are not used for curative purposes. Being a comparatively recent development of medical science, it found, when it came into the field, numerous remedies of undoubted activity in general use, and for many years it contented itself with attempts to investigate and explain the actions of these, but latterly the introduction into practical use of many medicines, such as paraldehyde, antipyrin, and strophanthus, has followed the study of their actions on animals, and this tends to be more and more the case. Pharmacology is a branch of biology just as physiology is. It is also closely connected with pathology and bacteriology, for certain drugs produce structural as well as functional changes in the tissues, and in germ diseases the peculiar symptoms are caused by foreign substances (toxins) formed by the infective organisms present in the body. The effects of many of these toxins bear a close resemblance to the action of certain well-known drugs, as in the case of tetanus toxin and strychnine, and are studied by the same methods of observation and research. It is impossible also to dissociate pharmacology from clinical therapeutics; the former investigates the agents which are used in the treatment of disease, the latter is concerned with their remedial powers and the conditions under which they are to be used. Hence the word "pharmaco-therapy" has come largely into use, and most of the newer standard text-books combine together the consideration of pharmacology and therapeutics. Pharmacology is also related to toxicology, as many remedial and other agents are more or less poisonous when given in large doses, but it does not include the detection, tests, and the other strictly medico-legal aspects of poisoning.

History.

Medical writers in ancient and mediæval times had a very good idea of the general symptoms produced in man by certain important drugs, such as opium, belladonna, and alcohol, and of the effects of certain purgatives, emetics, and so on, but they were without any accurate conception of the why or wherefore of these effects, and of the special organs on which their actions were exerted. Pharmacology necessarily had to wait on the development of chemistry, physics, physiology, pathology, and medical diagnosis. Until physiological research had investigated and explained the structure, function, and mechanism of the tissues and organs of the body in their normal conditions, it was hopeless to expect that the effect of drugs on them could be profitably studied. Pharmacology therefore took origin as the result of the application of strictly experimental methods to physiology. The discovery (early in the 19th century) that plants owe their remedial and poisonous qualities to small quantities of definite active principles, such as alkaloids and neutral bodies, which can be extracted in a chemically pure condition, had also a very important effect on its development. We meet first with some early experiments made by investigators who perceived that observations on man and animals might lead to a better understanding of the action of drugs. In 1676 Wepfer and Conrad Brunner demonstrated on dogs the tetanizing action of nux vomica, and similar rough experiments were repeated from time to time with other substances by later investigators. In 1755 Menghini published an elaborate study of the action of camphor on a great variety of different kinds of animals. Albert von Haller (born 1708) sought to elucidate the action of remedies by observations on healthy men, and in 1767 William Alexander made experiments on himself with drugs, which were, however, brought to an abrupt termination by his nearly killing himself. In 1776 Daries, by observations on himself and on cats, established the mydriatic action of belladonna and other atropaceous plants. Hitherto no attempt had been made to determine what particular parts of the body were especially affected by drugs, but Fontana showed, in his great work (Florence, 1765) on the venom of the viper and on other poisons, that the general symptoms were brought about by an action on particular organs. In the course of his researches he performed more than six thousand experiments, more than four thousand of which were on animals, and he determined the effects on the heart and other isolated parts. These analytical methods of research were well known to the second Monro in Edinburgh, and to his pupils, one of whom, William Alexander, wrote a thesis in 1790 entitled "De partibus corporis animalis quae viribus opii parent." His methods were doubtless known also to the French physiologist Magendie, who improved upon them, and who in 1809 published a research on the Upas Tieuté and other strychnine-containing plants, in which he showed that their effects were due to an action on the spinal cord. The researches of his pupil, Claude Bernard, on curare, were equally exact and logical, and have served as the model for many subsequent investigations. In consequence, from the time of Magendie pharmacology may be said to have been put on a more exact basis. By the middle of the 19th century there were many workers on the subject, and the actions of such drugs as digitalis, morphine, alcohol, and many others had been frequently and minutely investigated. About this time Buchheim, professor of materia medica in Dorpat from 1846 to 1879, founded the first pharmacological laboratory on modern lines in Europe, and he performed a still greater service by introducing a more rational classification of drugs than had hitherto been in use, arranging them in groups according to their pharmacological actions. In the herbals and older treatises on materia medica and therapeutics, no explanation is usually offered of the action of medicines, and in such works as that of Cullen (1789) only a few of the more obvious actions are occasionally explained according to the current theories of physiology and pathology. In works such as Pareira's *Elements of Materia Medica and Therapeutics* (1842), the physiological effects of medicines are usually described, but very briefly as compared with the materia medica. At the present day most text-books dealing with medicinal agents and treatment devote a large part of their space to pharmacology, and a corresponding change has taken place in the teaching of the subject in our universities and medical schools. Since Magendie's time very numerous papers dealing with pharmacological subjects have appeared in such journals as the *Journal of Anatomy and Physiology*, the *Journal of Physiology*, Virchow's *Archiv*, and the principal medical periodicals of all countries. In 1873 the *Archiv für experimentelle Pathologie und Pharmakologie* first appeared, and in 1895 the *Archives Internationales de Pharmakodynamie*, both chiefly or entirely devoted to pharmacology.

The methods of research are essentially those employed by physiologists, the action of substances being studied in the usual way on bacteria, leucocytes, frogs, rabbits, and other animals. Not only are the general symptoms investigated, but it is necessary to carry out experiments on the nerves, muscles, circulation, secretions, &c., so as to get a more exact knowledge of the reasons of the general action. It is true that many of these animals react somewhat differently to drugs, both as regards each other and as regards man, but for the most part the differences are quantitative rather than qualitative. After carrying out a series of observations on animals, the drug can be assigned to its special group, and a good idea can be obtained of its possible practical value or the reverse; hence there is a saving of time and an avoidance of the necessity of testing its effects on man. The action of a drug may be called direct, when it acts on any part to which it is immediately applied, or which it may reach through the blood; and indirect, when one organ is affected secondarily to another, as, for instance, in strychnine poisoning when the muscles are violently contracted as the result of the action of the alkaloid upon the spinal cord. In a few cases the action is merely physical, but most frequently it is chemical in its nature, and is exerted on the living cell, the activity of which is either stimulated or depressed. In some cases the substances actually enter into a chemical combination with the protoplasm, which may be temporary or (much less frequently) permanent; in other cases they seem simply to modify or disturb the usual chemical activity of the cells. Prolonged or excessive stimulation invariably leads to depression or paralysis, the tissues becoming, in fact, fatigued, and from this condition they may recover or they may not. When we come to consider more in detail the results of these actions, we find that the various secretions of the body, such as the sweat, gastric juice, bile, milk, urine, &c., may be increased or diminished; that the heart may have its muscular or nervous apparatus stimulated or depressed; that the nerve-centres in the brain, medulla, and spinal cord may be rendered more sensitive or the reverse; and that the general metabolism of the body may be altered in various ways. In addition, the fluid constituents, such as the lymph and blood, may have their composition and bulk considerably altered, while the special senses, the temperature, and, in short, every function and tissue, may be more or less affected.

Action of drugs.

Some drugs given in excess are poisons to all forms of protoplasm, but when given in doses much short of the lethal they usually exhibit a distinct tendency to affect specially, and at an early period, certain organs or tissues, and hence result differences in action; others may act only on certain organs, leaving the others practically untouched. It is often possible by appropriate dosage to contrive that these special parts or organs may be affected and the rest of the body left practically intact, and it is by taking advantage of these selective actions that remedial or therapeutical effects are usually obtained. Some substances have a very wide range of action, and involve a great variety of structures, while others, such as purgatives, have a very limited sphere.[1] The most important of these circumstances is age, but speaking broadly this is really a question of bulk, the child being affected as the adult, but by smaller doses. There are exceptions to this, however, as children are more affected in proportion by opium and some other substances, and less by mercury and arsenic. In old age also the nervous system and the tissues generally do not react so readily as in youth. Habit, race, personal temperament, emotional conditions, disease, the time and circumstances of administration, and other accidental causes may also modify the action in man. Some species of animals are much more susceptible to the action of certain drugs than others, a condition which depends on obvious or unknown structural or metabolic differences. In the same way some individuals show a special tendency to poisoning by doses of certain drugs which are harmless to the great majority of mankind, and hence we get unexpected or unusual results, these arising from special susceptibility on the part of certain organs. These idiosyncrasies are not confined to drugs, but are seen with a few articles of food, such as eggs and shell-fish. It is well known that the habitual consumption of certain drugs, such as tobacco, Indian hemp, opium, arsenic, alcohol, and many others, gradually induces a condition of tolerance to their effects, so that large doses can be taken without causing symptoms of poisoning. In all cases, however, there is a limit, and after it is reached the ordinary effects of these substances are seen. Some individuals, however, never become tolerant, and show poisonous effects on each repetition of the dose. The degree of tolerance often differs in individuals at different times and in different circumstances, and may become quite lost by breaking off the habit for a short time. The explanation generally given is that the nerve and other cells become accustomed to the drug, so that they cease to react, or that an antitoxin is formed which antagonizes the poison, or that the poison is rapidly destroyed in the body. Recent researches on arsenic and atropine, however, point to the leucocytes as playing an important part in the production of tolerance, as these gradually become capable of ingesting large amounts of the foreign substances, and thus render them more or less harmless to the tissues, until they are gradually excreted from the body. But in the case of arsenic an antitoxin also forms in the blood. When the amount is too large to be dealt with by the leucocytes, poisoning seems to occur even in the most habituated. Tolerance is therefore analogous to the immunity which takes place with the toxins of infectious diseases and snake poison. Certain substances, notably digitalis, lead, mercury, and strychnine, exhibit what is called a cumulative action—that is to say, when small quantities have been taken over a period of time, poisoning or an excessive action suddenly ensues. The explanation in these cases is that the drug is absorbed more rapidly than it is excreted, hence there is a tendency to its accumulation in the body until a point is reached when the amount becomes poisonous.

Bodies which have a close resemblance in their chemical constitution exhibit a similar resemblance in their pharmacological action, and as the constitution of the substance becomes modified chemically so does its action pharmacologically. Numerous researches have demonstrated these points with regard to individual groups of substances, but hitherto we have not been able to formulate any fixed laws regarding the relationship between chemical constitution and physiological action.

When drugs are swallowed no absorption may take place from the alimentary canal; but, as a rule, they pass from there into the blood, in which they circulate, and thus exert their action on different organs. Absorption may also take place from the skin, from the rectum, from the respiratory passages, or from wounds, and from direct injection into the subcutaneous tissue or into a blood-vessel. Very rarely, as in the case of silver salts, excretion does not take place; but usually the drug is got rid of by the bowel, urine, bile, saliva, bronchial mucous membrane, or the other ordinary channels of elimination. Just as drugs act upon the tissues, so they themselves are in many cases reacted upon, and broken up or altered. While in the alimentary canal they are subjected to the action of the digestive fluids and the varied contents of the stomach and intestines, and after absorption they come under the influence of the constituents of the blood and lymph, and of the chemical action of the tissue cells. Inorganic bodies, such as metals, may enter into albuminous combinations which may greatly modify their effects, and organic substances may be split up into simpler compounds by

[1] The action of drugs is often modified by circumstances peculiar to the individuals or animals to whom they are administered.

oxidation or reduction, or may be rendered more complex by synthesis.

The antagonism between certain drugs has been much studied in relation to their use as antidotes in poisoning, but what is aimed at in these cases is to counteract the effects rather than to obtain a direct physiological antagonistic action. The substances which directly antagonize each other by acting on the same tissue are few in number, but there are numerous instances in which the effects or symptoms may be obviated by acting on another tissue. Thus curare may stop strychnine convulsions by paralysing the terminations of motor nerves, and chloroform may exercise the same effect by abolishing the irritability of the spinal cord. If two poisons act on the same tissue, one stimulating and the other paralysing it, the paralysing substance removes the action of the stimulant substance, not by bringing the tissue back to its normal state, but by abolishing its excitability; hence, although life may be saved by such an action, yet it can only be so within certain limits of dosage, because the antagonism is never complete at every point.

Speaking in the widest sense, every substance has an action on living protoplasm, but for convenience' sake pharmacological substances have come to be limited to those which are used as drugs, or which have a distinct action upon the animal organism, although they may not be put to any practical purpose. Such substances are derived from (1) the chemical elements and their compounds; (2) plants; and (3) animals. The first class includes such substances as iodine, mercury, iron, carbon, and their various compounds, and such bodies as alcohol, chloroform, and chloral, all of which are found in Nature or can be prepared by ordinary chemical processes of manufacture. From plants many substances are obtained which at the present time we are unable to make in the chemical laboratory, and of the constitution or composition of which we are in many cases ignorant. Some of these, such as resins, gums, essential oils and fats, are readily obtained as natural exudations or by very simple manipulations, while others, such as the alkaloids, glucosides, and vegetable acids, often require to be extracted by very complex processes. Substances obtained from animals include gland secretions, pepsin and other ferments, musk, cod-liver oil, &c., and to these may be added various antitoxins. The classification of substances having pharmacological actions presents so many difficulties that no satisfactory or universally adopted method has yet been proposed. As a matter of fact, our knowledge presents so many gaps, and the mode of action of many remedies is so obscure and imperfectly understood, that any arrangement adopted must be more or less tentative in character. The close alliance between pharmacology, therapeutics, and clinical medicine has induced many authors to treat the subject from a clinical point of view, while, on the other hand, its relationships to chemistry and physiology have been utilized to elaborate a chemical and physiological classification respectively as the basis for systematic description. Certain writers in despair have adopted an alphabetical arrangement of the subject, while others have divided it up into inorganic, vegetable, and animal substances, following the botanical natural orders and the divisions of the animal kingdom. These last-mentioned methods, however, are far behind our present state of knowledge, and need not be discussed here. The objection to a strictly chemical classification is, that while many substances closely allied chemically have a somewhat similar action in certain respects, yet in others they differ very widely—a striking example of which is given in the case of sodium and potassium. A physiological classification according to an action on the brain, heart, kidney, or other important organ becomes still more bewildering, as many substances produce the same effects by different agencies, as, for instance, the kidneys may be acted upon directly or through the circulation, while the heart may be affected either through its muscular substance or its nervous apparatus. A clinical or therapeutical classification into such divisions as anæsthetics, expectorants, bitters, and so on, according to their practical applications, also leads us into difficulties, as many drugs are employed for numerous purposes, and they cannot therefore be strictly classified in this way. The ideal method of grouping pharmacological substances would be in reference to their chemical action on living protoplasm, but as yet our knowledge is too scanty for this. At the present time the method adopted by Buchheim, or some modification of it, is the most scientific. As the result of painstaking investigations he grouped together all those substances having similar actions, giving to each group the name of its best-known or most thoroughly investigated member. Once the groups were more or less fixed any new substance could, when its action was determined, be referred to its own group, and thus be placed or classified. As few substances are absolutely identical in action, but only broadly similar, it is often difficult to divide sharply one group from another. In a *résumé* it is manifestly impossible to pass in review every pharmacological substance, and we shall therefore confine ourselves to those groups which are of practical importance. Many of the individual drugs have been already described, and detailed information regarding them may be obtained by reference to the particular headings in the earlier volumes (ninth edition) of this Encyclopædia.

Classification.

Group I.—*Acids.*—This includes sulphuric, hydrochloric, nitric, phosphoric, tartaric, citric, acetic, and lactic acids, all of which owe their action to their acidity. Many of the other acids, such as carbolic and salicylic, have specific effects which have no relationship to their acid reaction. The concentrated acids have an intense local action, varying from complete destruction of the tissues to more or less irritation. When considerably diluted they lose this, and are only slightly irritating; externally applied and in the stomach they have an antiseptic action; they increase the secretion of saliva, and thus assuage thirst. In the intestine they combine with ammonia and other alkalis present, and are absorbed into the blood as neutral salts, being excreted chiefly in the urine. In small doses they somewhat increase general metabolism. Boric acid only belongs partially to this group, as it and its compound borax have certain specific actions in addition.

Group II.—*Alkalis.*—This includes caustic potash, caustic soda, solution of ammonia, their carbonates and bicarbonates, borax, soaps, lithium carbonate and citrate, quick lime, slaked lime, chalk, magnesia, and magnesium carbonate. All these substances, apart from any other actions, exert a similar effect upon the body in virtue of their alkalinity. When they are taken internally in small amounts they neutralize the acids in the stomach and other parts of the alimentary canal, and at the same time they increase the normal acid secretion of the stomach. After absorption into the blood, which they make somewhat more alkaline, they are excreted chiefly in the urine, to which they impart an alkaline reaction if given in sufficient quantity. Some of them by stimulating the kidney cells act as diuretics, but others apparently lack this action. Caustic potash and caustic soda are locally very irritating, and destroy the tissues, but lose this quality when combined with acids as in the case of their carbonates, bicarbonates, and borax. Quick lime is also caustic, but magnesia is bland and unirritating. Weak solutions applied locally saponify fats, soften the epidermis, and thus act as slight stimulants and cleansers of the skin. Calcium salts form insoluble soaps with fats, and combine with albumen in a manner which makes them soothing and astringent rather than irritating locally. Apart from alkaline effects, these metals differ considerably pharmacologically. Potassium and lithium have a depressing action upon the nervous system, ammonium salts have a stimulating action, while sodium practically speaking is indifferent. Calcium and magnesium have actions somewhat similar to that of potassium. Most of these substances are normal constituents of the body, and indispensable for healthy existence. They are contained in sufficient amount in our ordinary dietary to supply the needs of the organism.

Group III.—*Easily absorbed Salts.*—Sodium chloride may be taken as the type of those salts which diffuse readily, and which are therefore easily absorbed. Sodium nitrate, potassium nitrate, potassium chloride, ammonium chloride, the alkaline iodides and bromides, also belong partly to this group, although most of them have specific actions in addition. Locally they cause considerable irritation, and when swallowed in concentrated solution may cause vomiting. From the stomach and intestines they are rapidly absorbed, and rapidly excreted from the blood, increasing all secretions and the general metabolism. These effects are apparently due to their irritating action upon individual cells.

Group IV.—*Salts absorbed with difficulty.*—This group includes the sulphates of sodium, potassium, and magnesium, the acetate and tartrate of potash, citrate of magnesium, sodium phosphate, sodium tartrate, and similar salts. Locally their action is slight, but when taken internally, dissolved in water, they are not absorbed from the alimentary canal except in very limited amount. They therefore remain for the most part in the intestine, and as they attract and retain large quantities of water, and at the same time slightly stimulate the mucous membrane, they come to have a purgative action and form the well-known group of saline cathartics. The small portion which is absorbed exerts a diuretic action.

Group V.—*Heavy Metals.*—These include iron, manganese, aluminium, chromium, zinc, copper, silver, gold, platinum, lead, mercury, and probably antimony, arsenic, and bismuth. Although some of these differ very greatly in their actions after absorption, still locally they have certain effects in common due chiefly to their chemical action on albumen. Their soluble salts precipitate albumen and preserve it, strong solutions being extremely irritant or caustic, while weaker ones are astringent simply, or even soothing. They are all antiseptics. Their insoluble compounds are much less active locally than the soluble, and in many cases are only effective to the extent to which they are dissolved by the secretions. Some metals are only absorbed from the alimentary canal to such a very limited amount that they exert no general action, while others readily pass into the blood and give rise to more or less marked effects. All of them injected into the blood in large doses act as muscle and nerve poisons, and during their excretion by the kidney usually irritate it severely, but only a few are absorbed in sufficient amount to produce similar effects when given by the mouth. When iron is injected directly into a vein it depresses the heart's action, the blood pressure, and the nervous system, and during its excretion greatly irritates the bowel and the kidneys. When taken by the mouth, however, no such actions are seen, owing to the fact that very minute quantities are absorbed, and that these become stored in the liver, where they are converted into organic compounds and ultimately go to form hæmoglobin. Soluble salts of manganese, aluminium, zinc, copper, gold, platinum, and bismuth have, when given by the mouth, little action beyond their local astringent or irritating effects; but when injected into a blood-vessel they all exert much the same depressing effect upon the heart and nervous system. Silver resembles them closely, but differs by the circumstance that it is deposited permanently in minute granules in the tissues, and, without affecting the general health, stains the skin of a bluish colour (argyria). Mercury and lead are absorbed from the bowel in considerable quantities, and are capable of inducing acute irritant poisoning as well as chronic poisoning. In the case of lead, the metal poisons the muscular and nervous systems, and gives rise to paralysis, wasting, colic, and other symptoms, while in the case of mercury, tremors, salivation, anæmia, and very marked cachexia are induced. Arsenic and antimony do not form combinations with albumen, but they both greatly depress the central nervous system and circulation; and, if their action be long continued in large doses, they cause fatty degeneration of the viscera and disappearance of glycogen from the liver. Locally they are both very irritating, and antimony has a special tendency to cause vomiting.

Group VI.—*Halogens.*—This group includes iodine, bromine, and chlorine, in their free state or as compounds. Locally they are all three strongly irritant or caustic, owing to their chemical action on albumen. They are in addition powerful germicides, and by splitting up water may act as oxidizing agents. Owing to their strong affinity for the hydrogen of organic compounds, they often act as bleachers and deodorizers. Iodine has a special interest, from the fact that it is a necessary constituent of our food, and is present in the secretion of the thyroid gland. Apart from certain conditions of ill-health, the iodides, as such, have no very marked influence on the healthy body beyond their saline action. Alkaline bromides, in addition to their saline action, have in sufficient doses a depressing effect upon the central nervous system, and less markedly upon the heart. Chlorine compounds are not known to exercise any action of a similar kind.

Group VII.—*Sulphur.*—Sulphur itself has no action, but when brought into contact with the secretions it forms sulphides, sulphites, and sulphuretted hydrogen, and thereby becomes more or less irritant and antiseptic. In the bowel its conversion into sulphides causes it to act as a mild laxative. Baths containing sulphuretted hydrogen or alkaline sulphides have a slightly irritating effect upon the skin, and stimulate the general metabolism.

Group VIII.—*Phosphorus.*—This includes phosphides, and, according to some authorities, hypophosphites. Phosphorus is present in all cells, in considerable quantity in the nervous tissue, and in the bones as phosphates. It is therefore, in some form or other, a necessary part of our dietary. When the element itself is taken by the mouth it is an irritant poison in large doses; in small doses the only effects which are noticeable consist in an increased formation of bony and connective tissue, although it is also supposed to exert a gently stimulating effect upon the nervous system.

Group IX.—*Oxygen.*—When pure oxygen is inhaled the only effect is a slight increase of the amount of the gas in the blood, but this has no particular physiological effect. The pharmacological action of hydrogen peroxide (H_2O_2), potassium permanganate, powdered charcoal, and some other oxidizing agents depends on the readiness with which they give up oxygen.

Group X.—*Carbonic Acid.*—Carbonic acid gas, carbonic oxide (CO), and some other irrespirable gases produce their effects practically by asphyxiation. When dissolved in water, however, carbonic acid gas is a gentle stimulant to the mouth, stomach, and bowel, the mixture being absorbed more rapidly than plain water; hence its greater value in assuaging thirst. Nitrous oxide (laughing gas) was at one time believed to act simply by cutting off the supply of oxygen to the tissues, but in addition to that it has certainly a specific effect in producing paralysis of certain parts of the central nervous system, and hence its value as an anæsthetic; when given in small amounts mixed with air it simply produces a condition of exhilaration.

Group XI.—*Water.*—Water acts directly as a diluent and solvent in the body. It therefore increases all the secretions, especially those of the skin and kidneys, while it also stimulates the general metabolism of the body and the excretion of nitrogenous products. Mineral waters act in the same way, but their effects are very much modified by, and depend largely upon, other constituents, such as alkaline salts, iron, arsenic, sulphides, carbonic acid, &c.

Group XII.—*Tannic Acid.*—Tannic acid is present in small quantities in the great majority of plants, but in notable quantity in gall-nuts, oak bark, bearberry leaves, rhatany root, catechu, kino, red gum, bel fruit, logwood, and witch hazel, all of which are largely used as medicines. In these the variety of tannic acid is not exactly the same, but although there are slight chemical differences, they all possess the power of tanning raw hides and of preserving albuminous tissues. The action of tannic acid is strictly local, and depends upon its power of precipitating albumen and of destroying germs. It thus acts as an astringent on all mucous membranes. After absorption into the blood it loses this effect, as it is partly broken up into gallic acid and partly combined with alkalis, both of which changes nullify its action upon albumen.

Group XIII.—*Local Irritants.*—Although some of the drugs already considered have a local irritant action, they produce other effects which throw this into the background, but the substances which are here ranged under this heading depend entirely for their action on their local irritant effects.

(*a*) Those which act upon the alimentary canal:—Simple bitters such as quassia wood, columbo root, taraxacum, gentian, chiretta, and many others, irritate gently the mucous membrane of the stomach and bowels, and by increasing the secretions improve the appetite and digestion. The aromatic bitters such as camomile flowers, cascarilla bark, hops, absinthe, orange peel, and others, contain in addition small quantities of essential oils which increase their local action and give them a pleasanter flavour. The active principles in some of these bitters have been isolated pure, and have been found to be alkaloids or neutral compounds. Substances like pepper, cayenne pepper, mustard, horse-radish, and ginger irritate the stomach and bowel much in the same way, but are more pungent, and are consequently used as condiments. Some of these have a similar but less marked effect upon the skin. The large number of vegetable substances which are used as purgatives owe their action to an irritating effect upon the mucous membrane and the neuro-muscular apparatus of the bowel, whereby the secretions and peristalsis are more or less increased, as the result of which diarrhœa ensues. Some of them cause so much irritation that the discharge is very watery (hydragogue cathartics), while others, for example aloes, by acting gently on the lower part of the bowel and on its muscular coat, produce simply a laxative effect. A few of them, such as aloin and colocynthin, are also purgative when injected subcutaneously or into the blood, probably owing to their being excreted into the intestinal canal.

(*b*) Those which act on the skin:—The best known of these is cantharides (Spanish fly), the active principle of which is a colourless crystalline body—cantharidin—which is extremely irritating. On a mucous membrane or a delicate skin it exerts an irritant action, which occurs more quickly than on a thickened epidermis, such as the scalp, and according to the strength and period of application there may result redness, a blister, or an ulcer. Many other substances, such as chrysarobin, mustard, pepper, &c., are also capable of irritating the skin, the effect produced varying from mere dilatation of the cutaneous vessels to destruction of tissue.

Group XIV.—*Male-fern.*—This includes the male-fern, santonin, cusso, pomegranate bark, pumpkin seeds, and a very considerable number of other substances, all of which contain active principles which have a specific poisonous action on intestinal parasitic worms. Apart from this their actions vary considerably, but are of little practical importance.

Group XV.—*Ethereal Oils.*—This includes a very large number of substances which owe their action to the fact that they contain ethereal or essential oils. The best known of these are cloves, pimento (allspice), myrtle, eucalyptus, caraway, fennel, dill, coriander, rosemary, lavender, peppermint, spearmint, nutmeg, cinnamon, sandal-wood, turpentine, juniper berries, valerian, sumbul, and many other substances. In this group may also be included the oleo-resins, such as copaiba, cubebs, and Canada balsam; the gum-resins, such as asafœtida, myrrh, ammoniacum, and galbanum; and the true balsams, such as benzoin, storax, balsam of Tolu, and balsam of Peru. The resins when taken internally have much the same action as essential oils, which are closely allied chemically, while the benzoic and cinnamic acids present in the balsams modify their actions very slightly. Although individual essential oils may differ somewhat in action, yet chemically and pharmacologically they are fundamentally similar. They all have a poisonous action on protoplasm, which makes them useful in medicine as antiseptics, disinfectants, germicides, anti-fermentatives, and parasiticides; when locally applied they are more or less irritating, and, when very dilute, astringent. When swallowed in small doses they slightly irritate the mouth and gastric mucous membrane, increasing the secretions and producing a feeling of warmth. At the same time they increase the movements of the stomach, and also in this way hasten digestion, an action which extends to the upper part of the bowel. They are readily absorbed into the blood, and they are excreted chiefly by the kidneys in a more or less altered form, and probably also by the different mucous membranes, and even by the skin. After absorption their action, speaking generally, is exerted on the brain and spinal cord, and is at first slightly stimulant and afterwards depressing, even to the causing of sleepiness and stupor. Locally applied they depress the terminations of sensory nerves, and may thereby lessen pain. On the heart and circulation the effects are stimulant unless large doses are given, when the pulse becomes slow and blood-pressure much lessened. During excretion they irritate the kidneys and the sweat glands, and thereby increase the excretion of urine and of sweat. They also have the effect of increasing the number of leucocytes in the blood, and the more irritating of them increase the flow of blood to the pelvic organs, and may thus stimulate the uterus, or in large doses cause abortion. The various camphors, such as laurel camphor, Borneo camphor, menthol, and cumarin, are oxidized derivatives of essential oils, and differ only superficially from them in their action.

Group XVI.—*Phenol.*—This includes a very large number of bodies chemically allied to benzol, such as carbolic acid, sulpho-carbolates, creosote, wood tar, coal tar, oil of cade, thymol, salicylic acid, benzoic acid, naphthol, hydrochinon, cresol, guaiacol, ichthyol, saccharin, and many others. These all resemble carbolic acid more or less closely, and may be described as general protoplasm poisons. Locally their destructive and irritating effects vary a good deal, but even when very dilute they all have a marked poisonous action on bacteria, white blood corpuscles, yeast, and similar organisms. After absorption most of them exercise a depressing effect upon the nervous system, and are capable of reducing high temperature. They are mostly excreted in the urine.

Group XVII.—*Alcohol.*—This group also includes a very large number of chemical bodies, only a few of which are mentioned here. Ethylic alcohol is taken as a type of the action of methyl alcohol, amyl alcohol, propyl alcohol, ether, acetic ether, amyl ether, paraldehyde, sulphonal, chloroform, methyl chloride, ethyl chloride, chloral hydrate, butylchloral hydrate, and almost any number of derivatives from these. Some of them are so volatile that they produce their effects when inhaled, others when sprayed upon the skin cause intense cold and then anæsthesia; but taken in the broadest sense the action of all of them after absorption into the blood is very similar, and is exerted upon the central nervous system, more especially the cerebrum. Their effects are said to be brought about by a slight coagulating action on the substance of the grey nerve-cells. In all cases there is a longer or shorter period of excitement, followed by intoxication or narcosis, and with large doses this passes into paralysis and death from depression of the respiratory centre or of the heart. Small doses of any of them dilate the blood-vessels from an action on the vaso-motor centre in the medulla oblongata, as a result of which the heart beats more rapidly and the blood circulates more freely in the body; but larger doses have a general depressing effect upon the circulatory system. Under their action more heat is lost from the body, the general metabolism is diminished, and the temperature falls. With some of them, such as chloral and chloroform, the stimulation period is short compared with the narcotic period, while with others, such as ether, the reverse is the case.

Group XVIII.—*Nitrites.*—This group contains amyl nitrite, ethyl nitrite, methyl nitrite, nitroglycerin, sodium and potassium nitrites, erythrol-tetranitrate, and many other compounds containing nitrous or nitric acid The latter becomes reduced to nitrous in the body, and thereby exercises its characteristic effects. These consist chiefly in an action upon non-striped muscle, vaso-motor centres, blood-vessels, and the blood. When they are given by inhalation or by the mouth their first effect is to produce marked dilatation of the small arteries, with a fall of blood-pressure and a greatly increased rapidity of the heart's action. At the same time the non-striped muscles slightly lose their tonicity, and when very large doses are given the hæmoglobin of the blood becomes converted into the chocolate-coloured methæmoglobin. The volatile members of the group act much more rapidly and more transiently than the others.

Group XIX.—*Alkaloids.*—This embraces a very large number of important pharmacological substances, which differ a good deal in the details of their action, but which have this in common, that they all act upon muscle and nerve tissue. Some of them affect only certain portions of the nervous system, others have a much wider range of action; they may act in either case as stimulants or as depressants, and hence the symptoms produced by them vary very greatly.

(1) Morphine and the other opium alkaloids (codeine, narcotine, laudanine, &c.) have two prominent actions—a narcotic followed by a tetanic action. In the case of morphine, on the higher animals at least, the narcotic action is very marked, the tetanizing action slightly so; while in the case of thebaine there is practically little narcotic effect, but a tetanizing action like that of strychnine. Morphine exercises its effects chiefly upon the cerebrum and the medulla oblongata in man. It has in addition a markedly depressing action upon the respiratory centre, it lessens all the secretions except the sweat, and diminishes bowel peristalsis and the size of the pupil. Men are much more affected by it than birds, rabbits, dogs, and most other animals. Cats, on the other hand, show marked symptoms of cerebral excitement and increase of the reflexes. Compared with morphine, codeine and the other alkaloids are only slightly narcotizing.

(2) Strychnine and brucine very closely resemble each other in action, and under this heading curarine may also be included. These bodies stimulate the grey matter in the spinal cord, and cause tetanic convulsions. In the case of curare these are masked almost at once by paralysis of the terminations of the motor nerves.

(3) Caffeine is the active principle in tea, coffee, kola, maté, and guarana; while theobromine, a body closely allied to it, is found in cocoa and chocolate. They both stimulate the grey nerve-cells in the brain and cord, this being the foundation of their dietetic value and their use as nervine stimulants. They also markedly increase the secretion of urine by stimulating the secreting cells of the kidneys.

(4) Cocaine is the active principle of the coca leaf, which is chewed as a stimulant-narcotic in Peru and Bolivia. Small doses have an exciting effect on the nervous system, while larger doses are depressing. The chief action of cocaine from a practical point of view is its power of paralysing the terminations of sensory nerves.

(5) Atropine, hyoscyamine, homatropine, duboisine, daturine, and some other bodies have a paralysing action upon the ends of the motor and secretory nerves. They therefore lessen all the secretions, and among other actions dilate the pupil and increase the rapidity of the heart by paralysing the vagus. Besides this they have a stimulating action on the central nervous system.

(6) Nicotine, piturine, and lobeline are the active principles of tobacco and other substances which are smoked as stimulant narcotics. In large doses they are powerful nerve poisons, but as usually taken they exercise a gently stimulant effect upon the nervous system. Pilocarpine has an action closely allied to that of nicotine, but as it is much less poisonous (the effects produced by small doses being chiefly excessive sweating and salivation), it is capable of being utilized in medicine. Muscarine has a very close resemblance in action to pilocarpine.

(7) Physostigmine, the active principle of the Calabar bean, acts chiefly as a stimulant to voluntary and involuntary muscles, and at the same time exercises a depressing effect upon the spinal cord. It contracts the pupil.

(8) Conine, gelseminine, and sparteine all exert a paralysing effect on the terminations of the motor nerves, to the implication of which the weakened gait and other symptoms are due.

(9) Aconitine, delphinine, and many of their derivatives have a very widespread action on muscle and nerve, which are both depressed from the beginning.

(10) Apomorphine is essentially a muscle poison, but owing to the fact that minute doses stimulate the vomiting centre and cause emesis before any other symptoms are observable, its emetic action is the most prominent effect in man.

(11) Emetine acts as a gradual depressant to the nervous system in animals. In man its chief effect is its emetic action, which seems to be due entirely to local irritation of the stomach.

(12) Quinine. Several of the other alkaloids found in cinchona bark act very much like quinine, while phenacetin, antipyrin, acetanilide, and many other artificially-made substances of the same nature resemble it and each other closely. They all depress the conducting power and the grey matter of the spinal cord, and to a much less extent that of the brain. They lessen the general metabolism and lower febrile temperature. The cinchona alkaloids have a specifically poisonous effect on the parasites of malaria when present in human blood, and are in addition poisonous to all low organisms.

Group XX.—*Digitalis.*—This group-name has been given to a large number of substances which have an action similar to that of the foxglove leaves, including the active principles of strophanthus, squill, Urechites suberecta, Convallaria majalis, Nerium Oleander, Helleborus niger, Antaris toxicaria (the upas tree), and several others. The active principles of these vary a good deal in chemical composition, but they are all non-nitrogenous neutral bodies. Their action is exerted upon muscle, but chiefly upon the muscle of the heart and blood-vessels. The individual muscle-fibres contract and expand more perfectly, and thus the diastole and systole of the heart are rendered more complete, the pulse is slowed, and the blood-pressure is raised. The slowing of the heart is partly brought about by an action on the vagus centre.

Group XXI.—*Picrotoxin.*—In large doses the action of picrotoxin is exerted chiefly on the medullary nerve centres, whereby irregular tonic-clonic convulsions are produced; in minute doses it stops the secretion of sweat.

Group XXII.—*Saponin.*—Saponin and allied bodies form an abundant soapy-looking froth when shaken up with water, and they are contained in a very large number of plants, the chief of which are the Quillaia saponaria, Polygala senega, sarsaparilla, and others, known collectively as soapworts. They all act as local irritants in the alimentary canal, and after absorption are more or less depressing to the muscular and nervous systems. They produce slight nausea and increased secretion of mucus.

Group XXIII.—*Cyanogen.*—This includes compounds of cyanogen such as hydrocyanic (prussic) acid, cyanides of potassium, sodium, &c., cherry-laurel water, amygdalin, bitter almonds, and other chemical and vegetable substances which readily yield hydrocyanic acid. Hydrocyanic acid is a general protoplasmic poison, all the lower organisms being very susceptible to its action, while in the higher animals it speedily depresses or paralyses all forms of nerve tissue. It enters into combination with hæmoglobin, forming a bright scarlet compound and interfering with respiration. It kills by its paralysing effect on the motor ganglia of the heart and on the respiratory centre.

Group XXIV.—*Ferments.*—These include such bodies as pepsin, diastase, the pancreatic ferments, papain, the pine-apple ferment, taka-diastase, and others, and serve to convert starch into saccharine substances, or albumen into peptone and albumoses.

Group XXV.—*Animal Glands and Secretions.*—Of these the thyroid gland, the suprarenal bodies, the spleen, the bile, the bone marrow, the ovaries, and some others have been investigated fully. Speaking generally, when given in small doses their action on the healthy organism is slight or *nil*, but in disease some of them are capable of acting as substitutes for deficient secretions.

Group XXVI. — *Antitoxins.* — These are substances which antagonize the toxins formed in the body by pathogenic organisms, the toxins of snake venom and other animal poisons, and vegetable toxins such as abrin, ricin, &c. A healthy person can be rendered insusceptible by gradually accustoming him to increasing doses of these poisons, and this immunity is due to antitoxins which are found in the blood serum and which are products of the body cells. The nature of these antitoxic subtances is not definitely known, but they are supposed to combine with and destroy the poisons. In specific germ diseases a similar antitoxin forms, and in cases which recover it counteracts the toxin, while the germs are destroyed by the tissues. Antitoxins can be prepared by immunizing a large animal, such as a horse, by injecting gradually increasing doses of specific toxins into its subcutaneous tissue. In due time the horse is bled, the serum is filtered free of blood corpuscles, and then constitutes the antitoxic serum, which can be standardized to a certain potency. Such serums are injected subcutaneously in diphtheria, tetanus, streptococcic infections, plague, snake-poisoning, cholera, and other similar diseases. They do not harm healthy men even in large quantities.

Group XXVII.—*Neutral Fats.*—This includes cod-liver oil, almond oil, olive oil, lard, &c., all of which act as foods when taken internally, and have a merely physical emollient action when applied externally. Lanolin, linseed oil, wax, spermaceti, &c., also belong to this group. The paraffins, glycerin, and vaseline, although not fats, have much the same effect when applied externally, but they are not nutritive.

Group XXVIII.—*Sugars, Starches, Gums, Gelatin, &c.* —Although these and allied bodies are used in various ways, as drugs their action is for the most part purely mechanical or dietetic.

Phelps, Samuel (1804–1878), English actor, was born at Devonport, 13th February 1804. His parents dying when he was a boy, he was early thrown upon his own resources, and, after a short experience of work in various newspaper offices, took to the stage as an occupation in 1826. About the same time he married Sarah Cooper, a girl of sixteen. She bore him three sons and three daughters, and died in 1867. After playing a diversity of parts with touring companies in the north of England and in Scotland, he appeared in some south of England towns in a round of prominent tragic characters, and attracted sufficient attention to be spoken of as a rival to Kean. After a short season under Webster at the Haymarket, he joined Macready's company at Covent Garden, where he first appeared in October 1837. He was with Macready for about six years at Covent Garden, the Haymarket, and Drury Lane successively, and during this period was seen in a number of important parts. In 1844, having by this time firmly established his reputation, he became co-lessee of Sadler's Wells Theatre with Thomas Greenwood and Mrs Warner. Greenwood supplied the business capacity, Phelps was the theatrical manager, and Mrs Warner his leading lady. In this position Phelps remained for twenty years, during which time he raised the Sadler's Wells house to an important position, and himself appeared in a very extensive and varied repertory of characters. Thirty-four of Shakespeare's plays were presented there under his direction. In 1861 Greenwood retired from the partnership, and Phelps, finding himself unable to cope with the business responsibilities of the management, retired from it in the following year. For the next fifteen or sixteen years he acted under various managements, his last appearance being in 1878 as Wolsey in *Henry VIII.*, under Miss Litton at the Imperial Theatre. After this his health began to fail, and he died at Coopersale, near Epping, on 6th November 1878. He was essentially a sound and capable actor, rather than one of any marked genius; and, in spite of his predilection for tragedy, was most successful in such characters of comedy as called for dry humour. Perhaps Sir Pertinax Macsycophant in Charles Macklin's *The Man of the World* was his finest impersonation. He published an annotated edition of Shakespeare's plays, in 2 vols., 1852–54. (R. F. S.)

Philadelphia, the chief city of Pennsylvania and the third city in size in the United States, is situated on the west bank of the Delaware river, 96 miles from the Atlantic Ocean and 125 miles in a direct line north-north-east of Washington, D.C., and 85 miles south-west of the city of New York. It covers an area of 129·58 square miles, and the Schuylkill river, running north and south, divides the city. The length of river front on the Delaware is 18·8 miles, and the length of wharves 6·5 miles. On both sides of the Schuylkill the river front is 14·6 miles, and the length of wharves 3 miles. The channel of the Delaware river has been deepened to 26 feet below mean low water for the distance of 5·4 miles, giving a channel of this depth for 20 miles below the Philadelphia harbour, and it is being further deepened to 30 feet. The channel of the Schuylkill river has been deepened to 22 feet for a distance of 3 miles, and to 20 feet for a distance, above, of 17·1 miles. These improvements were begun in 1895 and completed in 1899. At the confluence of these two rivers is situated the United States Naval Station at League Island, covering an area of 997 acres and having a water front of 7 miles. This is the largest fresh-water naval station in America. Windmill or Smith's Island, in the Delaware river, lying between Philadelphia and Camden, New Jersey, which is on the east bank of the river, has been removed, giving clear navigation between the two cities by constantly-crossing ferry boats.

The city is divided into 42 wards, and there are plotted upon the city plans 955,165 separate town lots. There are laid down on these plans upwards of 3000 miles of streets, but only 1542 miles are at present opened. Of these, 413 miles are unpaved, 301 miles are laid with improved sheet asphalt pavements, 362 miles with granite blocks, 134 miles with vitrified brick, 226 miles with macadam, 61 miles with cobble or rubble stone, and 29 miles with blocks. Market or High Street and Broad or 14th Street are the most important thoroughfares. The former, running east and west, is 6 miles long, and Broad Street, running north and south, has a length of 13 miles, 10 of which are paved with sheet asphalt, making it the longest street so paved in the world. There are 1850 miles of pavement, 311 bridges, and 919 miles of sewers. There are 65 lines of electric street railway, covering 175,000 miles daily, and carrying an average of 1,000,000 passengers each day. The city has 9083 electric street lamps, at a cost of 30·17 cents per night, 20,373 gas lamps, and 14,355 gasoline lamps. There were, 31st December 1901, 5,045,977 feet of electric conduit, representing an aggregate of 26,288,119 feet of duct. At the same period there were 104 miles of telegraph and telephone cable, containing 4121 miles of wire; 14,135 miles of overhead wire and 99,550 miles of underground wire. There are 1379 miles of water mains, through which in 1901 there were distributed 102,191,040,693 gallons of water, or 279,975,453 gallons a day, being 211 gallons per day for each man, woman, and child, figures which seem to show an enormous wastage. A system of slow sand filtration was being constructed in 1902 at a cost of nearly $20,000,000, and by the end of that year 300,000,000 gallons of filtered water will be furnished to the citizens daily. There are 19 reservoirs or water basins, with a capacity of 1,417,860,400 gallons, into which there were pumped, in 1901, 101,836,624,094 gallons, at a cost of $871,886. The receipts of the water department for the same period were $3,331,437, showing a profit to the city of $1,807,236.

The city has 47 small public parks or air spaces, aggregating 627 acres, besides Fairmount Park, the area of which has been increased to 3341·328 acres. The total cost of the latter, to 1st May 1902, was $6,430,000, and there had been expended on improvements $3,559,000. The Schuylkill river runs through the park for 4·2 miles, and Wissahickon creek for 6·8 miles. The commissioners of Fairmount Park are the custodians of Willstack bequest of about $800,000 for a public art gallery which has been established in the park. A large number of statues and monuments have been placed in the park, the most important for size and cost being that erected by the Pennsylvania State Society of the Cincinnati to the memory of Washington.

Municipal Government.—By the governor's approval, 1st June 1885, of a legislative enactment known as "The Bullitt Bill," the government was radically changed. The Bill was drafted and passed in the interest of good government and economy, but this utopian purpose has sadly miscarried. The law went into effect 4th April 1887, and for the year prior thereto the cost of maintaining the city was $9,434,507. The first year of the new government cost the city $13,273,893, and from this it steadily rose until in 1901 the cost reached $24,522,804. By the Bullitt Bill extraordinary powers are conferred upon the mayor of the city as its chief executive officer, who holds office for four years, and serves until his successor is duly qualified, but is ineligible for re-election for the next succeeding term. He appoints, with the plenary power of removal, the Directors of the Departments of Public Works and of Public Safety, and the presidents and directors of the Department of Public Charities and Corrections, and of the Board of Health. The heads of departments form a cabinet, with whom the mayor must consult at least once a month; and he is *ex officio* a member of all boards, with the right to vote. The salary of the mayor is $12,000 per annum, and of the two directors $10,000 each. Under the Department of Public Safety is the administration of police affairs, matters pertaining to the public health, and to the fire and police force, while under the Department of Public Works are the supply and distribution of water and gas, the care of the public highways, sewerage system, &c. The city hall or municipal building, at the intersection of Market and Broad Streets, begun in 1871, is now completed, so far as construction is concerned, and the commission for its erection went out of existence 31st December 1900. There was expended on its construction to 30th June 1900, $17,868,067. In addition there was spent, on maintenance during construction and fittings, upwards of $5,000,000. The building contains 634 rooms, with an area of 14·5 acres. The height of the main tower is 548 feet above the pavement.

Fire and Police.—The records of the fire insurance patrol show that the year 1901 was Philadelphia's least disastrous year for fires in a decade. There were 3049. The loss was $2,657,099, of which $600,736 was on buildings and $2,056,363 on personal property. This loss was protected by insurance amounting to $37,071,305. To protect the city against fire there is a force of 844 men, 50 steam fire-engines, 44 combination waggons and chemical engines, 5 chemical engines, 11 hook and ladder trucks, 5 water towers, and 13,000 street fire-hydrants. The cost of the department for 1901 was $1,072,379.

The bureau of police deals with 34 districts, and the force in 1901 was 2890, of which 2427 were patrolmen. This is obviously a wholly inadequate force to protect properly an area of nearly 130 square miles and a population of over a million and a quarter. There are 620 patrol boxes, with telephone connexion with station-houses, and in 1901 there were 61,189 arrests, of which 40 per cent. were for intoxication. There were 5135 commitments to the House of Correction, of which 956 were women and 1455 foreign-born.

Finances.—On 1st January 1902 the funded debt was $59,932,895, maturing at different periods extending over 30 years, and bearing rates of interest varying from 3 to 6 per cent. Additional loans have been authorized by a vote of the citizens to the extent of $7,800,000, at a rate of interest not exceeding 3½ per cent. To provide for the payment of the debt at maturity there is a sinking fund, which amounted at the above date to $13,642,714. There was also a floating indebtedness of $1,441,606. To meet its expenses the city has almost unlimited power of taxation of real estate, which is assessed at $901,009,664 as subject to city tax for 1902. The tax rate for the last 15 years has been $1.85 per $100. In 1901 the receipts from all sources for municipal purposes were $36,922,333, of which $15,059,783 was from taxation of real estate. The city owns real estate assessed at $62,313,924. There are 37 trust funds of the city under control of a Board of City Trusts, which amounted, 1st January 1902, to $17,880,651, of which $15,902,235 is the residuary estate of Stephen Girard for the maintenance of the college for orphan boys that bears his name.

There are 35 national banks in Philadelphia, with an aggregate capital of $21,405,000, and for the week ending 30th April 1902 their loans were $146,378,183, reserve $59,192,000, deposits $226,109,602, and circulation $9,606,737. In addition to the national banks there were, on 25th November 1901, 4 banks chartered by the state, with a capital of $250,434 and $727,578 deposits; 42 trust companies receiving deposits upon which interest is paid, subject to check, with a capital of $31,757,661, a surplus of $21,810,867, and deposits of $139,192,677; and 8 mutual benefit saving funds, with assets of $99,095,813. On 1st January 1902 there were 16 joint-stock fire insurance companies, with a capital of $8,102,875, having in force policies to the amount of $2,237,158,865, of which $365,810,371 are perpetual risks; 4 joint-stock fire and marine insurance companies, with $4,202,875 capital and $5,252,027 marine risks; and 11 mutual fire insurance companies, with outstanding risks of $106,233,582. There are also 6 life insurance companies, with 178,624 policies in force amounting to $446,206,264; 2 surety companies, with $750,000 capital and $79,778,875 risks; 1 accident company, with a capital of $100,000 and $17,466,670 risks; 5 land title insurance companies, and 1 plate-glass insurance company.

Commerce.—Though the commerce is increasing, it has not kept pace with the progress made in other branches of industry. The total imports at this port during the year ending 31st December 1901 were $47,787,361, and the total exports were $79,354,025, in which there were 50,530,408 bushels of cereals, 309,208,841 barrels of petroleum, 43,827 head of cattle, 687,274 tons of coal, 35,176,536 pounds of glucose and grape sugar, and 100,936,062 pounds of linseed oil cake. In 1901, 159 American and 961 foreign vessels entered from foreign ports, and 152 American and 976 foreign vessels cleared for foreign ports. In the same period 4403 coastwise vessels entered and 4425 cleared. Regular lines of steamers run as heretofore, and the railway lines in the city are unchanged, except in the passenger terminals of the Pennsylvania and the Philadelphia and Reading roads. By a system of elevated tracks these two lines have been brought, one to 15th and the other to 12th and Market Streets, where large and imposing stations have been erected which accommodate also the general business offices of the corporations. The gross receipts for 1901 of the Pennsylvania Railway from all lines owned or operated by it, connecting directly with the city, were $101,329,795, and the gross expenses were $65,259,543. The total tonnage was 110,226,729 tons, an increase of 5·16 per cent. over 1900; and the number of passengers carried 43,136,511, an increase of 6·16 per cent. Its capital stock, 31st December 1901, was $203,272,100, and its funded debt $88,893,323. The gross receipts of the Philadelphia and Reading Company for the year ending 30th June 1901 were $62,143,470, and the gross expenses $46,621,006. It carried in the year 22,697,295 passengers. Its capital stock is $168,000,000, and its funded debt $116,117,143.

Industries.—Philadelphia is one of the great manufacturing centres of America, with the largest locomotive works in the world and the largest shipyard in the country. Here, too, are made a greater number of yards of carpet and of oilcloth per annum than in any other place. According to the census of 1900, there were in this city 15,887 manufacturing establishments, employing 246,445 wage-earners and engaging $476,529,407 of capital. The Cramp shipyard, founded in 1830, has a worldwide reputation, as has also the Baldwin locomotive works, founded the next year. To 30th April 1902 the Baldwins had built 20,391 locomotives, of which 1275 were turned out in 1901 and 498 in the first four months of 1902, which is at the rate of 1494 for the year. The number of men employed is 11,500, the horse-power used is 7000, and the works cover an area of 16 acres. The immense works of the Cramp yard cannot be shown so satisfactorily by mere figures. It may be stated, however, that the Cramps employ 7000 men, and that the weekly pay-roll reaches $84,000. The plant represents an investment of $10,000,000, and covers more than 52·4 acres, with a water front on the Delaware river of 1229 feet. On 1st May 1902 they had 10 vessels in all stages of construction, the contract price of which was upwards of $24,000,000. These include one first-class battleship and two large armoured cruisers for the U.S. navy, and one protected cruiser for the Turkish navy. The Russian battleship *Retvizan* was launched 23rd October 1900, and is the largest battleship ever built in America. During the last twelve years this yard has supplied the U.S. navy with seventeen modern warships, beginning with the double-turreted monitor *Terror*, and including the first-class battleship *Maine* and the great armoured cruisers *Colorado* and *Pennsylvania*; to the Japanese navy one first-class protected cruiser, and to the Russian navy one battleship and one protected cruiser. Philadelphia has always been noted for its shipbuilding, and has led America in this industry from colonial days. She is the birthplace of steam navigation in the United States. John Fitch in 1785, at Philadelphia, made the first attempt, which two years later was successful. Up to the year 1902, 105 vessels had been built at Philadelphia for the U.S. navy, beginning in 1776 with the frigate *Randolph* and ending with the first-class battleship *Maine*, which was launched 27th July 1901. There were in 1902 five being built, including the armoured cruiser *Pennsylvania*, which was to be launched during the year.

According to the census of 1900, the following were the principal industries of the city, with the capital invested and value of the product:—

Industries.	Capital.	Value of Product.
Foundry and machine-shop products	$45,935,567	$38,372,971
Sugar and molasses refining	23,992,552	36,163,817
Clothing	11,526,030	28,254,896
Carpets and rugs	16,866,764	21,986,062
Leather	9,932,990	19,956,125
Woollen goods	12,874,265	18,340,012
Worsted goods	14,079,859	16,242,250
Cotton goods	12,541,083	15,723,654
Hosiery	10,024,606	13,040,905
Liquors	27,636,289	12,606,551

Population.—According to the census of 1900, Philadelphia had a population of 1,293,697, an increase of 246,733 over the census of 1890, a gain of 23·6 per cent. By the census of 1890 the city had 511,112 males and 535,842 females, of which numbers 25·74 per cent. were foreign-born, and 44·59 per cent. were engaged in gainful occupations. In 1900 the males numbered 634,485, the females 659,212, the native-born 998,357, and the foreign-born 295,340. There were 62,613 negroes. Out of 257,575 adult native-born males, 3695 were illiterate (unable to write); out of 129,378 adult foreign-born males, 13,893 were illiterate; and out of 20,095 adult negro males, 2190 were illiterate. In 1901 there were 9912 marriages, 28,215 births, and 24,137 deaths registered. In 1901 the death-rate was 18·26 per thousand. The immigration has materially decreased, only 13,304 immigrants having been landed in the year 1902, of whom 8056 were males, and 2195 came from Ireland, 2921 from Russia, 1594 from Hungary, 823 from Italy, and 1986 from Great Britain.

Domestic Life.—Philadelphia is emphatically the city of homes, a name which is now applied to it more frequently than that of Brotherly Love. According to the census of 1890, there were 187,052 dwelling-houses occupied by 205,135 families, which, taking the population as given by that census, 1,046,964, gave 5·60 persons to each house; at the same time New York had 18·52 persons to a house, and Chicago 8·60. There were in 1900 upwards of 245,000 dwelling-houses in the city, of which about 70 per cent. were owned by the occupants. This result is largely due to building societies, a form of investment which has had great influence in developing Philadelphia, where it had its origin in 1831. There were 467 of these societies in operation in Philadelphia at the beginning of 1900, with assets of $43,401,384, loans to members of $36,603,702, and undivided profits of $3,977,702.

Education.—There are 328 school-houses in Philadelphia, valued at $10,000,000, with 152,889 pupils and 3650 teachers, only 209 of whom are men. The cost of public education for 1901 was $4,223,278, or $23.15 for each child. On 10th September 1900 a new building for the Central High School for boys was opened, with 1400 pupils and 54 professors and instructors. The building was begun in 1894, and cost, with ground and equipment, $1,533,000. It has accommodation for 2000 pupils. A recent bequest to the city, by Dr Thomas W. Evans of Paris, of about $3,000,000 is for the endowment of a college and museum of dentistry in Philadelphia. The University of Pennsylvania has within the last decade jumped from a merely local institution to a national one, taking an important part in university education. The list for 1901–02 gives the number of students at 2573, and the professors and tutors at 272. The property of the university amounts to upwards of $9,000,000, and the buildings, 29 in number, are situated on property covering an area of 56 acres.

Free Library.—In 1887 the state legislature enacted its first laws tending to the formation of free libraries, and on 18th February 1891 a private body was incorporated called The Free Library of Philadelphia. In October 1892 its first branch was started, and on 12th March 1894 the main library was opened. At the close of 1894 the city councils created a public board of trustees for establishing a free library, superseding the private body, and in 1896 appropriated to it $60,000. The appropriation for 1902 is $125,000. There is a central library on Chestnut

Street, with a children's department and one for the blind, and 14 branch libraries in remote sections of the city. In 1901 it had 101 travelling libraries in active operation. The central and branch libraries on 31st December 1901 contained 239,103 books, and the circulation in 1901 was 1,915,687 books, against 632,536 in 1894. The library has already received many important gifts, among them a special collection of 500 volumes printed before 1501.

Changes and Improvements.—The business centre has moved from its original locality at the eastern end of the city to the vicinity of Broad and Market Streets, the centre of the original city. This change has been brought about by the removal of the courts of law and of all departments of the city government from the old State House or Independence Hall to the new City Hall, and the removal of the business offices of the Pennsylvania Railroad to its passenger station at 15th and Market Streets. Large office buildings have been erected in the immediate vicinity, and are occupied by banks, trust companies, corporations, lawyers, and other business people, leaving 3rd Street, the old Threadneedle Street of Philadelphia, deserted and dead. Some of the new buildings are "sky-scrapers," one of them being 20 storeys in height. To prevent the extension of this style of building, recent legislation gives power to the city to limit the height of such erections. A great change has taken place within the last few years in the conduct of retail business, and there are now five immense retail department stores, where every article for domestic or personal use can be purchased, excepting food and drink (which, however, may be obtained for consumption on the premises). Among noted improvements are the successful restoration of Independence Hall to its original state, thus preserving this fine example of pure colonial architecture as it was in historic days; the widening of Delaware Avenue along the river front, for one mile between South and Vine Streets, from between 50 and 60 feet to a minimum width of 150 feet; the building of a subway under Pennsylvania Avenue for a distance of 11,000 feet, at a cost of $5,400,000, to do away with the passage of the Philadelphia and Reading Railway trains along the street. This work was begun in November 1896, and was ready for use 20th May 1900. It required the excavation of 1,083,422 cubic yards of earth and rocks, and the laying of 183,114 cubic yards of masonry. The new United States Mint, in the northern section of the city, has a frontage of 316 feet and cost $2,000,000. Two new theatres have also been constructed on Chestnut Street, one opened in 1901 and the other in 1902. (C. H. H*.)

Philippeville, the fourth seaport of Algeria, 54 miles north by east of Constantine, on the Bay of Stora. It is connected by railway with Constantine, Batna, and Biskra. The surrounding country is laid out in vines, and its forests of cork trees yield valuable products. The town possesses an archæological museum and a Roman theatre. The harbour works having been destroyed by a storm in 1878, a new and magnificent harbour was completed in 1882. From Cape Stora on the east a mole or breakwater projects 4592 feet in a west-north-westerly direction, while from Chateau Vert on the west another mole runs out in a northern direction 1312 feet, leaving an entrance to the port about 656 feet wide. The protected area comprises an outer and an inner basin. The works begun in 1870 are not yet completed, but will ultimately provide a harbour of 1200 acres area. The tonnage, 195,000 in 1893, had grown to 400,000 in 1898. Population (1886), 17,653; (1896), 19,615; (1900), 20,450.

Philippine Islands, The.—The boundary of the Philippine Islands, fixed by the Treaty of Paris, is a line running from W. to E. along or near 20° N. and through the middle of the navigable channel of Bachi from 118° to 127° E., thence along 127° E. to 4° 45′ N., thence along 4° 45′ N. to its intersection with 119° 35′ E., thence along 119° 35′ E. to 7° 40′ N., thence along 7° 40′ N. to its intersection with 116° E, thence by a direct line to the intersection of 10° N. with 118° E., and thence along 118° E. to the point of beginning. In the description of the northern limits the line through the navigable channel of Bachi governs, as against the statement that it shall follow along or near 20° N. The cathedral in Manila is in 14° 35′ 31″ N. and in 120° 58′ 03″ E., or $10^h\ 27^m\ 55{\cdot}6^s$ W. of Washington. Spanish maps, as a rule, reckon the longitude from the meridian of San Fernando, which is 6° 12′ 20″ W. of Greenwich. The date reckoning now conforms to European usage. Prior to 1845, however, there was a difference of one day. The change was made by suppressing the date following 30th December 1844, which would have been Tuesday, and calling it Wednesday, 1st January 1845. A careful recount of the islands, made in 1889 by the United States Coast and Geodetic Survey, fixed the number at 1725; and a remeasurement of the land surface gave a total area of 119,542 square miles. The following islands have an area of more than 100 square miles: Luzon, 47,238; Mindanao, 36,237; Samar, 5040; Negros, 4854; Panay, 4708; Mindoro, 3972; Palawan, or Paragua, 3937; Leyte (Leite), 2713; Cebú, 1742; Bohol, 1439; Masbate, 1290; Catanduanes, 680; Basilan, 350; Busuanga, 328; Marinduque, 287; Dinagat, 259; Tablas, 250; Sulu, or Jolo, 241; Polillo, 231; Tawi Tawi group, 183; Guimaras, 176; Burias, 163; Siargao, 134; Sibuyan, 131; Culion, 117; Samal, 105. The coast-line of the Philippines measures approximately 11,444 miles.

Volcanoes.

There are twenty-three volcanoes in the islands, of which the following are more or less active: in the Babuyanes Islands, Babuyan, Camiguin (2415 feet), and Diplicia; in Luzon, Mayon (8978 feet), Taal (1050 feet), Bacon (4592 feet), and Bulusan; in Negros, Canloon or Malaspina (4592 feet); in the island of Camiguin, Camiguin (10,824 feet); and in Mindanao, Apo (10,824 feet) and Macaturin. Those considered to be extinct are: Caua (3920 feet), Arayat (3506 feet), Maquiling (3723 feet), Banajao (7315 feet), and Isarog (6448 feet), in Luzon; Acudining, in Leyte; Magaso, in Negros; Dinata, Calayo, Matutun, and Butulan, in Mindanao; and Sarangani (3050 feet), on Balut Grande Island, south-west of Davao. Mayon still continues very active. After its long-continued eruption in 1881 and 1882 there were minor disturbances in 1885, 1886, 1887, 1888, 1890, and 1891, none of which occasioned more harm than the crushing in of roofs in neighbouring villages by falling ashes. In the eruption of 1892 the top of the volcano was lowered by about 100 metres. A similar eruption occurred in 1893, covering the ground thickly with ashes at a distance of 8½ miles from the base of the volcano. There followed slight eruptions in 1895 and 1896. In 1897 occurred the most violent outbreak since the famous one of 1814 which destroyed 1200 lives. The eruption of 1897 began practically without warning on 23rd June, became alarming on the 24th, and destructive on the 25th, ending on the 30th. Streams of lava completely destroyed the villages of San Antonio, San Roque, Santa Misericordia, Santo Niño, and San Isidro, and injured Bigaa, Libog, and the town of San Fernando. The lava flow extended more than 7 miles from the volcano to the east, one-fourth south-east. Highways were destroyed, and much valuable agricultural land was ruined. Two hundred and twenty-six dead were recovered. The total number of victims will never be known, as the village of San Antonio was completely buried. A rain of ashes extended 100 miles to the east and 75 to the west.

Earthquakes.

The Philippines are noted for the frequency and violence of their earthquakes. A seismic observatory has been established by the Jesuits at Manila, and the systematic work carried on there and at other points in the archipelago has greatly increased our knowledge of the seismic phenomena. Palawan and the Calamianes Islands seem to enjoy almost complete immunity from earthquakes, while on the other hand seismic foci, or centres of disturbance, have been shown to exist in the north-western mountains of Luzon; in Nueva Vizcaya; in the Babuyanes Islands; in the vicinity of Taal volcano; in the vicinity of Mayon volcano; in the vicinity of Canloon volcano; in Surigao province, Mindanao; in the vicinity of Mount Apo; in the valley of the river Agusan; in the vicinity of the volcano Macaturin; and in the neighbourhood of Camiguin. In March 1892 one of the severest earthquakes ever felt in Luzon wrought havoc in the provinces of Pangasinan, Union, and Benguet, ruining Binalenon, Mangaldan, San Jacinto, Pozorrubio, Santo Tomas, and Agoo, and more or less seriously damaging sixteen other towns. Other destructive earthquakes occurred on 10th February 1894 in the district of Davao in Mindanao; on 21st June 1893 and 29th June 1894 in the valley of the Agusan river in Mindanao, ruining many towns; on the 11th of December 1895, the 8th of September 1896, and the 8th of April 1897, in the same region; and at Dapitan in 1885. In 1897 a very destructive series of shocks ruined the town of Zamboanga. Considerable loss of life was caused by falling buildings and by immense sea-waves, which swept away structures along the shore. Serious damage was done throughout the entire province of Zamboanga, the south-western coast of Mindanao in general, and the Sulu Archipelago. A new island appeared at this time off the coast of Borneo, near Labuan.

Minerals.

Although there have been no recent additions to our knowledge of the geological formation of the Philippines, much prospecting has been done since the American occupation, and extensive and rich deposits of copper and gold have been located. The provinces of Benguet, Lepanto, Abra, and Bontoc, in Luzon, have been found to constitute a mineral district of exceptional richness. Present indications are that copper, coal, and gold will yield the largest returns, ranking in the order named. The coals thus far discovered in the Philippines are highly carbonized lignites. They burn with little smoke, leaving a clear, white ash, free from clinker. Recent analyses have resulted as follows:—

Place.	Fixed Carbon.	Volatile Matter.	Water.	Ash.	Caloric Volatile Matter.	Caloric Fixed Carbon.	Fuel.
Santa Rosa .	57·94	31·75	9·23	1·08	674	5353	89·69
Caridad .	54·56	34·53	9·60	1·31	1369	5643	89·09
Esperanza .	51·96	37·56	7·80	2·68	1632	5829	89·52

None of the deposits has as yet been worked to any considerable depth. Several of the coal-fields are very extensive. Valuable minerals are known to be distributed as follows: Luzon, coal, gold, copper, lead, iron, sulphur, marble, kaolin; Catanduanes, gold; Marinduque, lead, silver; Mindoro, coal, gold, copper; Cararay, coal; Batan, coal; Raparapa, coal; Masbate, copper; Romblon, marble; Samar, coal, gold; Sibuyan, gold; Semirara, coal; Panay, coal, oil, gas, gold, copper, iron; Biliran, sulphur; Leyte, coal, oil, sulphur; Cebú, coal, oil, gas; gold, lead, silver, iron; Negros, coal, copper; Bohol, gold; Panaon, gold; Mindanao, coal, gold, copper, platinum. Cinnabar has been reported in Panay and Leyte, but its existence there is doubtful.

Climate.

A meteorological observatory was established at Manila by the Jesuits in 1865. From small beginnings it has grown into a thoroughly equipped and admirably conducted institution. The following figures are taken from its records:—

1883–1898.

	Jan.	Feb.	March.	April.	May.	June.	July.	August.	Sept.	Oct.	Nov.	Dec.	Annual.
Mean temperature . . .	77°·0	77°·7	80°·4	82°·9	83°·3	82°·0	80°·8	80°·8	80°·4	80°·4	79°·0	77°·4	80°·2
Absolute maximum temperature	93·0	95·7	95·9	99·0	100·0	97·0	94·8	94·3	93·7	94·8	92·1	91·9	...
Absolute minimum temperature	65·1	61·0	63·3	66·0	71·1	70·9	70·0	69·1	70·5	68·7	64·9	60·3	...
Mean relative humidity . .	77·7	74·1	71·7	70·9	76·9	81·5	84·9	84·4	85·6	82·6	81·6	80·7	79·4
Mean rainfall (inches) . .	1·193	0·413	0·736	1·42	4·197	9·622	14·567	13·866	14·925	7·536	5·126	2·134	75·457

Absolute maximum temperature for the sixteen years, 100·0.
,, minimum ,, ,, ,, ,, 60·3.

There are three seasons: the hot and dry, the hot and wet, and the cool and dry. At Manila the hot and dry includes March, April, May, and often the first half of June; the hot and wet, the last half of June, July, August, September, and October; and the cool and dry, November, December, January, and February. On the Pacific coasts of Luzon, Samar, Leyte, and Mindanao the seasons are reversed, the rains beginning with the north-east monsoon. While the observations as to temperature, humidity, and amount of rainfall obtained at Manila may be considered as fairly typical of conditions throughout the lowland regions of the archipelago, it should be remembered that there is great individual difference between the islands. Zamboanga is some 425 miles farther south than Manila, yet it has a cooler climate. The rainfall in Mindoro is known to be much heavier than in Luzon. In the provinces of Benguet, Lepanto, Bontoc, and Abra there are extensive highlands with an elevation of 4000 to 5000 feet, having a maximum temperature of 77° Fahr. and a minimum of 45°. Observations at Baguio, Benguet, show a mean monthly temperature of 65·9° in August, 66·94° in September, and 67·4° in October. The mean daily variation for a period of ninety days was only 7·87°. The relative humidity and rainfall are somewhat less than at Manila. A highway affording connexion with this temperate highland region is in process of construction, and the preliminary survey for a railway has been completed. The Philippines are often swept by the violent cyclonic storms known as typhoons, which not infrequently cause heavy loss of life and property. Since 1880 no less than 397 typhoons have been felt at the Manila observatory. Twenty per cent. of these have occurred in September. During December, January, February, March, and April they are very rarely felt. In May, June, and July they become increasingly common. In August there is a falling off in the number, which reaches its maximum in September, gradually decreasing in October and November. In the famous typhoon of 1881, the vortex of which passed over Manila, an immense amount of damage was done in the city. Two thousand persons lost their lives in Samar and Leyte during the great storm of 1897. The typhoon warnings sent out from the Manila observatory annually save heavy loss of life and property.

Fauna.

Extensive additions to our knowledge of the Philippine fauna have been made by Everett, Platen, Whitehead, Keay, the Steere expedition (1887–88), and the Menage expedition (1890–93). The Philippines, politically speaking, and the Philippines, zoologically speaking, are not identical areas, Balabac, Palawan, and the Calamianes being characterized by the occurrence of numerous Bornean forms which are conspicuously absent from the remaining islands. While the Philippines are commonly held to form an eastern extension of the Indo-Malayan sub-region, there is nevertheless a large amount of specialization in the fauna of the islands to the eastward of the Palawan group.

Mammals are scarce. No marsupials occur. The edentates are represented by the pangolin (*Manis* sp. ?) of the Palawan group. In the seas are found the dolphin, cachalot, and dugong. Wild hogs of at least two species occur, and in some of the islands are abundant enough to do considerable damage to growing crops. The beautiful axis deer of Sulu has apparently been brought there by man. Red or brown deer occur in Basilan, Mindanao, Leyte, Samar, and the Calamianes Islands. The number of species and their respective ranges have not been satisfactorily determined. In Masbate, Panay, Guimaras, and Negros there is a dark-coloured species marked with buff spots. Deer are absent in Palawan, Tawi Tawi, Tablas, Romblon, Sibuyan, and Siquijor. Domestic goats are abundant, and do well. Sheep do not thrive in the lowlands, but are said to flourish in the highlands of Benguet. Humped cattle are raised on most of the islands. They are killed for their flesh, hides, and horns, and little attention is paid to their milk-giving properties. The Philippine horses are small, but well formed and tough. The water-buffalo, or caraboa, is the most important of the domesticated mammals. It occurs in a wild state in Luzon, Mindoro, the Calamianes group, Masbate, Negros, and Mindanao, but the wild herds are believed to have originated from domesticated animals. The domesticated water-buffalo is sluggish in its movements, and will not work through the heat of the day, but it is a wonderful swimmer, and makes its way through the worst quagmire with ease. It is universally used as a draught animal and beast of burden. The most interesting of the ruminants is the timarau (*Bubalus mindorensis*, Heude), peculiar to Mindoro. Unlike the water-buffalo, it does not bathe in water or wallow in mud. It is extremely wild, feeding by night and sleeping by day in the densest jungle. It sometimes charges the hunter without provocation, and is very dangerous when wounded. It attacks and kills the much larger wild buffalo. All attempts to domesticate it have failed. A chevrotain is found in Balabac. The house rat, which has been introduced by man, is a common nuisance, while mice occasionally become so numerous as seriously to damage sugar-cane and rice. Squirrels are confined to the eastern chain of islands from Basilan to Samar, and to the Palawan–Calamianes group. In the southern islands there is a tiny species the size of a mouse. Very large flying squirrels are found in Palawan and Mindanao. Squirrel-shrews occur in the Palawan–Calamianes group, and true shrews at various points in the Archipelago. Among the Carnivores may be mentioned the binturong and an otter, both found in the Palawan–Calamianes group; two civet cats, which range throughout the archipelago, and a wild cat of small size, which has been found in Palawan, Panay, Negros, and Luzon. Bats are very numerous, and a number of the species are peculiar to the Philippines. *Galeopithecus* and *Tarsius* range from Basilan to Samar, and the former occurs also in Bohol. In spite of all that has been said to the contrary, but one species of monkey (*Macacus philippinensis*, Geoff.) has been discovered in the Philippines. It occurs on every island of any importance. Its flesh is occasionally eaten by the natives. While albino specimens of this monkey are not uncommon, the pure white monkeys, not albinos, said to inhabit Mindanao, are mythical. The large fruit bats (*Pteropus*) occur in immense colonies, and are sometimes eaten by the natives. Especial importance attaches to the unexpected discovery by Whitehead of a new and peculiar mammalian fauna inhabiting a small plateau on the top of Monte Data in northern Luzon, at an altitude of 7000 to 8000 feet. Specimens of 15 species were obtained, embracing 5 new genera (Calæmomys, Chrotomys, Rhynchomys, Batomys, and Carpomys). Eight of the species were new and strikingly peculiar. Their zoological relationships are probably with Celebes and with Australia. Other discoveries include a few new squirrels and bats, and the occurrence of a lemur (*Nycticebus tardigradus*) in Tawi Tawi.

Birds.—The islands are as rich in birds as they are poor in mammals, the total number of species recorded up to 1897 being 590, of which 325 are peculiar to the Philippines. A study of their geographical distribution has demonstrated that the islands may be divided into a number of fairly well-marked groups, in each of which the birds show a degree of specialization closely correlated with diversity of environment and completeness and probable duration of separation from adjacent groups. Balabac, Palawan, and the Calamianes show a very strong Bornean element. Mindoro stands by itself. Luzon and the small neighbouring islands have 51 peculiar forms. A close relationship exists between the birds of the entire eastern chain of islands. Numerous genera and some families which are absent from the central islands range from Luzon to Basilan. These genera usually have distinct representative species in Luzon, Samar and Leyte, Mindoana, and in some cases in Basilan also. The greatest differences occur between Luzon and Samar and Leyte. The latter islands have 22 peculiar species.

Sulu and Tawi Tawi belong zoologically to the Philippines, but have 12 well-marked peculiar species, and many of the characteristic Mindanao–Basilan forms are lacking. Panay, Guimaras, Negros, and Masbate constitute a sharply-defined area, characterized not only by the occurrence of 30 peculiar species, but by the absence of important genera and even whole families represented in the eastern islands. Most of the mammals characteristic of the latter region are lacking. It is a curious fact that Cebú stands quite by itself, although the width of the deep channel separating it from Negros narrows at one point to about four miles. Cebú possesses 9 striking species of birds not known to exist elsewhere, and lacks many of the characteristic forms of the central and eastern islands. The zoological position of Bohol has never been satisfactorily determined, but all existing evidence indicates that it must be grouped with Samar and Leyte.

Among the more interesting birds may be mentioned the "mound-builder" (*Megapodius cumingi*, Dillwyn), which buries its large eggs in the soft sand along the sea-beach, or under great mounds of earth and dead leaves, often at a depth of three or more feet below the surface. The young are forced to dig their way out and shift for themselves. The eggs are highly prized by the natives. The jungle-fowl abounds. There are 35 species of pigeons and doves, many of them most beautifully coloured and all edible. Snipe, plover, turnstones, and other shore birds are abundant during the cool season, and herons, bitterns, and ducks at all times. The birds of prey number 45 species, of which 22 are peculiar to the group. They vary in size from a tiny falcon, not larger than a sparrow (*Microhierax*), to an immense monkey-catching eagle (*Pithecophaga jefferyi*, Grant), which is strong and active enough to seize monkeys in the air as they leap from tree to tree. But two specimens of this remarkable eagle have thus far been secured. There are 21 species of kingfishers, 15 being peculiar. Of the 12 species of hornbills, not one occurs outside of the Philippines. Frog-mouths, bee-birds, night-hawks, and swifts are found in considerable variety. One of the last (*Collocalia troglodytes*, Gray) is of some commercial importance, constructing the edible nests so highly prized by the Chinese. The best nests are obtained on the precipitous sides of the Peñon de Coron, between Culion and Busuanga.

There may also be mentioned 21 cuckoos, 1 cockatoo, 19 parrots and parroquets, 19 woodpeckers, barbets, broadbills, starlings, orioles, weaver-finches, larks, nuthatches, 24 beautifully coloured sun-birds, and 23 flowerpeckers, titmice, shrikes, swallow-shrikes, tailor-birds, thrushes, fruit-thrushes, fairy bluebirds, fire-birds, 42 fly-catchers, 4 swallows, and 5 species of most beautifully coloured ant-thrushes, as well as a large number of birds for which English names cannot be readily supplied.

Reptiles and batrachians are abundant, but have been little studied. Pythons occur throughout the group, and sometimes attain enormous size. There are numerous venomous serpents, but the mortality from snake-bite is low. Geckoes may be seen on the walls and ceilings of any house. Flying lizards abound in the forests. Large iguanas are numerous. Their eggs are prized by the natives, and the flesh of one species, known as ibit or pelubid, is highly esteemed. Crocodiles are extremely numerous in many of the streams, and are occasionally found in the sea along the coasts. Specimens have been obtained measuring 18 feet in length. Land turtles of small size are common. Very large sea turtles are often captured by the fishermen, and their flesh is highly appreciated as an article of food. A considerable business is done in tortoise-shell. Frogs occur in great variety. One small species appears in immense numbers with the oncoming of the rainy season, and at night the noise of its outcry almost deadens other sounds.

Fishes.—Marine fishes constitute an important source of food supply. Some of the fresh-water species are also largely used by the natives, notably the "dalag," which is found in the paddy-fields during the wet season. Fishes are more numerous and more varied and less well known than are any others of the vertebrates.

Molluscs.—The Philippines are famous for the variety, beauty, and abundance of their land molluscs. Fresh-water and marine molluscs are also very numerous. While most of the species are of interest chiefly to the conchologist, there are a number of edible forms which help to supply the natives with food. The shells of *Placuna placenta*, L., split into thin flat plates and cut into small squares, are almost universally used in place of window-glass.

The valves of the giant clam (*Tridachna*) sometimes attain a length of 5 feet and weigh hundreds of pounds. Pearl-oysters are abundant in the southern waters of the archipelago. Pearl-fishing is an important industry in the Sulu Islands. The shells of the pearly nautilus are commonly used by the Visayans for drinking-cups. From the great opercula of certain marine forms bracelets and other ornaments are carved, while the hard serrated edges of other species are sometimes employed in place of knives for harvesting rice. The land molluscs have been quite thoroughly classified, but much still remains to be done with the marine species.

Arthropoda are very abundant and as yet little known. Shrimps, crabs, and lobsters form an important source of food supply. Mosquitoes are numerous and troublesome in the wet lowlands. Bees are abundant, and wild honey and wax are gathered in considerable quantities. The number of species of ants is very large. Some of them infest dwelling-houses and swarm over the food. The termites, or so-called "white ants," inflict great damage on wooden buildings, often causing serious loss. Plagues of locusts occasionally ruin growing crops. An insect pest recently almost completely destroyed the coffee plantations of Batangas.

The remaining branches of the animal kingdom are abundantly represented in the Philippines, but have as yet been little studied. Land-leeches swarm in the damp lowland forests, to the serious annoyance of foot passengers. The coral beds of Mindanao and the Sulu Archipelago are of unsurpassed beauty, and Guimaras, Cebú, and Siquijor are completely covered with a thick cap of coral limestone, proving the important part that coral polyps have played during bygone centuries.

Flora and vegetable products.

There have been no important recent contributions to our knowledge of the Philippine flora, and the epoch-making work of Father Blanco continues to be the standard authority. Some progress has been made in the study of the woods. The number of species is known to exceed 450, of which 385 have been classified. Included in this list are numerous very valuable woods suitable for structural purposes, inside finishing, cabinet work, and carriage-making. The largest forests are in Mindoro, Palawan, and Mindanao, although there are immense tracts in many of the other islands. Timber forms one of the great natural sources of wealth in the archipelago, and the exploitation of the forests bids fair to become an important industry. Tobacco continues to be one of the most important products. Greater care in growing and curing would vastly improve the quality. Since the abolition of the Government monopoly in 1881, large companies have sprung up, which at present control the trade. Among these may be mentioned the Compañia General de Tabacos, with a capital of $750,000. This concern has 100,000 hectares of land under cultivation, and handles annually 500,000 quintals of tobacco. Its Manila factory turns out 100,000,000 cigars annually, and employs 10,000 labourers. In 1900 a company called the Cagayana, with a capital of $500,000, was formed for the purpose of purchasing the product of the Cagayan valley. The output of abacá, or Manila hemp, increased steadily up to the outbreak of the insurrection in 1896. The coffee plantations have been ruined by a borer which attacked the canes. A small quantity of coffee is still produced in Benguet, where the borer has not appeared.

Exports of sugar also increased steadily up to 1896. This industry was in 1902 still in its infancy in the Philippines. The introduction of modern machinery and methods of cultivation will enormously increase production. Although there are a number of small steam crushers in Negros and Luzon, much of the cane is still ground between wooden or stone rollers turned by draught animals. The methods of obtaining sugar from the juice are often equally primitive. Only a small part of the good sugar land is yet under cultivation.

Rice and sweet potatoes are the staple foods of the natives, although Indian corn is now extensively raised in Negros, Cebú, and parts of Luzon. Cacao does admirably, and properly conducted plantations are profitable. There is a steadily growing trade in copra and cocoanut oil. Peanuts flourish, but are not raised to any considerable extent. The trade in indigo has been ruined by the Chinese, who adulterated the Philippine product so that it earned a bad name. A red dye obtained from sibucao (*Cæsalpinia Sappan*, L.) constitutes an important article of export to China and England. There are eleven other woods furnishing dyes of more or less value. Sago-palms grow abundantly in some parts of the archipelago.

The distillation of alcohol from fermented sap obtained from the nipa palm has become a flourishing industry. The nutmeg grows naturally in Cebú and in Laguna province, but is not an article of commerce. Cinnamon, of rather poor quality, is abundant in the forests. The cultivation of pepper is diminishing. Valuable essential oils are obtained from the flowers of the ilangilang, sampaguita, and champaca. There are eleven resins of domestic or commercial value. Extensive deposits of almaciga (damar) exist in Palawan, Sibuyan, and Mindanao. There are also eleven valuable gum-resins, of which gutta-percha is the most important. At one time a considerable quantity of gutta-percha was exported from the southern islands, but adulteration by Chinese merchants has nearly destroyed the trade.

Manufactures.

Cigars and cigarettes are the only manufactured articles exported in any quantity. Except for the cigar factories, cotton mills, rope walks, carriage and furniture factories, brick kilns, pottery ovens, and sugar refineries of Manila and vicinity, the Philippines have no manufactories of importance, although some articles are produced in considerable quantity by the natives at their homes. Among manufactures of this class may be mentioned dyed cotton stuffs; beautiful fabrics called "piña" and "jusi," the former woven of pineapple-leaf fibre and the latter of this fibre mixed with silk; mattings, bags, hats (those of bamboo being extremely light and durable); patates, or sleeping-mats; shoes, leather, soap, and other small household articles. A considerable amount of salt is also made from sea-water. There is much fine water-power in the islands, but none of it is at present in use.

Communications.

The only railway extends from Manila to Dagupan, a distance of 122 miles. Elsewhere land transportation is by means of carts or sledges drawn by water-buffaloes or bullocks. Highways are bad at the best, and in many of the islands there are none. Water transportation is therefore employed when possible. There are 61 steamers, with a tonnage of 21,300, 49 sailing vessels, with a tonnage of 5863, and numerous small native vessels engaged in the coasting trade.

There is cable communication with Europe by way of Hong Kong; also with Panay, Negros, and Cebú. The line is in process of extension to Mindanao, Basilan, and Sulu. Military land lines extend throughout Luzon and connect the most important towns of Panay, Negros, Cebú, Samar, and Leyte.

Trade.

Exports increased steadily up to the year 1897, as will appear from the following table:—

Year.	Abacá.	Copra.	Sugar.	Tobacco.
	Piculs.	Piculs.	Piculs.	Quintals.
1890	1,012,310	74,447	2,360,422	179,054
1891	1,271,094	245,309	2,672,259	207,166
1892	1,581,106	259,539	3,955,263	253,850
1893	1,282,938	183,404	4,186,982	230,686
1894	1,591,162	532,233	3,110,202	190,904
1895	1,664,590	593,671	3,697,332	207,771
1896	1,551,786	607,529	3,671,024	219,729
1897	1,804,756	811,437	3,332,010	316,712
1898	1,585,212	263,402	2,859,661	175,170
1899	1,201,476	291,322	1,488,854	114,261

The total value of exports for 1894 was $3,237,760; for 1895, $3,333,095; for 1896, $3,440,800; for 1897, $3,721,450; for 1898, $3,409,605; for 1899, $3,161,284. The restrictive Spanish tariff on imports remained in force, with slight modifications, up to the close of 1900. Since the American occupation, the increase in imports, not including Government supplies, has been extraordinary, in view of the disturbed conditions which have prevailed. The largest annual collection of import duties at Manila under the Spanish régime was $4,055,696 in 1896. Collections fell to $3,536,788 in 1897. For the fiscal year ending 30th June 1900 there was collected $8,174,084. The total value of the imports for the year was $20,878,666. Of vessels engaged in the foreign trade there entered during this year 566, with a tonnage of 665,913, and cleared 501, with a tonnage of 641,975. The entries of vessels engaged in the coasting trade were 3346, tonnage 459,075; clearances, 3666 vessels, tonnage 480,992. During the year ending 30th June 1901 the imports from the United States amounted to $4,014,180, and the exports, of which vegetable and manila fibres were valued at $4,254,416, to $4,420,289. The ports of entry are Manila, Iloilo, Cebú, Zamboanga, Sulu or Joló, and Siassi.

Government.

The purely military government established shortly after American occupation was gradually replaced by a civil administration. The re-establishment of civil courts began on 29th May 1899, and the organization of civil municipal governments in July of the same year. There was no direct intervention in the affairs of the central government by civilians until 1st September 1900, when, by order of the President of the United States, the legislative power and the power to appoint and remove civil officers were taken from the military governor and vested in a civil commission of five members. This commission was further charged with the duty of completing the organization of civil government, beginning with the pueblos, provinces, and departments, eventually recommending a suitable form of central civil government, and suggesting the time when it should go into effect. Benguet was the first province in which civil government was established by the commission.

Population.

The total number of inhabitants is not accurately known. It has been placed as low as 6,000,000, and as high as 12,000,000. The study of the Philippine tribes is in a far from satisfactory state. Blumentritt, who has written more accurately concerning them than has any other author, had never visited the islands. There are three distinct races—Negrito, Indonesian, and Malayan. The Negritos are almost universally conceded to be the disappearing remnants of a people which once populated the entire archipelago. They are physical weaklings, of low stature, with very dark skins, closely curling hair, flat noses, thick lips, and large, clumsy feet. In intelligence they stand near the bottom of the human species, and they are apparently incapable of any considerable degree of civilization or advancement. As a rule, they are to be met with only on the forest-clad sides of the higher mountains of Luzon, Panay, Negros, and Mindanao, although in north-eastern Luzon they are found in the lowland forests near the coasts. They live a nomadic life, wandering almost naked through the forests, and subsisting on fruits, tubers, and such game as they can kill. They are divided into twenty-one tribes, variously known as Negritos, Aetas, Buquiles, and Manguyanes. The Philippine representatives of the Indonesian race are confined to the island of Mindanao. They are physically superior both to the Negritos and to the Malayan peoples, being tall and well developed, with high foreheads and aquiline noses, and with wavy hair; often, also, with abundant beards. The colour of their skin is quite light. Many of them are very intelligent. They are divided into sixteen tribes. All of these are pagan, and several are very warlike. The great majority of the inhabitants of the Philippines are of Malayan origin, although the Malayan race is not found pure in any of the islands, but is everywhere modified through intermarriage with other peoples. The number of Malayan tribes is forty-seven. The individuals comprising them are of medium size, with straight black hair. As a rule the men are beardless. The skin is brown, and distinctly darker than that of the Indonesians, though much lighter than that of the Negritos. The nose is short and considerably flattened. The various tribes show every degree of social advancement, from abject savagery to a relatively high degree of civilization. Seven of them are Christianized, seven are Mahommedan, and the remainder pagan. Although there are far more pagan tribes in the Philippines, the seven Christian tribes with the Mahommedans include the bulk of the population, as will appear from the following table:—

Tribe.	Approximate Number of Individuals.	Territory occupied (square miles).
Visayans	2,601,600	28,100
Tagalogs	1,663,900	15,380
Bicols	518,111	6,900
Ilocanos	441,780	6,170
Pangasinans . . .	365,500	1,950
Pampangas . . .	337,900	1,950
Cagayans	166,300	11,050
Mahommedans . . .	268,000	12,860
	6,363,091	84,360

These figures are only approximate. The number of inhabitants composing the wild tribes is still more a matter of conjecture, but can hardly exceed 2,500,000. Of these latter peoples it may be said that, while many of them are pacific and harmless when well treated, not a few are vicious. Head-hunting is practised by several of the North Luzon tribes, some of which are even accused of occasionally indulging in cannibalism. Several of the tribes practise polygamy, and the taking and keeping of slaves is not uncommon. Human sacrifices are practised by at least two of the Indonesian tribes in Mindanao. The number of Americans in the islands was estimated at 66,700 in December 1900, including an army of 2219 officers and 60,480 men. The Chinese at this time were estimated at 70,000, Spanish at 3000, British at 250, Japanese at 175, Germans at 125, Swiss at 90, French at 60, Portuguese at 30, Belgians at 25, Italians at 20; other nationalities, 30. (D. C. W.)

History.—The history of the Philippine Islands shows that nearly the whole period of the 327 years of Spanish dominion (1571–1898) was one of continual strife and discord between the clergy, the military and civil power, and the natives. The perpetual struggle for supremacy between the Crown officers and the monastic orders, the immorality of the clergy, the feud between their respective communities, the constant inflow of penniless Spanish adventurers and the venality of the officials, brought both laymen and ecclesiastics into lasting contempt among the natives. The government of the islands was inspired by the monks, and was based on the theory that the natives should for ever be regarded as minors. Education was entirely in the hands of the friars. In the course of time many natives acquired comparative wealth, the best education which the colony afforded, and a taste for European comforts. The natural consequence was a desire to throw off the absolutely dominant tutelage of Spain, and participate in the administration. To this end there were frequent risings, suppressed by the Spaniards with a severity the remembrance of which was preserved from generation to generation. In 1812, during the enforced absence from Spain of King Ferdinand VII., the famous Cortes de Cadiz was established. This parliament, extremely democratic in its composition, resolved to impose a constitution on the king when he should return. The constitution was to include direct representation of the colonies—indeed, delegates from each dependency (including the Philippines) were invited to Cadiz and took part in the deliberations. This ray of political sunshine for the Filipinos lasted, however, but a short while, for, on King Ferdinand's return, reaction set in, and the proceedings of the Cadiz parliament were annulled. But the desire for liberty lived on. On the other hand, the tyranny of the Spanish clergy increased as they found themselves face to face with an ever-growing body of enemies. Each parish had, in its friar incumbent, a secret Government agent, through whom men were suddenly wrested from their homes and deported to distant islands without trial.

Early conflicts.

The deposition of Queen Isabella II. in 1868 brought again into power the democratic political element in Madrid, and in 1869 it was decreed that a certain measure of participation in the civil government should be accorded to the Filipinos, by the formation of a native council to co-operate with the governor-general. The councillors were indeed nominated; but the hopes thus raised were once more thwarted by ultra-conservative influences, and the disappointment served only to fan the flame of discontent. The Filipinos then conceived a new plan. According to those decrees of the Council of Trent which define the status of the regular clergy, the services of a monk in any colony were limited to mission work. His duty ended when there were no more converts to be made, and he could only temporarily act as incumbent when there was no secular clergyman available. In 1871—three centuries after the conquest—the only unconverted natives were the aboriginal mountain tribes and the Mussulman inhabitants of Mindanao. Therefore the natives, championed by a certain Father Burgos, agitated for the fulfilment of the Council of Trent decrees whereby the incumbencies in Christianized villages should be held by the secular clergy. Filipinos had for generations been ordained in the priesthood, and parish curacies were actually held by them. The real aim of the natives was to diminish the power of the regular clergy, whose communities were, in fact, strongly organized secret societies, each one extremely jealous of the other, but ever ready to join issue against any Filipino movement. In 1872 the friars took the initiative in bringing matters to a crisis.

Through their secret agents a pretended plot was concocted, and the native garrison at Cavite was induced to mutiny. The priests immediately presented a bill of indictment against the richest, best educated, and most influential Philippine-born families in Manila. The proscribed persons, accused of treason, were the leaders of that class which aspired to national manhood. It was the object of the friars to banish this class, and to secure to themselves the incumbencies in perpetuity. They succeeded temporarily, for the flower of the Philippine-born population was deported to the Ladrone Islands, whilst Father Burgos and three other native priests were publicly garrotted, and the native clergy were formally declared to be thenceforth incompetent to have the cure of souls.

Steamer and telegraphic communication, both opened about the same time, may be said to have marked a new era in the Philippines, by bringing them more into harmony with the conditions of neighbouring colonies. The improved travelling facilities came at the time when intelligent natives were most anxious to flee from monastic tyranny. Some crossed over to Hong Kong; others travelled to Spain, where, under the republic, they found sympathetic listeners. The tragedy of 1872 gave birth to revolutionary notions, and Philippine committees were founded at Madrid and Barcelona. Steamers brought the Madrid newspapers to natives who hitherto had but a vague notion of European affairs. Filipinos, too, began to return with new ideas from Europe. The most distinguished of these returned native scholars was the late Dr Rizal. Born in Calainha and educated in Manila, he was sent to Europe at an early age to complete his studies. After gaining the degrees of Doctor of Medicine and of Philosophy, he published, among other works, his *Noli me tangere*—a sarcastic exposition of the immorality of the friars, written in the form of a romance. He returned to the islands, and disputed the Dominican order's title to lands actually in their possession in Laguna province. He became the arch-foe of the friars and the idol of his own countrymen. To escape the monks' vengeance he returned to Europe; but in 1892 he received assurances from Governor-General Despujols that he might enter the islands and remain there at liberty. On his arrival at Manila his enemies produced certain seditious leaflets, alleging that they were found in his luggage. He was therefore arrested on a charge of treason. The friars importuned the governor-general for his life, but the general persistently refused their demand, and met the case half-way by banishing Rizal to Dapitan in Mindanao. Incensed by the failure of their plot, the friars' relations with the general became so strained that, in accordance with precedent, the procurators of the religious communities in Madrid forthwith obtained the recall of Governor-General Despujols after only eight months' service. Meanwhile a reform party, initiated by Dr Rizal, was organized under the title of Liga Filipina. Its object was to procure, by pacific means, several reforms in the government of the islands, the chief of which were (1) the expulsion of the friars, and (2) the withdrawal of the governor-general's arbitrary power to deport Filipinos on his sole authority. The new governor-general, Ramon Blanco, was, like Despujols and many of his other predecessors, a humane man at heart, but he could do no more for the Filipinos than hold in check the most tyrannical schemes of the clergy. The banishment of Rizal convinced the reform party that peaceful endeavour to procure reforms was futile. A secret organization known as the Katipunan was therefore started to secure reforms by force of arms. Each member enrolled was bound by the ancient "blood compact." An incision was made in the arm, and with the blood which flowed therefrom the roll of membership was signed. In 1895 the friars suspected some movement, and consequently between the autumn of 1895 and August 1896 many hundreds of natives were banished.

The Katipunan leaders were completing their plans for open warfare, when the whole conspiracy came prematurely to light through a traitor. This man divulged the secret to his wife, who (in August 1896) went to Father Mariano Gil, parish priest of Tondo, and revealed the whole plot. The next day about 300 of the most prominent Filipinos were lodged in prison. The drawbridges of the walled city were put in working order, and troops were stationed along the approaches. News came shortly that the insurgents had attacked the civil guard about three miles outside the city. Native cavalry was sent there at once, and the insurgents fled. A week later some hundreds of insurgents suddenly attacked the powder magazine at San Juan del Monte, about three miles from the city. Troops were quickly on the spot; the insurgents, who were completely routed, left about eighty dead on the field, and fled in confusion towards the Pasig river. Many were shot dead in attempting to cross the river, whilst the rest were pursued for miles. Four chiefs were taken prisoners, and subsequently executed in Manila. This was the first of the numerous executions which took place all over the colony. Pandacan, Pasig, and several other parishes in the neighbourhood of the capital were unsuccessfully attacked by the insurgents during the following days. Ten days after the plot was discovered Manila and five other provinces were officially proclaimed in a state of siege. Insurgents were assembling in great numbers near Mariquina; Europeans, Chinese, and natives flocked into the city. News came that the whole province of Cavite was in revolt; San Roque was in insurgent hands. The insurgents concentrated all their energies upon Cavite province. They dug a trench about a mile south of the neck of land on which Cavite arsenal is situated. To defend the arsenal the Spaniards established a camp at Dalahican, which was held by the 72nd Visaya (native) regiment and Spanish volunteers under General Rios. From this camp the Spanish forces made a sortie, but were driven back with great slaughter. There was a general call to arms, and volunteers were enrolled. Several villages were in the hands of the insurgents, and, emboldened by their success at Dalahican, they seized a convent in the centre of Cavite province, fortified and provisioned it, and for several weeks repulsed the attack of the Spanish troops, until at length artillery was brought into action, when most of the besieged effected their escape. It was now that Emilio Aguinaldo came to be known as the insurgent commander-in-chief.

Revolt of 1896.

The difficult position of the Government was taken advantage of by the revolutionary chiefs. General Blanco had extremely few European troops at his disposal, and many of these were in Mindanao. Transports were at once despatched to bring them to the capital. It was doubtful how far native troops could be trusted against their own countrymen. Reinforcements were soon on the way from Spain, but the demands of Cuba had already depleted the Peninsula of the best fighting material. Most of the troops sent out to Manila were of weak physique and without military training. By those who understood least the true position Blanco was blamed for his apparent lethargy. There was constant friction between him and Archbishop Nozaleda, who urged the immediate adoption of bloodthirsty measures; but as Blanco declined to be led by the archbishop, he was recalled, and in December 1896 General Polavieja arrived as his successor, with General Lachambre as chief of staff. Before General Blanco left he released Dr Rizal and allowed him to go to Spain, but the friars caused a cablegram to be sent to arrest him. Rizal was therefore sent back, a prisoner, to Manila, where he was executed by Polavieja's orders in December 1896.

The reinforcements now numbered about 16,000 men, and Lachambre took the field in Cavite with energy, whilst Polavieja held in check the insurgents north of Manila. After repeated encounters in Cavite province, with great slaughter to the insurgents and no inconsiderable losses on the part of the Spaniards, General Lachambre succeeded in practically quelling the rebellion in that province, whilst General Jaramillo rendered effective service in Batangas province. Lachambre was then despatched north, where the insurgents were in arms all over the provinces of Bulacan, Pampanga, and Nueva Ecija. Numerous small battles were fought, those of any importance being Aliaga and Cabanatuan. The insurgents, routed everywhere, quietly reappeared in other places. An attack was made on Bolinao, and the cable station was threatened, but troops arrived just in time. Aguinaldo personally operated in the province of Bulacan, making frequent raids on the Spaniards and then retiring to his mountain fastness. No definite progress towards a finish was being made by either party. Polavieja's demand for more troops having been refused, he tendered his resignation on the ground of ill-health, and was succeeded (spring of 1897) by General Primo de Rivera, who had been governor-general of the colony sixteen years previously. Rivera was already personally acquainted with the leading Filipinos. A rising in Cebu city had been quelled by a gunboat; hostilities continued elsewhere in an indecisive manner, and the wet season (middle of the year) had fully set in, making operations extremely difficult. A certain Paterno volunteered his services to Primo de Rivera to negotiate peace, with the result that Aguinaldo agreed to quit the islands with thirty-five of his chiefs on the understanding that the Spanish Government would pay them an indemnity of $1,200,000 and introduce certain reforms. Consequently, on the 23rd December 1897, Aguinaldo and his colleagues left for Hong Kong. The "Treaty of Biacnabatò" in which it is said these conditions are set forth is of doubtful existence. However, according to agreement (verbal or written), a first instalment of $400,000 was paid to Aguinaldo. The Madrid Government having refused to confirm the terms of peace, further payment was suspended. As soon as Aguinaldo and his party were safely out of the colony, the peace rejoicings in Manila were followed by the persecution of all those who were known to have sympathized with the movement. The prospect of reform was as remote as ever, and other chiefs took the field in northern Luzon.

Spanish-American war.

When hostilities between America and Spain broke out, on the 23rd April 1898, there was already an American fleet in Far Eastern waters, which, under the command of Commodore (afterwards Admiral) Dewey, arrived in the Bay of Manila on the 1st of May, and totally destroyed or disabled the Spanish fleet. Dewey demanded the surrender of the city, which was refused. Cavite was at once occupied by the Americans, and Dewey awaited reinforcements of troops before attacking Manila. Shortly afterwards Aguinaldo and his party, at their request, were brought to Cavite in an American transport by Dewey's permission.

With the approval of Dewey, who allowed arms to be supplied to him, the rebel chief at once set to work to collect his forces, and with 30,000 men renewed the campaign against the Spaniards, harassing them on all sides, until practically all Luzon, excepting the city of Manila and the suburbs, was at his mercy. About 11,000 Spanish prisoners (soldiers and civilians) fell into the rebels' hands. At the same time rebel emissaries were despatched to the southern islands of Panay, Negros, and Mindanao to raise rebellion against the Spanish forces commanded by General Rios. Many encounters took place, but the Spaniards held possession until the treaty of peace was signed in Paris. The American reinforcements had already arrived, and on the 13th August, after a show of resistance, General Augusti (the successor of Primo de Rivera) surrendered the city of Manila. The capture of Manila coincided with the signing of the peace protocol at Washington.

Aguinaldo chafed at the refusal of the American commander, General Otis, to allow his troops to enter the city, and still more so when he was ordered to remove his camp farther away from the Manila suburbs. The fate of the islands was in suspense from August 1898 to February 1899, and during this period of abeyance the Filipino army remained quietly under arms, repudiated as a factor by the Americans. During this interval Aguinaldo went to Malolos, proclaimed the Philippine Republic, formed a ministry, presided over a parliament of deputies, and issued a new constitution. The American authorities were invited to attend, but did not do so.

The treaty of peace between America and Spain, by which the Philippine Islands passed into the hands of the Americans, had been signed in Paris on the 10th December 1898, but it was not until 6th February of the following year that the treaty was confirmed by the American Senate. On 4th February, however, hostilities had broken out between the American troops and the Filipino army. The next day the contending forces met at Paco, a Manila suburb, where the Filipinos were defeated with heavy loss. The American troops, following up the retreating enemy, drove them out of Malolos and San Fernando into Nueva Ecija, and then withdrew to Manila. A call for troops brought the total American army of occupation up to about 60,000 men.

Revolt against the Americans.

It is unnecessary to trace in detail the gradual conquest of the islands, or the hundreds of engagements, often small, between the rebels and the Americans, especially in the islands of Luzon, Panay, Leyte, Negros, Samar, and Mindanao. Owing to the nature of the country, the climate, the want of roads, and the fact that large parts of the islands had never really been subjected by the Spaniards, the war was prolonged for from two to three years. The Filipino forces were gradually disorganized and dispersed, and with the capture of Aguinaldo, 23rd of March 1901, and later of his successor as commander-in-chief, Malvar, the resistance became little more than that of guerilla bands, and by July 1902 these bands seemed to have been largely captured or crushed. During all this time the islands were under military government, but civil government was gradually introduced as fast as the different islands or provinces were conquered.

Civil government.

During the first year of the war a civil commission, under the presidency of Dr Schurman, was despatched to Manila by President McKinley to inquire into and report on the state of affairs. In February 1900 a second commission for perfecting the civil government was appointed, consisting of Judge W. H. Taft, Professor D. C. Worcester, General L. E. Wright, Mr H. E. Ide, and Professor Bernard Moses. According to the instructions of the President, "that part of the power of government in the Philippine Islands which is of a legislative nature is to be transferred from the military governor of the islands to this commission, to be thereafter exercised by them in the place and stead of the military governor. Exercise of this legislative authority will include the making of rules and orders, having the effect of law, for the raising of revenue by taxes, customs duties and imposts; the appropriation and expenditure of public funds of the islands; the establishment of an educational system throughout the islands; the establishment of a system to secure an efficient civil service; the organization and establishment of courts; the organization and establishment of municipal and departmental governments; and all other matters of a civil nature for which the military governor is now competent to provide by rules or orders of a legislative character." On the 1st of September the commission assumed its legislative powers. Its first Act was to appropriate one million dollars for the construction and improvement of roads. Another early Act provided for the improvement of Manila harbour at an expense of three million dollars. It was hoped that the harbour work would be completed in two years. Other legislation enacted by the commission provided for the organization of bureaus and departments of the central Government; the creation of municipal and provincial governments (of the latter, thirty-four were established between February and September 1901); the passage of a general school law, under which 1000 American teachers were brought to the Philippines, who, with the help of a much larger number of Filipino teachers, started schools in 500 different towns, attended by over 100,000 pupils; the organization of a judiciary, with courts culminating in a Supreme Court of seven members, four Americans and three Filipinos; the establishment of a provincial constabulary of 5000 men, which led to the rapid disappearance of ladronism; the adoption of a new tariff; the extension of the postal system; the enactment of a code of civil procedure; the establishment of a bureau of forestry, a health department, and an agricultural bureau; and the enactment of what were known as treason and sedition laws.

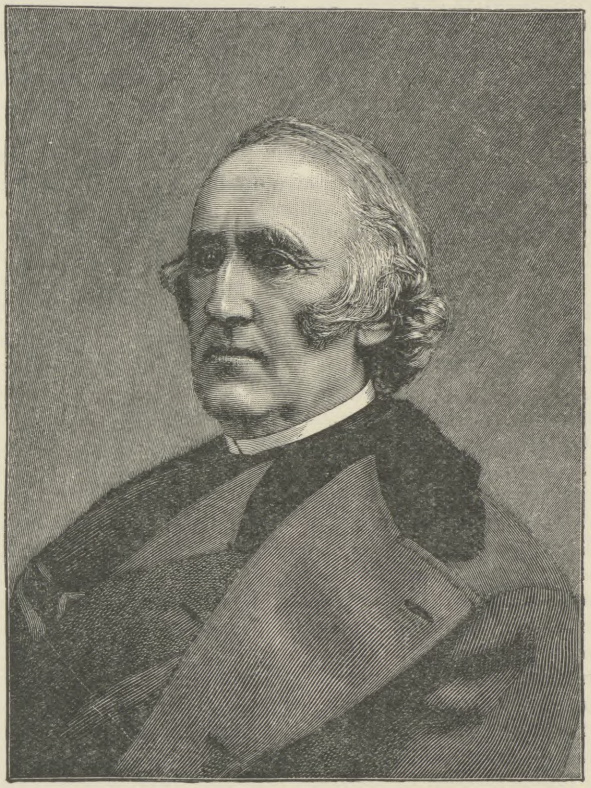
On the 1st of July 1902 President Roosevelt signed a new and important Bill for the civil government of the Philippines. Under this Bill a census was to be taken at an early date, and two years thereafter, should peace prevail, a legislative congress or assembly was to be authorized. The upper house of this assembly was to consist of the present commission of five Americans, with three Filipino members added, large powers being given to it through its control over appointments and salaries. As the majority was composed of Americans, no legislation hostile to the United States was possible. The lower house was to consist of members elected by property owners or persons who can speak English or Spanish. The Bill authorized the sale of the public domain in not larger lots than 2500 acres to any one person, and also the purchase of the land belonging to the hated friars. On the 4th of July President Roosevelt abolished the office of military governor, the military forces being largely recalled, and the part remaining being made henceforth subordinate to the civil authorities. He also granted a general amnesty to all rebels and political prisoners who would take the oath of allegiance to the United States. The most important question remaining was that connected with the ownership of land by the friars. The four orders—the Dominicans, the Augustinians, the Recoletos, and the Franciscans, none of which admit the natives to membership—were the owners of 400,000 acres of land, largely the best land in the islands, half of which are near Manila. No rents had been collected on these lands between 1896 and 1902. Through all the years of Spanish government the friars were the real rulers, and it was opposition to them that caused the rebellion of 1896. It was the object of the commission to buy out the friars as landowners, and to substitute for them as spiritual leaders American secular priests. With this object in view, Judge Taft proceeded to Rome in July 1902, and negotiations were in August 1902 progressing on the subject, the belief of the members of the American commission, as well as that of all other authorities, being that the removal of the friars was of the utmost importance for the peace and progress of the islands. (J. F*.)

Philippopolis, the capital of eastern Rumelia, principality of Bulgaria, finely situated in the midst of picturesque granite eminences on the Maritza, 96 miles east-south-east of Sofia and 97 west-north-west of Adrianople. Having communication by rail both with the port of Sedéaghatch on the Mediterranean and that of Bourgas on the Black Sea, and being situated in a remarkably fertile country, it has now become the chief commercial centre of southern Bulgaria, and is the seat of both a Greek and a Bulgarian archbishopric. The residences of the richer Greeks and Bulgarians occupy the slopes of the largest eminence, the Djambaz-tépé, in the centre of the town; between it and the Nobet-tépé, from the summit of which there is a magnificent view of the town, is the Armenian quarter; near the bridge over the Maritza is the poorer Turkish quarter; and south-west of the Djambaz-tépé there is a suburb of villas. On the Bounardji-tépé a monument has been erected by the Russians in commemoration of the war of 1877, and near this is the new palace of the prince of Bulgaria. The Sahub-tépé is crowned by a clock-tower. Not far from it are the beautiful Exhibition Park laid out in 1892, and the fine Djournaia-djami Mosque. Near the Maritza are the remains of the ancient Konak of the Turkish pashas, the public park formed by the Russians in 1877, the gymnasium, and the new Greek cathedral. The town has a large commerce in rice, attar of roses, and cocoons; other exports being corn, wine, tobacco, alcohol, and hides. Population (1892), 36,033, of whom the bulk were Bulgarians, Turks numbering about one-sixth and Greeks about one-ninth, the remainder being Armenians, Jews, Tziganes, and Bohemians; (1900), 42,849.

Phillimore, Sir Robert Joseph, (1810–1885), British judge, was the third son of the well-known ecclesiastical lawyer, Dr Joseph Phillimore, and was born at Whitehall, 5th November 1810. Educated at Westminster and Christ Church, Oxford, where a lifelong friendship with Mr Gladstone commenced, his first appointment was to a clerkship in the Board of Control, where he remained from 1832 to 1835. Admitted as an advocate at Doctors' Commons in 1839, he was called to the Bar at the Middle Temple in 1841, and rose very rapidly in his profession. He was engaged as counsel in almost every case of importance that came before the Admiralty, Probate, or Divorce Courts, and became successively Master of Faculties, Commissary of the Deans and Chapters of St Paul's and Westminster, Official of the archdeaconries of Middlesex and London, and Chancellor of the dioceses of Chichester and Salisbury. In 1853 he entered Parliament as member for Tavistock. A moderate in politics, his energies were devoted to non-party measures, and in 1854 he introduced the Bill for allowing *vivâ voce* evidence in the Ecclesiastical Courts. He sat for Tavistock until 1857, when he offered himself as a candidate for Coventry, but was defeated. He was appointed Judge of the Cinque Ports in 1855, Q.C. in 1858, and Advocate-General in Admiralty in 1862, succeeding Dr Lushington as Judge or Dean of the Court of Arches five years later. Here his care, patience, and courtesy, combined with unusual lucidity of expression, won general respect. In 1875, in accordance with the Public Worship Regulation Act, he resigned, and was succeeded by Lord Penzance as Dean of Arches. When the Judicature Act came into force, the powers of the Admiralty Court were transferred to the High Court of Justice, and Sir Robert Phillimore was therefore the last judge of the historic Court of the Lord High Admiral of England. He continued, however, to sit as judge for the new Admiralty, Probate, and Divorce Division until 1883, when he resigned. In literature Sir Robert will be remembered for his *Ecclesiastical Law of the Church of England*, a book which still holds its ground, for his *Commentaries on International Law*, and for his translation of Lessing's *Laocoon.* He married in 1844 Charlotte Anne, daughter of John Denison of Ossington Hall, Newark. He was knighted in 1862, and created a baronet in 1881. He died at Shiplake, near Henley-on-Thames, 4th February 1885. His eldest son, Sir Walter G. F. Phillimore (b. 1845), also distinguished as an ecclesiastical and admiralty lawyer, became in 1897 a judge of the High Court.

Phillipolis. See Orange River Colony.

Phillips, Wendell (1811–1884), American orator and reformer, was born in Boston, 29th November 1811. His father, John Phillips, a man of wealth and influence, was a graduate of Harvard College in 1788, and became successively "town advocate and public prosecutor," and in 1822 first mayor of Boston, then recently made into a city. Wendell Phillips himself attended the public Latin school, entered Harvard College before he was sixteen, and graduated in 1831 in the same class with the historian Motley. Both of them belonged emphatically to the aristocracy of Boston, and it is recorded that Phillips was the only man for whom the family carriage was habitually sent out from Boston to Cambridge on Saturday morning that he might spend Sunday at home. He graduated at the Harvard Law School in 1834, and was admitted to the Bar in Boston. He soon came under the influence of the anti-slavery movement, witnessing in 1835 the mobbing of Garrison. In 1837 a meeting was called at Faneuil Hall, to express the sentiments of the people on the murder of Elijah P. Lovejoy, at Alton, Illinois, for defending his press from a pro-slavery mob. In the course of the meeting a speech was made in opposition to its general current by James T. Austin, Attorney-General of the state, who said that Lovejoy had died "as the fool dieth," and compared his murderers to the men who threw the tea into Boston harbour during the American Revolution. The speech seemed likely to divide the audience, when Wendell Phillips took the platform. "When I heard," he said, "the gentleman lay down principles which placed the murderers of Alton side by side with Otis and Hancock, with Quincy and Adams, I thought these pictured lips [pointing to their portraits] would have broken into voice to rebuke the recreant American, the slanderer of the dead." This appeal not merely determined the sentiment of the meeting, but it gave Wendell Phillips his first fame and determined his career. Although loving his profession, and this especially for the opening it gave in the direction of public life, he practically stepped outside the sphere dearest to young Americans, and lived henceforth the life of an agitator, or, like his father, that of a "public prosecutor." Accepting unhesitatingly the leadership of Garrison, and becoming like him gradually a disunionist, he lived essentially a platform life, interested in a variety of subjects, but first and chiefly an abolitionist. He was not, however, like his great leader, a non-resistant, nor was he, on the other hand, like John Brown, borne on by irresistible necessity to overt action. Nor did he find, like his fellow-worker, Theodore Parker, the time to keep up his scholarship and lead in part the life of a student. Early study and travel had indeed furnished him with abundant material for rhetorical illustration; and he was also a great reader of newspapers, but he used to say that he knew in his whole life but one thing thoroughly, namely, the history of the English Revolution, and there were few occasions when he could not draw from it the needful illustration. His style of eloquence was direct and brilliant, but eminently self-controlled. He often surprised his hearers by the quietness of his beginnings, and these were very often the speeches which turned out most brilliant and most irresistible ere the close. He may be said to have introduced the direct and colloquial manner upon the American public platform, as distinct from the highly elaborated and often ornate style which had been established by Edward Everett; nor has there ever been a reversion since his day to the more artificial method. He was capable at times, nevertheless, of highly sonorous periods with superb climaxes, yet his favourite style was the conversational. His logic, while never obtruded, was rarely at fault; but he loved the flash of the rapier, and was never happier than when he had to face down a mob and utterly foil it by sheer superiority in fencing. The two volumes of his speeches, as edited by Mr Redpath, were fortunately made from verbatim reports, and they wisely enclose in parentheses those indications of favour or dissent from the audience which transformed so many of his speeches into exhibitions of gladiatorial skill. He was a tribune of the people, associated unflinchingly not merely with the unpopular, but—which is sometimes more difficult—with the unpolished; always carrying about him not merely a certain Roman look, but a patrician air. After slavery had fallen Phillips associated himself freely with reformers occupied in other paths, herein separating himself from the other patrician of the movement, Edmund Quincy, who always frankly said that after slavery was abolished there was nothing else worth fighting for. Phillips was not always the best judge of character, and was sometimes allied in these movements with men who were little more than demagogues. But the proof he gave by his transfer of energies that the work of reform was never quite finished—this was something of peculiar value, and worth the risk of some indiscretions. The life of a reformer did not in



Wendell Phillips.

itself make him thoroughly happy; he chafed more and more under its fatigues, and he always felt that his natural place would have been among senators or ambassadors; but he belonged essentially to the heroic type, and it may well have been of him that Emerson was thinking when he wrote those fine words: "What forests of laurel we bring and the tears of mankind, to him who stands firm against the opinion of his contemporaries." His domestic life was most happy, though his wife was a confirmed invalid, seldom quitting her room. She was a woman of heroic nature and very strong convictions. Her husband used to say that she first made him an abolitionist. They had no children, but adopted an orphaned daughter of a friend, Mrs Eliza Garnaut, and this young girl brought much light and joy into the household. Their worldly circumstances were easy, except that they were always ready to impoverish themselves for the sake of others. Wendell Phillips died at Boston on the 2nd February 1884. (T. W. H.)

Phillipsburg, a city of Warren county, New Jersey, U.S.A., on the east side of the Delaware river, opposite the mouth of the Lehigh and the city of Easton, Pennsylvania, in the western part of the state, at an altitude of 221 feet. Its site is hilly and the street plan irregular. It is on five railways—the Central of New Jersey, the Lehigh Valley, the Delaware, Lackawanna, and Western, the Lehigh and Hudson River, and the Pennsylvania, which afford ample facilities for communication. The city has large manufactures of iron and steel goods. Population (1880), 7181; (1890), 8644; (1900), 10,052, of whom 990 were foreign-born.

Philo.—Since the appearance of the article in the ninth edition of the *Encyclopædia Britannica* (vol. xviii. pp. 759–764; see especially p. 763) much valuable work has been done, the effect of which has been to establish, or at least to uphold, the genuineness of writings ascribed to Philo, but then held to be spurious. The works there impugned are the following: (1) Περὶ βίου θεωρητικοῦ ἢ ἱκετῶν ἀρετῶν (*De Vita Contemplativa*). This is both the shortest and historically the most important of the impugned writings, since it contains the sole original account of an ascetic community known as the Therapeutæ having their home on the shores of Lake Mareotis. These were held by Eusebius and many other Christian writers to be the earliest Christian monks, which of course could not be the case if it was a genuine work of Philo. On this account, amongst others, it was held to be spurious by Graetz and P. E. Lucius; and this view gradually received the assent of most modern scholars. Latterly, however, the tables have been turned. L. Massebieau has shown with great thoroughness that in language and thought alike it is essentially Philonic, and the genuineness of the book has also been affirmed by P. Wendland, and especially by F. C. Conybeare. Massebieau first conjectured that it was part of the Ἀπολογία ὑπὲρ Ἰουδαίων of Philo mentioned by Eusebius, and Conybeare has shown almost to demonstration that it formed the fourth part of his treatise in five books entitled Περὶ ἀρετῶν, which was probably the work referred to by Eusebius. In any case, whether it be held that the Therapeutæ actually existed in Philo's day, or that they are a utopian dream, it can no longer be doubted that the idea was Jewish, not Christian. (2) Περὶ ἀφθαρσίας κόσμου (*De Incorruptibilitate Mundi*), which has been declared unauthentic by Z. Frankel and J. Bernays. It has, however, been successfully defended by its latest editor, F. Cumont. (3) Περὶ κόσμου (*De Mundo*). It is generally agreed that, in L. Cohn's words, this is "nothing but a compilation from various portions of the περὶ ἀφθαρσίας κόσμου and other Philonic works." (4) Two discourses, *De Sampsone* and *De Iona*, extant only in Armenian, and certain other writings of the same kind. These appear only to been imputed to Philo by chance, and certainly cannot claim to be his work. In addition to these, two other tracts have been attacked: (1) Περὶ τοῦ πάντα σπουδαῖον εἶναι ἐλεύθερον (*Quod Omnis Probus Liber sit*) has been questioned by Z. Frankel and R. Ansfeld; but their arguments would rather point to its being an early work of Philo, which P. Wendland believes to be the case. (2) Περὶ προνοίας (*De Providentia*), which we possess as a whole only in an Armenian version: it consists of two books, the first of which appears to be in a Christian recension, but there is no reason for denying its Philonic origin. In a word, the effect of modern work upon the text has been to vindicate in a remarkable degree the genuineness of the works ascribed to Philo; and these results are accepted by Dr Leopold Cohn and Dr Paul Wendland, the editors of the critical edition.

Philology.—The history of philology since 1885 has been one of steady progress. In that period no discovery has been made equal to those that were made in the decade after 1870. As in previous periods of the history of the study of language, an era of discovery has been followed by an era of organization. The results of such discoveries as Verner's law have been far-reaching. It has taken time to grasp them in all their bearings and to tabulate the results. The working hypotheses which were furnished by the generalizations propounded in the 'seventies have been justified by their successful application to the multitudes of facts relating to language which had been collected before, or which have in even greater numbers been collected since. This very success has led discussion back to those principles which, first definitely propounded by Leskien in 1876, by Osthoff and Brugmann in 1878, led to an animated controversy culminating in a war of pamphlets in 1885. This controversy had no definite termination. The older school led by Georg Curtius practically came to an end with his death in 1885. Curtius's successor at Leipzig was Brugmann, the foremost exponent of the new principles. The school of Berlin represented by Johannes Schmidt, and that of Göttingen represented by Fick and by younger men like Bechtel and Collitz, though denying the originality of the new principles, and though deviating to some extent in terminology, have nevertheless been equally active in the employment of these principles as an engine of discovery. These principles were: (1) phonetic change proceeds according to laws which admit of no exceptions; (2) apparent exceptions are produced by the cross-action of a psychological influence-analogy. Besides the discussion of first principles attached to these two formulas, much has been done in investigating the effects of accent, though the results are still in too inchoate a condition to be treated here, while two practically new fields of investigation have been opened up. These are (*a*) Comparative Syntax, (*b*) the study of Semantics or the principles according to which the meanings of words develop and change.

In the study of phonetic laws several stages are traceable, and the meaning attached to the phrase *phonetic law* has varied at each of these stages. Moreover, the sweeping nature of the original generalizations has become so hedged in and contracted by limitations that a recent writer has been compelled once more to formulate the question whether phonetic laws actually exist. It must be admitted in the first place that the word *law* has been ill chosen for use in this connexion. In phonetic laws there is no element which can be identified as coming under the definition of a law as propounded by a jurist like John Austin. There is no authority which enunciates the law, there is no penalty for the breach of it. But the philologists who first used the term were not thinking of law in its strict signification, but of its use in such metaphorical expressions as scientific laws, for Schleicher and his followers in the middle of the 19th century had taken a keen interest in the development of the natural sciences, and had to some extent assimilated their terminology to that employed in those sciences. It was, however, soon recognized that the laws of language and those of natural science were not really alike or akin. A scientific "law" is only a brief method of expressing the fact that universal experience shows that certain causes universally produce certain effects. In chemistry two atoms of hydrogen and one of oxygen will make water, and they will make nothing else at any time or at any place the world over. Phonetic laws, however, do not hold true universally. They are often curiously limited in the area to which they apply. In ancient Greek, for example, the sound *-s-* between two vowels, which had been handed down from the original language whence Greek and the sister languages are derived, regularly disappears; in Latin, on the other hand, it changes into *-r-*; thus an original genitive of a neuter substantive we find represented in Greek by γένε-ος, a form which comparison with other languages shows to be traceable to an earlier **genes-os*, preceding the separation of the languages, while the same original stem with a different vowel in the ending appears in Latin as *gener-is*. Similarly an early **euso* appears in Greek as εὕω, in Latin as *uro*. This disappearance of original intervocalic *s* pervades all Greek dialects —the apparent exceptions come under the heading of analogical change; with a very few exceptions similarly explicable Latin intervocalic *s* has become *r*. But Latin was originally limited to a very small part even of Italy, and the next neighbours of the Latins on the east and south—the Sabines, Campanians, and Samnites—retained this intervocalic *s* without changing it into *r*. On the other hand, the neighbours to the north-east—the Umbrians in and beyond the Apennines—shared in this rhotacism. Yet the Kelts, who bordered on the Umbrians along the Po, and who spoke a language in many respects very closely akin to the dialects of Italy, in this regard agree rather with Greek than the Italic languages. In Latin, again, the period of action of the law which changed intervocalic *s* into *r* did not in all probability exceed the century from 450 B.C. to 350 B.C. So unlike, indeed, are phonetic laws to the laws of natural science in universality that an opponent of the dogma which declares that phonetic laws have no exceptions has compared them with the laws of fashion. The comparison is not so outrageous as it may seem at first sight. For in language there are two kinds of sound change, that which is unconscious, universal at a given time and within a given area, and, on the other hand, that which belongs only to a particular class or clique, deviates consciously from the pronunciation of the majority, is therefore not universal, and exercises no permanent influence on the language. The second kind of sound change corresponds exactly to the laws of fashion; it is in fact one of them. Such sound changes are the pronunciation of the English ending *-ing* as *-in'*, which was fashionable in the middle of the 19th century. This had, though probably without the knowledge of those who used it, a historical justification in the earlier forms from which most of the English words now ending in *-ing* are descended, and which survive in numerous local dialects. A similar conventional mispronunciation was the lisp affected by some would-be artistic persons at a somewhat later period. Belonging to an entirely different social stratum, and now equally obsolete, was the London pronunciation of the first half of the 19th century typified in Tony and Sam Weller's treatment of *v* and *w* in the *Pickwick Papers*. This, however, made a much nearer approach to being a genuine dialect peculiarity. It undoubtedly pervaded the pronunciation of the lower classes in London at one time; had it survived it might conceivably have spread over a wider and wider area until it embraced the whole population of England. A later change, that of the diphthong *ai* into *ei* (so that *day*, *daily* are pronounced *dy*, *dyly*), has spread from Essex and the East End of London over a large part of London and of the adjacent counties, and is still widening its range both geographically and socially. The history of these sound changes has not yet been investigated in detail with the thoroughness which it deserves.

There is, then, a part of sound change which is a matter of fashion and which is conscious. This sound change appears frequently in the pronunciation of individuals who have migrated from one part of a country to another. In many parts of Scotland, for example, the prepositions *with* and *of* appear in dialect only in the forms *wi'* and *o'*, which were originally the unaccented forms. In the conscious attempt to pronounce them as they appear in literary English, the educated Scotsman, if he remains in his native place, as a rule pronounces them as *with* (with the final sound unvoiced as it appears in the Scottish legal preposition *outwith*) and as *off*, the final sound here also being unvoiced. If he migrates to England or to Australia he will probably in course of time adopt the pronunciation with a voiced final sound. In the course of years habit will become second nature, and in this respect the speaker's pronunciation will become identical with that of his neighbours. It is clear, however, that changes of this nature cannot take place on a large scale. If a large number of persons migrate in a body and continue to live in close intercourse with one another and but little in contact with the outside world, changes such as take place in the pronunciation of the individual emigrant do not occur. There can be no imitation of alien sounds, for there are none; no greater effort to be intelligible is required, for the audience has not changed. Hence it has been often remarked that a population which history shows to have remained undisturbed for very long periods in the same geographical situation manifests but little change in its language. Thus in Arabia and Lithuania the population has remained practically unmixed in the same habitat for thousands of years, with the result that the languages spoken there remain at the present day the most archaic members of the linguistic families to which they respectively belong.

From what has been said it will be obvious that a phonetic law is only an observed uniformity in the treatment of a sound or a combination of sounds within a linguistic area at a given time. In the definition the term *linguistic area* is a very variable quantity. Thus it is a phonetic law that a sound of the original Aryan language, the precise pronunciation of which cannot be determined, but which was at any rate a palatal sound ($\hat{k}$), appears in the Aryan group (Sanskrit, Zend, Old Persian, with their descendants), in Armenian, in Balto-Slavonic and Albanian, in the form of a sibilant, while in

Greek, the Italic dialects, Germanic and Keltic, it appears as a *k*-sound. Here the linguistic area is extremely wide, and it is clear that the difference between the two groups of languages must be dated back to a very early period. Again, it is a phonetic law of Greek that the original combination *st-* at the beginning of words is retained in Greek. How then are we to explain the existence side by side of στέγος and τέγος? The former apparently complies with the law, the latter does not. The former has by its side the verb στέγω, while τέγος is supported only by the rare τέγη. Yet the forms of the verb and substantive found in the Germanic languages leave no doubt that the forms without *s-* represent an extremely old form, for the English *thatch* could not have changed its original *t-* into *th-* if it had been preceded by *s-*, the law being as strict for English as for Greek that initial *st-* remains unchanged. On the other hand, a phonetic law may be limited to a very small area. Thus in the dialect of Eretria, and nowhere else within the area of the Ionic dialect of Greek, do we find the change of the sound which appears elsewhere in Greek as -σ- between vowels into -ρ-: σίτηριν for σίτησιν (acc. sing.), παραβαίνωριν for παραβαίνωσιν (3rd pl. subjunctive). Why this change should take place here and nowhere else we do not know, although it may be conjectured that the cause was a mixture with immigrants speaking a different dialect, a mixture which ancient tradition supported. Undoubtedly such mixtures are the chief conditions of phonetic change, the effect of which is universal. The manner in which the change takes place is that the basis of articulation, the method in which the sound is produced, becomes changed. Thus along the "Highland line" in Scotland, where the English and Gaelic speaking populations had their linguistic frontier for centuries, the *wh-* of English, the Anglo-Saxon *hw-*, becomes universally *f-*, *wha?* becoming *fa?* *white*, *fite*, &c., *f* being the sound which it was most easy to substitute for the difficult *hw-*. The history of Spanish in the different communities of South America excellently illustrates this point. After the discovery of America there was a large influx of Spaniards into Chile, who ultimately, and chiefly by intermarriage, incorporated amongst them a considerable element from amongst the native Araucanian Indians. The result has been that the language of Chile is Spanish, pronounced not with the genuine sounds of Spanish, but with the sounds of the Araucanian language substituted for them. Elsewhere in Spanish America the language of the conquerors remained comparatively pure, because the Spaniards were much fewer in number and had therefore to maintain themselves as a caste apart. For the same reason Latin has split up into the numerous branches which we know as the Romance languages. The particular line of development which, *e.g.*, French followed as compared with Spanish or the language of the Rhaetian Alps was conditioned by the nature of the sounds in the language which preceded it in the same area, and which was spoken by the ancient Gauls who adopted Latin. The difficulty found in all of these cases is precisely of the same kind as that which an adult at the present day speaking one language finds in attempting to learn the pronunciation of another language. On the one hand, it is only with the greatest difficulty that muscles for many years accustomed to perform one set of movements can be forced into performing another set which are very similar but yet not identical; on the other hand, to an untrained ear the difference between the two sounds may remain unappreciated. The result is that the new language is pronounced with the sounds of the speaker's original language. If the new language is adopted by a whole people to whom it was originally foreign, the children naturally learn it from their parents with the sounds of the old language which has now become obsolete. Thus the basis of articulation is changed, and if, as was the case with Latin, this process be frequently repeated among peoples speaking languages with articulation widely differing one from another, it is clear that a series of different dialects of the adopted language has been created. This kind of change is immediate and universal throughout the whole area where linguistic change has taken place.

While the syntax of individual languages was one of the first features which attracted the grammarians' attention, at any rate in so far as particular authors differed from a given standard, it is only in very recent times that syntax has received methodical treatment from the comparative point of view. It may indeed be said that almost the whole fabric of the comparative syntax of the Indo-European languages as it exists to-day has been reared by one man—Professor Berthold Delbrück of Jena. In a series of brilliant studies beginning with a pamphlet on the Locative, Ablative, and Instrumental, published in 1867, and continued in his *Syntactical Researches* (*Syntaktische Forschungen*) in five volumes, comprising a treatment of the conjunctive and optative moods in Sanskrit and Greek (1871), the theory of the Sanskrit tenses (1877), the order of words in early Sanskrit prose (Çatapatha Brahmana) (1878), the foundations of Greek syntax (1879), and the syntax of the oldest Sanskrit (*Altindische Syntax*) dealing exclusively with the literature of the Vedas and Brahmanas (1888), Professor Delbrück laid the foundations for his treatment of comparative syntax in three volumes (1893, 1897, 1900), which has formed the completion of Brugmann's *Grundriss der vergleichenden Grammatik der indogermanischen Sprachen*. The only work by another hand (on a large department of the subject) which deserves to be mentioned by the side of Delbrück's studies is the small treatise by Hübschmann on the theory of the cases (*Zur Casuslehre*, 1875). For the comparative neglect of this field of investigation there are several reasons. The earlier philologists had so much to do in determining the languages which should be included within the Indo-European group, and in organizing the field of research as a whole, that it is not to be wondered at if they were unable to devote much attention to syntax. In the 'seventies, when attention began to be more directed towards comparative syntax, the remarkable discoveries made by Verner with regard to accentuation, and by Brugmann, Collitz, and others with regard to the phonology of the Indo-European languages, again distracted attention from the subject. Moreover, the research in itself is infinitely more difficult than that into sounds and forms; for the latter may be carried on by the help of grammars and dictionaries with a comparatively small knowledge of the literature of any individual language, while on the other hand the study of syntax is impossible without a thorough and intimate knowledge of the literature and modes of expression in each separate language. It is not, therefore, matter for wonder that Delbrück has confined himself in the investigation of syntax to a part only of the languages whose sounds and forms are discussed by Brugmann in the earlier volumes of the *Grundriss*. To cover the whole ground is beyond the powers of a single man, and there is a great lack of preliminary studies on the syntax of many of the languages.

For the early history of the syntax of the verb Greek and Sanskrit are important above all other languages, because in them the original forms and the original usages are better preserved than they are elsewhere. And it is in the verb that the great difficulties of comparative syntax present themselves. The noun system is so well preserved in several languages that, when the number of the original cases had once been determined, the sifting of the pro-ethnic usages attaching to each case was tolerably easy, for besides Sanskrit and (to a less extent) Latin, Lithuanian and Slavonic have kept the pro-ethnic case system almost complete. The ideas also which had to be expressed by the cases were on the whole of a very concrete character, so that here the problem was much simplified. On the other hand, the ideas expressed by the forms of the verb are of a much more subtle nature, while the verb system in all languages except Greek and Sanskrit has broken down earlier and more completely than the noun. It is clear that the verb of the original Indo-European language possessed two voices, and forms corresponding to what we call the Indicative, Subjunctive, and Optative moods, and to the Present, Imperfect, Future, Aorist, and Perfect tenses. The imperative mood seems primitively to have been confined to the second person singular, just as the vocative, which, like the imperative, is a stem form without suffix, was confined to the singular. The infinitive, as is well known, is in all languages of this system not originally a verbal but a substantival form. The pluperfect, where it has developed, seems to be a mixed form arising from the application of aorist endings to a perfect stem. Thus far the history of the verb system is tolerably clear. But when we attempt to define the original meaning of the moods and of the tenses we pass into a region where, in spite of assiduous investigation in many quarters during recent years, the scanty amount of light thrown on the problem has only served to make the darkness visible. As regards the tenses at least, it has been shown that without doubt there is no difference in formation between present, future, and aorist stems, while the earliest meaning of the perfect was that of a special kind of present expressing either repeated or intensive action or a state. It has also been proved that the original meaning of the aorist is not past in time, and that in fact the only element whereby these languages could express remoteness in time was the augment. The augment seems to have been originally a pronominal deictic particle. Thus, as there was no original pluperfect, as neither perfect nor aorist originally referred to past time, and as the future, except in Lithuanian (with slight traces in Slavonic) and the Indo-Iranian group, cannot be clearly distinguished from the aorist, the system as a method of expressing time absolutely breaks down. The tenses in fact did not originally express the times when the action took place, but the type of action which took place. Thus the present system in the main expressed continued or durative action, the aorist only the fact that the action had taken place. The action indicated by the aorist might have been of considerable duration, or it might have been begun and ended in a moment; its characteristics in this respect are not in any way indicated by the aorist form, which intimates only that the action is viewed as a completed whole and not as a continuous process. The present system, however, is built up in a great variety of ways (thirty-two according to Brugmann's enumeration). It is *à priori* unlikely that such a multiplicity of formations had not originally some reason for its existence, and Delbrück thinks that he has discovered a difference in syntactical value between various forms. The reduplicated present forms of the type seen in Sanskrit *jígāti*, Greek δίδωμι, &c., he regards as expressing originally an action which consisted of repeated acts of the same nature (iterative), though this iterative meaning frequently passed into an intensive meaning. Presents of the type seen in Sanskrit *tṛ́ṣyati*, "is thirsty," and Greek χαίρω, "am glad" (for * χαρι̯ω), where the ι̯ (*y*) of the suffix has modified the first syllable and disappeared, he regards as *cursive*—*i.e.*, they express continuous action without reference to its beginning or end. Verbs which have regard to the beginning or end of the action he calls terminative, and finds them represented (*a*) in verbs with *-n-* suffixes, Sanskrit *ṛṇóti*, ὄρνυσι, "sets in motion," ἄγνυμι, "break to pieces"; (*b*) in verbs with the suffix *-sko-*, Sanskrit *gáchati*, "goes" (to a definite destination), Greek βάσκω, &c. The roots he classifies as momentary (Punktuell) or non-momentary, according as they do or do not express an action which is begun and ended at once.

This method of classification was no doubt suggested in the first instance by the characteristics of the Slavonic verb system. In this system a clear distinction is drawn in nearly all verbs between those which express a process (durative verbs) and those which express a completed action (perfective verbs). When perfective and durative verbs are formed from the same root, the perfective are distinguished from the durative forms (*a*) by having a preposition prefixed, or (*b*) by having a different stem formation. Thus in the Old Bulgarian (Old Ecclesiastical Slavonic) *to strike* (hit) and *to strike dead* are expressed by the same verb, but in the latter meaning a preposition is found which does not appear in the former, *biti* (infinitive), "to strike"; *u-biti*, "to strike dead." *To strike* is *durative; to strike dead* is *perfective.* As an example of difference of stem formation expressing this difference of meaning, we may quote *sěsti*, "to sit down" (perfective), *sěděti*, "to sit" (durative). Verbs with a suffix in *-n-* have often a perfective meaning: cp. the Sanskrit and Greek verbs quoted above. The *perfective* verbs correspond in meaning to the Greek aorist, and are to be carefully distinguished from *perfect* forms. The same distinction of meaning is often achieved in other languages also by means of prepositions, *e.g.*, in Latin (Seneca, *Epp.* xciii. 10), *Quid autem ad rem pertinet, quamdiu* vites, *quod* evitare *non possis?* "What does it matter how long you go on avoiding [durative] what you cannot escape [perfective]." From this example, however, it is clear that, though the means employed to make the distinction are different, there is no difference in meaning between such perfective verbs and those classified by Delbrück as terminative. Here, as in many other parts of this study, the ideas are new, and grammatical terminology has not yet sufficiently crystallized, and still leaves something to be desired both in clearness and in precision.

As regards the moods, the difficulty has been to find any criterion whereby the functions of one mood should be differentiated from those of the others. It has long been recognized that the difference between indicative and subjunctive is one of meaning and not one of formation; that, *e.g.*, in Sanskrit *bharati* (3rd sing. pres. indic.), "bears," is morphologically identical with *hanati*, "may slay" (3rd sing. pres. subj.), and that the latter is described as a subjunctive only because of the meaning, and because there exists a dissyllabic form, *hanti*, which makes the indicative "slays." Similarly in Greek it is impossible to distinguish morphologically between παύσω, "I shall check" (fut. indic.) and παύσω, "let me check" (1st aor. subj.). Moreover, in the earliest forms of the languages which preserve the moods best (Greek and Sanskrit), the connexion syntactically between the indicative and the subjunctive forms is closest. Not only does the future express futurity, but also the determination of the subject to carry out the action expressed, which, in Delbrück's discussion of the moods, is precisely the point chosen as characteristic of the subjunctive. On the other hand, the present optative differs from the present (and future) indicative and present subjunctive in having a special mood suffix, and in having secondary while they have primary personal endings. Nevertheless its meaning overlaps that of the other forms, and some excellent authorities, like Professor W. W. Goodwin, see in future indicative, subjunctive, and optative only different degrees of remoteness in the future, the remoteness being least in the future and greatest in the optative. Delbrück, however, abides, with slight modifications, by the distinction which he propounded in 1871, that the subjunctive expresses Will and the optative Wish. Here again the problem has not been solved, and it is doubtful how far any definite solution is likely to be arrived at, since there are so many gaps in our knowledge of mood forms. These gaps, owing to the break-up of the system at so early a period, it is hardly probable we shall ever be able to fill. It is possible, however, to do a great deal more than has yet been done even in the most familiar languages. In Latin, for instance, even now, the facts for the uses of the moods within the two centuries of the classical period are very imperfectly known, and it is no exaggeration to say that more has been done in the last hundred years for Sanskrit than has been done in two thousand years of continuous study for Latin or Greek.

The second of the recent additions to the domain of Philology—the study of meaning—presents fewer difficulties, but until recent years has been equally neglected. The study is so recent that the literature of the subject is still extremely small. The only attempt to deal with it on a large scale is M. Bréal's *Essai de Sémantique* (1897), now translated into English under the title of *Semantics* (1900), with a valuable introduction and appendix by Dr Postgate. From the practical point of view many of the phenomena have been classified in works on rhetoric under the headings of Metaphor, Synecdoche, and Metonymy. The psychological principle behind this superficial classification is that of association of ideas. Here, as elsewhere, changes proceed not by accident, but according to definite principles. Here, as elsewhere in language, in history, and the other moral sciences, the particular principle in operation can be ascertained only by beginning with the result and working back to the cause. In the development of meaning much more than in phonetics is this necessarily the case. In phonetics all speakers of the same dialect start with approximately the same sound. But the same combination of sounds which we call a word does not recall the same idea to all persons who use that word. The idea that the phrase *railway station* calls up in the mind of a Londoner is very different from that which occurs to the mind of a child acquainted only with a wayside station serving the wants of a country village of a few hundred inhabitants. The word *herring* suggests one idea or train of ideas to the fisherman who catches the fish, another to the merchant who purchases it from the fisherman, a third to the domestic who cooks it, and so on. To members of the same family the same word may often have widely different associations, and, if so, the metaphors for which the word will be employed will differ in each case.

For the history of meaning it is necessary to have regard to all the forms of association of ideas which psychology recognizes. These are contiguity in place or in time, resemblance and contrast. Contrast, however, as J. S. Mill and Bain have shown, is not a simple form of association, but is evolved partly from contiguity, partly from resemblance. An artificial hollow generally implies also an artificial height made of the materials excavated from the hollow. Hence in most languages some words occur with the two contrasted meanings. Thus in English we find *dyke* in use both for a ditch and for a mound fronted by a ditch, the word *ditch* being, in fact, but a dialectal form of *dyke*. In Scotland, on the other hand, where earthen mounds and stone walls form more frequent boundaries between fields than in England, the word *dyke* is now practically limited to elevated boundaries, while *ditch* is limited to excavated boundaries. Thus the proverb, "February fill dyke," which in England implies that the February rains will fill the ditches, is often understood in Scotland to mean that in February the snow will be level with the tops of the stone or turf walls. Similarly in Latin Tacitus can say *fossas proruere*, which can only apply to levelling raised mounds; while in Greek Xenophon also talks of the ditch (trench) thrown up (τάφρος ἀναβεβλημένη). It is only natural, therefore, that other words with several meanings should be used similarly: *moat*, originally a mound of earth or peat, has come to mean a big ditch; while, conversely, soldiers in trenches are not so much in ditches, as the word ought to signify, as behind breastworks. Sometimes when two actions opposed to one another are contiguous, a word seems to change to the exact opposite of its original meaning. Thus the English verb *wean*, which meant originally to accustom (to cooked food), has been transferred to the necessary preliminary, to disaccustom to the breast.

Resemblances may be (i.) genuine, and (*a*) of external appearance, or (*b*) of other characteristics, or (ii.) fanciful or analogical. From resemblance in the external appearance of the object, the word *gem*, which in Latin (*gemma*) usually means a bud, has come to mean first a pearl and then by extension of the meaning any precious stone. From the concentric coats which appear in both, the Latin word for a pearl (*unio*, acc. *unionem*) appears in English as *onion*. Examples where the characteristics are not of external appearance are such as the German *kaiser* and the Russian *tsar*, which are descended from Julius Cæsar, while the Lithuanian word for king—*karãlius*—is *Carolus*, *i.e.*, Charlemagne. So in modern Persian, *Xusrev*, "Lord," comes from the Zend proper name Husravah (Chosroes). The resemblances which have established a connexion between *pert* and *impertinent* (properly irrelevant) are in sound only. The same is true of the supposed relation of the verb *cut* to *cutlass*, *cutler*, and *cutlet*. While *train oil* really means oil in drops like tears (cp. German *Thräne*), most people connect it with railway trains. The resemblance in some cases is merely in function. Thus, though the fir and the oak have no resemblance one to the other, the word *fir* is now generally identified with the Latin *quercus* in etymology (cp. *four* and *quattuor*), in the same way as the Latin *fagus*, "beech," is with the Greek φηγός, "oak," the users of the word having, in the course of their migrations, passed from a land with oaks to a land with firs in the one case, and from a land of beeches to a land of oaks in the other. Resemblance as the basis of metaphor has a very widely extended influence on language.

The most numerous and most varied forms of change in meaning depend, however, upon the law of contiguity. Perhaps the commonest of all forms of contiguity is that where the word indicating some accompanying feature or condition replaces the word for the object referred to. In the countries that border the Mediterranean the heat of mid-day is accompanied and intensified by the dying away of the wind, a characteristic remarked upon by Aeschylus (*Agam.* 565): "What time upon his noonday couch, windless and waveless sank the sea to rest." From the Greek word καῦμα, "burning heat," arises through late Latin the English *calm*, where the absence of wind is the only idea present, that of heat having altogether disappeared. Again, in *bugle*, which is abbreviated for *bugle-horn*, the word which survives properly means *wild ox*, and the originally more important element is lost. In a combination like *silver bugle* the word has gone a stage farther; the original meaning of *horn* has also disappeared. There is no longer any thought of an animal's horn; the only idea that survives is that of a musical instrument. From the cope or cloak (*capella*) of St Martin, which was preserved as a sacred relic by the Frankish kings, comes the word *chapel*. The word was first transferred from the cloak to the holy place wherein it was kept, and thence to similar shrines, and ultimately to any place, not being a church, where prayers were said. A *jig* was originally not the dance, but the fiddle which supplied the music for the dance. The names of liquors are often replaced by some accompaniment as of the place, *port, sherry, champagne*, or by a qualifying adjective as in *brandy*, properly "burnt" from the Dutch *brande-wijn*; or, again, only the less important element of the word is retained as in *whisky*, literally "water," for the older *usquebaugh*, a corruption of Gaelic words meaning the "water of life" (*aqua vitæ*). Replacement of substantives by their accompanying adjectives is common in most languages. One of the most common methods of coining a name for a new article is to give it the name of the place or people whence it comes. Thus we have arras, lawn (from Laon), cravat (Croat), coach from Kocs in Hungary, bilboes (both fetters and swords) from the iron mines of Bilboa in Spain. Equally common are the names of inventors—pinchbeck, tontine, silhouette, guillotine, derrick. In the word *cash*, which comes indirectly from Latin *capsa*, "a box," the thing contained has taken its name from the container. Similarly *mortar*, "cement," derives its name from the mortar in which it was mixed, while in *box* the material (boxwood, Lat. *buxus*, Greek πύξος) has usurped the place of the article made. In *leper* the disease (Lat. *lepra*, the rough disease, from Greek λεπρὰ νόσος) has been made into the name of the sufferer, who was earlier called a leprous man. As a consequence, a new substantive *leprosy* has to be taken from the adjective to indicate the disease. The various changes in meaning, which are classed together as synecdoche, have their origin in contiguity. Thus we have the species for the genus; the butcher, who properly kills goats only (Old French *boc*), has ousted the flesher. But we have also the genus for the species; corn, as a rule, means in England wheat; in Scotland, oats; in America, maize. The individual becomes collective as in corps, navy, body (of men); the collective becomes individual when Latin *racemus*, "bunch of grapes," passes into English "raisin." Here would come the so-called meliorative and pejorative developments in word-meaning, whereby, *e.g.*, *steward*, "the sty-ward," becomes the title of a great officer of the realm and the name of a line of kings; or, on the other side, *sou* (Latin *solidus*) passes from the name of a gold coin to that of one of proverbially insignificant value. Here, too, would come many euphemistic uses which are, for the most part, applications of more general terms to avoid the mention of some specific act or object which is unpleasant, as death, murder, bankruptcy, debt, &c., while metaphorical terms for the same things come under resemblance. These examples do not exhaust the forms of contiguity which appear in language, but they are enough to show how far-reaching the effect of this type of association of ideas is upon language, and how extensive the field is which still calls for investigation before the study of meaning attains the same development as the investigation of the other branches of the history of language.

Phœnix, a city of Arizona, U.S.A., capital of Maricopa county and of the territory, situated on the Salt river, a main branch of the Gila, and on the Santa Fé, Prescott, and Phœnix and the Maricopa and Phœnix railways, south-west of the centre of the territory. Population (1890), 3152; (1900), 5544, of whom 935 were foreign-born and 148 negroes.

Phœnix Islands. See POLYNESIA.

Phœnixville, borough of Chester county, Pennsylvania, U.S.A., situated on the Schuylkill river, at the intersection of branches of the Pennsylvania and the Philadelphia and Reading railways, in the south-eastern part of the state, at an altitude of 131 feet. It contains extensive iron-works, blast furnaces, and rolling mills. It is widely known for its manufacture of bridges, girders, columns, &c. Population (1890), 8514; (1900), 9196, of whom 2221 were foreign-born and 278 negroes.

Phonograph.—The phonograph is an instrument by which the mechanical effect of vibrations of sound can be imprinted on a moving surface of tinfoil or wax. By mechanical arrangements the sound can be reproduced from these imprints. The phonograph was invented by Thomas Edison in 1876, and the first design was patented in January 1877. Many attempts had been made by earlier experimenters to obtain tracings of the vibrations of bodies emitting sound, such as tuning-forks, membranes, and glass or metallic discs. In 1807 Thomas Young (*Lectures*, vol. i. p. 191) described a method of recording the vibrations of a tuning-fork on the surface of a drum; his method was fully carried out by Wertheim in 1842 (*Recherches sur l'élasticité, 1*r. *mém.*). Recording the vibrations of a membrane was first accomplished by Leon Scott by the invention of the phonautograph, which may be regarded as the precursor of the phonograph (*Comptes Rendus*, t. liii. p. 108). This instrument consisted of a thin membrane to which a delicate lever was attached. The membrane was stretched over the narrow end of an irregularly-shaped funnel or drum, while the end of the lever or marker was brought against the surface of a cylinder covered with paper on which soot had been deposited from a flame of turpentine or camphor. The cylinder was fixed on a fine screw moving horizontally when the cylinder was rotated. The marker thus described a spiral line on the blackened surface. When sounds were transmitted to the membrane and the cylinder was rotated, the oscillations of the marker were recorded. Thus tracings of vibrations were obtained. This instrument was much improved by the well-known physicist, König, of Paris, who also made with it many valuable observations. (For a figure of the improved instrument, see *Nature*, 26th December 1901, p. 184.) The mechanism of the recording lever or marker was improved by Barlow, in 1874, in an instrument called by him the logograph (*Trans. Roy. Soc.*, 1874). The next step was König's invention of manometric flames by which the oscillations of a thin membrane under sound-pressures acted on a small reservoir of gas connected with a flame, and the oscillations were viewed in a rotating rectangular mirror, according to a method devised by Wheatstone. Thus flame-pictures of the vibrations of sound were obtained (*Pogg. Ann.* cxxii. pp. 242, 660, 1864; see also *Quelques Expériences d'Acoustique*, Paris, 1882). Views of such flame-pictures may be seen in almost every text-book of physics. Clarence Blake in 1876 employed the drum-head of the human ear as a logograph, and thus obtained tracings similar to those made by artificial membranes and discs (*Archiv. für Ophthalmol.* vol. v. 1. 1876). In the same year Stein photographed the vibrations of tuning-forks, violin strings, &c. (*Pogg. Ann.*, 1876, p. 142). Thus from Thomas Young downwards successful efforts had been made to record graphically on moving surfaces the vibrations of sounds, but the sounds so recorded could not be reproduced. This was accomplished by Edison. In the first phonograph a spiral groove was cut on a brass drum fixed on a horizontal screw, so that when the drum was rotated it moved from right to left, as in the phonautograph. The recorder consisted of a membrane of parchment or gold-beater's skin stretched over the end of a short brass cylinder about 2 inches in diameter. In the centre of the membrane there was a stout steel needle having a chisel-shaped edge, and a stiff bit of steel spring was soldered to the needle near its point, while the other end of the spring was clamped to the edge of the brass cylinder over which the membrane was stretched. The recorder was then so placed beside the large cylinder that the sharp edge of the needle ran in the middle of the spiral groove when the cylinder was rotated. The cylinder was covered with a sheet of soft tinfoil. During rotation of the cylinder and while the membrane was not vibrating, the sharp edge of the marker indented the tinfoil into the spiral groove; and when the membrane was caused to vibrate by sounds being thrown into the short cylinder by a funnel-shaped opening, the variations of pressure corresponding to each vibration caused the marker to make indentations on the tinfoil in the bottom of the groove. These indentations corresponded to the sound-waves. To reproduce the sounds the recorder was drawn away from the cylinder, and the cylinder was rotated backwards until the recorder was brought to the point at which it started. The cylinder was then rotated forwards so that the point of the recorder ran over the elevations and depressions in the bottom of the groove. These elevations and depressions, corresponding to the variations of pressure of each sound-wave, acted backwards on the membrane through the medium of the marker. The membrane was thus caused to move in the same way as it did when it was made to vibrate by the sound-waves falling upon it, and consequently movements of the same general character but of smaller amplitude were produced, and these reproduced sound-waves. Consequently the sound first given to the phonograph was reproduced with considerable accuracy. Such was the first tinfoil phonograph. In 1878 Fleeming Jenkin and Ewing amplified the tracings made on this instrument by the sounds of vowels, and submitted the curves so obtained to harmonic analysis; that is to say, by the application of Fourier's theorem they were enabled to analyse the complex curves corresponding to the vibrations of vowel-tones into the simpler curves, in a harmonic series, of which they were composed (*Trans. Roy. Soc. Edin.* vol. xxviii. p. 745). The marks on the tinfoil were also examined by Grützner, Mayer, Graham Bell, Preece, and Lahr (see *The Telephone, the Microphone, and the Phonograph*, by count du Moncel, Lond. 1884; also *The Speaking Telephone and Talking Phonograph*, by G. B. Prescott, New York, 1878).

The tinfoil phonograph, however, was an imperfect instrument, both as regards the medium on which the imprints were taken (tinfoil) and the general mechanism of the instrument. From 1877 to 1888 Edison was engaged in working out the details of the wax-cylinder phonograph as we now have it, one of the most beautiful of instruments (see Fig. 1a and Fig. 1b). The improvements consisted chiefly (1) in substituting for tinfoil cylinders made of a waxy substance on which permanent records are taken; (2) in substituting a thin glass plate for the parchment membrane; (3) in improving the mechanical action of the marker; and (4) in driving the drum carrying the wax cylinder at a uniform and rapid speed by an electric motor placed below the instrument. In the first place, permanent records can be taken on the wax cylinder. The waxy material is brittle, but it readily takes the imprints made by the marker, which is now a tiny bit of sapphire. The marker, when used for recording, is shod with a chisel-shaped edge of sapphire; but the sapphire is rounded when the marker is used for reproducing the sound. The marker also, instead of being a stiff needle coming from the centre of the membrane or glass plate, is now a lever, heavily weighted so as to keep it in contact with the surface of the wax cylinder. A single vibration of a pure tone consists of an increase of pressure followed by a diminution of pressure. When the disc of glass is submitted to an increase of pressure, the action of the lever is such that, while the wax cylinder is rotating, the point of the marker is angled downwards, and thus cuts deeply into the wax; and when there is diminution of pressure, the point is angled upwards, so as to act less deeply. In reproducing the sound, the blunt end of the marker runs over all the elevations and depressions in the bottom of the groove cut on the wax cylinder. There is thus increased pressure transmitted upwards to the glass disc when the point runs over an elevation, and less pressure when the point runs over a depression on the wax cylinder. The glass disc is thus, as it were, pulled inwards and thrust outwards with each vibration, but these pulls and thrusts follow each other so rapidly that the ear takes no cognizance of the difference of phase of the vibrations of the glass plate in imprinting and in reproducing. The variations of pressure are communicated to the glass plate, and these, by the medium of the air, are transmitted to the drum-head of the ear, and the sound is reproduced with remarkable fidelity. It is necessary for accurate reproduction that the point of the marker be in the centre of the groove. In the older phonographs this required accurate adjustment by a fine screw, but in newer forms a certain amount of lateral oscillation is allowed to the marker, by which it slips automatically into the groove. Recently two other improvements have been effected in the construction of the instrument. A powerful triple-spring motor has been substituted for the electric motor, and the circumference of the wax cylinder has been increased from $6\frac{7}{8}$ inches to 15 inches. The cylinders make about two revolutions per second, so that with the smaller cylinder the point of the marker runs over nearly 14 inches in one second, while with the larger it runs over about 30 inches. The marks corresponding to the individual vibrations of tones of high pitch are therefore less likely to be crowded together with the larger cylinder, and these higher tones, in particular, are more accurately reproduced. In a form of instrument called the 200-thread machine, motion of the drum bearing the cylinder was taken off a screw the thread of which was 50 to the inch, and by a system of gearing the grooves on the cylinder were 200 to the inch, or $\frac{1}{200}$ of an inch apart. It was somewhat difficult to keep the marker in the grooves when they were so close together; and the movement is now taken directly off a screw the thread of which is 100 to the inch,

Fig. 1a.—Exterior of Edison Phonograph.

so that the grooves on the cylinder are $\frac{1}{100}$ of an inch apart. Thus with the large cylinder a spiral groove of over 300 yards may be described by the recorder, and with a speed of about two revolutions per second this distance is covered by the marker in about 6 minutes. By diminishing the speed of revolution, which can be easily done, the time may be considerably lengthened. Other forms of phonographs, some termed grammophones, have been invented, in which the records are taken on a flattened disc rotating horizontally, and so arranged that the recorder describes a series of spirals diminishing from the circumference to the centre of the disc; but they are all constructed on the general principle of the phonograph above described.

To understand how the phonograph records and reproduces musical tones, it is necessary to remember (1) that *pitch* or *frequency* depends on the number of vibrations executed by the vibrating body in a given period of time, or on the duration of each vibration, say a tone having a pitch or frequency of 200 vibrations per second, each vibration lasting $\frac{1}{200}$ of a second; (2) that *intensity* or *loudness* depends on the amplitude of the movement of the vibrating body; and (3) that *quality*, *timbre*, or *clang*, first, depends on the form of the individual vibrations, or rather on the power the ear possesses of appreciating a simple pendular vibration producing a pure tone, or of decomposing more or less completely a compound vibration into the simple pendular vibrations of which it is composed. If we apply this to the record of the phonograph on the wax cylinder, we find that, given a constant and sufficiently rapid velocity of the cylinder, a note or tone of a certain pitch will be heard when the marker runs over a number of elevations and depressions corresponding to the frequency of that note. Thus if the note was produced by 200 vibrations per second, and suppose that it lasted in the music for $\frac{1}{10}$ of a second, 20 marks, each made in $\frac{1}{200}$ of a second, would be imprinted on the wax. Consequently, in reproduction, the marker would run over the 20 marks in $\frac{1}{10}$ of a second, and a tone of that frequency would be reproduced. The loudness would correspond to the depth of each individual mark on the cylinder. The greater the depth of a series of successive marks produced by a loud tone, the greater, in reproduction, would be the amplitude of the excursions of the glass disc and the louder would be the tone reproduced. Lastly, the form of the marks corresponding to individual vibrations would determine the quality of the tone or note reproduced, by which we can distinguish the tone of one instrument from another, or the sensation produced by a tone of pure and simple quality, like that from a well-bowed tuning-fork or an open organ pipe, and that given by a trumpet or an orchestra, in which the sounds of many instruments are blended together. When the phonograph records the sound of an orchestra, it does not record the tones of each instrument, but it imprints on the wax cylinder the form of impression corresponding to the very complex sound-wave formed by all the instruments combined. This particular form, infinitely varied, will reproduce backwards, as has been explained, by acting on the glass plate, the particular form of sound-wave corresponding

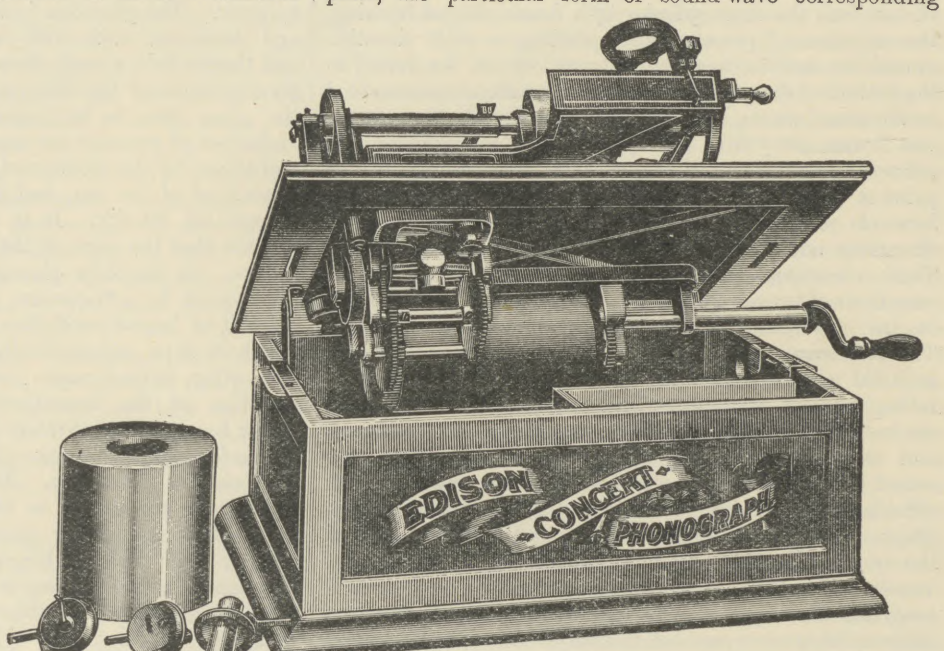

Fig. 1b.—Mechanism of Edison Phonograph.

to the sound of the orchestra. This is one of the wonderful feats of the phonograph. Numerous instruments blend their tones to make one wave-form, and when one instrument predominates, or if a human voice is singing to the accompaniment of the orchestra, another form of sound-wave, or rather a complex series of sound-waves, is imprinted on the wax cylinder. When reproduced, the

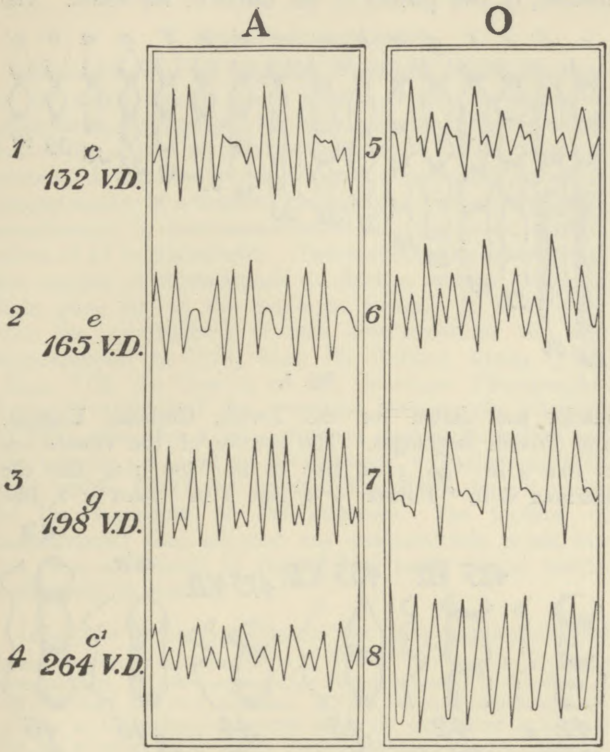

Fig. 2.

wave-forms again exist in the air as very complex variations of pressure, these act on the drum-head of the human ear, there is transmission to the brain, and there an analysis of the complex sensation takes place, and we distinguish the trombone from the oboe, or the human voice from the violin obbligato. The phonograph reduces all to mechanical simplicity; complexity arises when we have to deal with the effects on the human ear and brain.

Many efforts have been made to obtain graphic tracings of wave-forms imprinted on the wax cylinder of the phonograph. Thus the writer has taken (1) celloidin casts of the surface, and (2) micro-photographs of a small portion of the cylinder (*Journ. of Anat. and Phys.*, July 1895). He also devised a phonograph recorder by which the curves were much amplified (*Trans. Roy. Soc. Edin.* vol. xxxviii.; *Proc. Roy. Soc. Edin.*, 1896–97, Opening Address; *Sound and Speech Waves as revealed by the Phonograph*, Lond. 1897; and *Schäfer's Physiol.* vol. ii., Vocal Sounds, p. 1229). As already mentioned, so long ago as 1878 Fleeming Jenkin and Ewing had examined the marks on the tinfoil phonograph. Professor Hermann, of Königsberg, took up the subject about 1890, using the wax-cylinder phonograph. He obtained photographs of the curves on the wax cylinder, a beam of light reflected from a small mirror attached to the vibrating disc of the phonograph being allowed to fall on a sensitive plate while the phonograph was slowly travelling. (For references to Hermann's important papers, see *Schäfer's Physiology*, vol. ii. p. 1222.) Boeke, of Alkmaar, has devised an ingenious and accurate method of obtaining curves from the wax cylinder. He measures by means of a microscope the transverse diameter of the impressions on the surface of the cylinder, on different (generally equidistant) parts of the period, and he infers from these measurements the depth of the impressions on the same spot, or, in other words, he derives from these measurements the curve of the vibrations of the tone which produced the impression (*Archiv. f. d. ges. Physiol.* Bonn, Bd. 1, S. 297; also *Proc. Roy. Soc. Edin.*, 1898).

From a communication to the Dutch Otorhinolaryngological Society Dr Boeke has permitted the author to select the accompanying illustrations, which will give the reader a fair conception of the nature of the marks on the wax cylinder produced by various tones. Fig. 2 shows portions of the curves obtained by Hermann, and enlarged by Boeke one and a half times. The numbers 1 to 4 refer to periods of the vowel A (as in "hard"), sung by Hermann on the notes *c e g c'*. Numbers 5 to 8 show the curves of the vowel *o* (as in "go") sung to the same notes. The number of vibrations is also noted. Bocke measured the marks for the same vowels by his method, from the same cylinder, and constructing the curves, found the relative lengths to be the same. In Fig. 3 we see the indentations produced by the same vowels, sung by Hermann on the notes *c e g c'*, on the same phonograph cylinder, but delineated by Boeke after his method. The curves are also shown in linear fashion beside each group of indentations. From these measurements the curves were calculated and reproduced, as in Fig. 4. Thus the curves of the same vowel sounds on the same cylinder are shown by two methods, that of Hermann and that of Boeke. In Fig. 5 we see the indentations on the vowel *a*, sung by Dr Boeke, aged 55, on the notes *c d e f g a b c'*, and near the frequencies of 128, 144, 160, 170·6, 192, 213·3, 240, and 256. The numbers 33 to 40 show the marks produced by the same vowel, sung by his son, aged 13. It will be seen that the boy sang the notes exactly an octave higher. Fig. 6 shows the marks produced by some musical sounds. Each shows on the right-hand side the curve deduced from the marks, and under it a graphical representation of the results of its harmonic analysis after the theorem of Fourier, in which the ordinates represent the amplitude of the subsequent harmonic constituents. No. 41 is the period of the sound of a pitch-pipe giving *a'* (425 double vibrations per second), No. 42 the period of a Dutch pitch-pipe, also sounding *a'* (424·64 double vibrations per second). No. 43 is a record of the period of a sound produced by blowing between two

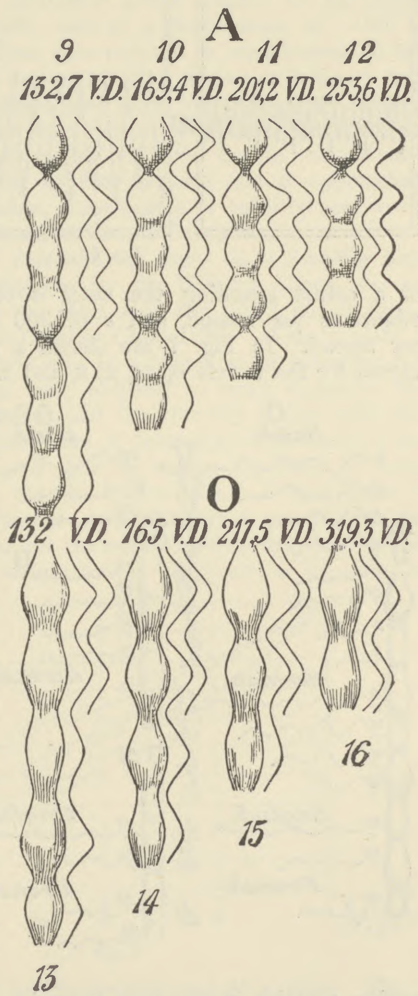

Fig. 3.

strips of indiarubber to imitate the vocal cords, with a frequency of 453 double vibrations per second. No. 44 is that of a telephone pipe used by Hermann (503 double vibrations per second). Nos. 45 and 46 show the marks

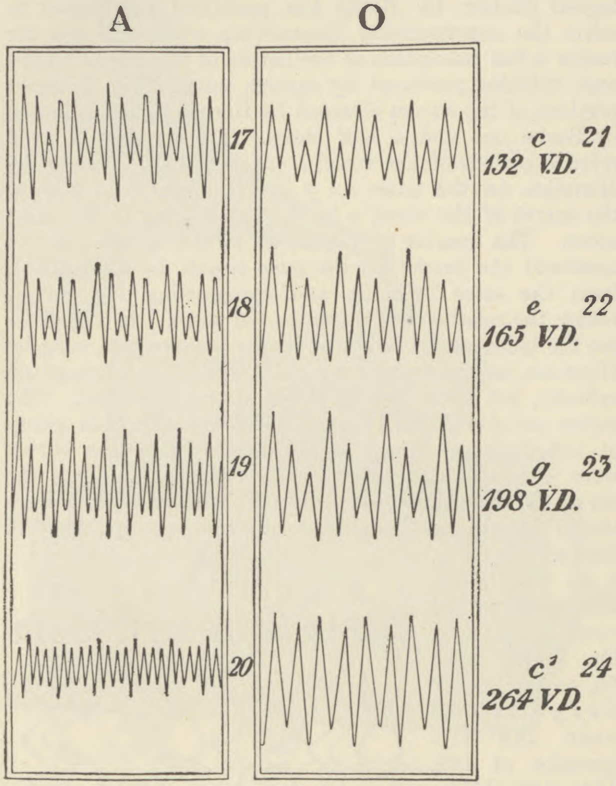

Fig. 4.

of a cornet sounding the notes a of $\pm$ 400 double vibrations per second, and e of 300 double vibrations per second. In Fig. 7 are shown a number of vowel curves for the vowels O, OE, A, E, and I. Each curve has on the right-hand side a graphical representation of its harmonic analysis. The curves are in five vertical columns, having on the left-hand side of each drawings, by Boeke's method, of two periods of the marks of the vowel. The

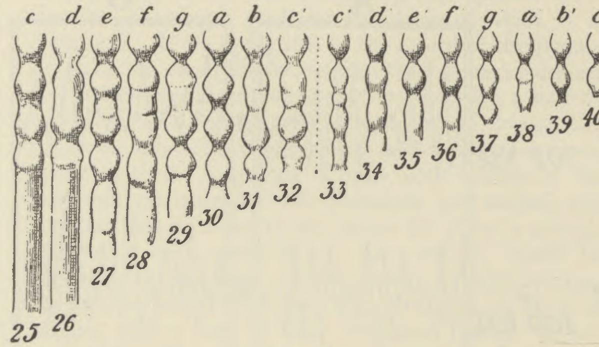

Fig. 5.

marks are shown for the Dutch, German, English, and French languages. The sounds of the vowels are *o*, like *o* in "go"; *oe*, like *oo* in "too"; *u*, like the German *ü* in "Führer"; *a*, like *a* in "hard"; *e*, like

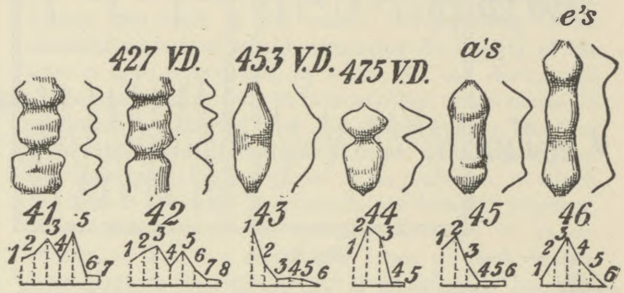

Fig. 6.

a in "take"; *ij*, not in English words, but somewhat like *ē* in "bell"; and *i*, like *ee* in "beer." The first section contains only Dutch vowel sounds, either sung or spoken by Boeke or members of his family. The second

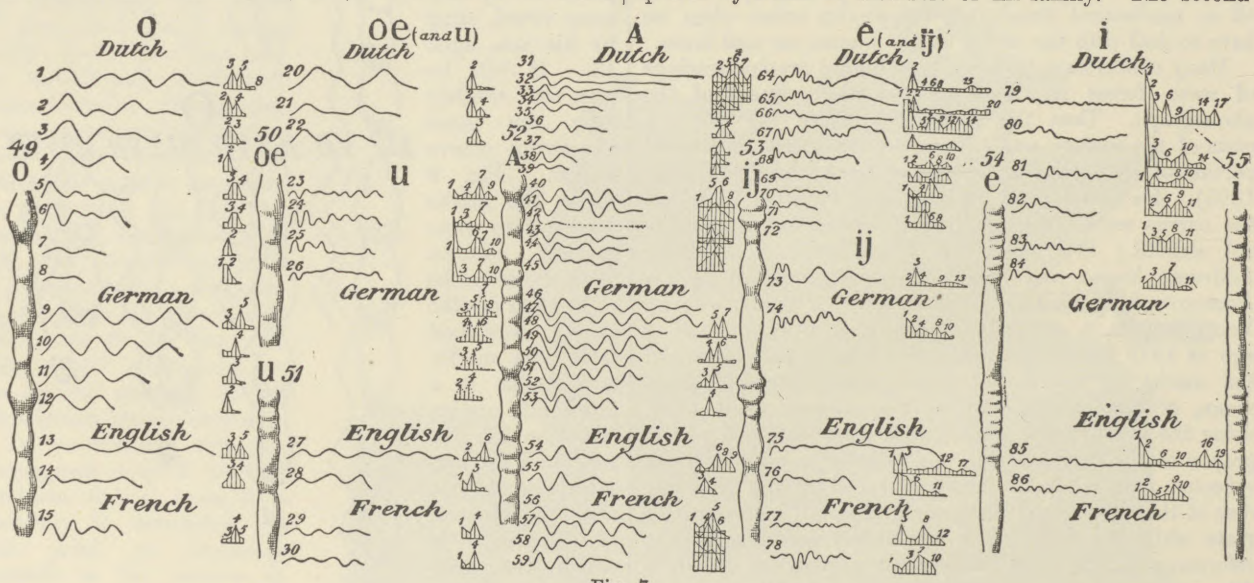

Fig. 7.

section contains curves from the voice of Professor Hermann, the third from the voice of the author from a cylinder sent by him to Dr Boeke, and the fourth from the voice of Mons. H. Marichelle, professeur de l'Institut des Sourds-Muets, also forwarded by him to Dr Boeke. Thus curves and marks of the same vowel are shown from the voices of men of four nationalities.

Apart altogether from the use of the phonograph in business and for the reproduction of music, it will be seen that it is an instrument of great value in the investigation of problems in acoustics, and that it illustrates these as no other instrument can do (see "Experimental Phonetics," by the author, *Nature*, 26th December 1901).

PHOTOGRAPHY.

I. Scientific Advances.

Measurement of the Rapidity of a Plate.—Since the date of the article in the ninth edition of the *Encyclopædia Britannica*, photography has advanced in a direction which before the advent of gelatine plates was hardly to be expected. It has now become a matter of everyday procedure among makers of a brand of photographic plates to gauge its sensitiveness by exact measurement, and express the result in terms of an empirical unit. This is effected by ascertaining the amount of silver-deposit to which a certain impact of light gives rise on the developed image. It is believed that the practicability of such determinations was first demonstrated in 1874, when Sir William Abney (*Phil. Mag.*, "On the Opacity of the Developed Photographic Image") established the connexion between the intensity of light acting for a given time on a sensitive surface and the opacity produced on development. He demonstrated that, within limits, the transparency of the deposit varies as the logarithm of the exposure. The method of measurement then adopted was comparatively crude, but ten years afterwards he showed how much greater exactitude could be ensured.

In 1888 Sir W. Abney pointed out that the speed of a plate could be determined by the formula $T = E^{-\mu(\log E + C)^2}$, where T is the transparency, E is the exposure (or time of exposure × intensity of light acting), and C a constant. If the abscissæ (exposures) are plotted as logarithms, the curve takes the same form as that of the law of error, which has a singular point, a tangent through which lies closely along the curve and cuts the axis of Y at a point which has a value of $2E^{-\frac{1}{2}}$. If the total transparency be unity, this ordinate has a value of 1·212, the singular point having a value 0·606. The ordinate of the zero point of the curve will be where the tangent to the singular point cuts the line drawn at 1·212. The difference between the measurements of this zero point for two kinds of plates (*i.e.*, C in the formula) from the points in the abscissæ marking the same exposure, will give the relative sensitiveness of the two plates in terms of $\log x^2$. In 1890 Hurter and Driffield, in a paper read before the Society of Chemical Industry (see *Journal* of that Society, 19th January 1891), worked out a far less empirical formula connecting the exposure E with the density of deposit, which in an approximate shape had the form $D = \gamma \log \frac{E}{i}$, where D is the density of deposit (or $\log \frac{1}{T}$), i the "inertia" of the plate, T the transparency of the deposit. In the customary way a small portion of a plate was exposed to a constant light at a fixed distance and for a fixed time, and another small portion to the same light for double the time, and so on. By measuring the densities of the various deposits and constructing a curve, a large part of which was approximately a straight line, it was found possible, by the production of the straight portion to meet the axis of X, to give the relative sensitiveness of different plates by the distance of the intersection from the zero point L. (See also *Exposure Meters*, below, under II. Apparatus.)

It is believed that neither formula can be absolutely correct, though both are approximately true and are sufficiently near to be of practical value. This belief is based on the further researches described below. [Those *applicable for the correction* of star magnitudes as determined by photography have been verified and confirmed by Schwarzchild, Michalke, and others.]

Effect of Temperature on Sensitiveness.—In the year 1876 it was shown that heat apparently increased, while cold diminished, the sensitiveness of a plate, but the experiments were rather of the qualitative than the quantitative order. In 1893 fresh experiments were undertaken by Sir William Abney, and it was found that the effect of a difference in temperature of some 40° C. invariably caused a diminution in sensitiveness of the sensitive salt at the lower temperature, a plate often requiring more than double the exposure at a temperature of about −18° C. than it did when the temperature was increased to +33° C. Fig. 1 shows the result of exposing a plate when at three different temperatures for the times shown in the scale of abscissæ, the transparency of deposit for the different exposures being shown as the ordinates. The general deduction was that increase in temperature involved increase in sensitiveness so long as the constituents of the plate (gelatine, &c.) were unaltered.

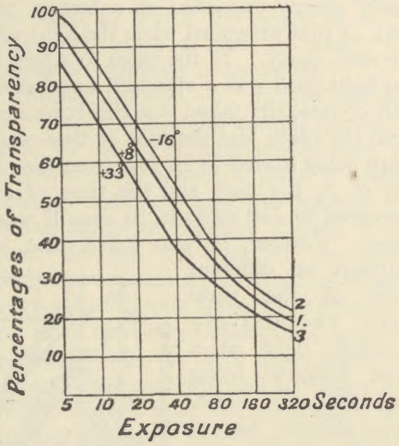

Fig. 1.

Professor Dewar stated at the Royal Institution in 1896 that at a temperature of −180° C. certain sensitive films were reduced in sensitiveness to less than a quarter of that which they possess at ordinary temperatures. It appears also from his subsequent inquiry, that when the same films were subjected to the temperature of liquid hydrogen (−252° C.) the loss in sensitiveness becomes asymptotic as the absolute zero is approached. Presumably, therefore, some degree of sensitiveness would still be preserved even at the absolute zero.

Effect of Small Intensities of Light on a Sensitive Salt.—Another investigation by Sir William Abney was described in brief in the *Proc. Roy. Soc.*, 1893, and in full in the *Journal of the Camera Club*, 1893. When a plate is exposed for a certain time to a light of given intensity, it is commonly said to have received so much exposure (E). If the time be altered, and the intensity of the light also, so that the exposure (time × intensity) is the same, it has usually been accepted that the energy expended in doing chemical work in the film is the same. A long series of experiments conducted under differing conditions has shown that such is not the case, and that the more intense the light (within certain limits) the greater is the chemical

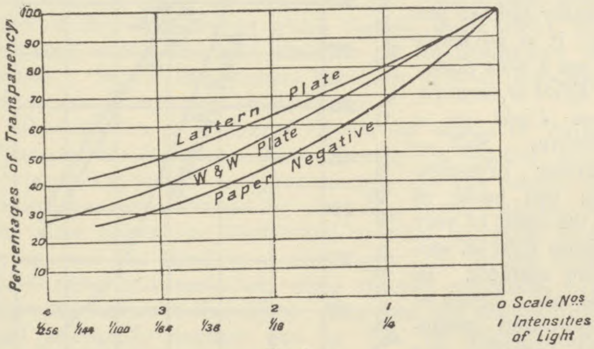

Fig. 2.

action, as shown on the development of a plate. Fig. 2 illustrates the results obtained in three cases. The exposure E is the same in all cases. The curves are so drawn that the scale of abscissæ is the intensity of the light in powers of −2, and the ordinates show the percentages of chemical action produced. If the chemical action remained the same when the intensity of light was reduced, E remaining the same, each of the curves would be shown as a straight line at the height of 100, which is the transparency of deposit with the unit of light. As it is, they show diminishing percentages as the light intensity is diminished. Thus when the intensity of the light is reduced to $\frac{1}{64}$ of the original, and the time of exposure is prolonged 64 times, the useful energy expended on a lantern plate is only 50 per cent. of that expended when the light and time of exposure are each unity. In the cases to which the diagram refers, the light used was a standard amyl-acetate lamp, and the unit of intensity taken was this light at a distance of 2 feet from the plate, and the unit of time was 10 seconds. The lamp being moved to 16 feet from the plate, gave an intensity of $\frac{1}{64}$ the unit, and the time of exposure had to be increased to 640 seconds, so that E was the same in both cases. Further, it was found that when the *times* of exposure on different parts of the plate were successively doubled, light at a fixed distance being used for one series, and altered for a second series, the slopes of the curves of transparency, as in Fig. 1 (the gradation), were parallel to one another. Fig. 3 shows this in a graphic manner, the units of the scales of abscissæ and ordinates being the same as before. This investigation is of use when camera images are in question, as the picture is formed by different intensities of light, not very different from those of the amyl-acetate lamp, the time of exposure being the same for all intensities. The deductions made from the investigation are that with a slow plate the energy expended in chemical action is smaller as the intensity is diminished, while with a quick plate the variation is much less. As a practical deduction, we may say that to obtain proper contrast in a badly lighted picture it is advisable to use a slow plate.

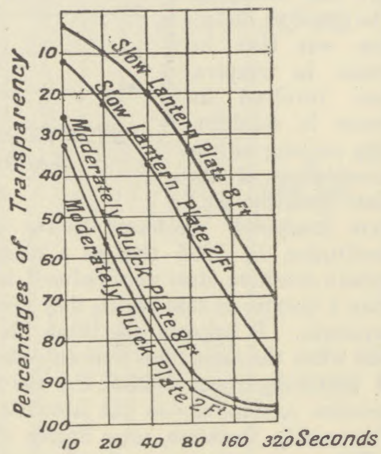

Fig. 3.

Effect of very Intense Light on a Sensitive Salt. — Another investigation was made as to the effect of very intense light on sensitive surfaces. In this case a screen of step-by-step graduated opacities was made use of, and plates exposed through it to the action of lights markedly differing in intensity, one being that of the amyl-acetate lamp, another that of the arc light, and a third the light emitted from the spark of a Wimshurst machine. The exposures were so made that one of the opacities produced on the plate from exposure to each source of light was approximately the same. Fig. 4 gives an example of the results obtained. The abscissæ are derived from the graduated opacities of the screen used, and their units and that of the ordinates are the same as before. The unit of intensity of light is of course in each case widely different. It will be seen that the slope of the curve due to the spark light is less steep than that due to the arc light, and the latter, again, is much less steep than that due to the amyl-acetate lamp. A further investigation was made of the effect of increasing the time of exposure when the intense light was diminished, and it was found that with all plates the useful chemical energy acting on a plate was least with the most intense light, but increased as the intensity diminished, though the time was correspondingly increased. This is the reverse of what we have recorded as taking place when a comparatively feeble light was employed. Further, it was proved that the variation was greatest in those plates which are ordinarily considered to be the most rapid. It follows, therefore, that there is some intensity of light when the useful chemical energy is at a maximum, and that this intensity varies for each kind of plate.

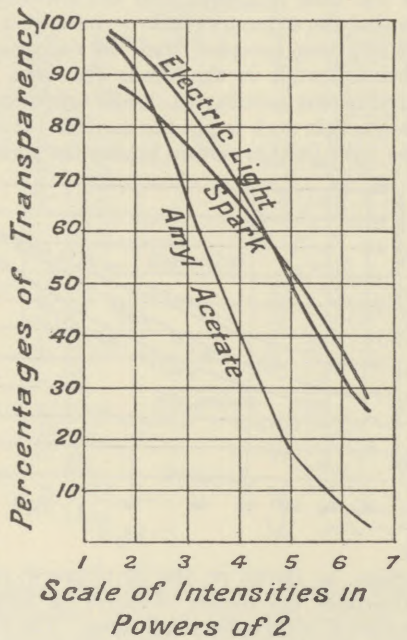

Fig. 4

Intermittent Exposure of a Sensitive Salt. — Sir William Abney has also shown that, if a total exposure is made up of intermittent exposures, the chemical action on a sensitive salt is less than it is when the same exposure is not intermittent. It was also shown that the longer the time of rest between the intermittent exposures (within limits) the less was the chemical action. We may quote one case. Exposures were first made to a naked light, and afterwards to the same light for six times longer, as a rotating disc intervened which had 12 apertures of 5° cut in it at equal intervals apart, and 720 intermittent exposures per second were given. The plate was moved to different distances from the light, so that the intensity was altered. The apparent loss of exposure by the intervention of the disc increases as the intensity diminishes, the ratios of the chemical energy usefully employed of the naked light exposure to that of the intermitting exposures being—

For intensity 1	. . .	1 to ·815
,, ,, $\frac{1}{4}$	. . .	1 ,, ·500
,, ,, $\frac{1}{16}$	. . .	1 ,, ·423
,, ,, $\frac{1}{64}$	. . .	1 ,, ·370

These results appear to be explicable by the theoretical considerations regarding molecular motion.

Effect of Monochromatic Light of Varying Wave-Lengths on a Sensitive Salt.—It has been a subject of investigation as to whether the gradation on a plate is altered when exposures are made to lights of different colours; that is to say, whether the shades of tone in a negative of a white object illuminated by, say, a red light, would be the same as those in the negative if illuminated by a blue light. Abney announced that the gradation was different; and, quite independently, Mr Chapman Jones undertook an investigation of the matter, and made a general deduction for isochromatic plates that, except with a certain developer, the gradation was steeper (that is, the curve shown graphically would be steeper) the greater the wave-lengths of the light to which the sensitive salt was subjected. Investigation shows that with plates made with the ordinary haloid salts of silver Chapman Jones's deduction requires modification. When monochromatic light from the spectrum is employed, it is found that the gradation increases with wave-lengths of light which are less, and also with those which are greater, than the light whose wave-length has a maximum effect on the sensitive salt experimented with. Thus with bromo-iodide of silver the maximum effect produced by the spectrum is close to the blue lithium line, and the gradation of the plate illuminated with that light is less steep than when the light is spectrum violet, green, yellow, or red. From the red to the yellow the gradation is much the steepest. Whether these results have any practical bearing on ordinary photographic exposures is not settled, but that they must have some decided effect on the accuracy of three-colour work for the production of pictures in approximately natural colours is undoubted, and they may have a direct influence on the determination of star magnitudes by means of photography.

Correct Rendering of Colours in Monochrome.—As to the materials used for the correct rendering of colours in monochrome, isochromatic plates have been improved in character, and there is a simple means of ascertaining what light-filter should be used for each brand of plate. Perhaps the best isochromatic plate is, at the time of writing, the "Cadett Spectrum" plate, which is sensitive from the ultra violet to the red of the spectrum, and which shows hardly any of that lack of sensitiveness in the region of the spectrum green which plates dyed with eosin derivatives always betray. When the spectrum is formed by light such as that of a paraffin lamp, the curve of sensitiveness is not far from the curve of luminosity of the spectrum of daylight; so that if a coloured object were illuminated solely by a paraffin light, a print from the negative would give a fair representation of the object in monochrome—that is, the shades of grey in the print would represent the daylight luminosity of the colours. As objects cannot usually be illuminated by this light, it becomes necessary to filter daylight through a coloured screen, which can be put in front of the camera lens. By proper means the luminosity of the light of day coming through a red, a green, a blue, and an orange glass can be very accurately measured; if $\frac{1}{2}$-inch squares of these coloured glasses, together with a white glass of the same area, be placed in a row and cemented on white glass, we have a colour-screen which we can make available for finding the kind of light-filter to be employed. This is readily done by reducing the luminosity of the light coming through all the glasses to that of the luminosity of the light coming through the blue glass. If the luminosity of the blue be 5 and that of the white light 100, then the luminosity of the former must be reduced to $\frac{1}{20}$ of its original value, and so with the other glasses. The luminosity of the light coming through each small glass square can be made equal by rotating in front of them a disc in which apertures are cut corresponding to the reduction required. The blue glass, for instance, would not be covered by the disc at all, while opposite the white square the disc would have an aperture of an angle of 18°. When a plate is exposed behind the row of glass squares, with the light passing through the rotating disc, the negative obtained would, under ordinary conditions, show square patches of very different opacity. A light-filter of some transparent colour, if placed in the path of the light, will alter the opacities, and eventually one can be found which will only allow such coloured light to be transmitted as will cause all the opacities in the negative to be the same. As the luminosities of the white light passing through the glasses are made equal, and as the photographic deposits are also rendered equal, this light-filter, if used in front of the camera lens, will render all coloured objects in correct monochrome luminosity. Another plan, based on the same principles, is to place segments of annuluses of vermilion, chrome yellow, emerald green, French blue, and white on a disc, and to complete the annuluses with black segments, the amount of black depending on the luminosity of the pigments, which can be readily measured. When the disc is rotated, rings of colour, modified in brightness by black, are seen, and each ring will be of the same luminosity. As before, a screen (light-filter) to be used in front of the lens must be found which will cause the developed images of all the rings to appear of equal opacity. It must be remembered that the light in which the object is to be photographed must be the same as that in which the luminosity of the glasses or pigments is measured.

Photography in Natural Colours.—A method, devised by M. Lippmann, of Paris, by which the natural colours of objects are reproduced by means of interference, may be briefly described as follows:—A sensitive plate is placed in contact with a film of mercury, and the exposure to the spectrum, or to the image of coloured objects to be photographed, is made through the back of the plate. On development, the image appears coloured when viewed at one particular angle, the colours being approximately those of the object. The necessary exposure to produce this result was very prolonged in the first experiments in which the spectrum was photographed, and a longer exposure had to be given to the red than was required for the blue. Lippmann at first employed collodion dry plates, prepared, it is believed, with albumen, and it required considerable manipulation to bring out the colours correctly. Lumière used gelatine plates dyed with appropriate dyes (orthochromatic plates); the exposure was much diminished, and very excellent representations were produced of all natural colours. The main point to aim at in the preparation of the plate seems to be to obtain a very sensitive film without any, or, at all events, with the least possible, "grain" in the sensitive salt. A formula published by Lumière seems to attain this object. Viewed directly, the developed images appear like ordinary negatives, but when held at an angle to the light the colours are vivid. They are not pure monochromatic colours, but have very much the quality of colours obtained by polarized light. It appears that they are produced by what may be termed "nodes" of different-coloured lights acting within the film. Thus in photographing the spectrum rays penetrate to the reflecting mercury and are reflected back from it, and these, with the incident waves of light, form nodes where no motion exists, in a somewhat similar way to those obtained in a cord stretched between two points when plucked. In the negative these nodal points are found in the thickness of the silver deposit. When white light is sent through the film after the image has been developed, theoretically only rays of the wave-lengths which formed these nodes are reflected to the eye, and thus we get an impression of colour. So far this process has been only of scientific value and of but small practical use.

Reproduction of Coloured Objects by means of Three Photographic Positives.—Ives's Process.—A practical plan of producing images in approximately the true colours of nature has been devised by preparing three positives of the same object, one illuminated by a red, the other by a green, and the third by a blue light; the images from these three transparencies, when visually combined, will show the colours of the object. This plan was scientifically and practically worked out by Ives of Philadelphia, though in France and elsewhere it had been formulated, especially by Hauron Du Cros. The following description may be taken as that of Ives's process:—By the trichromatic theory of colour-vision every colour in nature can be accounted for by the mixture of two or three of the three-colour sensations, red, green, and blue, to which the eye is supposed to respond. Thus a mixture of a red and green sensation produces the sensation of yellow; of a green and blue, that of a blue-green; of red and blue, that of purple; and of all three, that of white.

For the sensations we may substitute those colours which most nearly respond to the theoretical sensations without any material loss of purity in the resulting sensation. We must take the spectrum of white light as the only perfect scale of pure colours. From experiment it has been proved that the red sensation in the eye is excited by a large part of the visible spectrum, but with varying intensities. If, then, we can on a photographic plate produce a developed image of the spectrum which exactly corresponds in opacity and position to the amount of red stimulation excited in those regions, we shall, on illuminating a positive taken from such a negative with a pure red light, have a representation of the spectrum such as would be seen by an eye which was only endowed with the sensation of red. Similarly, if negatives could be taken to fulfil the like conditions for the green and for the blue sensation, we should obtain positives from them which, when illuminated by pure green and blue lights respectively, would show the spectrum as seen by an eye which was only endowed with a green or a blue sensation. Evidently if by some artifice we can throw the coloured images of the three positives on a screen, superposing them one over the other in their proper relative positions, the spectrum will be reproduced, for the overlapping colours, by their variation in intensity, will form the colours intermediate between those used for the illumination of the positives. For the purpose of producing the three suitable negatives of the spectrum, three light-filters, through which the image has to pass before reaching the photographic plate, have to be found. With all present plates these are compromises (see below). Roughly speaking, the screens used for taking the three negatives are an orange, a bluish green, and a blue. These transmit those parts of the spectrum which answer to the three sensations. When these are obtained, a coloured object can be reproduced.

Joly's Process.—Professor Joly, of Dublin, in 1897 introduced a colour process by which an image in approximately natural colours could be thrown upon a screen by an optical lantern, only one transparency being employed, instead of three, as in the Ives process. A "taking" screen was ruled with alternating orange, blue-green, and blue lines $\frac{1}{200}$ to $\frac{1}{300}$ inches apart, touching one another and following one another in the above order. When such a screen was placed in front of a sensitive plate in the camera, and exposure made to the image of a coloured object, there were practically three negatives on the same plate, each being confined to the area occupied by lines of the same colour. The shades of colour and the depth of the colours used in ruling depended on the brand of plate. When a perfect triune negative was obtained, a transparency was made from it, and in contact with this was placed a screen ruled with lines the same distance apart, but of the colours corresponding to the three colour sensations, namely, red, green, and blue. The red lines were made to fall on the image taken through the orange lines, the green on that of the blue-green, and the blue or violet on that of the blue. On the screen there are practically three differently-coloured images shown by one transparency. The different colours blend together and give a picture which shows approximately the correct colours of the original.

Three-Colour Photographic Printing.—Three-colour printing has made rapid strides. The most suitable negatives are those which have been described for Ives's process. Instead of using the colours which correspond to the colour sensations, their complementaries are employed, for reasons which will be evident if the absorption of dyes when superposed is considered. Thus to produce a yellow patch by Ives's process, that space must be almost bare in those positives through which red and green lights are transmitted, since red and green combined make yellow. The negatives must therefore be opaque where these spaces occur. If we use the negatives for producing (say) collotype plates, which are subsequently "inked" with coloured "inks," the spaces in the print from the "red" and the "green" negatives will "take" no colour, whilst that in the "blue" negative will have a full colour. Evidently, then, to produce a yellow when the three printings are superposed, the blue negative must be printed in yellow, the complementary to the blue that is used by Ives in the triple projection process. Similarly, for inking in the plate printed from the red negative the colour used must be a green-blue, and from the green negative a purple. These last two colours must be transparent colours if the first printing on a white surface is the yellow from the blue negative. If opaque, there would be a dirty image formed, of no particular colour. The colour next the white ground, however, may be opaque. We may expect that the difficulty of obtaining the exact depth of colour necessary for each printing will be overcome before very long, and that three-colour printings will give uniform results (see PROCESS).

Positives in Three Colours.—Ives was the first to show that a transparency displaying approximately all the colours in nature could be produced on the same principles that underlie the three-colour printing. This he effected by printing each of the three negatives, produced for his triple projection process as already described, on gelatine films sensitized by bichromate of potash. Each of the three transparent films was dyed with a colour complementary to the colour of the light which he transmitted through the positives when used for projection. Thus the "red" positive he dyed with a blue-green dye, the "green" positive with a purple dye, and the "blue" positive with a yellow dye. These three films, when superposed, gave the colours of the original object. Sanger Shepherd has made the process a commercial success, and produces lantern slides of great beauty, in which all colours are correctly rendered. Instead of using a dye for the "red" transparency, he converts the silver image of a positive image into an iron salt resembling Prussian blue in colour.

Sensitometers for Three-Colour Work.—Sir W. Abney has devised sensitometers for determining the colours of the screens to be placed before the lens in order to secure the three-colour negatives. Their production depends upon the same principles as that he devised for the correct rendering in monochrome of a colour object. When the sensitometer takes the form of glasses through which light is transmitted to the plate, the luminosities of the coloured lights transmitted are determined, and also the percentage composition of their colours in terms of the red, green, and blue lights used in the triple projection, and thence are deduced the luminosities in terms of red, green, and blue. For ascertaining what red screen should be used, the luminosity transmitted through each is so adjusted that the luminosity of the red components in each is made equal (see *ante*). This gives a sensitometer of equal red values. A coloured screen has to be found which, when placed in front of the lens, will cause the density of the deposit on the plate to be the same throughout. This is done by trial, the colour being altered till the proper result is obtained. In a similar way the "green" and "blue" screens are determined. Coloured pigments rotating on a disc can also be employed, as indicated in the paragraph on the correct rendering of colour in monochrome (see *ante*).

New Developers.—Some excellent developers have recently been brought out; formulæ for those most in vogue are appended:—

Eikonogen Developer.

Eikonogen . . .	25 parts.
Sodium sulphite . .	50 ,,
Sodium carbonate . .	50 ,,
Potassium bromide . .	½ ,,
Water	1000 ,,

This is a one-solution developer, and acts energetically.

Metol Developer.

Solution A.

Metol	2 parts.
Sodium sulphite . .	18 ,,
Water	100 ,,

Solution B.

Sodium carbonate . .	6 parts.
Potassium bromide .	1 ,,
Water	100 ,,

For use, take one part of A to from 1 to 3 parts of B.

Amidol Developer.

Amidol	3 parts.
Sodium sulphite . .	100 ,,
Potassium bromide .	1 to 3 ,,
Water	1000 ,,

This developer requires no addition of alkali.

Ortol Developer.

Solution A.

Ortol	15 parts.
Sodium metabisulphite .	7 ,,
Water	1000 ,,

Solution B.

Sodium carbonate . .	100 parts.
Sodium sulphite . .	125 ,,
Potassium bromide .	3 ,,
Water	1000 ,,

A and B solutions are mixed together in equal proportions.

Besides these, there are several more, such as Adurol, Glycine, Pyro-catechin, which have been used with more or less success. They all give a black in lieu of that dark olive-green deposit of silver which is so often found with pyrogallol developers. All are alkaline developers, and the image is built up from the sensitive salt within the film. They are applicable to gelatine or collodion plates, but for the latter rather more bromide of an alkali is added, to retard fogging.

Effect of Hydrogen Peroxide on Sensitive Plates.—Dr W. J. Russell instituted a series of experiments on the effect of exposure of sensitive plates to the action of vapours and gases for long periods. It has long been known that contact of plates with such substances as wood caused a sensitive surface to show "fog" on development. By a somewhat exhaustive series of experiments, Russell showed that the probable cause of this fog is peroxide of hydrogen, since substances which favoured its formation produced the same effect. This is somewhat remarkable, as this same substance will completely destroy the effect that light has had on a sensitive plate; indeed, it affords one way of destroying a light image on a sensitive collodion plate. The experiments of Russell give a warning to photographers to take care how they store exposed plates for brief periods. It appears that negatives wrapped in paraffin paper are secure from this danger.

(W. DE W. A.)

II. APPARATUS.

Since the ninth edition of this work was published, great changes have been made in ordinary photographic apparatus, chiefly due to the extended use of small hand cameras suitable for taking instantaneous photographs upon the rapid gelatine dry plates or films now available. These small pictures can easily be enlarged four times or more, so that the photographic travelling equipment may be reduced to a hand package. The result of this is seen in the immense expansion that has taken place in the use of photography for all purposes of illustration. The tendency in all portable cameras and apparatus has been towards lightness and compactness in construction and material. Aluminium and its alloys are largely used, instead of brass, for fittings and mountings. Instead of glass plates, flexible films of celluloid and other materials are available in single sheets like plates, or in rolls enclosed in opaque paper, which can be changed or replaced in daylight. The construction of lenses has also been improved, so as to obtain greater covering power, with flatness of field and freedom from astigmatism, with larger apertures than were available with aplanatic lenses. Greater rapidity of working is thus gained; and with the increased sensitiveness of the dry plates in use, subjects in rapid motion can be photographed with a perfection which formerly was quite unattainable.

Cameras.

The general requirements of a good camera are:—Thoroughly well-seasoned material, simplicity and strength of construction, parallelism and squareness of front and back, smoothness and regularity of movement in focussing. A rising and falling front, by which the lens can be raised or lowered to take in more or less foreground, is almost a necessity, and may be supplemented by a swing back or swing front, to prevent distortion of the image when the camera has to be tilted, or to equalize definition of objects at different distances from the camera. A side swing is specially useful for the latter purpose. These movements should be round the central horizontal or vertical axis of the back or front, as the case may be. When the rising front is used, the lens must be stopped down, or another of longer focus fitted which will cover a larger plate than the camera is made for, in order to obtain good definition over the extended area of the picture. It is convenient to have the camera square and fitted with a reversible back, so that the greatest length of the plate may be horizontal or vertical, as desired. The increase of weight and bulk is obviated in some French cameras by making the back part of the camera and bellows reversible, the former being placed upright or on its side, as required, while the small end of the bellows is made square or round, so as to fit in either position into the front of the camera behind the lens. The focussing screen may be ruled with parallel cross-lines for purposes of measurement, and as a check on the verticality of the camera when photographing buildings or other objects with vertical lines. The distance from the lens of the focussing screen, and of the sensitive surface of the plate in the dark slide, must coincide exactly. This can be tested by measurement, or by carefully focussing some bright and well-defined object on the screen and then on a ground glass plate placed in each of the dark slides to be examined. The camera and the plate-carriers must be perfectly light-tight, and all their inner surfaces dead black, to prevent any reflection from bright spots from being thrown on the plate. The plate-carrier or dark slide must permit of the sensitive plate being placed in the camera and exposed without risk of any light reaching it except that passing through the lens. The corner joints, the hinges in the shutters, and the openings at the sides and top in the book form of double carrier are all weak points, and require careful examination from time to time. They should be protected by metal plates. The plate-carriers should fit readily into their places without jerking, and the shutters must run smoothly when withdrawn and replaced. Frames may be provided for smaller plates than the carriers are made for, care being taken that the surface of the plate is at the proper distance from the lens. It is convenient to have the plate-carriers numbered in sequence, and provided with a small inlaid tablet for recording memoranda of plate, exposure, &c. A level or other means of showing that the camera is level and the plate vertical should be attached to the camera; also a view meter or finder showing the exact extent of the picture.

Studio cameras are made adjustable, both from the front and back, thus enabling short- or long-focus lenses to be used, with extra extension for copying and enlarging. As a rule they are fitted with repeating backs, for enabling two or more exposures to be made on one plate. The backs are usually square, so that the

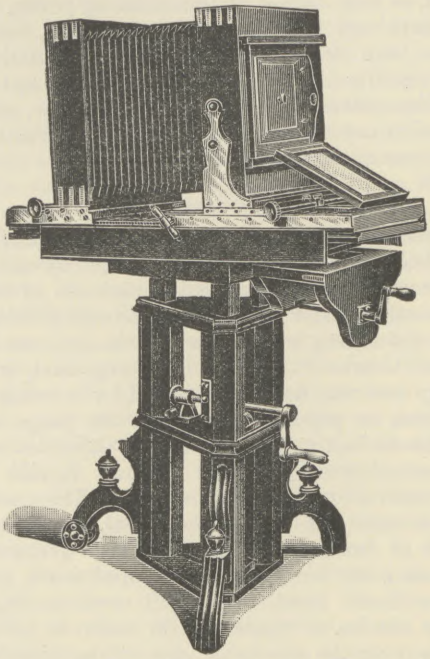

Fig. 5.—Studio Camera and Stand.

plates can be used upright or lengthways, and they are fitted with double swing movements. When single plate-carriers are used, they are sometimes fitted with a flexible shutter, by which jerking and movement of the camera are avoided. The ordinary studio cameras used for portraiture are usually mounted on strong pillar stands, raised or lowered with an endless screw or rackwork, and the flat top carrying the camera is arranged to have an angular motion vertically and horizontally. Large cameras, with long extension for copying purposes, should be mounted on substantial table stands, with adjustments for obtaining the various motions above noted. In all these stands absolute rigidity and freedom from shaking are essential. Figs. 5 and 6 show two types of modern

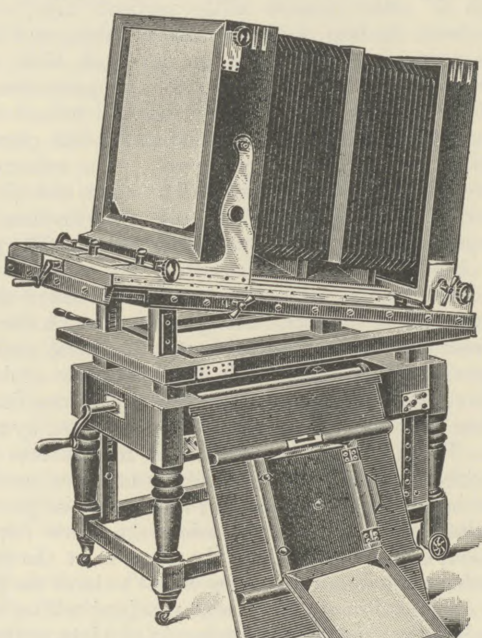

Fig. 6.—Studio Camera and Stand.

patterns of studio camera and stand. Descriptions of other apparatus of the kind will be found in the works noted at the end.

Ordinary *Field* and *Portable* cameras, other than special hand cameras, are now lighter and more compact, metal struts being used instead of wooden flaps for supporting and fixing the front and back when in use. They are made in a variety of patterns, the principal improvements being swinging fronts, tripod head and

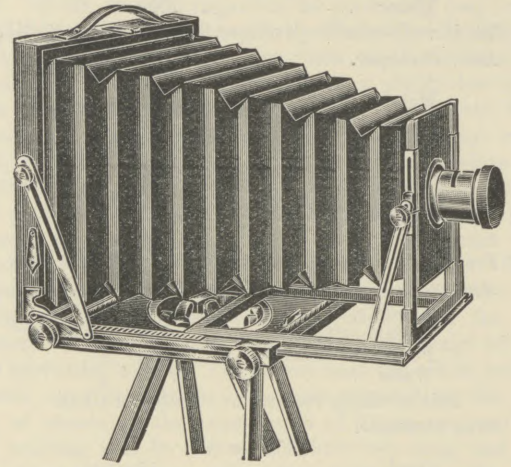

Fig. 7.—Field Camera adjusted for long focus. Turntable tripod head.

turntable in the baseboard, double-extension movements from the back and front for use with long- or short-focus lenses, and the use of aluminium for the metal-work. These cameras are fitted with a focussing screen and are intended to be used on a tripod stand, though some of the smaller sizes can be fitted with finders and used as hand cameras. As a rule the plates are carried in the usual double plate-carriers, but changing boxes for plates or cut films, or roll-holders carrying lengths of sensitive films for few or many exposures, can also be fitted. The latter are light and compact, and useful for travellers, the films being changed in daylight. Figs. 7 and 8 show a typical modern field camera adjusted for long or short focus. For photographing animals or objects in motion, when it is desirable to watch the movement till the moment of exposure, cameras fitted with twin lenses will be found useful (Fig. 9). The lenses must be of exactly the same focus, and focussed together by the same motion of the rackwork. The plate

Ready for use. Section to show working.

Fig 9.—Camera fitted with Twin Lenses. A, hood of finder; B, ground glass screen; C, mirror; D, viewing lens; E, working lens; F, shutter; G, focussing pinion; H, plate carrier; I, plate.

is kept ready for exposure in one compartment, while the object is viewed on the focussing screen of the other, and the plate exposed at the proper time. Several forms of binocular hand cameras are made on this principle. Field cameras are supported on wooden tripod stands, which usually fold in two or more sections, the head being separate, if not attached to the baseboard of the camera. The legs should be adjustable in length for use on uneven ground. A tripod stand may be light, but must be firm and rigid when set up.

For small field cameras the aluminium walking-stick tripods are very convenient (Fig. 10).

Folding cameras form a class of portable modern camera which has many conveniences for hand or stand work up to half or whole plate size. The best forms have most of the fittings and arrangements of a stand camera, but close up into a box which need not be larger or heavier than a hand camera, with the advantage that the camera, lens, and shutter are all in position for immediate use, while different lenses can be used if desired. With an apparatus of this kind, fitted with a light stand, any class of outdoor work can be undertaken, and glass plates, flat or roll films, can be employed, as most convenient. Some forms of these cameras are more of the hand camera type, focussing by finders and scale (Figs. 11 and 12).

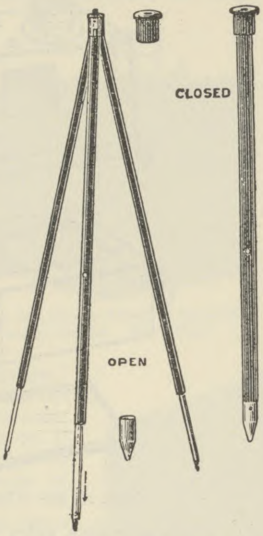

Fig. 10.—Walking-stick Tripods.

Hand Cameras.—One distinctive feature of the photography of the present day is the world-wide use of the hand camera. Its convenience, the ease with which it can be carried and worked, and the remarkably low prices at which practically useful instruments of this kind can be supplied, have conduced to this result. The close direct connexion of photography with the sciences of optics and chemistry, and its numerous artistic and scientific applications, must, when widespread as they now are by means of the hand camera, exert a powerful and important educational influence, in quickening artistic perception and scientific inquiry. Although small portable cameras for instantaneous pictures had been made by Scaife (Pistolgraph, 1858), Bertsch (1860), and others, the history of the modern hand camera dates from January 1881, when Mr T. Bolas brought forward his *detective* camera (*Photographic Journal*, 1881, p. 59). It consisted of a double camera (one used as a finder, the other for taking the picture) enclosed in another box suitably covered, which also contained the double plate-carriers, and had apertures in front of the lenses through which the pictures were viewed and taken. In another form the finder was omitted. Other similar box cameras quickly followed, but they did not come into very general use before 1888, when the Eastman Company, of Rochester, U.S.A., brought out their portable film camera under the name of Kodak, which has now become a household word and almost a recognized generic term for a hand camera.

In view of the multiplicity of forms and arrangements of hand cameras, it is difficult to classify them into distinct types. Dr

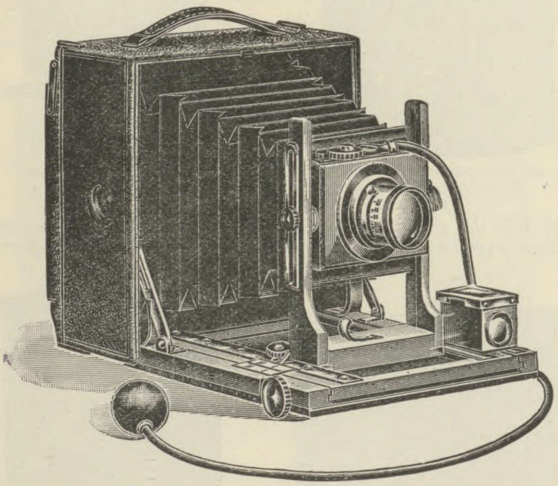

Fig. 11.—Folding Camera.

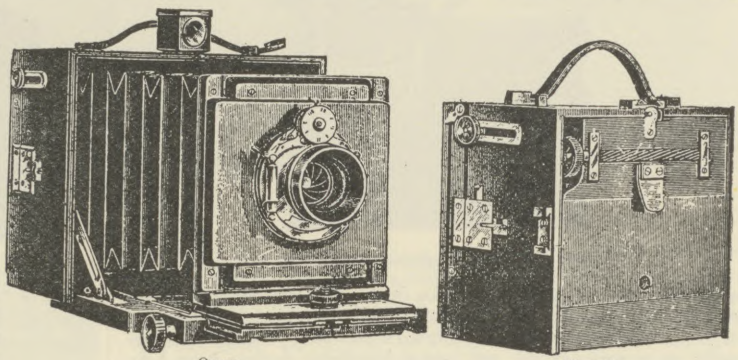
Krugener (*Die Hand Camera*) gives three principal groups: (1) for glass plates; (2) for stiff films; (3) for films in rolls. These, again, may be subdivided into *box* and *folding* cameras, and further, into (*a*) cameras with enclosed changing magazines, (*b*) with separate changing boxes or roll-holders, (*c*) with single or double plate-carriers. Most cameras that will take glass plates will take cut films in suitable sheaths, and holders for roll-films can be attached in place of holders for plates or cut films. The normal size for hand cameras is the quarter-plate ($4\frac{1}{4} \times 3\frac{1}{4}$ inches) or the Continental size, 9×12 centimetres. As a rule they do not exceed the half-plate size ($6\frac{1}{2} \times 4\frac{3}{4}$ inches), but many are made in much smaller sizes, as $\frac{1}{4}$ or $\frac{1}{2}$ quarter-plate. Sometimes these small cameras are disguised as field-glasses, books, watches, &c., or constructed for being hidden in the clothing, the lenses appearing as scarf-pins, waistcoat buttons, &c., but excepting the first, these disguises are not now so common as formerly. Such pictures are too small for use without enlarging. Hand cameras are constructed on much the same principles as stand cameras, but as they are specially intended for instantaneous work, they are simplified and adapted so that the picture may be focussed and exposed without delay. The focussing-screen is either superseded or supplemented by small finders, which should be properly arranged to show the exact limits of the subject on the plate. The focus is adjusted by a scale of distances, the accuracy of which should be carefully verified by measurement. In the "Reflex" forms (Fig. 13) the view is reflected by a mirror on to a horizontal ground glass, giving a full-sized image which can be seen and adjusted up to the moment of exposure. Swing backs and fronts are usually dispensed with, but a rising and falling front is an essential often overlooked. Quick-acting lenses of large aperture, such as $f/6$ or $f/8$, preferably of the anastigmatic type, well capable of covering the plate at full aperture and fitted with iris diaphragms, should be used. The cheap hand cameras are usually fitted with single landscape or rapid rectilinear lenses, but the want of intensity limits their use to well-illuminated subjects. For ordinary purposes the shutter should give instantaneous exposures from $\frac{1}{4}$ to $\frac{1}{100}$ of a second, and should also allow of time-exposures. It should be efficient and regular in action and readily released by



Open. Closed.

Fig. 12.—Folding Camera.

gentle pressure. Mechanism for automatically changing plates or films must be simple and certain in action and not readily put out of order, and care must be taken to avoid any rubbing or abrasion of the plates in changing or transport. In changing plates or films, the number of plates exposed should be recorded automatically. An accurately-adjusted circular level is desirable, and is best placed close to the finder.

The choice of a hand camera depends upon the circumstances in which it is to be used and the purpose for which it is principally required. For work near home, with facilities for carrying and changing plates, the folding hand or stand cameras, with full adjustments, will be found most generally useful. Magazine cameras, in which a supply of plates or films is carried ready for exposure, are very convenient and portable, and many patterns of them are available. They are generally of the box form; in some the lens is fixed in focus for all objects within a certain distance, and in others it is adjusted by the focussing scale. They are of two kinds—those with a single magazine and those

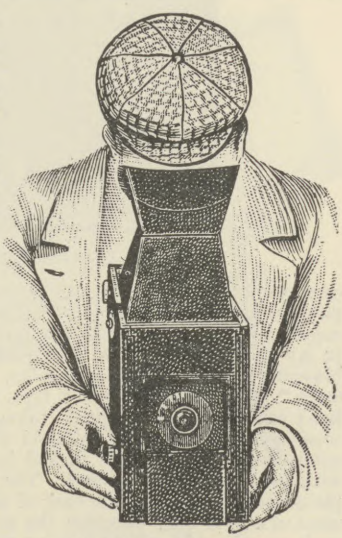


Fig. 13.—"Reflex" Hand Camera.

with two or more. One of the earliest forms of single-magazine cameras, and one still in use, is the "bag," in which a supply of plates or films in sheaths is kept at the back ready for exposure, after which the exposed plate is raised with the fingers into a bag or expanding chamber, above the magazine, and placed behind the rest of the plates at the back,—a fresh plate taking its place in front (Figs. 14 and 15). As a rule they carry 12 plates or a larger

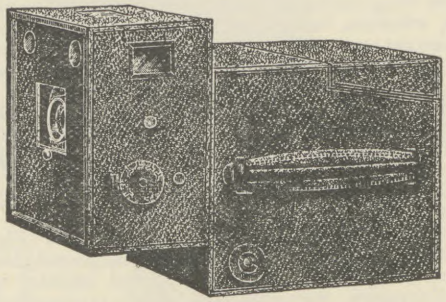

FIG. 14.—Single-magazine Box Camera.

number of cut films. In some forms the magazines are removable and replaceable by others. The arrangement is simple and effective; but the bag, usually made of soft leather or cloth, is liable to

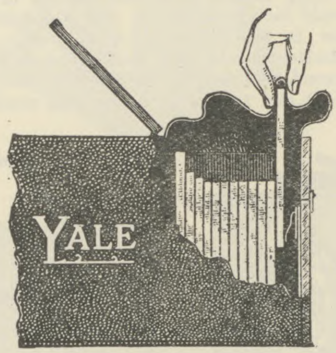

FIG. 15.—Single-magazine Box Camera.

wear and puncture, and may make dust. The arrangements with double magazines, in which unexposed plates are kept in one recess, exposed successively, and then transferred to a second recess, are much more complicated, and many ingenious devices have been invented for effecting the change (Fig. 16). Some of these

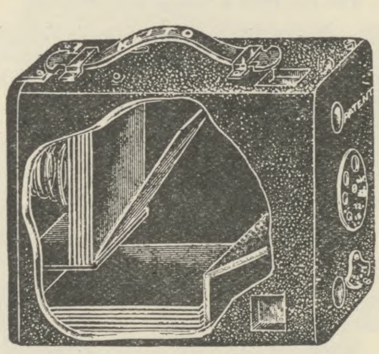

FIG. 16.—Double-magazine Box Camera.

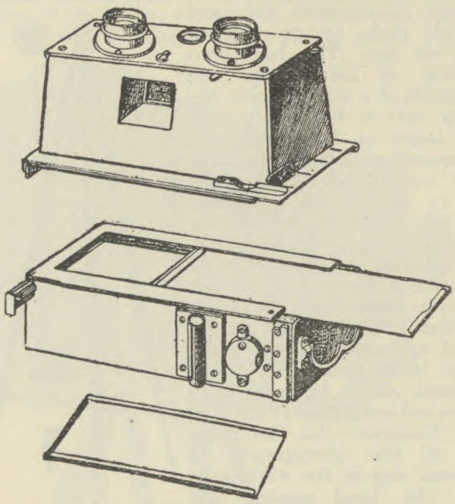
cameras are very effective, and popular on account of their compactness and convenience, but there is always a certain risk of the mechanism failing, and great care has to be taken, in charging them, to lay the plates truly in their places. Most of the very handy binocular cameras or *photo-jumelles*, of which Richard's "Verascope" (Figs. 17 and 18) is a type, are of this class, as are also hand cameras of the original "Frena" type (Fig. 19), specially constructed for using stiff celluloid films. In these the films are notched on two sides and packed in bundles of forty alternately with cards similarly notched. The pack of films and cards is placed in a magazine at the back of the camera, and by the movement of a lever after exposure the exposed film and its following card are released, and, by turning the camera down, are dropped into a second receptacle. The special advantage of this system is the large number of films that can be carried without increase of weight; but the necessity of having specially cut films, which may not be readily procurable, is an objection which has been avoided in other forms of magazine cameras for films. These cameras are



FIGS. 17, 18.—"Verascope" Binocular Camera.

also constructed with extra magazines. In many ways the most convenient and compact hand cameras are those made specially for

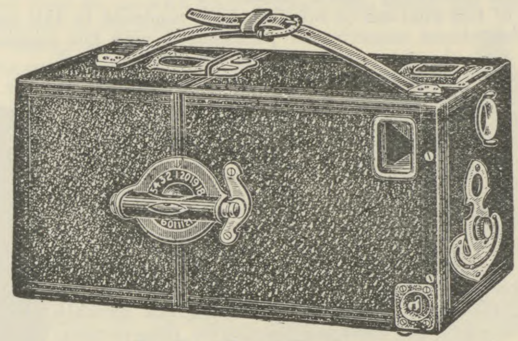


FIG. 19.—"Frena" Film Camera.

use with the roll-film cartridges in many different sizes, both in the "box" and "folding" forms, some of the latter being easily

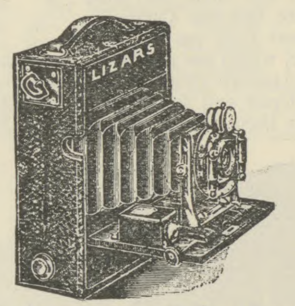

FIG. 20.—Interchangeable Hand Camera. Daylight-loading for films.

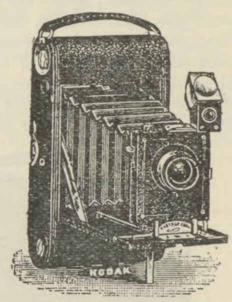

FIG. 21.—Folding Pocket Kodak.

carried in the pocket (Figs. 20 and 21). Those fitted with lenses of large aperture and rising and falling fronts are to be preferred.

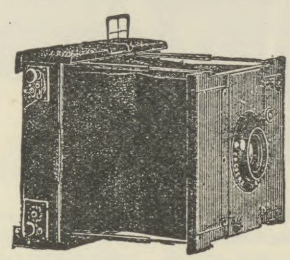

FIG. 22.—Goerz-Anschütz Camera ready for use. Front view.

FIG. 23.—Goerz-Anschütz Camera. Closed.

There are several other forms of very portable collapsible hand cameras available—the "Goerz-Anschütz," fitted with a focal plane shutter and a very quick-acting lens (Figs. 22, 23, and 24), also the "Xit," "Nydia," and the "Natti," may be mentioned as types.

In the cases which often arise, when time-exposures are necessary, it will be desirable to support the hand camera on a tripod stand. The light aluminium stands previously noticed are specially suitable; some of them are about the size and weight of a stout walking-stick, others about half the length, but all capable of extension to five feet. Details of the mechanism and construction of many hand cameras will be found in the photographic journals and year-books, and in some of the general and special treatises mentioned at the end.

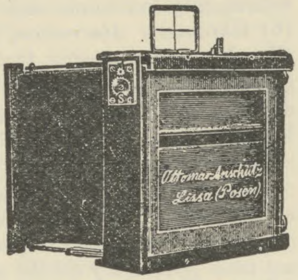

FIG. 24.—Goerz-Anschütz Camera ready for use. Back view.

Panoramic Cameras.—A large number of so-called "panoramic cameras" have been brought forward from time to time, but none of them seem to have come into general use till recently, when the use of curved surfaces of celluloid film has enabled thoroughly practical panoramic cameras of convenient size and weight to be put on the market. It is curious that these latest forms are on almost the same principle as the earliest one constructed by Martens, in 1845, to take curved Daguerreotype plates including an angle of 150°. In it the lens revolved on its centre and threw the image on to the cylindrical surface of the curved plate, through a slit which travelled with the lens. In 1861 Sutton devised a panoramic camera with a special spherical lens covering an angle of 120° for use with curved glass plates; these, however, were difficult to work, and the instrument never obtained a vogue. It was followed by Johnson's "pantascopic" camera and others, in which a long flat plate was moved tangentially to the surface of rotation of the apparatus, so that it was always perpendicular to the axis of the lens. In 1889 Moëssard greatly improved upon Marten's early apparatus in his "Cylindrograph," utilizing the property of the nodal points of any lens to form the meeting-point of the two portions of each secondary axis, one going towards the object, the other towards the image. A lens free from distortion may thus revolve round its nodal point of emergence, without the image being displaced on the sensitive surface; in fact, its position only depends on this nodal point and on the direction of the secondary axis from the nodal point of incidence to the object, which is always invariable. The instrument consists of a semicircular camera, the front of which is formed of light-proof cloth, and the back by the curved flexible carrier holding the sensitive film. The lens is fitted on a vertical axis, so that the nodal point of emergence remains motionless, and is revolved round it by means of a handle worked by hand and carrying a view meter. The illumination of the image is regulated by means of an adjustable slit in a tube attached to the lens inside the box, and by altering the rate at which the lens is revolved. The pictures taken embrace less than 180°. The apparatus folds together and is quite portable; it is fully described in Moëssard's *Le Cylindrographe*, Paris, 1889. The new "Al-vista" and the "Panoram Kodak" are apparently on the same principle as regards the rotation of the lens on the nodal point, but they are arranged as roll-holder cameras holding film sufficient for several exposures. They work instantaneously, the lens swinging rapidly round by pressure on a button. The angle included in the views is about 120° (Figs. 25, 26, and 27). Other more elaborate instruments have been made for making a complete tour of the horizon, being actuated by clockwork. Among them may be mentioned Damoizeau's "Cyclographe," which can be used with lenses of different foci and takes the pictures upon roll films, the film being unrolled as the instrument revolves, and thus the image always remains sharp (*Bull. de la Soc. Franc. de Photographie*, 1891, p. 183); Colonel Stewart's "Panoram" (1893); and the Bridges-Lee "Photo-theodolite," all of which, particularly the latter, are instruments suitable for photographic surveying.

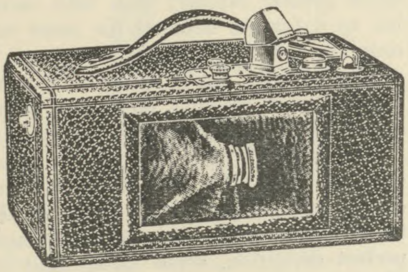

FIG. 25.—'Al-Vista" Panoramic Camera, closed.

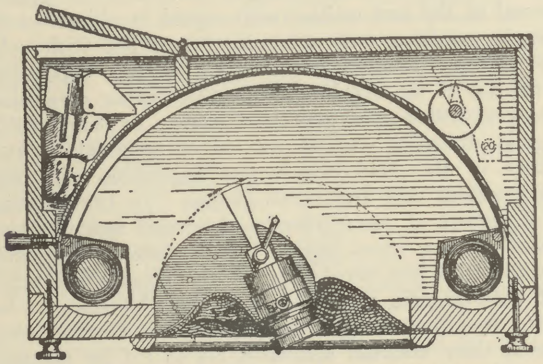

FIG. 26.—Section of "Al-Vista" Panoramic Camera.

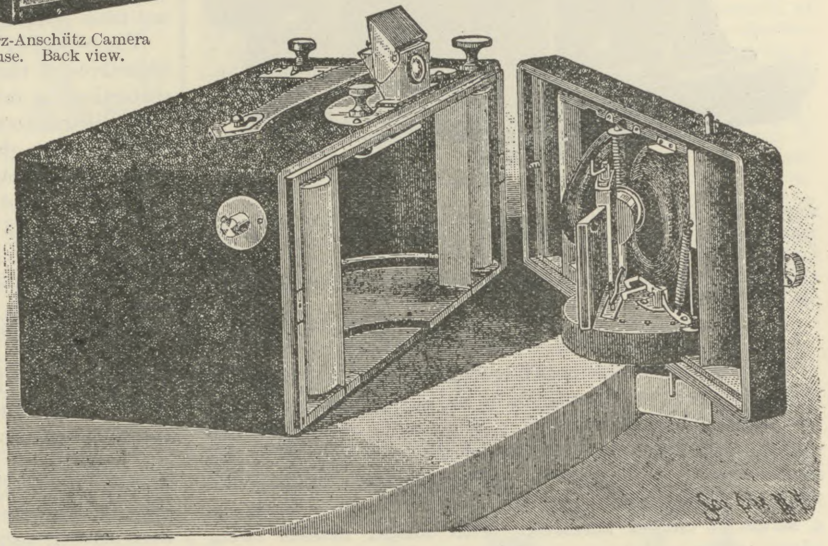

FIG. 27.—"Al-Vista" Panoramic Camera, open.

Enlarging Cameras.—A great many forms of enlarging cameras are made, depending on the nature of the illumination. They ordinarily consist of a double-extension arrangement for holding

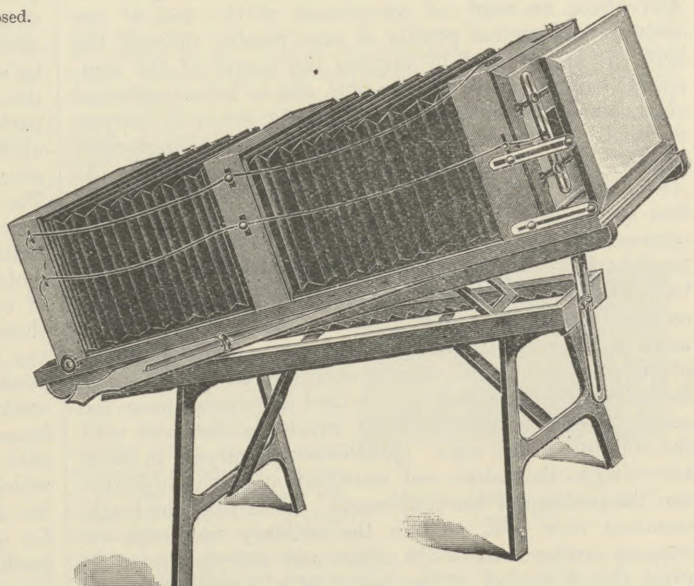

FIG. 28.—Enlarging Camera.

the negative at one end and the sensitive plate at the other, the lens being placed on a fixed partition between the two (Fig. 28). Others are made on the principle of a magic lantern for projecting an enlarged image on to a sensitive paper or plate fixed on a

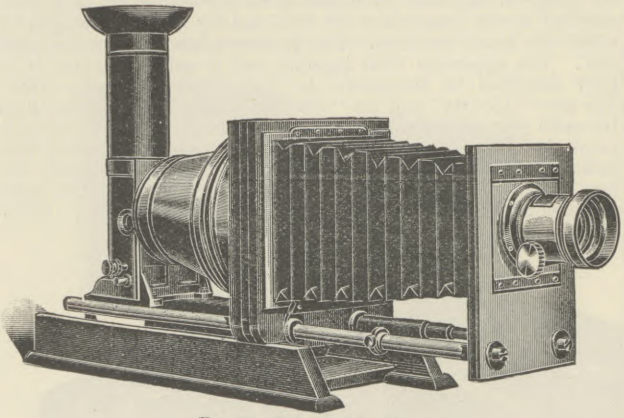

FIG. 29.—Enlarging Lantern.

screen (Fig. 29). A simple arrangement for daylight enlarging may be made by fixing a small quarter- or half-plate camera on to a larger one by a sliding front, and mounting the two on a studio stand, which can be tilted so that the image may be illuminated by the open sky.

Photographic Objectives or Lenses.

The objective is the most important item of photographic apparatus, because the success of the pictures depends upon the perfection with which it will correctly and distinctly depict upon the *plane* surface of the photographic plate actual images of objects in different planes, forming the field of view, which naturally would come to a focus on a series of *curved* surfaces. This image, besides being plane, must embrace a sufficiently wide angle and give fairly sharp definition all over the field of view it is intended to cover, even for objects at different distances from the lens. It must have sufficient luminous intensity to produce the required effect on the photographic plate with short exposures; the chemical and visual foci must coincide exactly; and it must be free from all distortion of straight or parallel lines. The fulfilment of these varied and conflicting conditions is complicated by the presence of sundry focal displacements, or aberrations, to overcome which requires the greatest optical skill and scientific knowledge. The principal of these are:—(1) *Spherical Aberration*, or want of coincidence of the foci of the central and marginal pencils of rays passing through the lens. It is corrected by varying the curves of the component lenses. (2) *Coma*, or blur, due to lateral spherical aberration of oblique rays, and mostly found in unsymmetrical combinations, such as portrait and single-view lenses. It is partly eliminated by the diaphragm. (3) *Astigmatism*, which always accompanies coma in single lens systems, and is usually present in objectives of the symmetrical aplanatic type, manifests itself by the formation of two sets of images of points off the axis, which lie in two separate curved surfaces, one set focussing tangentially as more or less horizontal lines, and the other radially as more or less vertical lines. It increases with the obliquity of the rays, and causes want of definition and difference of focus between horizontal and vertical lines away from the centre. (4) *Curvature of Field*, which also increases with the obliquity of the rays. (5) *Distortion*, varying in effect according to the nature and construction of the objective and the position of the diaphragm. Thus with the single meniscus view lens, used in the ordinary way with its concave surface towards the object and the diaphragm in front, the distortion of the image of a square will make the sides appear convex or barrel-shaped, while if the convex surface be turned to the object and the diaphragm placed behind, the sides of the square will appear concave. It can be overcome by using two such lenses, with their convex sides outwards and the diaphragm in the centre. (6) *Chromatic Aberration*, produced by the dispersion of the white light passing through a lens, and the different-coloured rays composing it coming to a focus at different distances from the visual focus in the order of their wave-lengths. It is corrected by the use of glasses of different refractive powers, but, if present, may cause a want of coincidence in the position and size of the images formed at the visual focus about the yellow, and at the chemical or photographic focus of the blue and violet rays, which act most powerfully on the sensitive films in ordinary use.

The object of the optician in constructing photographic objectives is therefore to neutralize these aberrations and distortions as far as possible, by regulating the curves of their different components, and the refractive and dispersive indices of the glasses from which they are made, so as to produce an image on the sensitive plate which shall be well defined and free from distortion. In the older types of objectives in use before 1887 these corrections could never be fully carried out; and although distortion of straight and parallel lines could be overcome in the way mentioned, there was always more or less residual curvature of field, spherical aberration, astigmatism, and, in some forms, coma, which had to be remedied as far as possible by the use of a diaphragm, which lengthened out the rays and caused them to define clearly over a larger surface, but at the expense of luminous intensity and rapidity of working. Few portrait lenses could be worked effectively with larger apertures than $f/8$, or landscape lenses with apertures larger than $f/16$ or $f/22$, and so were slow in action. Although the introduction of rapid gelatine dry plates enabled photographs to be taken with much greater rapidity than with earlier methods, it only led to a further demand for more rapidity in lenses, in order to satisfy the requirements of the necessarily very rapid exposures made in hand cameras. For studio and copying work rapidity is also an important desideratum, especially in cloudy weather and in winter.

The rapidity of a lens with a light of given intensity depends upon the size of its aperture, or that of the diaphragm used, relatively to the focal length. In order, therefore, to obtain an increase of rapidity combined with perfect definition, some means had to be found of constructing photographic objectives to work with larger effective apertures. This principle had been recognized by several of the best makers with regard to objectives of the single meniscus and aplanatic types, but with only partial success, because such objectives are dependent upon the use of the diaphragm for the further correction necessary to obtain good definition over an extended field. The great difficulty was to get rid of astigmatism and curvature of the field, which was impossible with the ordinary optical flint and crown glasses. In 1886 Messrs Abbé & Schott, of Jena, introduced several new varieties of optical glasses, which rendered it possible to overcome these difficulties, and revolutionized the science and practice of photographic optics by enabling objectives to be produced free from astigmatism, which can be effectively worked at their nominal apertures, $f/2$ to $f/4$ for portrait lenses, $f/6$ to $f/8$ for views, &c., with great flatness of field independently of the diaphragm, the principal use of which now is to extend the area of definition or increase the angle of view, and also the so-called "depth of focus" for objects in different planes. For full information regarding the theory and construction of photographic objectives, the reader may be referred to the works mentioned at the end.

Photographic objectives may be divided into the following classes:—

(1) Single achromatic combinations or "view lenses."
(2) Unsymmetrical doublets—old types.
(3) Symmetrical doublets—old types.
(4) Anastigmatic combinations, unsymmetrical and symmetrical.
(5) Triple combinations—old types.
(6) Telephotographic objectives.

(1) *Single Achromatic Combinations.*—In its ordinary form the single landscape lens of the old type consists of an achromatic compound meniscus, formed of a biconvex positive crown cemented to a biconcave negative flint, in order to secure achromatism and partially correct the spherical aberration. It may thus be looked upon as the type of the "old photographic achromat" (Fig. 30).[1] It is mounted with its concave surface towards the object, with the diaphragms in front of it, thus producing the convex distortion already noticed, which is inherent in this type of objective. In order to obtain further partial correction for astigmatism, spherical aberration, and coma, as well as depth of definition and covering power, the full aperture of these objectives has to be largely reduced by a diaphragm; consequently it is slow, though it has been much improved from its original form.

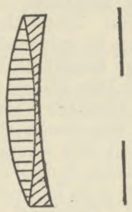

Fig. 30.—Single Landscape Lens.

These lenses have always been popular for pure landscape work, on account of the equality of the illumination over the plate and the brilliancy of the images they give, owing to their comparative thinness and freedom from reflecting surfaces. In the older forms their use was limited on account of their tendency to show "outward" distortion of the vertical lines of buildings, &c., but this is not very noticeable if they are worked well within their power and the camera is kept level. Objectives of this type are still largely used, and in some of their improved and "long-focus" forms are preferred by some portraitists for large heads, on account of the general softness of definition they give when used with large apertures. In T. Grubb's "Aplanatic" (1857) the positions of the crown and flint elements were reversed, the effective aperture increased and spherical aberration diminished (Fig. 31). J. H. Dallmeyer's "Wide-Angle Landscape Lens" (1865), composed of three cemented glasses, a flint concave between two hard crown menisci, included an angle of 75°. In it distortion was reduced and better marginal definition obtained with an aperture of $f/15$. The "Rapid (Long Focus) Landscape Lens," of the same maker, brought out by his son (1884), is a modification of the former, with an extra light flint in place of the anterior crown (Fig. 32). Working at $f/12$ it is said to give good definition with great brilliancy over an angle of about 40°, and with large apertures up to $f/8$ can be used for portraiture of large heads. The same advantages were gained in Wray's "Landscape Lens" (1886), a combination of two glasses working at $f/11$, the larger sizes working at $f/8$ being useful for portraiture. Voigtländer's "Wide-Angle Landscape Lens" (1888), constructed of Jena glasses, worked at $f/15$ over an angle of 90°, with great covering power and depth of focus. T. R. Dallmeyer's "Rectilinear Landscape Lens" (1888) was composed of three glasses, and quite novel in construction (Fig. 33). It works at $f/14$, is quite free from distortion, and has been recommended for copying purposes on account of the clearness of the lines resulting from the brilliant working of the single combination. Ross's "Wide-Angle Landscape Lens" (1890) is a triple cemented lens, made with Jena glasses, which works at $f/16$. Many other excellent lenses of this type have been made by English and foreign makers, but they are not so well suited for general purposes as are the new fully-corrected anastigmats specially constructed to work singly, such as Rudolph's (Zeiss) four-lens anastigmat, Series VII., or the single elements of many of the anastigmatic doublets, as will be noticed more fully later (§ 4).

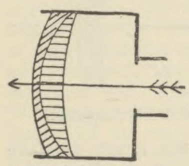

Fig. 31.—Grubb's "Aplanatic" Lens.

[1] In the diagrams of lenses which follow, a uniform system of indicating the nature of the glass employed by means of the shading has been adopted.

Flint glass is indicated thus:—

Crown glass of low refractive power thus:—

Crown glass of high refractive power thus:—

(These two are used indiscriminately in lenses made before the introduction of the new Jena glass.)

Extra light flint glass thus:—

(2) *Unsymmetrical Doublets—Old Types.*—In this class are included objectives formed of two dissimilar combinations, which in most cases correct each other, and may or may not be capable of being used independently as single lenses, the diaphragm being placed at the optical centre between them. All the older "portrait" lenses, some of the doublets and the "orthoscopic" lens, now disused, belong to this category. Even under the vastly improved conditions of the present day, the special requirements of the portraitist working in a studio demand a quick-acting objective of large effective aperture and comparatively short focus, giving a brilliant and fairly well defined image of near objects in different planes over a restricted field of view. Such was the original portrait objective of the Petzval type, which is still largely used and preferred by many portraitists for their special purpose, though it has many defects which render it useless for any other purpose unless largely stopped-down and at the risk of "flare." The introduction of more rapid dry plates caused it to be supplanted to some extent by lenses of the rapid aplanatic or rectilinear type, but the use of Jena optical glass has enabled several improved and well-corrected combinations, of specially large aperture and small angle, to be made for portraiture and the most rapid instantaneous work. The Petzval portrait objective consists of two dissimilar achromatic combinations widely separated. In earlier forms the diaphragms were placed in front, but now they are usually between the combinations. The front element is a plano-convex, composed of a biconvex crown cemented to a plano-concave flint; while the back element is a double convex, composed of a biconvex crown, separated by an air-space from a concavo-convex flint in front of it (Fig. 34). In 1866 J. H. Dallmeyer made some essential changes in the form and relative positions of the components of the back element, and thus obtained a flatter field and freedom from "flare-spot" (Fig. 35). In this form the back element is a compound meniscus consisting of a meniscus crown in front, with its concave surface towards the diaphragm, and a meniscus flint behind, with its convex surface towards the plate. When the two components are in contact, sharp definition is obtained; but by separating them, more or less spherical aberration can be introduced, so that the definition is more diffused and the depth of focus increased. These objectives are made to cover an angle of 60° without distortion, and in three intensities, $f/3$, $f/4$, and $f/6$.

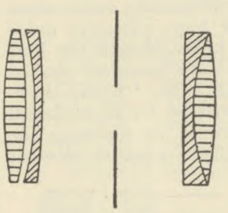

Fig. 34.—Portrait Lens.

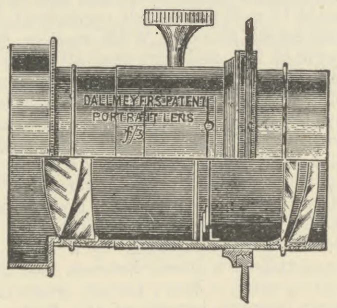

Fig. 35.—Dallmeyer's Portrait Lens, $f/3$.

Dallmeyer also brought out an extra quick-acting portrait objective for small portraits, with a working aperture of $f/2$. It differs from the preceding in the form of the back element, which is more like the original Petzval type, with a fixed air-space between the anterior flint-meniscus and the posterior biconvex crown (Fig. 36). In 1875 Dr Adolf Steinheil brought out an unsymmetrical aplanatic portrait combination of peculiar construction working at $f/3{\cdot}2$ (Fig. 37). Though it was a masterpiece of calculation and had many good qualities, it did not come into general use, and in 1881 was superseded by the "Portrait Antiplanet," which is also a distinct type, differing from the ordinary Steinheil

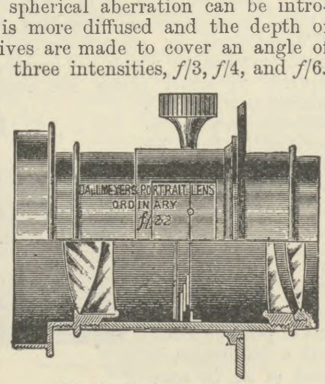

Fig. 36.—Dallmeyer's Portrait Lens, $f/2{\cdot}2$.

antiplanets and more nearly approaching a triplet, there being six reflecting surfaces (Fig. 38). It worked at an aperture of $f/4$; the

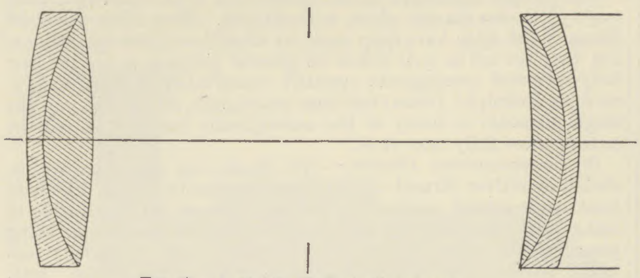

FIG. 37.—A. Steinheil's Portrait Aplanate.

spherical correction was not so complete as in the last lens, but astigmatism was removed over an angle of 14°, and the curvature of field was but slight. Steinheil's unsymmetrical "Group Aplanats" (1879), working at $f/6{\cdot}4$ over a field of about 70°, were an improvement upon the ordinary "Aplanats," but difficult to make, and were replaced in 1881 by the "Group Antiplanets," an unsymmetrical doublet of a distinct type (Fig. 39). They were made of the old

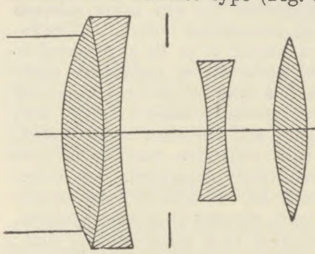

FIG. 38.—Portrait Antiplanet.

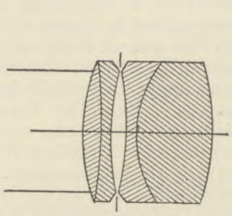

FIG. 39.—Group Antiplanet

optical glasses, and were a still further advance on the "Aplanats," working at larger apertures and giving better definition. They could be used at the full aperture of $f/5$ for instantaneous pictures and small groups. With smaller diaphragms they covered an angle of 70°, and were generally very useful lenses. According to Mr Dallmeyer, this lens is particularly interesting as being the first in which the principle was adopted of eliminating astigmatism by combining a "crown-shaped" lens of high refractive index with a "flint-shaped" of lower refractive index, though the Jena glasses were not available. All Dr A. Steinheil's lenses are marked by their originality and diversity of design. The "Group Antiplanet" was modified and greatly improved by Dr R. Steinheil (1893), as regards astigmatism and otherwise, by replacing the thick back combination by a triple long-focus negative element consisting of a crown between two flints, and by using a heavy barium crown in the front element instead of the flint. The new form has increased covering power, with a working aperture of about $f/6{\cdot}5$ (Fig. 40). Voigtländer, who was the original constructor of the Petzval portrait combination, improved it in 1878–79, and later in 1885, apparently on similar lines to Dallmeyer's improved portrait lenses of 1866. More recently he has constructed a rapid combination of this kind, working with an intensity of $f/2{\cdot}3$, intended for astrophotography, cinematograph work, and other purposes for which the greatest intensity of illumination is required on small plates not exceeding 4 inches square. An entirely new portrait combination was constructed in 1895 by Messrs Dallmeyer, for Mr Bergheim, to give a generally soft but well-defined and detailed image (Fig. 41). It is composed of a single uncorrected meniscus front lens of positive focus, with a diaphragm in front of it, in combination with a single uncorrected back lens of negative focus, and in the larger sizes it has great range of focal length on the telephotographic principle. The amount of spherical and chromatic aberration produced by the uncorrected single lenses gives the diffusion of focus which produces the peculiarly soft and delicate effect. It is most useful for large heads and life-size studies, the great depth of focus conducing to uniformity of definition. It works perfectly free from distortion, and by stopping-down to about one-third perfect definition can be obtained. Owing to both elements being single glasses, the combination gives great brilliancy. It is not achromatic.

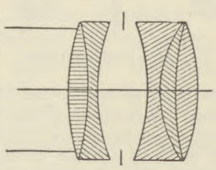

FIG. 40.—R. Steinheil's Improved Group Antiplanet.

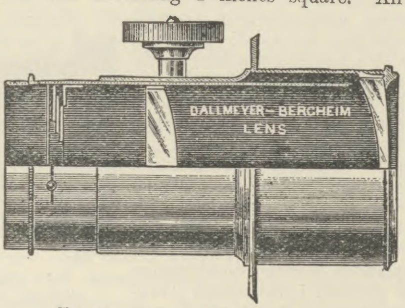

FIG. 41.—Dallmeyer-Bergheim Lens.

(3) *Symmetrical Doublets—Old Types.*—This class includes objectives formed of two similar combinations of lenses, usually of the convergent or positive meniscus form, with their concave surfaces inwards, and a diaphragm between them; consequently they are rectilinear and free from distortion of straight and parallel lines. Until the introduction of the anastigmatic doublets they were in universal use for almost all purposes. Even now they are very largely used, and have been greatly improved by the use of the Jena glasses in their construction.

Although Cundell (1844) described a symmetrical combination of two uncorrected meniscus lenses with a diaphragm between them, and several lenses of this type were brought out by various makers, it does not seem to have been recognized that this was the true cure for rectilinear distortion till C. A. Steinheil brought out his "Periskop" in 1865. This was a non-achromatized symmetrical doublet formed of two plain crown glass menisci with a central diaphragm (Fig. 42). It included an angle of 90°, and gave a much larger field than objectives of the "globe" or spherical type, because the lenses were closer together. Being non-achromatic, it had to be adjusted for the chemical focus. It was, however, perfectly free from distortion, and constructed so that the field might be as flat as possible and both nodal points together. It is said to be the best possible combination of two plain lenses, and is still manufactured for use with some of the cheaper hand cameras with fixed focus, the difference of the visual and chemical foci being allowed for. Newer objectives of this kind are fitted with mounts adjustable for the chemical and visual foci. Rodenstock's "bistigmats" are of this class. Zentmayer made a similar lens, but not symmetrical. In Adolf Steinheil's "Aplanat" (1866) the same principle was carried out with achromatized lenses, and this was a great improvement. It consisted of two positive cemented flint menisci, the outside one having a negative focus and the inner a positive one, glasses of different densities being used, but both having their concave surfaces facing the centre (Fig. 43). This use of flint glass alone was peculiar, because former achromatic lenses had been made of flint and crown. It was made to cover an angle of 90° at $f/30$, but could also be used with the larger aperture $f/8$. It was afterwards made in three different rapidities: (*a*) "ordinary," working with a relative aperture of $f/6$ or $f/7$ over an angle of 60°; (*b*) "landscape," working at $f/12$ to $f/15$ over an angle of 90°, and used largely in convertible sets; (*c*) "wide-angle," working at $f/20$ to $f/25$ over an angle of 104° for landscapes and interiors. In the aplanats of large aperture the components are from $\frac{1}{3}$ to $\frac{1}{6}$ the focal length apart, the largest diaphragm being nearly the full aperture of the lens. Spherical aberration is corrected at the expense of the angle of view. The inner curvature of the lenses is small, and consequently there is a good deal of astigmatism, and they are dependent on the diaphragm for good marginal definition. By the use of the newer and more transparent Jena glasses, as in the "Universal Aplanat" (1886), the component elements were brought closer together, the intensity of the combination increased, and the instrument made more portable. In the "Landscape Aplanats" the diaphragms were relatively smaller, the separation of the elements less, the radius of inner curvature smaller, giving less astigmatism and better marginal definition. In the "Wide-angle Aplanats" the intensity was still less, smaller stops were required, and everything was arranged to secure the greatest sharpness over a wide angle of view. The component lenses had much greater curvature and were much nearer together. J. H. Dallmeyer had been working in the same direction simultaneously with Steinheil, and in 1867 brought out his "Wide-angle Rectilinear," working at about $f/15$ and having the posterior element smaller than the front one (Fig. 44). This was also a great improvement on previous doublet combinations, and was succeeded, in 1868, by the well-known "Rapid Rectilinear," on the same principle, with the components made of menisci of flint and crown (Fig. 45). It works at $f/8$, and is largely used for copying. Ross's "Rapid" and "Portable Symmetrical" lenses, Voigtländer's "Euryscopes," and other similar lenses of

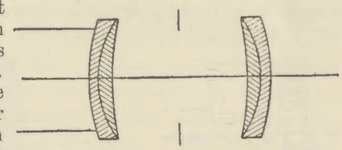

FIG. 43.—A. Steinheil's "Aplanat."

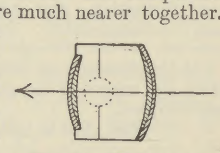

FIG. 44.—Wide-angle Rectilinear Lens.

English and foreign manufacture, are of the same type, and still largely in use. They are excellent lenses for general purposes, but more or less astigmatism is always present; and although they can be used with much larger apertures than the triplet lenses they displaced, they are dependent on the diaphragm for securing good marginal definition over the size of plate they are said to cover. They are being superseded by the anastigmatic combinations.

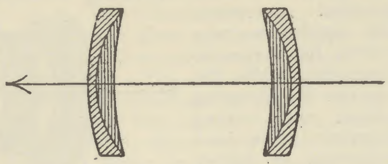

FIG. 45.—Rapid Rectilinear Lens.

(4) *Anastigmatic Combinations, Unsymmetrical and Symmetrical.*—As already stated, it was impossible to obtain flatness of field together with freedom from astigmatism in objectives constructed with the old optical glasses. In the "Antiplanets" Steinheil endeavoured to do so, but was only partially successful. The Jena glasses put a new power into the hands of opticians, by largely increasing their choice of glasses with different refractive and dispersive powers. Whereas the old glasses had high refractivity with higher dispersion, in the new ones high refractivity with lower dispersion can be set against lower refractivity with higher dispersion.

The first lens made with the new glasses was Dr Schroeder's "Concentric," patented in 1888, though not brought out by Messrs Ross till 1892 (*Phot. Journ.* xvi. 276). It is a symmetrical doublet of quite novel construction (Fig. 46), consisting of two similar combinations, each composed of a plano-convex crown glass of high refractivity, cemented on the plane surface to a plano-convex lens of lower refractivity but about equal lower dispersion. Both the uncemented surfaces are spherical and concentric, and in consequence of its shape it has considerable spherical aberration. At $f/16$ it gives equally sharp definition over a large and quite flat field of 75°. It is almost free from astigmatism, shows no distortion or "flare-spot," and gives great sharpness and depth of definition. Owing to the small working aperture it seems slow, but is not so for the definition and flatness of field obtained. It is an excellent copying lens. Both combinations can be used alone as single lenses of about double the focus. Dr Miethe calculated the data for two lenses brought out by Hartnack (1889), one of them a symmetrical anastigmatic aplanat, in which a crown of high refraction and low dispersion was combined with a flint of low refraction, thus diminishing astigmatism and giving perfect definition over a large field with a maximum aperture of $f/7 \cdot 7$. Though astigmatism was removed, other defects remained, and the lenses did not come into use. Fritsch, of Vienna, in 1888, constructed a wide-angle "Apochromat" of the symmetrical aplanatic type, composed of two similar combinations made of baryta flint and phosphate crown glasses, by which it was claimed that the secondary spectrum for the rays F, G, H was eliminated, and the dispersion of the chemical image reduced to a minimum, so that the definition was better and the image photographically more intense (*Photo. Correspondenz*, xxvi. 14). Many of the early lenses made with the Jena glasses suffered from the want of stability of the glass, and it was not until the principle of sandwiching the soft glasses between two hard ones was adopted that this was overcome. Dr Paul Rudolph, of Messrs Carl Zeiss & Co., of Jena, was the first to work out (1890) a new and practically successful method of constructing a photographic objective in which astigmatism of the oblique rays can be eliminated without loss of rapidity, and the want of marginal definition due to astigmatism removed, so that a comparatively extended field can be covered with a large aperture. This he effected by a combination of two dissimilar systems of single lenses cemented together, the positive element (converging lens) of each having in one case a higher and in the other a lower refractive index than that of the negative element (dispersing lens) with which it is associated. Both systems are approximately achromatic, the first, in which the glass of highest refraction has also the greatest relative dispersion, being what is termed a normal, or old, achromat, and the other, in which the highest refraction is accompanied by the lowest dispersion, an abnormal, or new, achromat. Both systems being spherically and chromatically corrected for a large aperture, the field is flattened, the astigmatism of the one is corrected by the opposite astigmatism of the other without destroying the flatness of field over a large angle. [A full description of the principles on which these lenses are constructed will be found in Eder's *Jahrbuch der Photographie*, 1891 and 1893; also in Prof. S. P. Thompson's translation of Lummer's *Photographic Optics.*] Several series of them have been made by Messrs Zeiss and their licensees since 1890. In England they are made by Messrs Ross. The first series were constructed

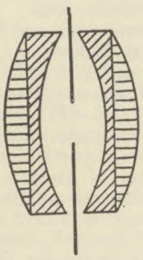

FIG. 46.—Concentric Lens.

in two different types. The more rapid had five lenses (Fig. 47), two made of ordinary glasses in the front normal achromat, which effects the spherical correction of the whole, and three in the back abnormal achromat, two crowns of exceedingly high refractive power, with a negative flint of exceedingly low refractive power

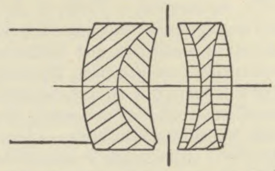

FIG. 47.—Anastigmat. Series II. $f/6 \cdot 3$.

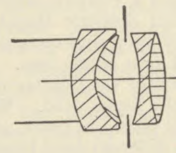

FIG. 48.—Anastigmat. Series IIIa. $f/9$.

between them. This component effects the anastigmatic flattening of the system. The fifth lens is useful in removing spherical aberrations of higher orders with large apertures. The second type (Fig. 48) has only two lenses in each component, the functions of which are as above. These combinations cannot be used separately as single lenses. Dr Rudolph also turned his attention in 1891 to the perfecting of the single landscape lens, and constructed on the same principle a single combination of three lenses, of which the centre one had a refractive index between the indices of the two others, and one of its cemented surfaces was diverging, while the other was converging (Fig. 49). This lens gave an astigmatically flat image, with freedom from spherical aberration on or off the axis. It was, however, not brought out till 1893, as a convertible lens or "Satz-anastigmatic," Series VIa (Fig. 50).

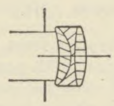

FIG. 49.—Anastigmat. Series VI. $f/14 \cdot 5$.

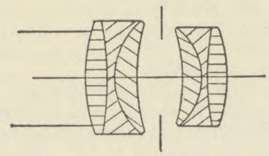

FIG. 50.—Satz Anastigmat. Series VIa. $f/7 \cdot 7$.

In the meantime Dr E. von Hoëgh had independently calculated for Messrs Goerz, of Berlin, a fully-corrected anastigmatic single lens on the above principle, consisting of a negative lens enclosed between two positive lenses, one of which has a higher and the other a lower refractive index than the negative (Fig. 51). Though

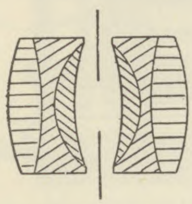

FIG. 51.—Ross-Goerz Series III.

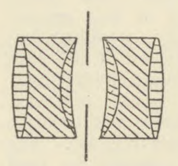

Ross-Goerz. Series IV.

a lens of this kind could be used alone, Messrs Goerz preferred to put two of them together to form a symmetrical doublet of the "aplanat" type, and brought out the lens in 1893 under the name of "Double Anastigmat." These lenses are also manufactured by Messrs. Ross in two series—III., a universal lens, working at $f/7 \cdot 7$, and IV., a wide-angle copying lens, working at $f/11$. Both these series of lenses, at full aperture, cover a field of 70° to 75°, and with smaller diaphragms, 90°. In 1893 Messrs Zeiss issued their Series VI. and VIa of fully-corrected anastigmatic lenses with triple cemented components, which could be used either alone or as doublets, in combinations of two lenses of the same or different focus. These lenses have practically been replaced by Series VII. and VIIa, of "Convertible Anastigmats," now known as the convertible "Protar," consisting in the same way of single lenses formed of quadruple cemented components (Fig. 52). Each component comprises within itself a normal

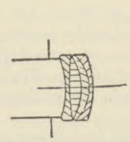

FIG. 52.—Series VII. $f/12 \cdot 5$.

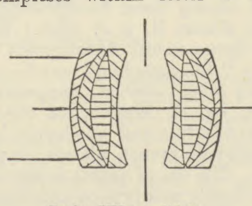

Series VIIa. $f/6 \cdot 3$.

achromat of two old glasses and an abnormal achromat of two new glasses. Mr Dallmeyer, in his presidential address to the Royal

Photographic Society in 1900, says that this is the most perfectly-corrected single lens that has yet been evolved; for Dr Rudolph has not only succeeded in obtaining freedom from spherical aberration and astigmatism, but has also made a very successful attempt at the elimination of coma. The single "Protar" lenses of Series VII. have a relative rapidity of $f/12{\cdot}5$, embracing a field of 85°. With full aperture they have great anastigmatic flatness of field and only very slight marginal distortion—a condition not hitherto realized in a single lens. With the doublet combination, forming Series VII*a*, the relative rapidity varies from $f/6{\cdot}3$ to $f/8$, according to the lenses used. When lenses of unequal foci are used, the larger is placed in front, and with such a combination three objectives of different focal length are available. Quadruple convertible single lenses have also been patented by Goerz and by Voigtländer, but do not seem to have come into use.

Under the names "Planar" and "Unar," Messrs Zeiss, and in Great Britain Messrs Ross, have brought out two new anastigmatic lenses of large aperture which embody quite new features of construction. The first is a symmetrical doublet formed of two elements, each consisting of three lenses, the two inner ones being a double concave and a double convex cemented together and separated by an air-space from the outer one, which is a convex meniscus (Fig. 53). Its special points are its freedom from chromatic differences of the spherical aberration and the large relative aperture and intensity, varying from $f/3$ to $f/6$, according to the size and application of the lens, with perfectly sharp definition and anastigmatic flatness of field over an angle of view varying from 62° to 72°. The single combinations cannot be used alone, except with very small stops. It is a very rapid wide-angle lens, useful for the most instantaneous kind of work with the cinematograph; also for portraits and groups, photomicrography, and sharp reproduction. It is based on the principle of the Gauss achromatic telescope objective, and is described in Eder's *Jahrbuch*, 1898, p. 79; also Thompson's edition of Lummer's *Photographic Optics*, p. 81. The Unar (1899) consists of two unsymmetrical combinations, each formed of two thin single lenses of very transparent glass, separated by positive and negative air-spaces (Fig. 54). The halves cannot be used alone as single lenses, neither being fully corrected for colour. It works with an aperture varying from $f/4{\cdot}5$ in the small sizes to $f/5{\cdot}6$ in the largest, and gives sharp definition, with freedom from astigmatism, over a comparatively flat field of 65°. It is well adapted for portraiture, copying, and enlarging, and especially for hand-camera work, on account of its covering power combined with large relative aperture.

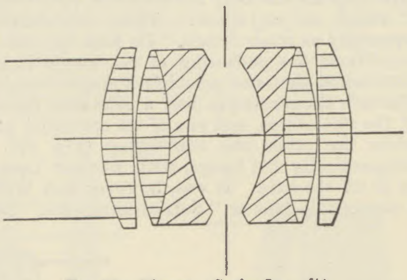

Fig. 53.—Planar. Series I*a*. $f/4$.

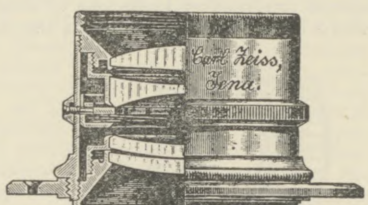

Fig. 54.—Unar Double Lens.

In 1899 Goerz brought out a double anastigmat with quintuple single lens components as a convertible lens, for which greater sharpness of definition and intensity, with perfect freedom from astigmatism and distortion in the single combination, were claimed; but, like the earlier analogous quintuplet of Turner and Reich (1895), they do not seem to have been adopted in practice. The extra cost of the number of glasses to be worked, and the difficulties of centring and construction, do not appear to be compensated by the additional advantages claimed. Several combinations of triple lenses, constructed more or less on the principles enunciated by Dr Rudolph, have been brought out by several English and foreign makers, among them Steinheil's "Orthostigmats," made in England by Messrs R. & J. Beck; Wray's "Platystigmats"; Ross's "New Symmetrical Anastigmats"; Voigtländer's "Collinears"; Lacour's "Eurygraphes," may be noted. Suter, of Basel, has introduced an 8-lens doublet, composed of two quadruple lenses. An account, by E. Wallon, of the newest types of anastigmatic doublets of triple and quadruple lens systems made in France, of Mantois's new French glasses, is given in Eder's *Jahrbuch*, 1901, p. 225. The use of quartz is also noted.

A distinctly new type of anastigmatic objective, involving several new principles of construction, was invented by Mr H. L. Aldis, who has fully described it in the *Photographic Journal*, 1896, xx. 117. It was brought out in three series by Messrs Dallmeyer, under the name of "Stigmatic." Series I. is a portrait combination, working at $f/4$, and consisting (Fig. 55) of two compound elements, the front one a deep converging meniscus with strong positive spherical aberration, but approximately correct for chromatic aberration, while the rear one is a diverging system with strong negative spherical aberration to correct the positive aberration of the front lens, and also approximately achromatic; the whole forming a converging system corrected for spherical and chromatic aberration, free from distortion, and almost free from astigmatism. It gives equal definition over a flat field, and covers an angle of about 60° with great equality of illumination. By unscrewing the back cell a certain amount of spherical aberration can be introduced, giving more equal distribution of definition over different planes. It may be noted that all the flint lenses have lower indices of refraction than the crowns. Series II. is on the same principle, but differs in construction (Fig. 56). It works at $f/6$ over an angle of 85° as a universal and convertible lens. The front or back component can be used alone, giving the choice of two additional focal lengths, $1\frac{2}{3}$ and twice the focal length of the complete lens. Series III. (Fig. 57) works at $f/7{\cdot}5$, and at $f/16$ will give sharp definition over a plate two sizes larger. The single components are not convertible. Another anastigmatic combination, also of English origin, and containing some remarkable new features, was constructed in 1893 by Mr H. Dennis Taylor, of Messrs T. Cooke & Sons, and brought out by Messrs. Taylor, Taylor, & Hobson under the name of the "Cooke Lens." It is also made by Messrs Voigtländer, under the name of "Triple Anastigmat." It is a triple combination consisting of three single lenses; two of them are positive crossed lenses of crown glass, with their most convex sides outwards, and between them, in front of the diaphragm, there is a single biconcave lens of light flint glass (Fig. 58). In Series III., which is a universal or general-purpose lens, the relative aperture is $f/6{\cdot}5$ (Fig. 59), and in Series V. $f/8$. These lenses are not convertible, but an arrangement has been made by which the focus can be lengthened by removing the back lens and replacing it by an "extension" lens of lower power. Series of them can

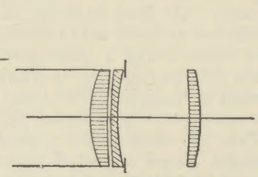

Fig. 59.—Cooke Lens. Series III.

be carried, either separately or mounted on a rotating wheel fitted inside the camera. A portrait lens, working at $f/4{\cdot}5$ over an angle of 45°, is on the same principle. An adjustment is provided with it for the introduction at will of spherical aberration evenly over the plate. In the "Process" lens, Series V. $f/8$, the combination is adjusted to secure identical size and sharpness of each colour-image in three-colour process work, and it has a screw-fitting for the attachment of a reversing prism. It is highly spoken of for its good definition and covering power in copying work. (For a full description of the principles on which these lenses are constructed, see *Photo. Journ.* 1895, xix. 64.)

Dr Harting has recently discussed the correction of the secondary spectrum in photographic lenses, and described the method followed in constructing Messrs Voigtländer's "Apochromatic Collinear Lens" (*Photo. Journ.*, 1901, xxv. p. 323). It is claimed that the colour correction of this lens is complete between C and G, and the images given by it of an object illuminated by any kind of monochromatic light fall in the same plane and are identical in size. This is of great importance in three-colour reproductions.

(5) *Triple Combinations—Old Types.*—This class comprises objectives composed of three separate combinations or glasses widely separated from each other. An early form of this type was made by Andrew Ross (1841) for Fox Talbot, others by Goddard (1859) and by Sutton (1860), but they never came into general use. J. H. Dallmeyer's well-known "Triple Achromatic Lens" (1860), though now out of date, was an excellent lens, and very useful for copying (Fig. 60). As made by Dallmeyer, the inner surface of the front and back lenses (achromatic menisci) is slightly concave, but in similar lenses made by T. Ross it was flat. The centre lens was an achromatic negative serving to flatten the field. They worked at $f/15$, giving an image fairly flat and quite free from distortion of straight lines.

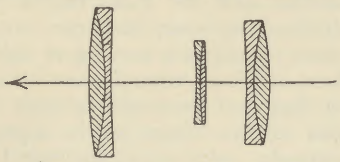

Fig. 60.—Triple Achromatic Lens.

(6) *Telephotographic Objectives.*—During the last few years special objectives, or attachments, have been constructed for photographing near or distant objects on an enlarged scale with an ordinary camera, the extension required being very considerably less than would be needed to obtain an image of the same size by means of an ordinary long-focus lens without enlargement. They consist of a combination of a positive converging with a negative dispersing lens, by which the image is picked up and enlarged to varying degrees, according to the system of lenses used and the extension given to the camera, thus producing the same effect as a positive lens of very much longer focus. Enlarged images of this kind can also be made by a combination of two converging lenses, one of them forming an image of the object, which is received on the other of shorter focus and projected on the sensitive plate, being enlarged more or less according to the optical conditions and relative positions of the lenses and sensitive plate. The photoheliographs at Greenwich and other solar observatories, designed by Dr de la Rue, are on this principle. A portable apparatus of the kind was made in 1869 by Borie and Tournemire, and later by Jarret, but this system requires much greater extension of the camera, entailing more loss of intensity of the image, and has never come into use.

The modern telephotographic combination is generally looked upon as an application of the principle of the "Barlow" lens, but it really goes back very much farther, and is contemporaneous with the telescope on the so-called Galilean system. J. B. Porta mentions the combination of concave and convex lenses for giving enlarged and clearer images of near and distant objects (*Magia Naturalis*, lib. 17, cap. 10, 1589). Kepler showed that by a combination of a convex with a concave lens images of objects could be depicted on paper of a larger size than by the convex lens alone, but reversed (*Dioptrice, Prob.* cv. 1611). Scheiner made use of the same principle in his "Helioscope" for solar observations (*Rosa Ursina*, cap. vii., 1630). If for the simple uncorrected glasses then used we substitute a system of photographically-corrected positive and negative lenses, suitably mounted, and put a sensitive plate in place of the paper, we have the modern telephotographic arrangement. Porro seems to have been the first to use a combination of this kind for photographing an eclipse in 1857, and later for terrestrial objects. It consisted of a small achromatic single lens combined with a concave lens. Many attempts were afterwards made in France, and also in England, to utilize the principle, but special lenses for the purpose were not available. Steinheil constructed one in 1889 for the Brussels Observatory, and another in 1890 for the Marine Department in Berlin. In 1891, curiously enough, three such combinations were worked out quite independently and patented, by T. R. Dallmeyer in London, A. Miethe in Berlin, and A. Duboscq in Paris. Since that time these combinations have been greatly improved. They are exceedingly valuable for obtaining details of inaccessible objects at a distance, whether architectural or topographical, and for photographing animals without approaching them too closely. Large portraits can also be taken with much better perspective effects, and more conveniently, than by using long-focus lenses much nearer to the sitter. With the very perfect telephotographic objectives now available, the loss of intensity of illumination, which no doubt was the bar to early progress in this direction, has been overcome, and definition has also been improved, so that snap-shots can readily be made with combinations of high intensity, while with those of ordinary intensity the exposures are not unduly prolonged, and good definition can be obtained over an extended field.

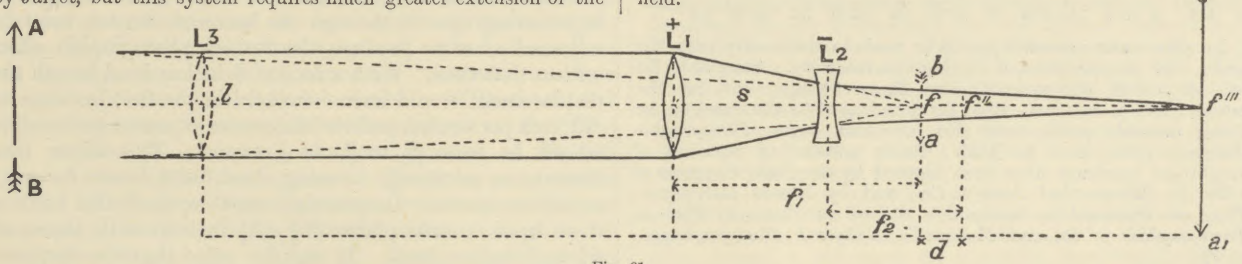

Fig. 61.

The optical principle on which these combinations are based is very simple, and will be understood from Fig. 61. It depends mainly on the fact that in order that a *real* image may be thrown on the screen of an object AB, the rays proceeding from it, which pass through the positive system L_1, must come to a focus at a point f within the secondary focus f'' of the negative system L_2. Falling within this limit, they will be intercepted by L_2 and made less convergent, so that instead of coming to a focus at f, they will continue to converge till they reach the screen at f''', and will there form a proportionally larger image $a'b'$ of AB than the image ab given by the positive lens alone at f; just as stated in Kepler's problem. Moreover, this image $a'b'$ will be of the same size as if it had been produced directly by a positive lens L_3 with a focal length equal to lf''', and this distance is the equivalent focal length of the entire system. It can be found from the formula $F=\frac{f_1 f_2}{d}$, where f_1 and f_2 are the focal lengths of L_1 and L_2 respectively, and $d=f_1+f_2-s$, s being the distance between the lenses. In many instruments of the kind a scale showing the value of d is engraved on the mount. If the rays from AB come to a focus in front of L_2, on it, or beyond f'', no real image can be projected on the screen. There is therefore a certain limit, which is greater in proportion to the length of focus of the negative system, within which the focus of the positive system L_1 may fall and produce a series of well-defined images on the screen, which can be varied in size by altering the amount of separation of the two systems of lenses within the above limit, and the distance of the screen from L_2. Every change in the position of the screen will involve a corresponding adjustment of the lenses. The greater the extension of the camera and the closer the lenses, the greater the size of the image, and *vice versâ*. The camera extension for a given magnification can be found by multiplying the focal length of the negative system by the number of magnifications, less one. The magnification produced by a given camera extension is found by dividing the latter by the focal length of the negative system, and adding one.

In its usual form (Fig. 62) the telephotographic combination consists of a quick-acting portrait lens, or an anastigmatic doublet of large aperture and relative intensity, varying in focus from 6 to 10 inches, fitted at one end of a tube, in which slides a smaller tube carrying a properly-corrected negative system, which may vary in focus from 1 to 5 inches, but must be of shorter focus than the positive (usually about half); the shorter the focus the greater the magnifying power for a given extension of camera. The amount of separation of the lenses is limited on the one hand by the position of the focus of the positive system, and on the other by the focus of the negative system, as explained above, and can be adjusted within these limits by a rack and pinion. The tubes are adjusted so that when closed up the two foci may

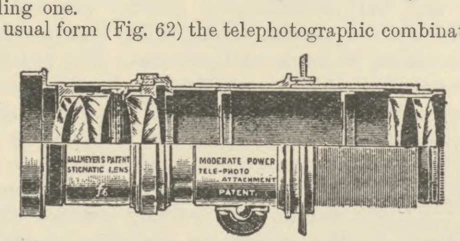

Fig. 62.—Telephotographic Combination.

coincide, or nearly so, and $d=0$, or its minimum value; and when opened to their fullest extent the focus of the positive may fall upon the negative system, or so that d may not exceed the focal length of the negative system. Within these limits the focal length of the combination will be positive, and a real image formed on the screen. Mr T. R. Dallmeyer, to whom many of the improvements in these lenses are due, has very fully discussed and explained the optical problems connected with their construction and use in his book on *Telephotography*. The other works noted at the end of this article may also be referred to.

Lens Diaphragms.—In order to regulate the intensity of the illumination by the lens, to enlarge its field, and, in the case of the older forms of objectives, to extend the area of good marginal definition, diaphragms are used, usually with circular apertures. They are made in different ways: (1) as single metal plates, fitting into a slot in the lens tube (Waterhouse diaphragms); (2) Rotatory: a single plate revolving on a central axis and pierced with apertures cut to fit centrically in the opening of the lens; (3) Iris: a form of diaphragm now very generally used, and very convenient, because it can be easily adjusted as required for intermediate apertures.

In order to provide a uniform system of diaphragm apertures, the Royal Photographic Society in 1881 drew up some rules, which were revised in 1891, and again quite recently. The former standard unit $\frac{f}{4}$ and the numerical notation used with it have been abolished. Intensity ratio is defined as dependent upon the effective aperture of a lens, and not upon the diameter of the diaphragm in relation to the focal length of a lens. The effective aperture of the lens is determined as follows:—The lens must be focussed for parallel rays. An opaque screen is then placed in the principal focal plane, and a pinhole is made in the centre of the plate (in the axis of the lens); an illuminant is placed immediately behind the pinhole itself, when the diameter of the beam emerging from the front surface of the lens may be measured. (It will be found that, except in the case of the diaphragm being placed in front of the lens, the diameter of the diaphragm itself is seldom that of the effective aperture.) Every diaphragm is to be marked with its true intensity ratio as above defined, but the present intensity ratios are retained in their order of sequence:—

$$\frac{F}{1}, \frac{F}{1{\cdot}4}, \frac{F}{2}, \frac{F}{2{\cdot}8}, \frac{F}{4}, \frac{F}{5{\cdot}6}, \frac{F}{8}, \frac{F}{11{\cdot}3}, \frac{F}{16}, \frac{F}{22{\cdot}6}, \frac{F}{32}, \frac{F}{45{\cdot}2}, \frac{F}{64}, \text{\&c.}$$

In other cases apertures are to be made in uniformity with the scale, with the exception of the highest intensity. Standards for the screws of photographic lens flange fittings, and for the screws fitted to cameras, either for attachment to the stand or for fixing movable parts, have also been laid down (*Photographic Journal*, 1901, xxv. p. 322). Other systems of notation of diaphragm apertures have been adopted by the Paris Congress of 1889, by Messrs Carl Zeiss & Co., and by Messrs Dallmeyer. They are discussed in Boursault's *Calcul du Temps de Pose en Photographie*, p. 33, and Moëssard's *L'Objectif Photographique*, p. 12.

Instantaneous Shutters.

The general use of very rapid dry plates and hand cameras rendered it necessary to have some mechanical means of regulating exposures in small fractions of a second, and the instantaneous shutter has become an essential part of modern photographic equipment in an immense variety of forms and patterns. For quick studio work, slow-acting shutters working to $\frac{1}{10}$ of a second are sufficient. Open-air exposures will usually range from $\frac{1}{10}$ to $\frac{1}{100}$, though less than $\frac{1}{30}$ of a second is seldom necessary. For objects in quick motion the range may be from $\frac{1}{100}$ to $\frac{1}{200}$, and for very rapidly moving objects from $\frac{1}{500}$ to $\frac{1}{1000}$ of a second. In ordinary practice exposures of less than $\frac{1}{100}$ of a second are not often required, and few of the shutters on the market in general use give higher speeds.

The rapidity required of a shutter in photographing moving objects is regulated by the minimum time necessary to produce a well-exposed image upon the plate, with a loss of definition, or blurring, by displacement not exceeding $\frac{1}{100}$, or preferably $\frac{1}{200}$ to $\frac{1}{250}$ of an inch, if enlargement is intended. The time required to produce a well-exposed image depends on the state of the light and the illumination of the object, the relative intensity of the lens as measured by its effective aperture and focal length, the sensitiveness of the plate, and the amount of effective light passing through the shutter during the exposure. The amount of displacement to be guarded against depends upon the rate of movement of the object, the direction in which it is moving with reference to the axis of the lens, its distance from the camera, and the focal length of the lens. It will be proportionately less as the distance of the object increases, and as the rate of its motion and the focal length of the lens for a given distance decrease, and *vice versâ*. It will be greatest when the object is moving at right angles to the axis of the lens, and least when the motion is directly towards it; but in that case there will be some increase in the apparent size of the object as it approaches the camera. For example:—An object moving 1 mile an hour advances 17·6 inches per second. With a lens of 5-inch focus this would represent a displacement on the ground glass, for an object 50 feet away, amounting to $\frac{1}{46}$ inch per second, and it would require exposures between $\frac{1}{15}$ and $\frac{1}{37}$ of a second to give maximum or minimum displacements of the image between $\frac{1}{100}$ and $\frac{1}{250}$ of an inch. An object at the same distance moving ten times as fast would require $\frac{1}{10}$ of the above exposures. If, however, the distance be increased, the possible exposure may also be increased in the same proportion, so that the object moving 10 miles an hour at 500 feet distance would only require the original exposures of $\frac{1}{15}$ to $\frac{1}{37}$ of a second. On the other hand, the limits of exposure for an object moving 1 mile an hour within 10 feet of the lens would be between $\frac{1}{75}$ and $\frac{1}{185}$ of a second. This is entirely independent of the sensitiveness of the plate, and only represents the maximum duration of exposure permissible in order to reduce the blurring of the image between certain limits. The sensitiveness of the plate, and the intensity and amount of light acting upon it through the lens and shutter, must be adjusted so as to produce the desired photographic effect within that time. With a lens of 8 inches focal length the displacement would have increased in the first instance to ·23 inch per second, and the maximum exposure permissible would be from $\frac{1}{23}$ to $\frac{1}{57}$ of a second. This shows that there is an advantage in using short-focus lenses for very rapid exposures. In practice, most work of this kind is done upon quarter-plates ($4\frac{1}{4} \times 3\frac{1}{4}$ inches) with lenses of $4\frac{1}{2}$ to 5 inches focus. It may be noted that the displacement will be greatest for an object moving at a right angle across the axis of the lens, so that an exposure sufficient for this case will be sufficient for any other. Sir William Abney has discussed this question practically in his *Instantaneous Photography*, and it is treated mathematically by Mr W. B. Coventry in his *Technics of the Hand Camera*, in which will be found formulæ and tables for ascertaining the distances and limiting exposures for moving objects, allowing for a blur of $\frac{1}{100}$ of an inch. In foreign treatises the limit is usually calculated for a displacement of $\frac{1}{10}$ of a millimetre, or about $\frac{1}{250}$ of an inch.

An efficient shutter should fulfil the following conditions:—It should be light and compact, simple in construction, but strongly made, and not liable to get out of order; capable of being set without admitting light into the camera; quite free from any tendency to shake the camera; and easily released with a very slight pressure of the finger if a pneumatic release is not fitted. It should open and close quickly, allowing the largest possible proportion of the exposure to be made with the full aperture, and it must not cut off any of the effective light passing through the lens, but should distribute it evenly all over the plate: though in landscape work it is an advantage to give the foreground more exposure than the sky. It should be adjustable for variable instantaneous and for prolonged or "time" exposures. With a good shutter there is less risk of shaking the camera in short "time" exposures, from $\frac{1}{4}$ to 1 second, than there is in taking off a cap. Shutters working between the lenses must permit of the use of diaphragms in the lenses. Above all, they must be constant in their action, giving short and variable exposures always correctly or relatively so, an important condition which apparently is not often fulfilled, and the exposures marked on the indicator should be capable of being always repeated with certainty. Shutters should also be capable of being used with different lenses. They are usually released by the pressure of the finger on the end of a lever holding the moving part in a state of tension; or better, by Cadett's system of pneumatic pressure, applied by means of a compressible rubber bulb and tube, which drives a piston acting on the lever holding the shutter, or which may inflate a collapsible bulb at the other end of the tube, and thus exert the necessary pressure on the lever. In many cases both methods can be used as desired, the pneumatic release being preferable on account of its convenience and freedom from liability to shake the camera. For hand cameras, however, the trigger pressure stud is more general, though in some forms a lever is drawn across from right to left, or *vice versâ*, being always set in both positions. Pressure is, however, better than a pull.

The following are the principal types of instantaneous shutter:—(1) Flap, (2) drop, (3) combined drop and flap, (4) rotary, (5) roller-blind, (6) focal plane, (7) lamellar, (8) moving disc or sector, (9) iris. They can be applied in four different positions: (*a*) in front of the lens; (*b*) centrally, near the diaphragm; (*c*) behind the lens; (*d*) immediately in front of the sensitive plate. They all, however, come under two main classes, *Lateral*, including those in which the exposure commences and ends at the circumference of the lens aperture, and *Central*, those in which the exposure begins and ends at the centre of the aperture. Some of them are "lateral" in their single form and "central" when double. With the "focal plane" shutters, however, different portions of the plate are exposed in succession, the lens working at its full aperture throughout the exposure. The form and position of the effective aperture of a shutter, relatively to the lens and plate, have a strong influence, either favourable or unfavourable, on the amount of effective light passing through the lens, and its even distribution over the plate. This is especially the case during the incomplete phases of opening and closing the aperture. It seems to be agreed that the best position for shutters of the lateral type is behind the objective, and for those of the central type, between the component lenses. In this latter position the whole of the plate is illuminated during the full period of exposure, with a gradually increasing intensity during the first phase, until the second phase of full opening is reached, and then the illumination gradually falls off again during the third phase until the shutter is closed again. The most effective shutter is one in which the first and third phases of incomplete illumination, during the opening and closing, are the shortest compared with the phase of full opening.

To secure successful results in using instantaneous shutters, the operator must make himself thoroughly acquainted with the working of his shutter in various circumstances of exposure with the lenses, plates, and developer he proposes to use; he should also verify the value of the various exposures marked on the indicator, and, what is more important, determine how far they can be depended on for regularity. There are many simple ways in which the actual time of exposure from opening to closing can be ascertained sufficiently closely for practical purposes. They depend upon the measurement of the trace left on a sensitive plate by the passage of a brightly illuminated object revolving at a known speed or falling vertically through a known distance, when photographed with different speeds of the shutter against a dark background. These, and the more elaborate methods for obtaining more accurate determinations of the shutter-exposure periods and of the corresponding effective exposures—*i.e.*, showing the actual effect of the shutter through its different phases from opening to closing—have been described by Sir William Abney in the work already mentioned, by Londe in *La Photographie Moderne* and *La Photographie Instantanée*, and in other works mentioned at the end of this article.

(1) *Flap Shutters.*—The simple flap shutters consisting of a hinged flap opening upwards in front of the lens, though favourites in early days for landscape work, have been almost superseded by quicker and more compact forms. They are, however, still in use with single and double flaps for portraiture and studio work, for which purpose they are made to act noiselessly and not attract the attention of the sitters. Guerry's (Figs. 63 and 64) is a good example of the type.

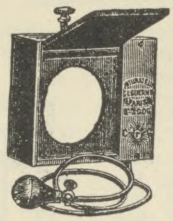

FIG. 63.—Guerry's Single-flap Shutter.

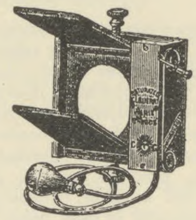

FIG. 64.—Guerry's Double-flap Shutter.

(2) *Drop Shutters.*—The old simple drop shutter, in which a plate having an opening in it falls in front of the lens aperture, has been superseded by the more compact and quicker-working roller-blind shutters, which act on much the same principle. It had a theoretical interest in connexion with the effect of different forms of aperture—circular, square, or elongated—used with shutters of the lateral type, but it is now generally recognized that a more or less extended rectangular opening, of at least the full width of the lens aperture, is best for securing the even admission of light from all parts of the image with shutters of the rectilinear lateral type, to which this and similar shutters, in which a single opening passes across the lens aperture, belong.

(3) *Combined Drop and Flap Shutters.*—In early dry-plate days several forms of this kind of shutter were brought out, under the names of Phœnix, Phantom, &c., but they are now little used. In these shutters, in addition to the drop slide, there was also a lifting flap, which on release opened from below, and, having fully uncovered the aperture, released the drop slide, which fell and closed the shutter. They were useful and effective in the smaller sizes, but heavy and cumbrous in the larger. The use of indiarubber bands for giving tension was also an objection.

(4) *Rotary Shutters.*—These are of the lateral type, and consist of a circular metal disc revolving on an axis eccentric to the axis of the lens, and furnished with a radial sector-shaped or elongated opening with circular ends, which passes laterally in front of the lens aperture when the tension of a spring is released (Fig. 65). They are largely used in various patterns in hand cameras, usually in front of the objective, though they may be placed behind it or between the component lenses. So long as the opening is at least equal to the size of the lens aperture, the illumination is sufficiently even, but the openings are usually somewhat elongated so as to give a longer period of full opening.

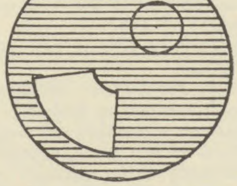

FIG. 65.—Rotary Shutter.

(5) *Roller-Blind Shutters.*—For general use the well-known roller-blind shutter of the single lateral type, as made by Thornton-Pickard and others, is undoubtedly one of the most popular and efficient. It possesses most of the qualities laid down as essential to a good shutter, gives good illumination, appears to be fairly regular in its action, and can be used for time or instantaneous exposures. It consists of a light mahogany or aluminium box, arranged so that it can be fitted in front of or behind the objective. It is made in different sizes, and each size can be adjusted to smaller objectives

Fig. 66). By pulling a cord an opaque black curtain with an elongated rectangular aperture is unrolled from the lower roller on

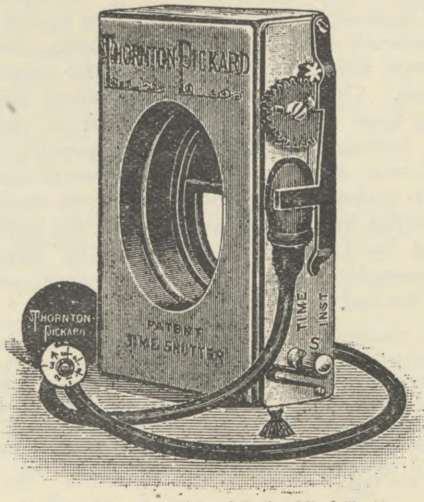

FIG. 66.—Thornton-Pickard Roller-Blind Shutter.

to the upper one, and held by a coiled spring on the lower roller (Fig. 67). Pressure on a pneumatic bulb inflates a second smaller bulb, raising a lever which releases the spring, and thus brings the blind down with a rapidity which can be adjusted by turning a handle actuating the spring, the corresponding speed being shown on the indicator. For time exposures, pressure on the bulb opens the shutter, and another pressure closes it, but an arrangement is now made by which time exposures of $\frac{1}{5}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 3 seconds can be given automatically (Fig. 68), the pressure of the bulb opening the shutter, which closes of itself at the expiration of the exposure required. The theory of shutters of this type has been very fully discussed by Mr Coventry (*op. cit.* p. 50), who shows that for any given tension of the spring the actual exposure decreases as the size of the lens aperture diminishes, while the effective exposure remains constant for all apertures. This is peculiar to the lateral shutter. He also shows that with plates of very different rapidities, though the exposure may be the same, the actual exposure effective is less with the rapid plate and a small stop, than with the slow plate and a large stop; consequently the blur due to the movement of the object would be proportionately less on the rapid plate than on the slow one. He also shows that for any given lens the smaller the shutter the more rapid the exposure can be made, though with the same lens a larger shutter is capable of giving a more efficient though less rapid exposure. It is better, therefore, for moderate exposures, to have a larger shutter than the size of the lens requires. Sir William Abney has given diagrams of the action of this shutter in his book referred to; these show clearly that the centre of the plate gets more exposure than the margins; but practically this is not very noticeable, and the action is very regular.

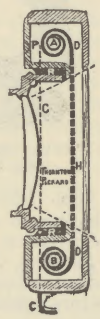

FIG. 67. — Mechanism of the Thornton-Pickard Roller Blind Shutter.—A, upper roller; B, lower roller; C, cord; D, black curtain; H, aperture in curtain; R, rubber ring adapter.

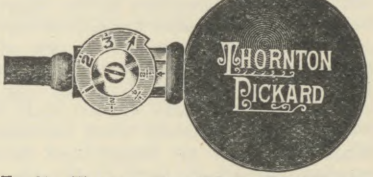

FIG. 68.—Thornton-Pickard Roller-Blind Shutter —Automatic Exposure Appliance.

(6) *Focal-Plane Shutters.*—These are also roller-blind shutters, with mechanism similar to the foregoing, but they are arranged so that an adjustable slit moves at a rapid speed a short distance in front of the plate, exposing different portions of it in turn, the intensity of the exposure being regulated by the width of the slit, which is adjustable. In this way the lens can act on the plate with its full intensity. The construction of this shutter (Fig. 24) makes it capable of giving very rapid exposures with a narrow slit, and it has been used by Anschütz for his remarkable instantaneous studies of animals, &c., in rapid motion. It is made by Thornton-Pickard, Goerz, and others. The theory of it is discussed by Coventry (*op. cit.* p. 69). As the slit moves progressively over the plate, it may in certain circumstances cause distortion of the quickly-moving images, especially if near the camera, or with a narrow slit and slow movement, but practically it is not often very perceptible.

(7) *Lamellar Shutters.*—These are a distinct type of lateral shutters, introduced abroad but not common in England. They act on the principle of a venetian blind, with a series of parallel blades or plates, which turn through a semicircle on an axis during the exposure. They are said to have the advantage of giving a *uniform* very rapid exposure, but the blades cut off a great deal of light, whether placed before or behind the lens.

(8) *Moving Disc Shutters.*—These shutters, in which two thin metal plates with round or rectangular apertures, or in other cases two curved blades, pass very quickly over each other in opposite directions, are now very generally used in a variety of patterns. Formed of two single lateral shutters, they become in most cases central, opening and closing in the centre of the lens aperture. The exposure takes place during the short period when the openings pass each other, or the curved blades open out and close again. The size of the openings generally corresponds with the diameter of the lens. If each plate moves as fast as a drop shutter, the combination gives double the speed, corresponding to half the exposure. High speeds of $\frac{1}{100}$ or $\frac{1}{200}$ of a second can therefore easily be attained, and rectangular apertures are the most effective. The plate will be most evenly and strongly illuminated when the leaves of the shutter work inside the lens near the diaphragm, as in Bausch & Lomb's (Fig. 70). This necessitates the shutter being made for the lens. Some forms are, however, suitable for use in front of the lens, such as the "Constant," Lancaster's "See-Saw" (Fig. 69), the double roller-blind, &c. In these the rectangular form of aperture is the best, circular apertures cutting off a good deal of the light, as in the case of drop shutters. Coventry has also discussed the action of the double roller-blind shutter as typical of the central class of shutters, and shows that while with the lateral shutter the effective exposure is constant and the actual exposure variable, it is the reverse with the central shutters, and it will not be so easy to calculate exposures with different-sized stops. A central shutter gives a more efficient exposure than a lateral shutter of the same dimensions as long as the opening is greater than the diameter of the lens. The greater rapidity of the double blind shutters is partly due to the spring being stronger.

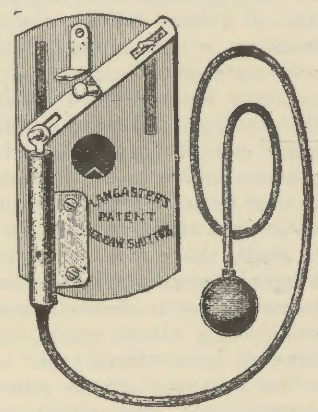

FIG. 69.—Lancaster's "See-Saw" Shutter.

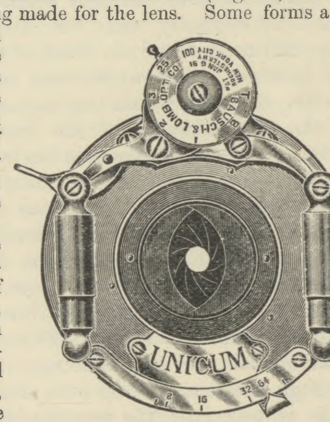

FIG. 70.—Bausch & Lomb's "Unicum" Shutter.

(9) *Iris Shutters.*—These shutters are a further development of the double curved-blade central shutters, and are constructed on the principle of the "Iris" diaphragm, to open out from the centre of the lens and close again (Fig. 71). They are in all cases fitted between the components of double objectives, and can be made very light and compact. This central position of the shutter is theoretically the best, and the "Iris" is the best form. They require very great care in construction and fitting to the lens, and consequently are expensive. They can, however, be used with convertible sets of lenses of different foci fitting the same mount. Several forms of them are made by English and foreign makers, but the principle is much the same in all, and ensures the most equal distribution of light over the plate.

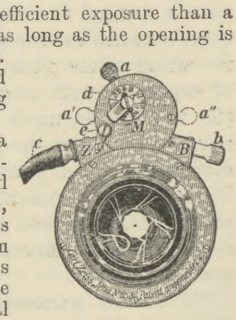

FIG. 71.—Mechanism of the "Iris" Shutter.—*a,a,'a,"* winding lever; *b*, speed brake; *c*, hand release; *d*, index for iris; *e*, index for exposures and also release; *B*, brake; *M*, instantaneous exposures; *Z*, tune exposures.

Exposure Meters.

When gelatine dry plates came into general use, and were made of many different degrees of sensitiveness, the want of a guide to the proper exposure for the various makes of plates under different conditions of lighting began to be felt, and several methods were devised for meeting the want. Some of them depend solely upon data derived from observations of the action of the principal factors affecting the result, namely: (1) The speed of the plate; (2) the actinic power of solar light for the time of year in a given latitude; (3) the time of day, with reference to the position of the sun; (4) the effective diaphragm aperture of the lens; (5) the nature and illumination of the subject. With others these data are supplemented by, and practically based upon, actinometric observations of the action of the light upon sensitive paper exposed near the camera or the subject at the time. Both methods are in many cases of undoubted use, but the information given by instruments of this kind can only be considered as approximate, and much is left to the judgment of the operator, whose surest guide will be an intelligent study of the principles on which these instruments are based, together with carefully-recorded observations of the combined working of his lenses, shutters, plates, and methods of development under the varying conditions of practical work. Before using any of these instruments, it is necessary to know approximately the relative sensitiveness or "speed" of the plate in use. In the early days of gelatine dry plates, their rapidities were stated as so many times wet plates, or as "ordinary," "instantaneous," "rapid," or "extra-rapid," terms which, though suitable for one make of plate, were of no value with reference to others. This was improved upon by the adoption of Warnerke's "Sensitometer," which was in use as a standard for some years. It consisted of a transparent scale of 25 squares of different intensities, marked with opaque numbers and arranged so that each third number indicated a doubled rapidity. This was placed in a frame in front of the sensitive plate, and exposed for thirty seconds to the constant light emitted by a phosphorescent tablet, supplied with the instrument, which was previously excited by burning one inch of magnesium ribbon in front of it. The exposed plate was then developed and fixed, and the highest number visible indicated the rapidity of the plate. In 1890 Messrs Hurter & Driffield introduced an entirely new system of calculating the sensitiveness of plates of different rapidities. They make a series of exposures in seconds on different parts of the plate in geometrical progression with a standard candle at one metre distance. After development for a certain fixed period with a standard developer, fixing, washing, and drying, the "densities," or logarithms of the opacities, of the different parts are measured by a special photometer and plotted on a skeleton diagram, producing a curve, one portion of which will practically be a straight line. The position of this line with reference to a scale of exposures given on the diagram decides the rapidity of the plate, while its length indicates the "capacity" of the plate for the truthful rendering of tone. The elaborate investigations by which these results were obtained are of great interest, and were published in the *Journal of the Society for Chemical Industry*, 1890, 1891, and later ones in the *Photographic Journal*, 1898. A paper read before the Photographic Convention in 1893 may also be noted. The sensitiveness given on the H. & D. scale is directly proportional to the number given. The method has been adopted by several dry-plate makers in denoting the sensitiveness of their different brands, and is more or less the basis on which the plate-speeds for the modern English dry-plate actinometers and exposure meters are calculated. Several systems of photometry and measurement of the speeds of dry plates were discussed at the meetings of the Congrès International de Photographie, in Paris, 1889, and Brussels, 1891, but no definite standard was finally adopted. In Germany the use of Scheiner's sensitometer has been adopted, and appears to be extending. It is based on a system of photographing the graduated tints given by rotating sectors. A full account of the instrument, and of a system of sensitometry based on its use, is given by Dr Eder in the *Photographische Correspondenz*, 1898, p. 469, and 1900, p. 244. Mr Chapman Jones has recently brought out a convenient plate-tester on the same principle as the Warnerke sensitometer, but extended by the addition of a colour sensitometer, which is useful for the comparison of orthochromatic dry plates, colour screens, light filters, &c. It consists of a screen plate, $4\frac{1}{4} \times 3\frac{1}{4}$ inches, containing a series of twenty-five tints of graduated densities; a series of coloured squares, blue, green, yellow, and red, and a strip of neutral grey, all five being of approximately equal luminosity; a series of four squares of special pure colours, each representing a definite portion of the spectrum; also a space of line design, over which is superposed a half-tone negative. To use the instrument, a quarter-plate of the brand to be tested is exposed behind the screen for a few seconds to the light of a standard candle placed at the distance of a foot, developed, fixed, and washed. An examination of the plate will show the sensitiveness, range of gradation, possible range of exposure, sensitiveness to colour, size of grain, amount of halation, and the most suitable light for development. It can be used for many other tests, and enables any brand of plates to be readily tested by the user and compared with any standard he may find convenient. In making these and similar tests, a standard developer should be allowed to act for a fixed period and at a uniform temperature (*Phot. Journ.* 1901, xxv. p. 246).

The next important factor is the actinic power of the light. It depends normally on the height of the sun for the latitude of the place at the time when the photograph is taken, and exposures in bright sunlight are found to vary approximately as the cosecant of the sun's altitude above the horizon. The light of the sun itself is practically the same at any given time and place year after year, but is liable to more or less local and temporary diminution by the amount of cloud, haze, dust, &c., present in the atmosphere at the time. It is also affected by the time of day, increasing from sunrise to noon, and then decreasing to sunset. The remaining factor is the effective diaphragm aperture of the lens in relation to its focal length. In most cases of ordinary outdoor exposures this can be taken at its normal value, but becomes smaller and increases exposure if the focal length is much increased for photographing near objects. Besides these principal factors, the nature and colour of the objects, their distance, and the amount of light received and reflected by them, have a very great influence on the result. Mr Coventry (*op. cit.* p. 75) shows how the "light coefficient" for full sunlight can be found, and gives a table for the latitude of London for every half-hour of the day in periods of ten days throughout the year; also, roughly, the relative coefficients for "diffused light," "cloudy," "dull," and "very dull." Convenient tables showing the normal exposures for each month in the year and at every hour of the day, together with others showing the influence of the different factors affecting exposure, have been published in some of the printed "Exposure Note-books." The reader may also be referred to H. Boursault's *Calcul du Temps de Pose en Photographie*, and similar works by A. de la

Baume-Pluvinel and G. de C. d'Espinassoux for a discussion of the subject in all its aspects.

Based on the same principle as these exposure tables, various portable exposure meters have been brought out, in which scales representing the coefficients for plate-speed, light, and diaphragm are arranged as in a slide rule, so that, when properly set, the normal exposure required can be found by inspection, and increased or diminished according to circumstances. In Hurter & Driffield's "Actinograph," the light coefficient is given by a printed card showing the curves for every day in the year and for every hour of the day, the unit being the $\frac{1}{100}$ part of the brightest possible diffused daylight when the altitude of the sun is 90°. The "lens" scale shows the ratios of aperture to focal length in general use, and is calculated for single, double, and triple systems of lenses. The "speed" scale is based on the exposure in seconds which with one actinograph degree of light will produce a perfect negative of an ordinary landscape. An additional scale is given for five different degrees of illumination—"very bright," "bright," "mean," "dull," "very dull." A table of factors for "Views," "Portraiture," "Interiors," "Copying," is also given, and these regulate the figure to be taken for the exposure. The scales are engraved on boxwood, and there are two sliding pieces (Fig. 72).

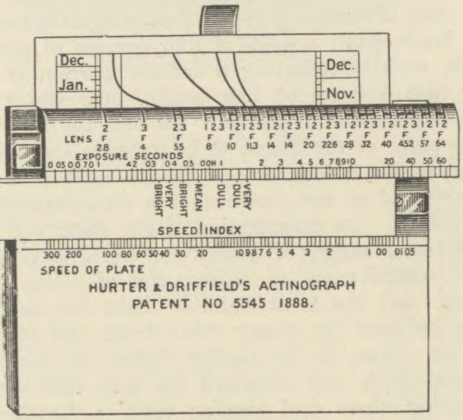

FIG. 72.—Hurter & Driffield's Actinograph.

It is specially adapted for use with plates of speed numbers agreeing with the H. & D. scale, but can be used with any plate of which the relative speed number is known. Another convenient exposure meter is made by Watkins, of Hereford, in different forms. In the first the scales of "light," "speed," "diaphragm," and "exposures" are arranged round a cylinder, and in a later pattern on a dial, but the plate speeds are taken from a table, and the light coefficient is ascertained at the time by exposing a piece of sensitive paper under a blue glass for the number of seconds requisite to match a fixed tint, a pendulum being supplied with the instrument for counting seconds. In the "dial" instrument there are four apertures, marked "Plate," "Stop," "Act." and "Exp." above the corresponding scales. The numbers showing the speed of the plate in use, the diameter of the stop, and the actinometer exposure in seconds are brought into the respective apertures, and the exposure required is read off in the "Exp." aperture (Figs. 73 and 74). Other forms are made for hand cameras and indoor exposures. Wynne's exposure meter is also in dial

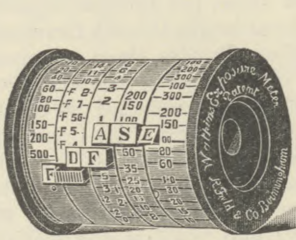

FIG. 73.—Wilkin's Exposure Meter. Cylindrical form.

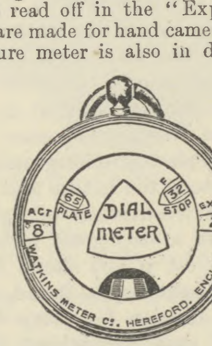

FIG. 74.—Dial Meter.

form, but the sensitive paper is exposed directly, no pendulum is used, and the scales are open on the dial. In use, the glass carrying the movable scale is turned until the actinometer time in seconds upon the exposure scale is opposite the diaphragm number of the plate; the correct exposure will then be found against each stop given on the scale. There are practically only two scales: the scale of diaphragms representing the diaphragm apertures, the speed of plate and the variation of exposure due to subject; and the time scale, representing the actinometer time and the exposure. It is thus very simple. In another smaller form the scales are on the circumference of a locket and the actinometer at the back (Figs. 75 and 76). A "Print meter" is also made for showing the exposures in contact-printing on sensitive papers, but it can also be used for testing speeds of plates and papers. Another form of exposure meter is Decoudun's, in which the exposure is estimated by the disappearance of a series of clear spots on a graduated scale

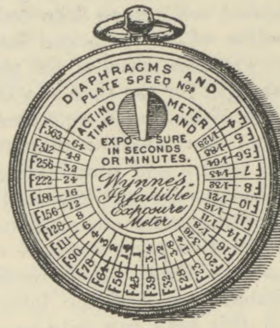

FIG. 75.—Wynne's Exposure Meter (ordinary form).

FIG. 76.—Wynne's Exposure Meter (locket form).

of densities laid on the most important parts of the image as seen on the ground glass. Its indications are not so definite as those given by the instruments noted above, and the scale is liable to change in density after a time. Other simple actinometers are in use for carbon and process printing, and usually consist of a graduated scale of different thicknesses of tissue paper, or coloured gelatine in different densities. Papers are not suitable for making actinometer scales of this kind, on account of their tendency to turn yellow with age; coloured gelatine is better.

Sensitive Plates and Films.

The special feature of modern photography is the use of trustworthy ready-prepared sensitive dry plates and films in different grades of sensitiveness, so that there is no necessity for the photographer to prepare his own plates, nor, indeed, could he do so with any advantage. The practice of outdoor and studio photography has thus been very greatly simplified; and although with wet collodion there was the advantage of seeing the results at once and retaking a picture if necessary, the uncertainties connected with the use of the silver bath and collodion, and the amount of cumbrous apparatus necessary for preparing and developing the plates, far outweighed any advantage. There is also an enormous saving of time, in using dry plates as compared with wet, by deferring development. On the other hand, the uncertainty of more or less random exposures on ready-prepared plates must not be overlooked. Besides their use in taking negatives, gelatine dry plates are also largely used for printing transparencies, lantern slides, enlargements, &c. For negative work the dry plates are prepared with an emulsion in gelatine of silver bromide, alone or with the addition of silver iodide or chloride, and are to be obtained in five or six degrees of rapidity: "slow," for photomechanical or "process" work; "ordinary," for general purposes when quick exposures are not required; "rapid," for landscape and portraits; "extra rapid," for instantaneous exposures; and "double extra rapid," for very quick snapshot work in dull weather or for special subjects. These latter kinds are exceedingly sensitive, and require great care in use to avoid fog. In order to prevent halation, or irregular action by reflection from the back surface of the glass, dry plates are coated with a non-actinic "backing," which can easily be removed before development.

The method of rendering photographic plates isochromatic, or sensitive to all colours, by dyeing them with eosine or other suitable dyes, was noticed in the 9th edition of this work. Colour-sensitive plates of this kind are now largely manufactured and used for the reproduction of paintings, as well as for portraiture, landscapes, and all subjects presenting contrasts of colours which could not be satisfactorily reproduced in their relative luminosities on ordinary plates, which are insensitive to the most luminous, or yellow, rays, and still more so to the red. The manufactured plates are of two kinds: the ordinary isochromatic, sensitive for yellow or yellow-green, and the panchromatic, which are more or less sensitive for red, orange, or yellow, as well as for the green, blue, and violet. To obtain the best results from these plates, it is necessary to use light-filters of yellow or orange glass, or glass cells containing solutions of suitable dyes or salts. For three-colour reproductions by the Sanger Shepherd, Ives, and other processes, special colour-sensitive plates and carefully selected red, green, and violet filters have to be used, and are on the market.

In order to avoid the weight of glass plates, which may become very burdensome on a tour, and also the risk of breakage of valuable records, thin films or sheets of celluloid or hardened gelatine coated with emulsion may be used instead of glass plates, with a great saving in bulk and weight. There is, however, more liability to loss of sensitiveness in gelatino-bromide films coated on celluloid, so they should not be kept too long before exposure; and if they have been kept, should be tested, if possible, before use, and should always be developed soon after exposure. They are generally placed in sheaths, for exposure, in order to keep them flat. In other respects they are treated exactly in the same way as plates.

For some years past sensitive films have been prepared in long strips of different widths suitable for use in hand cameras, particularly of the Kodak type, and in roll-holders. In the early forms of roll-holders the films were used alone, and had to be changed in the dark room, but, as already stated, they are now supplied in cartridges, which can be changed in ordinary diffused light. Silvy, so long ago as 1870, seems to have been the first to employ this method. In these cartridges the film is attached to a much longer strip of black paper and rolled up with it, so that several turns of the paper have to be unrolled before the film is ready for exposure, this point being marked on the outside paper and visible through a red glass at the back of the holder. The different lengths of film for the successive pictures are similarly indicated by numbers; and when all have been exposed, the black paper is rolled on for several turns, and when taken out of the holder the loose end is fastened up till the film is developed. Paper coated with sensitive emulsions has also been used successfully in the same way as the flat or roll celluloid films, and is very much cheaper, but is more liable to change and become insensitive from the action of the air after exposure. Such films should be developed within a short time after exposure; otherwise there is great risk of the impressed image fading and becoming undevelopable. In order to overcome the granular appearance sometimes given by paper negatives, stripping films upon a paper support have been introduced by Messrs Wellington & Ward, in sheets or rolls. Such films have the advantage that they can be printed from either side without perceptible loss of definition, which is very useful in printing by the single transfer carbon process. Flexible films in sheets and rolls have also been prepared upon hardened gelatine, but with these it is difficult to retain the original dimensions of the film, owing to expansion of the gelatine.

Photographic Printing Papers.—*Pari passu* with the supply of ready-prepared plates, facilities for obtaining all kinds of photographic printing papers ready for use have been made available, so that the photographer has now practically nothing to do with the preparation of his plates or papers. The most notable change in recent years is the supersession of albuminized papers by papers coated by machinery with emulsions of silver haloids in gelatine, the chloride being used for most of the printing-out papers, which contain more or less free silver nitrate, while the bromide forms the basis of most of the developable papers used for enlarging and direct copying, which contain no free silver nitrate, and with which the image is brought out by development, much in the same way as with dry plates. Some of the printing-out papers are also made with emulsions of silver salts in collodion. Considerable use is also made of ready-prepared platinotype paper, sensitized with salts of platinum and iron, which can be printed out entirely or only partly printed and developed with potassic oxalate. These prints have the advantage of being permanent, which is also shared by carbon or pigment prints (autotype, &c.), for which tissues, consisting of paper coated with pigmented gelatine, are now available in a great range of colours, as are also similar papers prepared with pigmented gum, instead of gelatine, for the practice of what is known as the "gum bichromate" process. For architects and engineers, cyanotype and ferrogallic papers are prepared in rolls of considerable width for the direct reproduction of tracings and drawings, as blue or black prints by these methods. The manufacture of these different photographic papers has become an important industry in Europe and the United States, as well as in Great Britain.

III. Pictorial Photography.

Pictorial photography differs from other branches of photographic practice in the motive by which it is prompted. Employing the same methods and tools, it seeks to use photographic processes as a means of personal artistic expression. If a given subject or theme were rendered in the same medium by a Robinson, a Davison, a Holland Day, and a Demachy, the results would differ as much as the respective authors' handwritings. To trace the development during the last quarter of the 19th century of that particular phase or application of photography which, in contradistinction to the scientific and technical, is termed pictorial, is to record in something approaching chronological order the influences which have gradually secured for it the position it now holds, rather than to notice improvements in methods of production, of which, indeed, its advancement is to a great extent independent. The growth of pictorial photography and the multiplication of amateur practitioners of photography generally, may be said to be synchronous. If the term "amateur" is taken to include those who devotedly practise for the satisfaction of their own desires rather than according to prescription and rule at the behests of another, then the two things are to be connected still more closely. At the present time, whether or not they fully understand the thing they are pursuing, by far the larger number of those in Great Britain who practise photography admit that their interest is in the pictorial side of the craft. To write the story of its progress is to show how each advance has been made by those who, in the attempt to realize their own artistic ideals, have had the courage and independence to depart from the traditions and formulæ laid down by those who have brought the mechanical process to a degree of perfection. The technician spends his best efforts on photography as a process, and the elimination of errors and defects is one of his chief aims; the pictorial worker employs the process from choice, merely as a means to an end, and if he can make a "picture" which pleases him, he does not care whether or not, as an example of photographic work, it be of the highest modern or approved type. Thus in the early days of Fox Talbot's calotype, about 1846, David Octavius Hill, a successful Scottish painter, took up this method of portrayal, and, guided by an artist's knowledge and taste, and unfettered by photographic convention, which indeed had then scarcely begun to grow, produced portraits which for genuine pictorial quality have perhaps never been surpassed, especially if some allowance be made for the necessary imperfections of the "Talbotype" (see Plate). Whether they were in their day typical examples of Talbotype with all the latest improvements, Hill probably never cared. When, again, a few years later, Sir William J. Newton, the eminent miniature painter, read a paper before the newly-formed Photographic Society of Great Britain (now the Royal Photographic Society), his recommendation to depart from the custom of defining everything with excessive sharpness caused his address to be almost epoch-making. "I do not conceive it to be necessary or desirable," he said, "for an artist to represent, or aim at, the attainment of every minute detail, but to endeavour at producing a broad and general effect. . . . I do not consider that the whole of the subject should be what is called 'in focus'; on the contrary, I have found in many instances that the object is better obtained by the whole subject being a little out of focus." The doctrine has been persistently repeated ever since, but only within the last decade of the 19th century was the suppression or diffusion of focus received by photographers generally with anything better than ridicule or contempt, because it was unorthodox. O. G. Rejlander, Mrs Julia Margaret Cameron, H. P. Robinson, and others, by precept or practice, strove against such photographic conventions as had arisen out of those technical exigencies to which pictorial qualities were so often sacrificed. As late as 1868, in the *Manual of Photographic Manipulation*, by Lake Price, the old advice to arrange a group of persons in crescent form, so as to adapt the subject to the curve of the field of the lens, was repeated, with the additional recommendation of plotting out on the ground beforehand the "curve of the focus" as a guide. As a defiance to this dictum, Rejlander, in 1869, produced a group of the members of the Solar Club in which some of the chief figures were set widely out of the "curve of the focus." The mere technical difficulties of this performance with wet collodion plates, and in an ordinary upper room, need not be touched upon here, but it is to be noted as one of those triumphant departures from convention which have marked the progressive stages of pictorial photography. At about the same period, Mrs Cameron, carrying the recommendation of "a little out of focus" rather farther, regardless of how her lens was intended to be used by its maker, secured the rendering dictated by her own taste and judgment, with the result that many of her portraits, such as those of Tennyson, Carlyle, &c., are still in their way unsurpassed. Contemporaneously, Adam Salomon, a talented sculptor, "sunned" down the too garish lights of his photographic prints, and strengthened the high lights by working on the back of the negative.

But, during the concluding quarter of the 19th century, probably the most powerful influence in pictorial photography was that of H. P. Robinson, who died in February 1901, and, but for a brief period about the year 1875, was one of the most prolific "picture makers." Inspired by Rejlander, of whom he was a contemporary, Robinson will perhaps be best remembered by his earlier advocacy of combination printing. As early as 1855 Berwick and Annan exhibited a photograph which was the result of printing from more than one negative, a figure from one plate being cunningly introduced into a landscape print from another. Then came from Rejlander "The Two Ways of Life," in which, with wonderful ingenuity, thirty different negatives were combined. Robinson followed, and between 1858 and 1887 exhibited numerous examples of combination-printing, one of the most popular and fairly typical examples being "Carolling" (see Plate), which received a medal in the Exhibition of the Royal Photographic Society in 1887.

Though in this combination-printing one may perhaps perceive the germ of incentive towards the production of special effects not seen in the original, yet the practice was not destined to become very popular, for even in the most capable hands there remains the difficulty, if not impossibility, of fitting a portion of one negative into a print from another and still preserving true relative tonality, and even true proportion. Skilfully produced, eminently popular in character though "Carolling" may be, such errors are not absent. Of this combination-printing Dr P. H. Emerson has said: "Cloud printing is the simplest form of combination-printing, and the only one admissible when we are considering artistic work. Rejlander, however, in the early days of photography, tried to make pictures by combination-printing. This process is really what many of us practised in the nursery, that is, cutting out figures and pasting them into white spaces left for that purpose in the picture-book. With all the care in the world the very best artist living could not do this satisfactorily. Nature is so subtle that it is impossible to do this sort of patchwork and represent her. Even if the greater truths be registered, the lesser truths, still important, cannot be obtained, and the softness of outline is easily lost. The relation of the figure to the landscape can never be truly represented in this manner, for all subtle modelling of the contour of the figure is lost."

Pictorial photography received a large accession of votaries in consequence of the greater facilities offered by the introduction of the gelatino-bromide, or dry-plate, pro-

"Carolling." By H. P. Robinson.

cess, which, although dating from 1880, did not notably affect photographic communities until some years afterwards; and although improvement in appliances and instruments has had little to do with the advance of the pictorial side of photography, yet, indirectly at least, the dry-plate and the platinotype printing process have had an undoubted effect. The former gave enormously increased facility, and dispensed with tedious manipulations and chemical knowledge, while its increased light-sensitiveness decreased the limitations as to subjects and effects. The platinotype process was discovered in 1874–80 by W. Willis, who employed his chemical skill and knowledge to give the world a printing process more likely than the hitherto prevalent silver papers to satisfy artistic requirements.

Up to 1882 but few outdoor photographers had ventured to run counter to the general dictum that photographs should only be taken during sunshine, or good bright light, and unquestioning consent would have been given everywhere to the proposition that it would be absurd to work when anything like fog or atmospheric haze was present. Isochromatic plates, introduced for the purpose of equalizing the actinic power of various colour luminosities, and so rendering colours in correct relative value, were recommended by one writer, who applauded their supposed advantage of enabling the photographer to photograph distance without any suggestion of atmosphere. That evening or morning haze might enhance the beauty of a landscape, or that the mystery of half-concealment might itself be beautiful, does not seem to have occurred to the photographer, who had become infatuated by the exquisite clearness and sharpness which, with a minimum of labour, he was able to achieve. It is therefore interesting to note one of the first photographic successes which broke away from this convention, just as Rejlander's Solar Club group defied the formula of arranging human figures like the tiers of an amphitheatre. William M'Leish, of Darlington, a Scottish gardener who had taken to photography, and who seems to have been less under the influence, or it may have been that he was ignorant, of the old *dicta*, sent to the Royal Photographic Society's Exhibition in 1882 a photograph entitled "Misty Morning on the Wear," a very beautiful view of Durham Cathedral as seen through the mist from across the river. The judges, although they that year awarded eleven medals, passed this by; but appreciation came from outside, for newspaper critics, and practically all those who were not blinded by prejudice and conventionality, declared it to be *the* photograph of the year. Thenceforward the landscape photographer cast aside the old doctrine, and began to learn that there was such a thing as atmosphere, and that it was not undesirable even when enveloping the chief features in the view. The exhibitions immediately succeeding revealed numerous imitators of M'Leish, and both figure and landscape work began to be shown in which there was evidence of greater freedom and originality.

Meanwhile the Photographic Society of Great Britain had drifted away from its artistic starting-point, and had become chiefly absorbed in purely scientific and technical subjects. But the general apathy which existed in respect of the artistic aspirations of some workers was the forerunner of a period of renaissance which was to end in lifting the pictorial side of photography into a greatly improved position. In 1886 Dr P. H. Emerson read before the Camera Club a paper on "Naturalistic Photography," which served as an introduction to the publication (1887) of his book under that title. Unquestionably this book struck a powerful blow at the many conventionalities which had grown up in the practice of photography, the chief doctrines set forth being the differentiation of focus in different planes, a more complete recognition and truer rendering of "tone," a kind of truthful impressionism derived from a close study and general acquaintance of nature, and a generally higher and more intellectual standard. After the publication of a second edition in 1889, Dr Emerson publicly renounced the views he had published, by issuing in January of 1891 a bitterly-worded, black-bordered pamphlet, entitled *The Death of Naturalistic Photography*. But the thoughts which the book had stirred were not to be stilled by its withdrawal. Towards the end of the same year the conflict which within the Photographic Society had become apparent as between the pictorial enthusiasts and the older school, culminated in connexion with some matters respecting the hanging of certain photographs at the exhibition of that year, and a number of prominent members resigned their membership as a protest against the lack of sympathy and the insufficient manner in which pictorial work was represented and encouraged. This secession was to prove the most important event in the history of that branch of photography. The secessionists being among the most popular contributors to the annual exhibition, gathered round them numerous sympathizers. In the following year they formed themselves into a brotherhood called "The Linked Ring," and in 1893 held their first "Photographic Salon," at the Dudley Gallery, Piccadilly. This has since been held annually, exclusively for the public exhibition of such photographs as in the opinion of the responsible committee give evidence of personal artistic feeling. The most noteworthy of the early adherents attracted to the new body was James Craig Annan, whose work was practically unknown until he exhibited it at the first Salon, and almost at once he, by general consent, took a position amongst pictorial photographers second to none (see Plate).

Aroused into greater activity by these events, the Royal Photographic Society began to pay more attention to what had now become the more popular phase. At subsequent exhibitions the technical and scientific work was hung separately from the "Art Section," and a separate set of judges was elected for each section. It became the custom to allot by far the greater amount of space to the "artistic"; and later, artists were elected as judges, by way of encouraging those who were devoted to the pictorial side to send in for exhibition. In the autumn of 1900 the New Gallery was secured, and a comprehensive exhibition of all phases of photography was held; and the experiment proving successful, it was repeated in the following year.

It is interesting to note that as a distinct movement pictorial photography is essentially of British origin, and this is shown by the very gratifying manner in which organized photographic bodies in Vienna, Brussels, Paris, St Petersburg, Florence, and other European cities, as well as in Philadelphia, Chicago, &c., following the example of London, have held exhibitions on exactly similar lines to those of the London Photographic Salon, and have invited known British exhibitors to contribute. The international character of the "Linked Ring" encouraged an interchange of works between British and foreign exhibitors, with the result that the productions of certain French, Austrian, and American photographers are perfectly familiar in Great Britain. This, in the year 1900, led to a very remarkable cult calling itself "The New American School," which has been very widely exploited in England. The prints have a certain generic similarity, but are the work of some forty or fifty photographers in the United States of America. In their total disregard of the qualities which even the least conventional person is accustomed to expect in a photograph, the extreme seems to have been reached, and this, moreover, in the nature of the subjects chosen, as well as in the composition adopted. It is a question whether, in the suppression of detail, in the toning down of contrasts, and in the attempt to invest the photographic "picture" with a mystery that may appeal to the spectator by mere suggestion rather than by representation, some of the American works contain sufficient to inspire imagination. Nevertheless, the intense earnestness and serious purpose which pervade the whole as a class, command respect. Moreover, if the doctrine of the "artist-photographer" be true, there are present in the "New American School" the very conditions which should lead it to mark a period and an advance. Many of its members are trained painters and successful art students, who have taken up photography not as an aid to art work, but as an independent means of possible artistic expression; as a consequence, they have employed photographic means with entire indifference to the instructions of the chemist and the rules of the technical expert. That the "New American School" has had a powerful influence on contemporaries in Great Britain there are already clear indications.

In this review of the principal successive influences which have been brought to bear upon and have built up the pictorial photography of to-day, we have now reached the close of the 19th century, and it may be well to glance at such improvements of process or apparatus as have not been direct and essential means to pictorial advance, but rather modifications and improvements made in response to the requirements of the artistic aspirant. Such improvements are of two orders—those which are devised with the aim of securing greater accuracy of delineation, the correction of distortion and of apparent exaggeration of perspective, and the more truthful rendering of relative values and tones; and those which seek to give the operator greater personal control over the finished result. While during the past few years great advances have been made in photographic optics, it cannot be said that pictorial work has been thereby materially assisted, some of the most successful exponents preferring to use the simplest form of uncorrected objective, or even to dispense with the lens altogether, choosing rather to employ a minute aperture, technically called a "pinhole." This is but one example of many which might be quoted to bear out the statement, that in photography the advance of anything in the nature of artistic qualities has not been correlative with mechanical improvements. The hand camera can only be said to have had an indirect influence: it has increased the photographer's facilities, and by removing the encumbrance of heavy tools has widened his sphere of operations; but it is perhaps in connexion with the plates and printing processes that more direct advantages have been gained. The fact that the actinic power of colours is not proportional to their luminosity, was long regretted as an obstacle to correct representation, but by the introduction of orthochromatic or isochromatic plates in 1886 (when B. J. Edwards bought the Tailfer and Clayton patent, under which he shortly brought out his orthochromatic plates) this original disability was removed, while with increased rapidity in the isochromatic plate colour values may still further be corrected by the use of coloured screens or light filters, without interfering with the practicability of making sufficiently rapid exposures for most subjects. Again, by a better knowledge of what is required in artistic representation, certain modifications in the formulated treatment of ordinary and uncorrected plates are found to do much towards removing the evil; hence, with an ordinary plate "backed" so as to counteract over-exposure of the higher lights, an exposure may, except in extreme cases, be given of length sufficient to secure the feeble rays of the less actinic colours, and by subsequent suitable development a result hardly distinguishable from that of a colour-corrected plate may be secured. Chemical experiment has placed in the photographer's hands improved and easier means of entire, unequal, and local intensification and reduction, but utility of these is restricted. By the artistic worker it is claimed that the lens and camera are but the tools, and the negative the preliminary sketch or study, the final print standing to him in the same relation as the finished painting does to the artist. In the production of the print various means of personally controlling the formation of the image have been resorted to. Thus the local development of platinotype by means of glycerine has its champions, but it seems to have been little used, its resuscitation being chiefly due to two or three prominent workers in New York. Here should also be mentioned the revival in 1898 of rough-surface printing papers, chiefly those sensitized with silver, the roughest texture drawing papers being employed to break up the excessive sharpness of the photographic image, and by the superficial inequalities introducing the effect of luminousness to over-dark shadows and variety to blank whites. The almost forgotten process of Pouncy, and of Poitevin, now known as the gum bichromate process, was rehabilitated in 1894 by M. Rouille Ladeveze expressly to meet the needs of the pictorial worker. Perhaps the best results that have been achieved by it are those of M. Robert Demachy of Paris, though many English workers have used it with remarkable success. In it paper of any kind may be selected as the support. The power of the operator to modify the printed image to almost any extent, even to introducing and eliminating lights and shadows, and in other ways to depart widely from the image given by the negative, depends upon the fact that the coating of gum and pigment (which, being bichromatized, becomes insoluble in proportion as it is acted upon by light) holds the pigment but imperfectly, and yields it up upon a vigorous application of water. According, therefore, to its application or retention, the operator can lighten or deepen in tone any portion. Numberless variations of other methods, such as brush development and local toning or stopping, have been suggested with the same object. Other workers have shown that by dexterously shutting off and admitting the light to various parts of the negative whilst printing, the disposition of the lights and shades in the print can be modified to so great an extent as to alter the general contour of the scene. Examples of an original unaltered print, and one which has been thus modified, are shown in the accompanying Plate. Portions are shaded in by allowing the light to have access to the print, either through the negative—in which case the image, with all its details, prints more deeply—or by removing the negative, when the action of the light is to flatten and suppress both detail and contrast. Such a course opens up innumerable possibilities whereby contrasts may be intensified, shadows made light, and light areas shaded down. Latterly some few have resorted to extensive working on the negative, both on the back and on the film; drawing by hand is practised on the film to render too prominent features less obtrusive, and objects in the background are merged by an intricacy of lines and cross-hatching. Many of the results are very pleasing, although one hesitates to justify the means, however good the end. On the other hand, to exclaim for purity of method and the exclusion of extraneous aids is very like setting up an arbitrary standard no less unreasonable than those conventions against which pictorial photography has so long striven.

Photometry, Stellar.—In the earlier volumes (ninth edition) of this Encyclopædia was an article on PHOTOMETRY, CELESTIAL, which gives an adequate sketch of the history of stellar photometry down to about 1885. The three modern forms of instrument for measuring the *visual* brightnesses of the stars, there briefly described, may be called Zöllner's photometer, Pickering's meridian photometer, and Pritchard's wedge photometer. It is mentioned in a footnote that extensive catalogues of stellar brightnesses or "magnitudes" had just been published by Professor E. C. Pickering of Harvard, using the second of the above instruments, and by Professor Pritchard of Oxford, using the third; but as regards the first form it is stated in the text that "this ingenious form of photometer has enjoyed considerable reputation, but no astronomer has yet persevered in producing a complete 'uranometria' by its aid." This omission has since been repaired by the labours of the late E. Lindemann of the Pulkowa Observatory (*Photometrische Bestimmung der Grössenclassen der Bonner Durchmusterung*. St Petersburg, 1889), and by a more extended work at the Potsdam Observatory by Müller and Kempf (see *Public. Potsdam Observ.*, vols. ix. and xiii.). No mention is made in the article of photographic photometry, for the reason that such work had at that time scarcely been begun, or at any rate had attracted very little attention. There is also a third method by which a star's radiance may be assessed, by measuring the amount of heat, or more properly, energy, which it conveys; and though the delicate apparatus of Mr C. V. Boys (*Proc. Roy. Soc.* April 1890) has furnished us so far with a negative result, even this is of considerable importance. In the present supplementary article it is proposed to describe rather more fully the three visual photometers mentioned above, to summarize what has been done in photographic photometry and with the "radio-micrometer," and to give a brief discussion of the effect of "colour" on all such determinations.

Pickering's meridian photometer.

Pickering's meridian photometer (see *Ann. Astron. Obs. Harv.*, vols. xiv. and xxiii.) consists of two telescopes placed side by side pointing due east, the light from stars on the meridian being reflected into them by two mirrors inclined at an angle of 45° to this direction. If there were a star exactly at the Pole, one of these mirrors would be absolutely fixed and would constantly reflect the light of this star down the axis of its telescope; in practice a slight motion can be given to the mirror so as to keep in view the polar star selected, whether Polaris, with which the brighter stars were compared, or λ Ursæ Minoris, which was used for fainter stars. The second mirror (which projects a little beyond the first so as to get an unobstructed view of the meridian) can be rotated round the axis of the telescope by means of a toothed-wheel gearing, and can thus be made to reflect any star on the meridian down the second telescope; it is also provided with a small motion in the perpendicular direction, so as to command a degree or two on each side of the meridian. Near the common eyepiece of the telescopes there is a double image prism which separates the light received from each into two pencils; the pencil of ordinary rays from one object-glass is made to coincide with that of extraordinary rays from the other, and the two remaining pencils are excluded by a stop. The two coincident pencils then pass through a Nicol prism to the eye of the observer, who by rotating the prism round its axis can equalize them at a definite reading depending on their relative intensities. This reading gives in fact the difference of magnitude between the two stars selected for comparison. It may be remarked that the position of the double image prism is important. It should be just *within*, not *at*, the common focus: this position prevents any noticeable colour in the images, and gives the ordinary and extraordinary pencils a sufficient separation at the eye-stop to permit the entire exclusion of one without the loss of any part of the other. If the prism were exactly at the focus, and any part of the superfluous images were admitted, the resulting secondary images would coincide with the others and thus lead to errors in observing. But in the actual construction of the instrument the secondary images would appear, if at all, only as additional stars near those under observation, and too faint to produce any inconvenience. It is worthy of note that Professor Pickering has extended his survey into the southern hemisphere, so that the Harvard photometry is the most complete of all. Each observation consists of four comparisons; after the first two the observer reverses the position of the star images in the field, and also reverses the double-image prism. The former precaution is necessary in order to eliminate a curious error depending on the relative position of the images, which may amount to several tenths of a magnitude. Errors of this kind affect *all* estimations of the relative brightness of two stars in the same field, as has been repeatedly shown; a striking instance is given by Mr A. W. Roberts of Lovedale, South Africa (*Mon. Not. R.A.S.*, April 1897), who found that his eye-estimations of the brightness of variable stars required a correction depending on the position-angle of the comparison star ranging over nearly two magnitudes.

Zollner's photometer.

In Zöllner's instrument an artificial star is taken as the standard of comparison. There is only one telescope, and inside the tube near the eye end is a plate of glass placed at an angle of 45° with the axis, so that the rays from a lamp which enter the tube from the side are reflected down the tube to the eyepiece, while the light from the star passes through the plate unobstructed. The lamplight passes through a Nicol prism and a plate of rock crystal, which give control over the colour; through two Nicols which can be rotated round the axis of the beam to definite positions read off on a graduated circle; and then through a convex lens which forms an image reflected by the glass plate to focus alongside the star. The whole of this apparatus is carried in a compact form on the eye end of the telescope, it being arranged that the lamp shall always stand upright. The measures are made by rotating the Nicols until the brightness of the artificial star is equal to that of the star viewed through the object-glass, and reading the graduated circle.

The wedge photometer.

With regard to Pritchard's wedge photometer, the principle of which was sufficiently described in the *Ency. Brit.*, vol. xviii. p. 841, two material improvements suggested by Dr E. J. Spitta are worthy of notice. The first (*Proc. Roy. Soc.*, Dec. 1889) corrects a slight defect in the form of the instrument. If a pencil of rays passes through a thin wedge of tinted glass, the rays do not all pass through the same thickness of glass. Dr Spitta proposes to substitute a pair of wedges with their thicknesses increasing in opposite directions. By sliding one over the other we obtain a parallel plate of glass of varying thickness, and a uniform beam of light of sensible dimensions can then be extinguished satisfactorily. He has also pointed out a source of error in the method of "evaluating" the wedge and shown how to correct it. The scale value was determined by Professor Pritchard by the use of a doubly refracting prism of quartz and a Nicol prism. Using this method subsequently, Dr Spitta found that internal reflections within the Nicol prism interfered with the accuracy of the result, but that this error could be eliminated by using a suitable diaphragm (see *Mon. Not. R.A.S.*, March 1890; Abney, *Ibid.*, June 1890).

The Purkinje phenomenon.

Since 1885 systematic catalogues of stellar brightness have been constructed with all these instruments, and it has been of great interest to compare the results. The comparison has in general shown a satisfactory agreement, but there are small differences which are almost certainly systematic, due to the difference of method and instrument. One cause of such differences, the reality of which is undoubted, but the effects of which have as yet not been perhaps fully worked out, is the "Purkinje phenomenon" (*Pflüger's Archiv*, vol. lxx. p. 297, and *Psychol. Rev.*, vols. v. and vi.). If a blue source of light and a red source appear equally bright to the eye, and if the intensity of each be diminished in the same ratio, they will no longer appear equally bright, the blue now appearing the brighter; in more general terms, the equalizing of two differently coloured lights by the eye depends upon their intensity. It is clear that this phenomenon must affect all photometric work unless the stars are all exactly of the same colour, which we know they are not. For let us suppose that both the comparison star of the meridian photometer and the artificial star of the Zöllner photometer were equalized with a bright star A, and that they could be also compared *inter se* and found equally bright. Then when a faint star B comes under observation and the intensities of the comparison stars are both reduced to equality with B, they will no longer appear equal to one another unless they are exactly the same in colour. In other words, the observed ratio of intensities of A and B will vary with the colour of the comparison star, and similarly it will also vary with the aperture of the telescope employed. To allow for this variation by direct observation would entail a large amount of work which is yet to be undertaken—the exact evaluation of the colours of stars (or at least of the comparison stars) and the effect on the eye with different intensities. It is not impossible to undertake such a detailed investigation, and so calculate the differences between the two methods, but it would be extremely laborious, and we rather look to observed differences between the results to indicate the magnitude of these effects, the general nature of which is well understood.

One complete set of numerical results has, however, been obtained by Sir W. Abney (*Proc. Roy. Soc.*, May 1891, and *Mon. Not. R.A.S.*, April 1892), viz., the limiting intensity at which each pure colour vanishes. If we start with lights C D E F G of the colours usually denoted by these letters in the spectrum, and each so bright that it appears *to the eye* as bright as an amyl-acetate lamp at 1 foot, and if then the intensity of each be gradually diminished, the C light will disappear when the original intensity has been reduced to 22,000 ten-millionths of the original value. The other colours will disappear at the following intensities, all expressed in ten-millionths of the original: D at 350, E at 35, F at 17, and G at 15. If then we had a mixture of two lights, one of C colour as bright as before, and the other of G colour 1000 times fainter (a combination in which the eye would be unable to distinguish the G light at all), and if we continually reduced the combined intensity, the luminosity of the C light would diminish so much more rapidly than that of the G that the latter would begin to assert itself, and when the combined intensities were reduced to 22,000 ten-millionths of the original value, the C light would have all disappeared, while the G light would not. Hence the colour of the light would appear pure violet, though it was originally deep red. This extreme case shows that the "last ray to disappear" when a light is gradually extinguished may be very different in colour from that of the original light, and when more usual light-mixtures are considered, such as those of sunlight and starlight, which appear nearly white to the eye, the "last ray to disappear" is found to be in the green, very near E in the spectrum. This result has two important bearings on the use of the wedge photometer. In the first place, either the wedge itself should be of a greenish hue, or green light should be used in finding the scale-value (the constant B in the formula $m = A + Bw$). In the second, star magnitudes obtained by extinction with the wedge will agree better with those obtained by photography than those obtained with other visual photometers, since photographic action is chiefly produced by rays from E to G in the spectrum, and the E light of ultimate importance with the wedge photometer is nearer this light in character than the D light with which other photometers are chiefly concerned. It would also appear that results obtained with the wedge photometer are independent of the aperture of telescope employed, which is not the case with other photometers.

Passing now to the consideration of photographic methods, it is found that when a plate is exposed to the stars, the images of the brighter stars are larger and blacker than those of the fainter ones, and as the exposure is prolonged the increase in size and blackness continues. Much of the light is brought to an accurate focus, but, owing to the impossibility of perfect achromatism in the case of refractors, and to uncorrected aberration, diffraction, and possibly a slight diffusion in both refractors and reflectors, there are rays which do not come to accurate focus, grouped in rings of intensity gradually diminishing outwards from the focus. As the brightness of the star increases, or as the time of exposure is prolonged, outer and fainter rings make their impression on the plate, while the impression on the inner rings becomes deeper. Hence the increase in both diameter and blackness of the star discs. As these increase concurrently, we can estimate the magnitude of the star by noting either the increase in diameter or in blackness, or in both. There is consequently a variety in the methods proposed for determining star magnitudes by photography. But before considering these different methods, there is one point affecting them all which is of fundamental importance. In photography a new variable comes in which does not affect eye-observations, viz., the time of exposure, and it is necessary to consider how to make due allowance for it. There is a simple law which is true in the case of bright lights and rapid plates, that by doubling the exposure the same photographic effect is produced as by increasing the intensity of a source of light twofold, and so far as this law holds it gives us a simple method of comparing magnitudes. Unfortunately this law breaks down for faint lights. Sir W. Abney, who had been a vigorous advocate for the complete accuracy of this law up till 1893, in that year read a paper to the Royal Society on the failure of the law, finding that it fails when exposures to an amyl-acetate lamp at 1 foot are reduced to $0^s{\cdot}001$, and "signally fails" for feeble intensities of light; indeed, it seems possible that there is a limiting intensity beyond which *no* length of exposure would produce any sensible effect. This was bad news for astronomers who have to deal with faint lights, for a simple law of this kind would have been of great value in the complex department of photometry. It is satisfactory to know that the law holds in certain important cases. The Astronomer Royal found in 1892 (*Mon. Not. R.A.S.*, January 1892) that it was sensibly correct for stars to the eleventh magnitude photographed according to the methods adopted for the International Astrographic Chart, although Dr Scheiner of Potsdam had previously found a very serious deviation in a similar case. Just where it begins to fail seems to be dependent on a variety of circumstances. Sir W. Abney has remarked that it is important not to use bromide plates, for instance, and there is no doubt that caution must be exercised in applying the law to the faintest star images on a plate—those just discernible as discolorations of the film. But with plenty of light (*i.e.*, a large telescope) and a rapid plate we should be able to compare the magnitudes of two stars by the ratio of the exposures required to give similar images both in size and blackness. If the approximate ratio is known, we may obtain the exact ratio by varying the exposure of one star slightly, and noting which of the series most closely resembles the other star.

Photographic photometry.

But there are many cases where it is inconvenient to give more than one exposure to a field of stars, and the question arises how to compare their magnitudes from their size or (and) blackness on a photographic plate. The easiest quantity to measure is the diameter of the image, and when measurements of position are being made with a micrometer, it is a simple matter to record the diameter as well, in spite of the indefiniteness of the border. Accordingly we find that various laws have been proposed for representing the magnitude of a star by the diameter of its image, though

Diameter as test of magnitude.

these have usually been expressed, as a preliminary, as relations between the diameter and time of exposure. Thus Bond found the diameter to increase as the square of the exposure, Turner as the cube, Pritchard as the fourth power, while Christie has found the law that the diameter varies as the square of the logarithm of the exposure within certain limits. There is clearly no universal law—it varies with the instrument and the plate—but for a given instrument and plate an empirical law may be deduced. Or, without deducing any law at all, a series of images may be produced of stars of known brightness and known exposures, and, using this as a scale of reference, the magnitudes of other images may be inferred by interpolation. A most important piece of systematic work has been carried out by the measurement of diameters in the Cape Photographic Durchmusterung (*Ann. Cape Obser.*, vols. iii. and iv.) of stars to the tenth magnitude in the southern hemisphere. The measurements were made by Professor Kapteyn of Gröningen, on photographs taken at the Cape of Good Hope Observatory; he adopts as his purely empirical formula

$$mag = \frac{B}{\text{diameter} + C}$$

where B and C are obtained independently for every plate, from comparison with visual magnitudes. C varies from 10 to 28, and B from 90 to 260. The part of the sky photographed was found to have an important bearing on the value of these constants, and it was in the course of this work that Kapteyn found a systematic difference between stars near the Milky Way and those far from it, which may be briefly expressed in the law, *the stars of the Milky Way are in general bluer than the stars in other regions of the sky.* It is intended, however, in the present article to discuss methods rather than results, and we cannot here further notice this most interesting discovery.

Of methods which choose the blackness of the image rather than the diameter for measurement, the most interesting is that initiated independently by Pickering at Harvard and Schwarzschild at Vienna, which consists in taking star images considerably out of focus. The result is that these images no longer vary appreciably in size, but only in blackness or density; and that this gradation of density is recognizable through a wide range of magnitudes. On a plate taken in good focus in the ordinary way there is a gradation of the same kind for the faintest stars; the smallest images are all of approximately the same size, but vary in tone from grey to black. But once the image becomes black it increases in size, and the change in density is not easy to follow. The images-out-of-focus method seems very promising, to judge by the published results of Dr Schwarzschild, who used a prepared comparison scale of densities, and interpolated for any given star from it. The most satisfactory photographic method would certainly be to take account of both size and blackness, *i.e.*, to measure the total deposit in the film; as, for instance, by interposing the whole image in a given beam of light, and measuring the diminution of the beam caused by the obstruction. But no considerable piece of work has as yet been attempted on these lines.

Images out of focus.

Although rather outside the domain of photometry, strictly so called, a word or two may be said here about the "radio-micrometer" of Mr C. V. Boys. This is an extremely delicate instrument for measuring radiant heat, which consists of a very light thermo-electric circuit (two tiny bars of antimony and bismuth soldered together at one edge, the outer edges being connected by a hoop of copper wire) suspended by a quartz fibre (a torsion fibre of the very greatest sensitiveness) in a strong magnetic field. A minute quantity of radiant heat falling on one of the junctions of the circuit sets up a current in the circuit, which thus rotates in the magnetic field until brought to rest by the torsion of the fibre. For use on the heavenly bodies the radiant heat is collected to focus by a reflecting telescope (an object-glass would absorb it), and when the telescope is pointed to the moon the varying radiation from different parts of the disc is beautifully shown. No heat comes from the unlit portion, and of the illuminated portion the maximum is obtained from near the limb. But when pointed to the brightest stars no indications are obtained, although the instrument is sensitive enough to detect the heat from a candle more than a mile off. It seems certain that indications of heat from the stars obtained by previous observers must be spurious. We may place alongside this result that obtained by Mr W. J. Dibdin (*Proc. Roy. Soc.*, April 1892), who compared candle-light with twenty-one stars ranging to the sixth magnitude, and found the light of a second magnitude star equal to that of ·0075 of a candle at 109 feet, or of a whole candle at 1260 feet.

No heat from the stars.

The whole domain of stellar photometry has increased in importance and in activity so rapidly since 1885 that much has necessarily been omitted in this sketch. As an instance of new applications of its methods, we may quote the systematic observations of the eclipses of Jupiter's satellites by Pickering at Harvard. Instead of merely noting the instant of disappearance or reappearance of the satellite, he has organized a regular series of measurements of the diminution of its light, both by visual and photographic observations. The result has been to determine the moment of disappearance with greatly increased accuracy; some of the observations were placed in the hands of Prof. Sampson of Durham, who is of opinion that they will afford sufficient material for forming new and improved tables of Jupiter's satellites. The photometric work done at the Harvard Observatory alone since 1885 probably far exceeds all that was done previously. As an instance again of the novelty of results now being obtained, attention may be called to the fact, discovered also at Harvard, that in certain clusters there are numerous variable stars. In the cluster M_5, for instance, Mr S. I. Bailey finds that about eighty-five stars are variable, and that their variations show a striking similarity (*Astrophys. Journ.*, November 1899). Each goes through its cycle in about twelve hours; each begins by a gradual diminution of light, remains at half brightness for a time, and then suddenly springs back to maximum again. We seem to be only beginning to understand the vast scope of photometric work. (H. H. T.)

Phrenology.—Gall's great work on phrenology (see the earlier volumes of this Encyclopædia, ninth ed.) contains a very considerable number of clinical and pathological observations that are of some value, though his deductive reasoning has failed to stand the test of time; and an attempt has lately been made to bring phrenology back into good repute, and to show that Gall's doctrines are confirmed by the modern physiological and pathological facts concerning cerebral localization. This attempt to advance phrenology to the level of the natural sciences may be studied in the volume published in 1901 by Dr Bernard Holländer, entitled *The Mental Functions of the Brain*, and bearing as a sub-title *The Revival of Phrenology.* Two chief doctrines are involved in the acceptance of phrenology, in the ordinary sense of the word. They are: i. That the outer table of the skull is so finely and accurately modelled to the surface of the brain that it is an exact copy of that surface. ii. That the grey matter on the surface of the brain is divided into thirty or more departmental regions, corresponding to certain universal habits, passions, propensities, and the like activities of consciousness. The first of these doctrines, the old belief in craniology and in "bumps," is lightly passed over by Dr Holländer. It stands in the way of every attempt to make phrenology an exact science. The varying thicknesses of different skulls, and of the same skull in its different parts, the existence of air-spaces in the frontal bone, and the mere features of the skull, which may fairly be called matters of chance, offer a fatal objection to popular phrenology; and Dr Holländer's purpose is not, primarily, to uphold popular phrenology, but to bring Gall's clinical and pathological instances into line with more modern observations. He deprecates the craniology of Gall, and honours him, with justice, as an admirable and dexterous anatomist; he calls attention to many carefully recorded clinical and pathological facts that are scattered through Gall's writings and are worth saving out of the wreck of his system; and he endeavours, by this method, to establish an unbroken connexion between phrenology, in the Greek sense, and our present knowledge of cerebral localization.

The substance of Holländer's work is of two kinds. The one kind is a tabulated statement of many hundred cases of different forms of mania, with injury or disease limited to one portion of the brain; the other kind is a tabulated statement of cases of injury or disease of the brain, followed by perversion, or exaltation, or loss of some definite instinct or faculty of consciousness.

He divides the tabulated cases of mania into three groups: i. Melancholia; ii. Irascible Insanity, "Mania Furiosa"; iii. Mania with suspicion and delusions of persecution. For these three groups of cases he lays down the following rules: i. Melancholia is especially associated with injury or disease of the parietal lobe of the brain, more particularly with injury or disease of the convolutions underlying the parietal eminences of the skull, *i.e.*, the supramarginal and angular convolutions. ii. Mania Furiosa is especially associated with injury or disease of the central portion of the temporal lobe. iii. Mania with suspicion and delusions of persecution is especially associated with injury or disease of the posterior portion of the temporal lobe.

The second kind of cases, where injury or disease of the brain, strictly localized to one part or another of its grey matter, was followed by perversion, exaltation, or loss of some one instinct, habit, or faculty, includes cases of kleptomania, cases of voracious hunger and thirst, cases of sexual desire exalted or lost, and cases of loss of certain special memories, as of words, tunes, numbers, and the like.

These two collections of recorded cases, taken from a vast mass of clinical and pathological literature accumulated during the past century, have been arranged by Dr Holländer with great industry; and they clearly express his purpose to extend the limits of the study of cerebral localization, and to advance it from the observation of the motor areas and the special sense centres to the observation of the higher acts and states of consciousness. This, we may be sure, is the tendency of all modern researches into the working of the central nervous system: to seek a higher level of interpretation, and a statement of the departmental life of the brain in terms of ever-increasing complexity. Physiology, from its objective point of view, is engaged over finer and finer issues of microscopic and experimental work; and, from its subjective point of view, is becoming more and more psychological. The motor centres, governing the voluntary purposeful movements of the body, are not simply motor, but "psycho-motor"; the speech-centres are not homogeneous, but are differentiated into sub-centres for the utterance of words, the recognition of words, and the understanding of words; the visual centres are in like manner subdivided according to the consciousness involved in the complete act of vision. There is room, therefore, for a "higher phrenology," if it can show clear evidence in favour of the localization, in determinate regions of the brain, of the physical changes accompanying certain states of consciousness.

Of the two kinds of cases that Dr Holländer has tabulated, it cannot be said that the cases of mania are convincing. Some of them are altogether beside the mark; *e.g.*, he quotes two cases of melancholia, after an injury over the left parietal bone, which were cured by an operation limited to the scalp (excision of a painful scar, removal of a small nerve-tumour of the scalp); in neither case was anything done to the skull or to the brain, but both patients were cured of their melancholy. Again, the acceptance of these rules as to the localization of these insane thoughts involves the localization of sane thoughts in the same areas of the brain, and this in turn involves assumptions that are wholly unwarranted by our present knowledge. Moreover, cases of mania are so common that it might be possible to find an equal number of cases to controvert his rules: we want *consecutive*, not *picked* cases. If 5000 consecutive fatal cases of these different kinds of mania, with the *post-mortem* record of each case, were tabulated, we should then begin to stand on surer ground. Again, though Dr Holländer seems to argue well, where he says that the facial and other movements, induced by direct electrical stimulation of certain convolutions, are such as express the mental states which he attributes to those convolutions, yet this argument is insecure, partly because Sherrington's recent work, on the motor area of the anthropoid apes, has rendered it necessary to reconsider the present localization of the motor area in man, and partly because the interpretation of facial and muscular movements as representing this or that state of the emotions is always in danger of fallacy. Altogether, these doctrines as to the cerebral areas involved in the chief forms of mania fail of their effect. They suggest many subjects worthy of consideration and of future study, but they make no solid contribution to physiology.

The second kind of cases, where injury or disease limited to one portion of the brain is followed by perversion, exaltation, or loss of some special instinct or habit, is more valuable and more convincing; especially the cases of voracious hunger and thirst, those of true kleptomania, and those of the loss of certain special memories. It is not so easy to believe that the cerebellum is in any primary way associated with sexual desire: its position, its structure, and its proved association with the co-ordination of muscular movements, seem clearly to indicate that its work is wholly subordinate and complementary to the work of the cerebral hemispheres; and the evidence adduced in favour of its being the "seat" of the sexual impulses hardly amounts to more than a probability that it may transmit or co-ordinate the performance of the sexual act.

We come to this conclusion, that phrenology is seeking to rehabilitate itself by an alliance with physiology; and that it is encouraged to take this step by the fact that physiology, in its interpretation of the central nervous system, is becoming more and more psychological. The old idea, that the brain "moves as a whole," has passed away; and the principles of cerebral localization are, after all, only a scientific statement of matters that are of general belief. We are all more or less phrenologists. Every time that a man apologizes for this or that defect in his mind, and for his "curta supellex," he appeals to a purely local weakness of his brain. "I have no ear for music—I have no memory for dates"—these common excuses are direct appeals to the doctrine of the differentiation of the work of the brain. And, as though it were to justify these appeals, physiology is beginning to feel its way forward from the localization of muscular movements and special sense-centres to the localization of the simpler faculties and instincts: working, not as Gall worked, by deduction and guess, but by induction; yet it may find a use for the clinical and pathological facts that are worth rescuing from the downfall of Gall's phrenological system.

Phylloxera, a genus of insects belonging to the family of Aphidæ, or Plant-lice, in the order Homopterous Hemiptera. It is chiefly known from the causal relation of one of its species to the most serious of vine-diseases. The name (Gr. φύλλον ξηρόν) was first given in 1834 to a plant-louse which was observed to "dry up the leaves" of oaks in Provence. About twenty-seven species are now known, all characterized by length not exceeding ·06 of an inch, flat wings, three articulations in the antennæ, one or two articulations in the tarses, with digitules, but without cornicles on the abdomen. A full description of the only species which attacks the vine, the *Phylloxera vastatrix*, or grape-louse, will be found in the earlier volumes of this Encyclopædia (ninth edition, vol. xxiv. p. 239).

The insect has a curious life-history, which may here be briefly repeated. It first appears as a minute louse (about $\frac{1}{30}$ inch in diameter) which lives on the roots of the vine. These root-forms are all parthenogenetic females, and spend their short life in sucking the juices of the vine and laying eggs, which hatch into similar forms, each of which attaches itself to the root in a suitable spot and proceeds to lay eggs. They are so prolific that a single individual might have twenty-five million descendants in six months. As the summer advances, some of the eggs of the root-forms give birth to winged females, which are capable of transporting the disease by flight over distances of many miles.

These winged females—still parthenogenetic—lay eggs which produce wingless males and females. Their brief life is wholly devoted to sexual reproduction, whereby new vitality is given to a race that would gradually die out if confined to parthenogenesis. The female lays a single egg—the so-called "winter-egg"—which remains in the crevices of the vine-bark without development through the cold weather, and gives birth in spring to a "stock-mother," closely resembling the original root-form. This creature forms a gall in the young leaf, within which it produces a large number of eggs, some of which form new galls and multiply in the leaves, whilst others crawl down to the roots and become root-forms, with which the cycle recommences. Attacked both in its leaves and roots, and deprived thus of its fair nutriment, the vine which is once infested with these rapidly multiplying pests slowly withers away, being stunted in its growth, discoloured in its leaves, and bearing imperfect grapes which do not ripen. In a year or two the vine dies.

The particular species of phylloxera which attacks the vine is a native of the United States, probably originating among the wild vines of the Colorado district. It was first observed in 1856 by Asa Fitch, who had no suspicion of its evil nature, and called it *Pemphigus vitifoliæ*. In 1863 it was independently discovered by Westwood in an English vinery at Hammersmith; he was ignorant of Fitch's observation, and called it *Peritymbia vitisana*. From 1858 to 1863 there were many importations of American vines for grafting purposes to Bordeaux, Roquemaure, and other parts of France, England, Ireland, Germany, Portugal, &c. It is practically certain that the deadly phylloxera was imported on these plants. A year or two later certain vine-growers in the South of France began to complain of the new vine-disease. M. Delorme of Arles, in 1865, appears to have been the first who recognized its novelty and had a presentiment of disaster. The disease steadily spread outwards in concentric circles from its first place of lodgment near Roquemaure. Within two or three years whole departments were infested. In 1866 a second centre of infection made its appearance near Bordeaux. The vine-growers were at their wits' end to account for this new plague, which threatened to be even more costly than the oïdium. The completeness of the ruin which threatened them may be illustrated by the statistics for a single commune, that of Graveson, whose average annual production of wine in the years 1865–67 was about 220,000 gallons. In 1868 this fell to 121,000 gallons, in 1869 to 48,400 gallons, in 1870 to 8800 gallons, and by 1873 to 1100 gallons.

In 1868 Planchon proved that the disease was due to a new species of phylloxera which was invariably found on the roots of the affected vines, and to which he accordingly gave the prophetic name of *Phylloxera vastatrix*. During the next ten years a series of students, of whom only Riley and Balbiani need be mentioned here, worked out the natural history of *Phylloxera vastatrix*, and proved its identity with the American grape-louse. Its devastations rapidly assumed gigantic proportions. In France, where the disease was by far the most prevalent—owing in great part to the obstinacy with which the vine-growers at first refused to take any reasonable precautions against its spread—M. Lalande, President of the Chamber of Commerce at Bordeaux, in 1888 calculated the direct loss to the country by the phylloxera at 10 milliards (£400,000,000), or double the indemnity which had been paid to Germany in 1871! Nearly three million acres of vineyards had then been destroyed. In the Gironde, where the phylloxera first became serious about 1877, the mean annual production of wine in 1876–85 was reduced by more than twenty-six million gallons. In the Côte d'Or the phylloxera appeared in 1878, and the annual crop at once declined from thirty-four to eleven million gallons. The effect of the phylloxera in France was to diminish the wine-crop by about one-half, while in certain parts—as in the Gironde from 1881 to 1887—the production of good wine was practically stopped altogether by the phylloxera and other pests, such as mildew.

The phylloxera has made its appearance in almost every vine-growing country in the world. Thus it appeared in Austria-Hungary in 1868; in Italy, in spite of the frantic efforts made—as in other countries—to keep it out by strict legislation against the import of vines, in 1879; in Russia in 1880; in Germany, on the Rhine and Moselle, and in Switzerland in 1872; in Madeira, Spain, and Portugal about 1876. The pest even crossed the oceans, and appeared in Australia, at Geelong, about 1880; it has since twice broken out in Victoria, and has ravaged the vineyards of South Australia and New South Wales. At the Cape, in spite of a long endeavour to prohibit the import of the phylloxera, it appeared about 1884. In 1885 it crossed the Mediterranean to Algeria. There was only one country where its ravages were long unimportant; that was its home in the United States, where the native vines had become, by the operation of natural selection, immune to its attacks. Yet no imported vine has ever lived there more than five years, and in 1890 the phylloxera crossed the Rocky Mountains, and seriously damaged the vineyards of California, where it had previously been unknown.

Three different methods of fighting the pest have been successfully adopted. One is to kill the phylloxera itself; another, to destroy it along with the infected vines, and plant fresh and healthy plants; the third, to adapt the secular therapeutics of nature, and to introduce American vines which a long acquaintance with the phylloxera has made immune to its ravages. Of the various plans adopted for killing the phylloxera, which included absurdities like burying live toads at the roots of the vines, or douching them with Lourdes water, few have survived. One consists in submerging the infected vineyard under water for at least forty days. This plan, introduced by M. Faucon of Graveson, is effective, but is clearly out of the question in the majority of vineyards, since, as Virgil said, *Vitis amat colles*. Yet large sums were spent in France on canals intended for this purpose, and much good was done in low-lying districts like those of the Gironde. Insecticides, of which the bisulphide of carbon (CS_2) and the sulpho-carbonate of potassium ($KSCS_2$) remain in use, were injected into the earth to kill the phylloxera on the roots of the vine. These methods were chiefly advocated in vineyards of the first class, where it was worth while to spend a good deal of money and labour to preserve the old and famous vines: the Château Leoville Poyferré and Clos Vougeot are instances. Some good judges attribute the peculiar and not unpleasing flavour of certain clarets of 1888 to means thus adopted to kill the phylloxera. The second plan was largely adopted in Switzerland and on the Rhine, where measures resembling those taken with cattle suspected of anthrax were applied to all diseased vineyards. The third plan, which consists in replanting the affected vineyard with American vines—such as the *Vitis labrusca*, *V. riparia*, *V. rupestris*, or *V. monticola*—has proved the most generally successful.

The department of the Hérault, which produces more wine than any equal area in any part of the world, in 1899 contained 453,000 acres of vineyards, of which 445,435 were grafted on American stocks, and the wine-crop was larger than was the case before the phylloxera appeared. The French Department of Agriculture now "looks upon the phylloxera scare as a thing of the past, it having been successfully combated and beaten" by the introduction of American stocks. Thus the total wine-crop of France, which had fallen in 1894 from 1300 to 650 million gallons, rose again in 1899 to more than 1480 millions.

A very good bibliography will be found in *Les Insectes de la Vigne*, by Professor MAJET of Montpellier (1890), which is the best book on the subject. Reference may also be made to the classic memoirs of PLANCHON, culminating in *Les Mœurs de la Phylloxera de la Vigne* (1877); DREYFUS, *Ueber Phylloxerinen* (1889); LICHTENSTEIN, *Histoire du Phylloxera*; the *Rapports Annuels à la Commission Supérieure du Phylloxera*; and the excellent *Report on Phylloxera* drawn up by the Hon. J. W. TAVERNER (Victoria, 1899, No. 68).

(W. E. G. F.)

PHYSIOLOGY.

I. General.

EVER since men began to take a scientific interest in the problems of life, two distinct rival explanatory principles of vital phenomena have claimed attention: a natural and a mystical principle. The first outcome of the scientific attempt to explain vital phenomena after the natural method and by a unitary principle was the doctrine of the *Pneuma*, held by the followers of Hippocrates, which found its clearest expression in Galen's system. According to this doctrine, the origin of all vital phenomena was a very fine substance, the Pneuma, which was supposed to exist in atmospheric air, to be inhaled into the lungs of man, and thus through the blood to reach all the parts of the body, where it produced vital phenomena. This doctrine—an attempt to explain the phenomena of life which was not only altogether natural, but even materialistic—was accepted by the Middle Ages together with Galen's system. With its translation into the Latin *spiritus*, however, the conception of the Pneuma lost its original force. The *spiritus animales* of the Middle Ages developed ere long into mystical powers, the result being the explanation of vital phenomena by a supernatural theory. Not until the scientific Renaissance of the 16th and 17th centuries did views again undergo a change. After the establishment of a scientific method in physiology by Harvey, and the development of Descartes' mechanical system of regarding living bodies, the natural explanation of vital phenomena once more universally found favour. Two schools arose, which endeavoured by dissimilar methods to find a mechanical explanation of vital phenomena: the *iatrophysical*, originating with the gifted and versatile Borelli, and the *iatrochemical*, founded by the Dutchman, Delbœ Sylvius. But when both chemical and physical methods of explanation failed at such problems as, for instance, irritability and evolution, another change in opinion took place. By degrees there emerged once more the tendency to explain vital phenomena by mystical means, finding expression in the *Animism* of Stahl, to quote an example; and in the second half of the 18th century *Vitalism*, originating in France, began its victorious march throughout the whole scientific world. Again the opinion came to be entertained that the cause of vital phenomena was a mystical power (*force hypermécanique*)—that "vital force" which, neither physical nor chemical in its nature, was held to be active in living organisms only. Vitalism continued to be the ruling idea in physiology until about the middle of the 19th century, and its supremacy was only gradually overthrown by the great discoveries in natural science of that century. The chemical discoveries resulting from Wöhler's synthesis of urea first showed that typical products of the animal body, the production of which had hitherto been supposed to be solely the result of the operation of vital force, could be obtained artificially by purely chemical methods. Then above all came the discovery of the law of the Conservation of Energy by Robert Mayer and Helmholtz, and its application to the living organism by Mayer, Helmholtz, Dulong, Frankland, Rubner, and others, to prove that the manifestations of energy by the organism are simply the result of the quantity of potential energy received into the body by means of food. Finally, the stupendous results arrived at by Darwin and the establishment of the fundamental law of "biogenesis" by Haeckel, prepared the way for a natural explanation of the enigma of evolution and structure of organisms. Thus by the second half of the 19th century the doctrine of vital force was definitely and finally overthrown to make way for the triumph of the natural method of explaining vital phenomena, which down to the present time has continued to spread and flourish with an unparalleled fertility. It would, it is true, appear as if in our day, after the lapse of half a century, mystical tendencies were again disposed to crop up in the investigation of life. Here and there is heard once more the watchword of Vitalism. But all the so-called *neo-vitalistic* efforts (such as those of Bunge, Rindfleisch, Reinke, and others) have nothing to do with the older vitalism. They originate solely in a widespread confusion with regard to the boundaries of natural science, their principal tendency being to amalgamate psychological and speculative questions with problems of purely natural science. In the face of all these efforts, which by their unfortunate designations of Vitalism and Neo-vitalism give rise to entirely false conceptions, and which by their intermingling of psychological questions and questions of natural science have led to mere confusion in research, it is essential that natural philosophy should be called upon to realize its own limits, and above all clearly to understand that the sole concern of physical science is the investigation of the phenomena of the material world. Physiology, as the doctrine of life, must therefore confine itself to the material vital phenomena of organisms. It is self-evident, however, that only such laws as govern the material world will be found governing material vital phenomena,—the laws, that is, which have hitherto been brought to their most exact and most logical development by physics and chemistry, or, more generally speaking, by mechanics. The explanatory principles of vital phenomena must therefore be identical with those of inorganic nature—that is, with the principles of mechanics.

The problem of life.

Vitalism and Neo-vitalism.

The investigation of vital phenomena in this sense requires, in the first place, an exact knowledge of the substratum in which these phenomena are manifested, just as in chemistry and physics a thorough knowledge of the composition of the material world is a necessary premise to the investigation of the phenomena of inorganic nature. The knowledge of the composition and structure of organisms has in the course of the scientific development of anatomy attained to an ever-increasing minuteness of detail, without having as yet reached a definite limit. The last important step in this direction was the discovery by Schleiden and Schwann that all organisms are built up of elementary living structural components, namely, of cells. For the details of the anatomical construction of organisms, see Anatomy. We would here merely point out that a cell is the simplest particle of living substance which appears to be permanently capable of life. Different elements are essential, however, to the existence of the cell—two, at least, so far as has hitherto been discovered—the protoplasm and the nucleus. It must at present be regarded as at least very doubtful whether the *centrosome*, which in recent times it has been possible to demonstrate as existing in very many cells, and which appears sometimes in the protoplasm, sometimes in the nucleus, is a general and third independent cell-constituent. On the other hand, the number of special constituent parts which appear in various cell-forms is very large. A question which has long been discussed, and which has received special

Ultimate elements of life.

and animated attention, is that with regard to the finer structure of the cells—with regard, that is, to the protoplasm and the nucleus lying in it. Views on this subject have diverged very widely, and several totally diverse theories have been opposed to one another. One theory maintains that the living cell-substance has a reticular structure; another, that it is fibrillous. According to a third theory, the essence of the construction of the cell-substance lies in the granules which it contains; and according to a fourth, it lies in the ground-substance in which these granules are embedded. One view holds this ground-substance to be homogeneous, another regards it as possessing a fine foam-structure. It may at present be regarded as incontrovertible that living substance is more or less fluid, and that there does not exist any *general* structure for all cell-forms. But in some special cases all the theories which have been quoted are to a certain extent correct. In different cells there are reticular, fibrillous, and granular differentiations respectively, and differentiations in foam-structure; in many cells, however, the protoplasm appears to be beyond doubt homogeneous and without a distinct structure, and only under certain conditions to assume changing structures. But the fact which is of most importance for the right understanding of vital phenomena is that the cell-substance is always more or less fluid, for only in a fluid substratum can such intense chemical processes be enacted as are to be found in every living cell.

Where the analytical powers of the microscope in anatomy can go no farther, chemical analysis of the composition of the cell steps in. By its means the discovery is made that there is no *elementary* difference between organic and inorganic nature, for only such chemical elements as are known to exist in the inorganic world are found in the organic. On the other hand, however, the living cell-substance possesses chemical *compounds* which find analogues nowhere in inorganic nature. The characteristic organic substances which are present in every cell are proteids and proteid-compounds. Besides these there occur, widely disseminated, carbohydrates, fats, and other organic substances, which partly originate in the decomposition of proteids and their compounds, and are partly used for their construction. Lastly, there are in addition great quantities of water and some inorganic salts.

Such are the structure and composition of the substratum in which vital phenomena play their part. When we consider vital phenomena themselves in the various living organisms—in protista, plants, animals, man—there appears an incalculable diversity of phenomena. Here, however, as in the case of the structure of organisms, we have to analyse and to penetrate ever farther and deeper till we reach the fundamental phenomena. We then find that the great variety of vital manifestations may be traced back to a few fundamental general groups, which are precisely the same groups of phenomena as those to be observed in inorganic nature. All the processes that take place in the organic world may be regarded from the three different standpoints of their changes in substance, in energy, and in form; for substance, energy, and form are all necessary to our conception of matter. Accordingly, the general elementary vital phenomena likewise fall into three groups—metabolism, the mechanism of energy, and the assumption of form. Every cell, so long as it is living, takes in certain substances from its environment, submits them to chemical transformation in its interior, and gives out other substances. This *metabolism* is manifested in several special functions—in nutrition and digestion, respiration and circulation, secretion and excretion.

General phenomena of life.

The essence of the whole process is the fact that while out of these ingested stuffs living substance is always again being formed by the living substance which already exists, it is itself continually undergoing decomposition, and the products of this decomposition are what the cell gives off again to the outside. With metabolism, however, there is inseparably associated a *transformation of energy*. These substances taken in by the cell contain a large quantity of potential energy, which is transformed into kinetic energy. This has for its result the manifold activities of the organism, more especially motion, heat, electricity, and light. Finally, the chemical transformations in living substance may also manifest themselves outwardly in *changes of form*, as is the case generally in the matter of growth, reproduction, and development. The three general elementary groups of vital phenomena are therefore in reality merely the expression of the various aspects of one and the same process—of the actual vital process itself. The ultimate object of all physiology is to discover what this vital process is, that is to say, what is the exact cause of these manifold vital phenomena—a goal from which it is at the present day still very remote.

Conditions of life.

As every physical and chemical phenomenon of inorganic nature occurs only under distinct conditions, so vital phenomena are also dependent upon certain conditions of life. Every living body, every living cell, requires food, water, oxygen, and, further, a certain temperature, and a certain pressure in its environment. These are the *general* conditions of life. But the *special* conditions on which depends the continued existence of the individual forms of organism are as numerous as the forms of organisms themselves. Now, just as the physicist or chemist varies those conditions under which a phenomenon occurs in order to get at its causes, so does the physiologist try to experiment with vital phenomena, altering the vital conditions and testing the changes which are thereby produced. The great importance of this method consists in the power it gives the experimenter of analysing vital phenomena systematically from definite points of view. Every change in its normal vital conditions which produces any effect whatsoever upon an organism is termed a *stimulus*. This is the only general definition we have for a conception which is of such vast importance to physiology. According to it, experimental physiology is entirely a physiology of stimuli. It further follows from this conception of stimulation that there must be an enormous multiplicity of stimuli, since each particular vital condition may be subjected to some change capable of acting upon it as a stimulus. But, besides this, other factors may be brought to bear upon organisms which have absolutely no place among their vital conditions, for instance, many chemical reagents and electric currents. These influences come under the general definition of stimulus, because they likewise imply a change in the conditions under which the organism lives. From their qualitative nature stimuli are distinguished as chemical, thermal, photic, mechanical, and electrical. Each of these several varieties may, however, be applied quantitatively in various degrees of intensity, and may in consequence produce quite different results. This opens up to experimental physiology a vast field of research. But the physiology of stimulation is not only of the greatest value as a *means* of research: its importance is much increased by the fact that in nature itself stimuli are everywhere and constantly acting upon the organism and its parts. Hence the investigation of their action comes to be not merely a *means*, but a direct *end* of research.

Although it is not at present possible to define all the laws that govern stimulation, on the one hand because the number of stimulating effects known to us in the whole organic world is as yet too limited, and on the other because those already known have not yet been thoroughly analysed, yet it is within our power to classify stimulating effects according to their various characteristics, and to ascertain a few facts concerning their general and fundamental conformity to law.

Actions of stimuli.

The first fact, apparent from a glance at a great many of the various forms of stimulation, is that all their effects are manifested in either a *quantitative* or a *qualitative* alteration of the characteristic vital phenomena of each living object. The quantitative is the usual mode of action of stimuli. It is generally found that a stimulus either increases or diminishes the intensity of vital phenomena. In the first case the effect is one of excitation; in the second, of depression. It is the more important to bear in mind this twofold operation of stimuli, owing to the fact that in former times physiologists were very apt to conceive of excitation and stimulation as identical. It is now, however, an undisputed fact that depression may also occur as a typical effect of stimulation. This is most apparent in cases where the same stimulus that produces excitation may, on being applied for a longer period and with greater intensity, produce depression. Thus narcotics (alcohol, ether, chloroform, morphia, &c.) on certain forms of living substance produce the phenomena of excitation when their action is weak, whereas when it is stronger they produce complete depression. Thus, likewise, temperature stimuli act differently upon vital phenomena according to the degree of temperature, very low temperatures depressing, medium temperatures exciting with increasing intensity, and higher temperatures from a certain height upwards again depressing. The effects of stimulation are not, however, always manifested in merely quantitative changes of the normal vital phenomena. Sometimes, especially in the case of long uninterrupted and chronic stimuli, stimulation is found gradually to produce phenomena which are apparently quite foreign to the normal vital phenomena of the cell in question. Such *qualitative* alterations of normal vital phenomena are perceptible chiefly in chronic maladies in the cells of different organs (the heart, liver, kidneys, spleen, &c.), in which the vital conditions become gradually more and more modified by the cause of the malady. To this category pertain all the so-called chronic processes of degeneration which in pathology are known as fatty degeneration, mucous degeneration, amyloid degeneration, and so forth. The characteristic element in all these processes is that the normal metabolism is diverted into a wrong channel by the altered vital conditions of the cells of the organ affected, so that substances are formed and accumulated in the cell which are entirely foreign to its normal life. But this class of stimulation is still very obscure as regards causes and inner processes, and it is within the range of possibility that the ultimate cause of the qualitative changes in the normal metabolism is to be found simply in the processes of excitation and depression which chronic stimulation produces in separate parts of the metabolism. Thus, at least with regard to fat-metamorphosis (fatty degeneration), it is highly probable that fat is deposited in the protoplasm simply because, owing to an inadequate supply of oxygen, it cannot, when it originates, be oxidized in the same proportion as it is formed, whereas in the normal cell all fat which originates in metabolism is consumed as soon as it is produced. According to this conception, therefore, fatty degeneration is attributable primarily to a depression of the processes of oxidation in the cell. If we may accept this view as correct with regard to the other metamorphic processes also, the qualitative changes in vital phenomena under the influence of stimuli would after all depend simply upon the excitation or depression of the constituent parts of the vital process, and, according to such a view, all stimuli would act primarily only as exciting or as depressing agents upon the normal process of life.

In accordance with the three groups into which general vital phenomena are divided, it follows as a matter of course that the excitation or depression produced by a stimulus can manifest itself in the cell's metabolism, assumption of form, and manifestation of energy. The effects of excitation upon the production of energy are the most striking, and were therefore in former times frequently thought to have a claim *par excellence* to rank as stimulating effects. These reactions attract most attention in cases where the production of energy is proportionately very great, as with muscle, for instance, which is made to twitch and perform work by a feeble stimulus. Processes of discharge (Auslösungsvorgänge), however, lie at the bottom of cases like these. Potential chemical energy, which is stored up in a considerable quantity in living substance, is converted by the impulse of the stimulus into kinetic energy. Therefore the amount of the effect of stimulation—that is to say, the quantity of work performed—bears no proportion whatever to the amount of energy acting as a stimulus upon the muscle. The amount of energy thus acting may be very small as contrasted with an enormous production of energy on the part of the living substance. It will not do to make generalizations, however, with regard to this proportion, as was frequently done in former times. All processes of stimulation are not processes of discharge. The influence of many stimuli, as has been observed, consists far more in depression than in excitation, so that in certain circumstances a stimulus actually diminishes the normal liberation of energy. There is therefore no general law as to the proportion which the amount of energy acting as a stimulus upon living substance bears to the amount of energy liberated.

Among special varieties of stimulation there is one class of stimuli which has attracted particular attention, namely, those which act unilaterally upon free-moving organisms. It is principally with the lowest forms of life that we have here to do—unicellular protista and free-living cells in the bodies of higher organisms (sperm-cells, leucocytes, &c.). When from one direction a stimulus—be it chemical, thermal, photic, electrical, or of any other kind—acts upon these organisms in their medium, they are impelled to move in a course bearing a definite relation to the source of the stimulus—either directly towards that source or directly away from it, more rarely in a course transverse to it. This directive action of stimulation is under such a fixed conformity to law, that it vividly recalls such purely physical processes as, for instance, the attraction and repulsion of iron particles by the poles of a magnet. For example, if light falls from one side upon a vessel full of water containing unicellular green algæ, according to the intensity of the light these organisms swim either towards the illuminated side, where they form a compact mass on the edge of the vessel, or away from it, to cluster on the opposite edge. In the same way infusoria in water are observed to hasten towards or to flee from certain chemical substances, and leucocytes in our bodies act in the same manner towards the metabolic products of pus-forming bacteria which have penetrated into an open wound. The suppuration of wounds is always accompanied by an amazing conglomeration of leucocytes at the seat of the lesion. Perhaps the most striking effects, however, are those of the constant electric current upon unicellular organisms, since in this case the motion follows the cause with absolutely auto-

Directive stimulation.

matic regularity, certainty, and rapidity. Thus, for example, after the establishment of the current many Infusoria (Paramæcium) accumulate at the negative pole with great celerity and without deviation, and turn round again with equal celerity as soon as the direction of the current is altered. As such cases of directive stimulation may occur among all varieties of stimuli whenever stimuli act unilaterally, they have been designated, according to the direction in which they occur in relation to the source of the stimulus, as positive or negative Chemotaxis, Phototaxis, Thermotaxis, Galvanotaxis, and so forth. The strange and perplexing element in these phenomena becomes clear to us as soon as we know the characteristic method of locomotion for each form of organism, and whether the stimulus in question in the given intensity exercises an effect of excitation or of depression upon the special form. The direction of motion is the essential mechanical result of unilateral stimulation of the organs of locomotion. Seeing that these reactions are exceedingly widely distributed throughout the whole organic world, and possess a deep biological significance for the existence and continuance of life, the interest they have awakened is thoroughly justified.

One of the most important physiological discoveries of the 19th century was that of the "Specific Energy of Sense-substances." Johannes Müller was the first to establish the fact that very different varieties of stimuli applied to one and the same organ of sense always produce one and the same variety of sensation, and that, conversely, the same stimulus applied to the different organs of sense produces a different sensation in each organ—the one, in fact, which is its specific attribute. Thus, for example, mechanical, electrical, and photic stimuli applied to the optic nerve produce no other sensation than that of light; and, conversely, any one variety of stimulus—take the electrical, for example—produces sensations of light, hearing, taste, or smell, according as it affects the optic, auditory, gustatory, or olfactory nerves. This law of the "Specific Energy of Sense-substances," as Johannes Müller called it, has come to have a highly important bearing upon scientific criticism, since it proves experimentally that the things of the outer world are in themselves in no way discernible by us, but that from one and the same outward object—the electric current, or a mechanical pressure, for instance—we receive altogether different sensations and form altogether different conceptions according to the sense-organ affected. But this law does not possess significance for psychology alone; as regards physiology also it has a much more general and more comprehensive force than Müller ever anticipated. It holds good, as demonstrated by Hering and others, not of sense-substances only, but of living substance generally. Each cell has its specific energy in Johannes Müller's sense, and in its extended form there is no more general law for all the operations of stimuli than this law of specific energy. To take examples, whether a muscle be stimulated by a chemical, mechanical, thermal, or electrical stimulus, the result is in each case the same, namely, a twitching of the muscle. Let a salivary gland be stimulated chemically, mechanically, electrically, or in any other way, there always follows the same specific action—a secretion of saliva; no matter what be the kind of stimulus acting upon it, the liver-cell always reacts by producing bile, and so on. On the other hand, one and the same stimulus—the electric current, for example—gives in each form of living substance a specific result: twitching in the muscle, secretion of saliva in the salivary gland, production of bile in the liver-cell, &c. That is, of course, with the proviso that the effect of the stimulus be exciting and not

"Specific energy."

depressing. The following general formulation, however, of the law of specific energy brings the depressing stimuli also within its scope: "Different stimuli produce in each form of living substance an increase or a diminution of its specific activity." As already observed, it will probably be found that those weak chronic forms of stimulation which produce qualitative changes may also be comprised under this general law.

The knowledge thus far acquired from analysis of vital phenomena and their changes under the influence of stimuli affords but a very indefinite temporary basis for the theory of the actual vital process itself, of which vital phenomena are the outward manifestation. The conceptions to which physiological research has hitherto attained in this matter are of a more or less doubtful nature. The facts contained in them still require to be linked together by hypotheses if we are to obtain even a vague outline of what lies hidden behind the great riddle of life. Such hypotheses, serving as they do to link facts consistently together, are absolutely essential, however, to the further progress of research, and without their aid any systematic investigation would be impracticable. But at the same time it must never be forgotten that these hypotheses are merely provisional, and that whenever they are found to be no longer in harmony with the widening range of new experiences and ideas, they must either be proved to be facts or be subjected to modification. This is the point of view from which we must deal with modern ideas concerning the nature of the actual vital process—the mechanism of life.

Mechanism of life.

The fundamental fact of life is the metabolism of living substance which is continually and spontaneously undergoing decomposition, and building itself up anew with the help of the food-substances it takes in. These processes of decomposition and of reconstruction may be briefly designated as *Dissimilation* (Catabolism) and *Assimilation* (Anabolism) respectively. Now the question arises: How are we to understand this process of dissimilation and assimilation from a mechanical standpoint? It is quite evident that we have to do with some chemical occurrence; but *how* are the chemical transformations brought about? There are obviously two possibilities. It is conceivable that the decomposition of foodstuffs and the formation of excretion-products in the cell-body are caused by the repeated casual encounter of a great series of chemical combinations and by their repeatedly reacting upon one another in the same manner, bringing about transformations and forming waste products which are excreted, while at the same time certain chemical affinities are always taking in from without new chemical combinations (food-stuffs) and uniting them. This theory was in fact occasionally advanced in former times, particularly in its chemical aspect, and the belief was especially entertained that the enzymes in living substance might play an important part in these transformations. This assumption, however, leads to no clear and lucid image of what takes place, and moreover draws too largely upon auxiliary hypotheses. It has therefore met with but little acceptance. The other possible explanation of metabolism is, that its whole process is confined to one single class of chemical combinations whose tendency it is to be constantly undergoing spontaneous decomposition and regeneration. This latter theory was founded by Hermann, Pflüger, and others, and has met with universal recognition because of its naturalness, simplicity, and clearness.

Metabolism.

Starting with this hypothesis, the path of further research lies clear and well-defined before us. In the first place, we are obviously met by the question: What conception are we to form of these combinations on which hinges the whole vital process? Among the organic matters which compose living substance, proteids perform the most important part. Proteids and proteid-compounds form the only organic matter which is never absent from any cell. They form also the greater part of all the organic compounds of the cell, unless reserve-stuffs are accumulated to a considerable extent, and they are by far the most complicated of the compounds of living substance. While animal life is impossible without proteid food, there are on the other hand animals which can continue to subsist on proteid alone. This series of facts proves very conclusively that proteids and their compounds play by far the most important part of all organic matter in the processes of life. The idea thus naturally presents itself that the required hypothetical compound forming the central point of metabolism will be found to bear a very close relation to proteids. But another point must be here considered. The proteids and their compounds known to us are, comparatively speaking, stable compounds, which never undergo spontaneous decomposition so long as they are protected from outward injury, whereas the hypothetical combination which lies at the centre of organic metabolism is extraordinarily labile and continually undergoing spontaneous decomposition. Therefore we have to think not of ordinary proteids in this case, but of still more complicated combinations, the atoms in the molecule of which have a strong tendency to group themselves in new arrangements. Owing to their fundamental importance, these combinations have been termed "biogens." When we come to inquire how such labile biogen molecules are built up out of the proteids of food, we find our knowledge very much restricted. Doubtless the intramolecular addition of inspired oxygen has much to do with it, for living substance when deprived of oxygen loses its irritability, that is to say, its tendency to decomposition. The fact that the decomposition of living substance is always associated with the formation of carbonic acid—a circumstance obviously necessitating the aid of oxygen—also points to the absolute indispensableness of oxygen in the matter. Pflüger has further suggested that the molecule of living substance owes its lability and its tendency to form carbonic acid when joined by oxygen atoms principally to cyanogen groups which are contained in it. According to this view, the following is supposed to be the process of the formation of biogen molecules: It is assumed that the biogen molecules already present in living substance take out of the proteids of food certain groups of atoms, and dispose them so as to produce cyanogen-like compounds. The addition of oxygen atoms then brings the biogen molecule to the maximum of its power of decomposition, so that—partly spontaneously, but more especially when impelled by a stimulus—it breaks down somewhat explosively, causing the formation of carbonic acid. In this proceeding, according to the hypothesis which is the most widely accepted and the most fruitful in results, would lie the very germ of the vital process.

Proteids.

If we accept these views as far as their general principle is concerned, assimilation is the re-formation of biogen molecules by those already existing, aided by food-stuffs; dissimilation, the decomposition of biogen molecules. To this primary process, however, is attached a whole series of secondary chemical processes, which serve partly to work upon the food so as to fit it for the building up of biogen molecules, and partly to form out of the direct decomposition-products of the biogen molecules the characteristic secretion-products of living substance (excretions and secretions). The various workings of matter in the cell are rendered very much more complex by the circumstance that the living cell exhibits various morphological differentiations—above all, the differentiation in protoplasm and nucleus. Again, a transformation of energy is inseparably connected with metabolism. Along with food and oxygen potential chemical energy is continually being introduced into the cell, to be accumulated in the biogen molecules, and at their decomposition transformed into kinetic energy, which finds an outlet in the various manifestations of energy in the cell—motion, heat, and so forth. In the light of this hypothesis the operations of stimuli also become comprehensible. Seeing that there is an initial tendency to the occurrence of certain definite chemical processes, which are associated with the reconstruction and decomposition of biogen molecules, various stimuli will either further or hinder the course of this metabolic series. A cell which is exposed to no outward disturbance, and which continues always in the unvarying medium provided by an exact sufficiency of food, will be in "metabolic equilibrium"; that is to say, its assimilation and its dissimilation will be equal ($A = D$). When, however, the influence of external stimuli is brought to bear upon them—that is to say, any change in their environing vital conditions—A and D will either be altered in similar proportion, or their mutual equilibrium will be disturbed. In the former case the vital processes will merely be intensified in their course; in the latter and usual case the result will be determined according to the part of metabolism excited or depressed. When the effect of a stimulus is to excite D continuously in a high degree without correspondingly increasing A, the result is a dying off—an atrophy. In the contrary case, when A remains continuously greater than D, the result is growth, increase, and reproduction of the cell. Experience proves, however, that A and D stand in a certain relation of mutual dependence to each other, with the result that when D has been increased by a stimulus, for example, A correspondingly increases during the stimulation, and continues to do so after its cessation, till the loss in living substance produced by the stimulation of D is eventually made good, and metabolic equilibrium is restored. The muscle may be taken as an example of this self-regulation of metabolism common to all living substance (Hering's *Selbststeuerung des Stoffwechsels*). When a muscle has been fatigued by some stimulation causing an enormous increase of D, there is a corresponding spontaneous increase in A. After some time the muscle is observed to have recovered. It has once more become capable of performing work; its metabolism is again in equilibrium.

Mechanism of cell-life.

Metabolic equilibrium.

The vital phenomena of the cell may be derived mechanically from metabolism and the changes it undergoes under the influence of stimuli. Our ability to do this will increase more rapidly as we become better acquainted with the details of the metabolism of the cell itself. The foregoing outline must be regarded, of course, as embodying only a fragmentary hypothesis, which can serve as a guide for further research only so long as it does not clash with facts, and which must be amplified, specialized, and developed with the widening of specific knowledge regarding the cell's metabolism. The relations already known are so exceedingly complex, that only by slow degrees can we pursue the investigation of separate fragments of the entire metabolic series. The differentiation of nucleus and protoplasm in the living substance of the cell alone gives rise to an extraordinary complication in the metabolic process, for these two parts of the cell stand in the most complicated correlation with one another as well as with the environing medium—a fact of which the experiments made by vivisection in various free-living cell-forms have furnished abundant evidence. The farther such knowledge advances, the more rounded, clear, and free from hypotheses will be-

Cell-processes the secret of life.

come our conception of the cell's metabolism. But the cell is the elementary component part of all organisms, and from the life of individual cells is constructed the life of the separate tissues and various organs, and thus of the entire organism. Hence the cell is the only vital element which the organism possesses, and therefore the investigation of the vital processes in its separate cells leads ultimately to a knowledge regarding the mechanism of life in the whole. (M. V.)

II. Nutrition.

Living matter is living in virtue of the persistence of a constant cycle of chemical changes, consisting in a continual breaking down (Catabolism) on the one hand and a continual building up (Anabolism) on the other. By the breaking-down changes the energy is evolved which is required for the constructive processes by which the mass of living material is maintained or grows, and for the production of motion, of heat, and of all the various phenomena associated with vitality. Nutrition deals specially with the way in which these changes are carried on, with the manner in which the necessary energy-yielding material is supplied to and utilized by the protoplasm, and with the disposal of the waste material resulting from the catabolism. The present article deals with the nutrition of Vertebrates, and more especially with the nutrition of mammals.

A. *Metabolism.*

Anabolic changes.

Protoplasm, or living matter, is not a substance but a vortex of substances, a vortex constantly sucking in fresh material and as constantly throwing off the old. To attempt to analyse it is hopeless; but when its metabolism is stopped—when it is no longer protoplasm—it is found that the most abundant solid present belongs to the group of *Proteids* (see p. 724). Many speak of proteids as the essential constituent of protoplasm; but how, and in what form, they are present is unknown, owing to the important molecular changes which go on at death, as indicated by the liberation of carbon dioxide and lactic acid in considerable quantities. Whatever be the true relationship of proteid to protoplasm, the fact is clear that a supply of the former is necessary for the continuance of the latter. In green plants the proteid is built up from nitrates, water, and carbonic acid, but in animals it must be supplied ready made from plants or from other animals. The proteids are complex substances with large molecules, which, when built into the protoplasm molecule, readily break down into simpler substances with the liberation of energy. Many organisms are capable of repairing the expenditure of matter and of energy, and of continuing to live on proteids, along with water and salts; but the vast majority of animals have the power of using *Fats* and *Carbohydrates* as additional sources of energy, and many procure from these substances the greater amount of the energy they evolve. Thus man, on an ordinary diet, gets five times as much energy from these as from the proteids of the food. (For the energy-value of each of these materials, see DIETETICS.) For the liberation of their energy these substances must be *assimilated*, drawn into the vortex, and built up to form an integral part of the protoplasm. Some plants, like the yeasts, have the power of evolving the energy of sugar through the action of one of their products, but all the evidence indicates that in animals assimilation is an essential step to utilization.

This is clearly indicated by the following considerations:—(1) Of the innumerable organic compounds which in their disintegration liberate energy, the animal body can use only a very limited number, belonging to the three groups of Proteids, Fats, and Carbohydrates; only a few substances outside these groups can be assimilated and used to a small extent as sources of energy, *e.g.*, alcohol. (2) Proteids, Carbohydrates, and Fats, when in the blood undergo no such changes as they undergo when they become part of the living protoplasm. (3) Ammonium lactate, which undergoes no change in the blood, when introduced into the body of a living mammal is changed to urea, and in a living bird to uric acid; while urea injected into the bird is in part changed into uric acid, and uric acid in the mammal may be changed into urea. In each case the substance must become part of the living protoplasm, and undergo profound alteration.

(4) A number of substances, as benzyl alcohol, $C_6H_5CH_2OH$, and salicylic aldehyde, $C_6H_4{COH \atop OH}$, are not oxidized in the blood, but when taken up by the protoplasm of the tissues are changed into benzoic acid, $C_6H_5CO_2H$, and salicylic acid, $C_6H_4{CO_2H \atop OH}$.

In all probability the degree of assimilation which is necessary for the chemical changes in various substances acted on by living protoplasm varies greatly. Thus proteids must be carried in to the inmost and most essential vortex, while gelatine, carbohydrates, and fats must also take part in the more intimate chemical changes. On the other hand, the changes of lactate of ammonia, of urea, of uric acid, and the various chemical substances mentioned above, probably go on more towards the edge of the vortex, and without ever taking part in the fundamental series of changes.

It was formerly supposed that the *oxygen* of the air directly oxidized the constituents of living matter, but the fact that the same changes go on in the living tissues of the frog for some time after they have been deprived of all free oxygen, shows this idea to be erroneous. The oxygen must be assimilated, must be part of the protoplasm, must be what Pflüger calls *intramolecular*. Its presence in the complex molecule along with carbon, hydrogen, and nitrogen of course greatly increases the molecular instability. Living matter has a great affinity for oxygen, and not only takes it greedily from the air, but can actually separate it out of various chemical compounds, such as oxyhæmoglobin, or even from more stable pigments, such as alizarin blue.

Catabolic changes.

Protoplasm thus built up by the assimilation of Proteids, Fats, and Carbohydrates, with oxygen, undergoes changes by which it is broken down and the energy of these substances is liberated. These changes are accompanied by an oxidation, the intramolecular oxygen of the protoplasm being distributed in simpler and more stable compounds. Proteids, Carbohydrates, and Fats, when burned outside the body, yield carbon dioxide and water, and in the body these are the chief products of the disintegration of living matter. But the proteids contain nitrogen and sulphur, which are also oxidized. In the animal body the sulphur is in great part converted to sulphuric acid, though some is got rid of in a less oxidized state. The nitrogen, on the other hand, is in fishes, amphibia, and mammals excreted chiefly as carbamide (urea), and to a smaller extent as ammonia and various diureides (see below, *Chemistry of Animal Body*). In birds and reptiles the diureides are the chief waste nitrogenous products. But while the waste nitrogen is thus got rid of in substances more complex than ammonia, the fact discovered by Minkowski, that in the goose exclusion of the liver from the circulation causes the appearance of lactate of ammonia in place of uric acid in the urine, tends to show that in all cases ammonia, or a closely allied substance, is actually formed, and is built up into somewhat more complex substances, probably to facilitate excretion. The catabolism of the nuclein compounds (see p. 724) of the protoplasm is somewhat more complex. The proteid moiety is broken down in the manner just described, and the nucleic acid is split into phosphoric acid and a series of bodies which E. Fischer names the Purin Bases — Hypoxanthin, Xanthin, Uric Acid, Adenin, &c. The amounts of these formed vary with the amount of nucleic acid which is broken down, but they are all capable of being further changed into urea.

The metabolic processes of protoplasm appear to be modified in response to various stimuli. For example, in carnivorous animals the result of administering acids is the formation of ammonia in sufficient quantities to combine with them. Free fatty acids determine the production of glycerin in the intestinal wall, and benzoic acid gives rise to amido-acetic acid, with which it links, to be excreted as hippuric acid.

Metabolism of muscle.

In vertebrate animals muscle plays the most important part in the general metabolism. Not only is it the most constantly active and by far the most abundant of the tissues—in man it constitutes about 43 per cent. of the total weight—but, since its two great functions are the production of heat and mechanical work, it is the great energy-liberating machine, the great expending tissue of the body. For its nourishment food is procured and digested, and the purpose of the various organs of excretion is to get rid of its waste products. The metabolism of muscle is therefore the great governing factor in the nutrition of the body. The proportion between the amount of energy set free in mechanical work and in heat production has been studied by many investigators, but the most trustworthy results have been obtained by Zuntz and his fellow-workers at the Veterinary School of Berlin. By investigation on men, horses, and dogs, they have shown that under the most favourable conditions about $\frac{1}{3}$ of the energy liberated by the muscle may be used for mechanical work, while about $\frac{2}{3}$ is used in heat production; while in less favourable circumstances a much smaller proportion of the energy is available for mechanical work.

Muscle contains about 20 per cent. of proteids, some of which are soluble, others insoluble, in salt solution. The insoluble part consists of the collagen of the connective tissue, and of a phosphorus-containing proteid Myostromin, which makes up the framework of the fibres. The soluble proteids are of the nature of globulins, and two of these (Myosinogen and para-Myosinogen) tend to pass into an insoluble condition (Myosin). This occurs after death, and leads to the familiar stiffening of muscle. Another globulin, Myoglobulin, takes no part in the formation of the myosin. The remaining organic substances, amounting to 1 or 2 per cent., consist of glycogen, glucose, and fats, and of waste matters, such as methyl-guanidin-acetic acid—creatin. The ash amounts to about 1 per cent., the most important base being potassium and the most abundant acid phosphoric acid.

When work is done, the disintegration of muscle substance is proportionately increased. Thus Zuntz found the excretion of carbon dioxide in a dog to vary as follows:—

	CO_2 per min. in cubic centimetres.
Resting, lying	124·7
,, standing	170·2
Forward movement (unloaded)	525·0
,, ,, (drawing weight)	798·9

He further found that the more rapidly work is done, the greater is the disintegration. The simple oxidized compounds of the greater part of the carbon and hydrogen are given off from the muscle, and, with or without further modification, are excreted from the body as carbon dioxide and water. Nitrogen in simple combinations also appears to be set free, for the proportion of nitrogenous substances soluble in alcohol is increased after contraction in excised muscle. But in muscle in the body, waste nitrogen is not given off proportionately to the work done; indeed, increased excretion is not a necessary accompaniment of the performance of muscular work. Provided the work is moderate, and provided the supply of non-nitrogenous food is sufficient for the energy required, and the supply of oxygen adequate for repair, there is no increased excretion of nitrogen. But when the work is excessive in relation to the amount of food absorbed and the amount of oxygen taken up, at once the waste nitrogen is thrown off in increased quantities. An increase in the excretion following muscular work is therefore correlated with deficiency of the materials required for reconstruction. It thus seems that, except under special conditions, the nitrogen, instead of being thrown off, is used again, and, in combination with fresh carbon and hydrogen in fats and carbohydrates, and with oxygen, is rebuilt into the muscle protoplasm.

Measure of metabolism.

The course of metabolism and the rate of combustion of proteids and fats in the body may be studied with considerable accuracy in the human subject. It is necessary to ascertain the amount of nitrogen and of carbon excreted by the various channels—the kidneys, the lungs, the skin, and the bowel. By the two last almost negligible quantities are given off, so that it is usually sufficient to confine the analysis to the urine and the expired air. In proteids there is 16 per cent. of nitrogen to 54 per cent. of carbon, and hence in the excreta every gram of nitrogen derived from proteids must be accompanied by 3·4 grms. of carbon. Any carbon above this amount must be derived from the fats of the body during fasting, or from the fats and carbohydrates of the food. The data for such studies are these:—

N excreted $\times$ 6·2 = proteids used.

C (*a*) an amount equal to N $\times$ 3·4 is from proteids.

(*b*) all above this is from fats and carbohydrates, and during fasting from fats. The amount of fats is obtained by multiplying by 1·3.

Metabolism in fasting.

In fasting, the breaking-down changes by which energy is liberated continue, but since no energy from without is introduced, the animal's own tissues are used. The rate of wasting depends simply upon the amount of energy required for muscular work and for heat production; an individual kept warm and at rest will endure a fast for a much longer period than one exposed to cold and compelled to carry on strenuous labour. In the course of a fast the tissues do not waste equally: the more essential live on the less essential. The heart muscle hardly loses weight, and it must therefore subsist upon the proteids of the less essential skeletal muscles, which lose considerably, in turn deriving their supply of energy from the stored fat of the body. At the commencement of a fast the rate of wasting is rapid, but after a time it diminishes and the animal lives more economically, more especially as regards its proteids. This is well shown by the observations made in a case of prolonged voluntary fast undertaken by an Italian:—

Day of Fast.	Proteid Waste.	Fat Waste.
1st	104 grms.	—
10th	51 ,,	170 grms.
20th	33 ,,	170 ,,
29th	31 ,,	163 ,,

So long as fats remain, they are used in preference to the proteids, and it is only when they have nearly disappeared that the proteids are called upon to supply the energy. Taking food increases the work of the muscles and glands of the alimentary canal, and hence when an animal which has been fasting is fed, there is a rise in the excretion of carbon dioxide and nitrogen. If the animal has been wasting 33 grms. of proteid and 170 grms. of fat per diem, and if a diet containing these quantities be given, on account of the increased demand for energy in digestion, the food is insufficient to maintain the weight.

Internal secretions.

Certain organs of the body produce substances which are carried to the muscles and other tissues, and exercise an important influence on the chemical changes going on therein. (For information as to the structure of these organs, see ANATOMY.)

Thyroid Gland.—The removal of this structure leads to a train of symptoms which varies somewhat in different animals, but is essentially the same in nearly all. The connective tissues tend to revert to the embryonic conditions, and the amount of mucin increases. The temperature falls, muscular tremors appear, the functions of the higher nervous system become sluggish, and the animal usually dies. By administering the substance of the thyroid, or by giving extracts of it, most of these symptoms may be delayed or prevented. When thyroid gland or extract is given to healthy animals in moderate doses, it causes an increased metabolism of both fats and proteids, and thus may induce emaciation. It would appear as if one function of the organ is to produce this internal secretion, in order to regulate the rate of the metabolic processes in the body by increasing them when such an increase is desirable.

Ovaries and Testes.—It is well known that removal of these organs causes characteristic changes in the animal, a tendency to the deposition of fat being produced and the activity of the central nervous system being somewhat modified. Several years ago Brown-Séquard maintained that by the administration of testicular substance the general effects of atrophy of these organs might be obviated; and more recently, as a result of clinical experience, the administration of extracts of the ovaries has been said to relieve certain of the nervous symptoms which supervene on their removal or atrophy. It has been found, too, that ovarian substance when given to dogs, whether male or female, causes a marked increase in the rate of proteid disintegration, but no similar action has been found with testicular substance. There is thus evidence that the ovaries, like the thyroid, form an internal secretion having an important action in accelerating the metabolism; and it is at least probable that the testes produce a similar substance.

Pancreas.—That the pancreas is the most important of the digestive glands, has for long been known, but in 1889 von Mering and Minkowski demonstrated a further function. They discovered that excision of the pancreas produces a condition of diabetes—an increase of sugar in the blood, the appearance of sugar in the urine, an increased excretion of nitrogen, and a general emaciation. These symptoms do not occur when the duct is tied or occluded, but they are invariable when a sufficient amount of the gland is cut away. They are not prevented by the administration of pancreas, either fresh or as extracts. In this condition sugar seems to be formed from the proteids, because it appears after all the glycogen has been removed, and its amount is proportionate to the amount of nitrogen excreted. Normally, proteids are a source of carbohydrates in the body, and it would seem as if the pancreas in some way exercises a restraining influence in this splitting of proteids, and that the removal of the organ permits it to occur to an excessive extent. Since the only respect in which the pancreas differs in histological character from the parotid gland—removal of which has no effect on the metabolism—is in the presence of epithelial islets, one is inclined to ascribe this action to them.

Pituitary Body.—Removal of this causes in cats and dogs a fall of temperature, lassitude, muscular twitchings, dyspnœa, and ultimately death. Injection of extracts of the substance is said to diminish these symptoms, but so far no study has been made of the influence of such injection on the metabolism of healthy animals.

Suprarenal Body.—Long ago Brown-Séquard stated that removal of these bodies causes great muscular weakness, loss of tone of the vascular system, loss of appetite, and finally death in a short time. Addison had already pointed out that a similar set of symptoms, accompanied by pigmentation of the skin, is associated with diseased conditions of these organs in man. Within the last few years it has been demonstrated that injections of small quantities of the central portion of the bodies has a powerful effect on the muscular system generally, and especially on the muscles of the vascular system, an enormous rise in the blood-pressure being produced. So far the influence of the suprarenal on the general rate of metabolism has not been investigated.

B. *Blood and Lymph.*

The blood circulates in a system of closed tubes, the smallest of which—the capillaries—form a network in the tissues and have their walls composed of a single layer of flattened endothelial cells. From the capillaries fluid escapes into the spaces between the tissue elements, to form the lymph. The lymph from these spaces is conducted by a series of tubes—the lymphatics—which, after passing through lymphatic glands, join together and finally enter the blood-stream just as the blood is returning to the heart. The whole arrangement resembles an irrigation system, the blood being comparable to the water in the trenches, the lymph to the water as it percolates through the soil.

The blood is a red fluid, having a bright cinnabar colour when oxygenated, and a dark, more purple hue when deprived of oxygen. In man its specific gravity is about 1060. Its reaction is alkaline —the alkalinity corresponding to about 0·3 per cent. of carbonate of soda. It is opaque, on account of the presence of numerous pigment-containing cells, which float in a more or less colourless fluid, the plasma. These cells constitute about 48 per cent., the plasma about 52 per cent., of the blood, which when dried is found to contain 20 per cent. of solids, with 10 per cent. of blood pigment —hæmoglobin—and about 8 per cent. of other proteids. The remaining 2 per cent. is made up of other organic bodies and inorganic salts. The cells are of three kinds—Red, White, and Platelets. When shed, the plasma forms a jelly enclosing the cells, and the blood is said to have clotted. This process of clotting takes place at different rates in different animals and under different conditions. In man, under ordinary conditions, it occurs in about three minutes. The clot contracts and squeezes out a fluid—the blood-serum. The process is due to a change in at least one of the proteids of the plasma, of which there are three, Serum Albumen, Serum Globulin, and Fibrinogen—a globulin. Under the influence of various factors, when blood is shed the fibrinogen becomes changed into a stringy tough insoluble substance—Fibrin—which forms the clot. It is possible that the chief cause of the clotting is the breaking down of white cells, with the liberation of a substance which may be called Fibrin Zymin.

The *Plasma* contains, in addition to the above proteids: (1) A small quantity (about 0·15 per cent.) of glucose, partly free and partly in organic combination, probably as jecorin; (2) a small quantity of fat, varying in amount with the character of the diet, but present even in starvation; (3) traces of various, more or less simple, combinations of nitrogen, the result of the disintegration of the tissues; and (4) various inorganic salts, of which the most abundant is chloride of sodium, but the most important are the phosphate and carbonate of soda. When carbonic acid is not being poured into the plasma from the tissues, the soda is all taken up by phosphoric acid to form Na_2HPO_4; but when carbonic acid is in abundance, it takes up a certain quantity, and bicarbonate of soda is formed. The way in which the carbonic acid is carried from the tissues to the lungs is considered under RESPIRATION. As to the source of the constituents of the plasma: (i.) The water is usually ingested; but when it is withheld, it is derived by the plasma from the tissues in which it has been stored. (ii.) The proteids are primarily derived from the food; but whether the peptone formed during digestion and taken up by the white cells is liberated as albumen or globulin, or as both, is not known, although various attempts have been made to show that in starvation it is the albumen which is diminished. But the blood proteids are also derived from the tissues, and in starvation proteid is carried in the blood from one tissue to another, *e.g.*, from the skeletal muscle to the heart muscle, and (in the salmon) from the muscles to the growing ovaries and testes. (iii.) The glucose and fats are derived from the food, but they may also be derived from the tissues in which they have been stored. (iv.) The urea and other nitrogenous substances are derived from the tissues. (v.) The salts are primarily derived from the food, but it is also possible that they may be given off from tissues in which they have been stored; *e.g.*, the phosphates stored in the muscle of the salmon pass to the ovaries and testes. The proteids, carbohydrates, and fats are used in the nourishment of the tissues, while the nitrogenous waste products are excreted.

Cells.—The source of the various blood-cells is described under ANATOMY (9th edit.), and the chemistry and functions of the red cells and their pigment below under RESPIRATION. That the life of the white cells is short, is shown by the rapid appearance and disappearance of digestive leucocytosis. After a meal of meat the leucocytes in the dog may increase 100 per cent., and in five or six hours again fall to their normal number. It is more difficult to determine the life-duration of the red cell. That they are constantly breaking down, is shown by the constant excretion of bile pigment and urinary pigment, which are both derived from hæmoglobin. From the small amount of these pigments daily produced, it is certain that the red cells continue in existence much longer than the white cells. Whether they break down in the general blood-stream or in special organs, is not fully investigated. The salts of the bile acids are powerful solvents of red cells, and since these salts are absorbed from the intestine, it is probable that the solution of old red cells goes on in the portal system. Evidence has been adduced that the spleen also plays an important part in the process.

Lymph.

It is through the lymph that the blood is brought into relationship with the cells of the body. Lymph is a colourless or yellow fluid, resembling closely the blood plasma in all its characters. Its reaction is alkaline. It contains about 6 per cent. of solids, though the amount varies in different parts of the body. About 1 per cent. is inorganic and about 5 per cent. organic. It is the latter constituents which vary in amount. The chief organic substances are the proteids. In the lymph of the limbs these amount to about 2 to 3 per cent., in the lymph of the intestine to 4 to 6 per cent., and in the lymph from the liver to 6 to 8 per cent. They are serum albumen, serum globulin, and fibrinogen. On account of the presence of the last, lymph clots like blood under the influence of the factors, causing the change of fibrinogen to fibrin. The lymph in the tissue-spaces is practically devoid of formed elements, but after it has passed through lymph-tissue it contains leucocytes in greater or lesser numbers. These are chiefly of the small round nucleated variety—the lymphocytes. When the animal is on a fatty diet, the lymph from the intestine—the chyle—is rendered milky by the presence of fat in a fine state of subdivision. Within the last few years the origin of lymph has been much studied, and it has been shown to have a double source—first from the blood, and secondly from the tissues. Heidenhain thus speaks of *Blood-Lymph* and *Tissue-Lymph.* The former has for long been recognized, and it was formerly regarded as an exudation from the capillary blood-vessels. Ludwig believed that the amount produced depended on the intravascular pressure; but the fact that in the limbs where the blood-pressure is high, lymph-formation goes on very slowly, while in the liver, where pressure is low, it is very rapid, shows that intravascular pressure alone is not a sufficient explanation. Heidenhain considered that this absence of relationship between blood-pressure and lymph-formation indicated that the blood-lymph is produced by a process of secretion by the endothelium of the vessels, and, in his opinion, the increased lymph-formation caused by the injection of extract of the muscle of the crab, by proteoses, &c., is due to an increased activity of the endothelium. Starling, on the other hand, points out that this secretion theory is unnecessary, and considers that lymph-formation is governed, first, by the varying permeability of the capillary walls in different parts of the body, and, secondly, by the pressure within the vessels. More lymph is produced in the liver than in the limbs, because of the greater permeability of the capillaries. The permeability is increased by injuring the vitality of the endothelial cells, as by injecting hot water; and, according to Starling, Heidenhain's so-called lymphagogues—crab's muscle, proteoses, &c.—act by poisoning the vessel walls, and by thus diminishing their resistance to the passage outwards of the plasma constituents. That lymph is formed by the withdrawal of water from the tissues, is shown by the injection into the blood of substances of high osmotic equivalent, such as sugar, neutral salts, &c. This causes not only a dilution of the blood, from the passage of water into the vessels, but also an increased formation of lymph, which must of course come from the tissues. Substances which thus produce an increased lymph-flow Heidenhain has called *Tissue Lymphagogues.*

C. *Supply of Matter and Energy required by the Tissues.*

The supply and intake of oxygen are dealt with under RESPIRATION, and the sources from which the necessary supply of proteids, fats, carbohydrates, and salts are procured in the various food-stuffs are considered in the article DIETETICS. Before these food-stuffs are available they have to undergo certain preparatory processes, either outside the body by cooking, or in the alimentary canal by digestion, the processes of which are very fully dealt with in the 9th edition (see NUTRITION, vol. xvii.).

Digestion.

One of the most striking results of recent work on digestion has been to emphasize the importance of the pancreatic secretion as *the* essential digestive fluid. The salivary glands may be cut out without causing any change in the health of the animal, and the stomach may be excised without the individual manifesting any marked disturbance, but exclusion of the pancreatic secretion from the intestine causes great alteration in the digestion of all classes of food-stuffs.

The other main advances have been in the elucidation of the influence of the nervous system on the gastric and pancreatic secretion, and the more complete working out of the stages of the chemical changes in the food-stuffs which constitute digestion, and of the course and duration of digestion in various parts of the alimentary canal.

Nerves of Digestion.—Pawlow, by dividing the œsophagus in the dog and bringing both divided ends out in the neck, was able to allow the animal to feed without the food reaching the stomach. He showed that this "pseudo-feeding" leads to a free flow of gastric juice. This reflex flow is brought about by the vagi, since it occurs after section of the splanchnics, but is stopped by section of both vagi. Stimulation of the lower end of the cut vagus by slow induction shocks brings about a flow of gastric juice after a somewhat prolonged latent period. That the vagus is the secretory nerve of the pancreas, as was indicated by the investigations of older physiologists, has been also more clearly demonstrated by Pawlow by the method of stimulating some days after section. Stimulation of the central end of the cut vagus, or of the lingual, brings about a reflex secretion, but, as shown by Popielski, the vagus also contains efferent inhibitory fibres, so that it has a double action in the pancreatic centre.

Course of Gastric Digestion.—Numerous studies of the course of

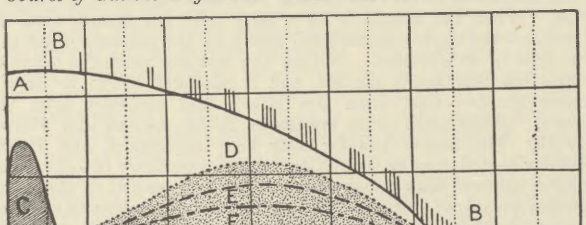

Diagram illustrating the course of Gastric Digestion in Man. A, Solids in stomach; BB, opening of pylorus; C, amylolytic digestion; D, peptic digestion; E, total HCl; F, combined HCl.

gastric digestion in man have been made by removing the contents of the stomach at various periods after a meal by means of a soft rubber tube. The result of these studies may be tabulated in the foregoing diagram. The steps by which the complex proteid molecules taken in the food are in the stomach broken down into the simpler peptone molecules, have arrested the attention of several chemists, some of whom have increased rather than dispelled the obscurities surrounding the problem. Neumeister, however, shows that the process may be divided into the following stages:—

Native Proteid.
Syntonin (Acid Proteate).
Proto-proteose. Hetero-proteose.
Deutero-proteose.
Peptone.

That a splitting of a large into smaller and smaller molecules takes place in the process, is shown by the proportion of metallic salts combining with these various bodies. The molecular weight of such a native proteid as egg albumen is probably no less than 15,000, that of its proto-proteose 2400, and of peptone 400. Thus six peptone molecules will be yielded by one of proto-proteose. It appears that the hetero-proteose molecule is about five or six times the size of the molecule of proto-proteose.

Curdling of Milk.—The way in which milk is clotted by the gastric juice has been considerably elucidated. It has been shown that the casein occurs in milk as a neutral lime salt, and that a mineral acid splits this, taking the lime and causing the casein to be precipitated. But under the action of rennin, in neutral or even in faintly alkaline solution, a lime salt of para-casein is set free, with a small amount of "whey albumen." This salt of para-casein is insoluble, and hence it separates as the curd. If lime salts are precipitated, the process cannot go on. The para-casein is acted on by pepsin and hydrochloric acid, and is changed into proteose and para-nuclein, which very slowly splits into proteose and para-nucleic acid containing phosphorus. The rennin or milk-curdling zymin of the pancreatic juice has a somewhat peculiar action. It forms a granular precipitate at the body-temperature, which changes to a coherent curd when the milk is cooled. The process is not prevented by the precipitation of the lime salts with oxalate of potash. The true chemical nature of the precipitate has not been studied.

Pancreatic Splitting of Proteids.—It has for long been known that pancreatic juice has a more profound action on proteids than the gastric juice; that it does not merely reduce them to the simplest proteid molecule—peptones—but that it breaks these down into yet simpler molecules. For long only two of these combinations, leucin and tyrosin, were known, but it has now been ascertained that these bodies may be classified as follows:—

Amido-Acids of the Fatty Acid gives	Bases.	Aromatic Bodies.	Other Bodies.
Amido-caproic acid (leucin)			Tryptophan.
Diamido-caproic acid (lysin)	Methyl-guanidin-propionic acid (lysatinin).		
Amido-valerianic acid	Ammonia.	Para-oxy-phenyl-amido-propionic acid (tyrosin).	
Amido-succinic acid			
Amido-pyrotartaric acid			

The main interest of this decomposition is the light it throws upon the constitution of the proteid molecule, nearly all the derivatives being amidogen compounds.

Intestinal Secretion.—Investigations have proved that the great chemical action of the intestinal secretion is to convert disaccharids into monosaccharids. Thus maltose is changed to dextrose, cane sugar to dextrose and lævulose. Apparently, however, lactose is not split, although it undoubtedly is split before it passes into the blood. The secretion has also a slight diastatic action; but as this is possessed by all secretions containing mucin, and by nearly all the tissues, it is of no special importance.

Bile.—The flow of bile, which begins in intra-uterine life, persists throughout life, even during protracted starvation; and while the taking of food increases it, the increase does not reach its maximum for many hours. In these respects it differs from the other secretions poured into the alimentary canal. In man the amount secreted per diem is probably about 800 c.c. with about 15 grms. of solids. Although the secretion of bile is not immediately connected with the taking of food, it is influenced by the character of the food. The most marked increase in secretion follows a proteid diet, the next most marked a fatty diet, the least marked a carbohydrate diet. Bile may leave the liver as it is secreted, or it may accumulate in the bile passages and gall bladder, to be expelled afterwards. For this reason the flow is very irregular, and is influenced by such factors as the pressure of the viscera upon the liver and the reflex stimulation of the nerve passing to the muscular walls of the bile passages. The slight increased flow of bile immediately after the ingestion of food is due to this expulsion of bile.

The older analyses were made on bile taken from the gall bladder, where it appears to be concentrated from the absorption of water. Various observations have now been made on bile escaping from a fistula, and these show that the percentage of solids usually given is too high. In such bile the solids amount to between 1·5 to 2·0 per cent., the inorganic solids being about 0·6 to 0·8 per cent. The salts of the bile acids are about 0·4 to 0·8 per cent., and are by far the most important organic constituents. That the salts are formed in the liver cells is demonstrated by the fact that when the liver is excluded from the circulation and the bile duct ligatured, they do not appear in the blood. In man the chief salt is glycocholate of sodium; the acid of this salt splits into amido-acetic acid and cholalic acid. In dogs, taurocholate of sodium is the chief salt, and the taurocholic acid yields amido-ethane-sulphuric acid and cholalic acid (p. 725). Both, therefore, are amidogen compounds. These salts must therefore be derived from the proteid constituents of the tissues or of the food.

The pigments of the bile are iron-free, and are derived from the hæmatin moiety of the hæmoglobin molecule. They are formed in the liver cells, exclusion of the liver from the circulation preventing their appearance. Not only can the liver cells form these pigments, but they can take them, as well as other pigments, from the blood and excrete them. Cholesterin, the important constituent of most gall-stones, is formed within the liver, and not merely excreted by it. The investigations of Naunyn have led him to the conclusion that it is derived from the breaking down of the cells in the bile passages, and not from the liver cells. The fat and lecithin are apparently derived from the fats and lecithin always present in the liver tissue.

The action of the bile in digestion is of small importance, and its exclusion from the intestine does not seem to have a prejudicial effect, either on men or on animals. Its main, if not its only, digestive function is to act as adjuvant to the pancreatic juice. It dissolves the fatty acids freed by the fat-splitting zymin, and thus assists their absorption. For this reason exclusion of bile from the intestine markedly diminishes the absorption of fats, about 30 per cent. escaping. Bile, indeed, is not so much a digestive secretion as an excretion. This view is confirmed by the following facts:—(1) The small importance of bile in digestion. (2) The presence of a pigment, the result of breaking down of hæmoglobin. (3) The chemical nature of the acids, indicating their origin from the decomposition of proteids. (4) The secretion of bile before birth and during starvation. (5) The absence of any immediate relationship of bile secretion to the ingestion of food.

Synopsis of Digestive Processes.

Section of Alimentary Canal.	Chemical Change.	Active Agent.
I. Mouth	Starch to maltose.	Ptyalin.
II. Stomach (first ½ hr.)	1. Starch to maltose.	Ptyalin.
	2. Maltose to lactic acid.	Bacteria.
(Reaching maximum in 3 or 4 hrs.)	3. Proteids to peptone.	Pepsin and HCl.
III. Intestine.		
(*a*) Pancreatic secretion	1. Proteids to peptone.	Trypsin.
	2. Starch to maltose and dextrose.	Amylopsin.
	3. Fat to glycerin and free acids (soaps).	Pialin.
	4. Peptone to tyrosin, &c.	Trypsin.
(*b*) Succus entericus	Disaccharids to monosaccharids.	Zymin.
(*c*) Micro-organisms		
(1) Small intestine	Sugar to organic acids.	*B. lactis*, &c.
(2) Large intestine	Proteids to indol, &c.	*B. coli communis*, &c.

Micro-organisms in Digestion.—The micro-organisms of the alimentary canal have been extensively studied. A very large number of bacteria are swallowed in the saliva and with the food. How far their passage downwards is checked by the leucocytes which are poured out into the saliva from the lymphoid tissue of the tonsils, has not been definitely settled, but it is highly probable that it is so checked. When the stomach is reached, the organisms swallowed with the food continue to act, and thus sugar is changed to lactic acid; but when free hydrochloric acid appears, the growth of nearly all organisms is checked, while some—*e.g.*, the comma bacillus of cholera—are destroyed. Most of the organisms pass on into the intestine; and as the free hydrochloric acid becomes combined and neutralized, the acid-forming organisms again become active and proceed to split up sugar, setting free lactic, acetic, and other acids, and so, by keeping the contents of the small intestine acid prevent the growth of putrefactive organisms. Under normal conditions the alkalis formed in the intestine gradually neutralize the acids produced; and by the time the large intestine is reached, the putrefactive organisms are able to grow, and to split up the proteid molecule to form various aromatic bodies, such as tyrosin, indol, scatol, &c. Of the organisms of the large intestine, the *bacillus coli communis* is by far the most constant and most abundant. The theory has been advanced that these organisms play an important part in digestion; but by procuring fœtal guinea-pigs directly from the uterus with aseptic precautions, and feeding them on sterilized food, it has been shown that micro-organisms in the intestine are of secondary importance.

Absorption of Food.—The portions of the food which are to be used in the metabolism are absorbed from the alimentary canal. As a result of digestion, the three proximate principles of the diet are changed—the carbohydrates to monosaccharids, chiefly dextrose, the proteids to peptones, and the fats to soaps, fatty acids, and glycerin. Absorption does not occur uniformly throughout the canal. Thus, while sugar and peptones are absorbed from the stomach, water is absorbed only to a small extent. That absorption is not due merely to a process of ordinary diffusion or osmosis, is clearly indicated by many facts. Heidenhain has shown that absorption of water from the intestine takes place much more rapidly than diffusion through a dead membrane. The relative rate of absorption of different substances does not follow the law of diffusion. Grübler's peptone passes more easily through the intestine than glucose, but glucose passes more readily through parchment paper, while sodium sulphate, which is more diffusible than glucose, is absorbed much less readily. Again, as shown by Reid, an animal can absorb its own serum under conditions in which filtration into blood capillaries or lacteals, osmosis and adsorption, are excluded; and this absorption is stopped or diminished when the epithelium is removed, injured, or poisoned, in spite of the fact that removal must increase the facilities for osmosis and filtration.

There are two channels of absorption from the alimentary canal: the veins which run together to form the portal vein of the liver, and the lymphatics which run in the mesentery, and, after passing through some lymph glands, enter a *receptaculum chyli* in front of the vertebral column. From this the great lymph vessel, the *thoracic duct*, leads up to the junction of the left subclavian and innominate vein, and pours its contents into the blood-stream.

While peptones are formed from proteids by digestion, they undergo a change in the intestinal wall before passing to the tissues. It is probable that they are taken up by the leucocytes of the adenoid tissue of the wall of the alimentary canal, since under a proteid diet these increase in number and stream away in the blood, to produce a digestive leucocytosis. By breaking down in the blood-stream they probably set free the proteids for use in the tissues. When an excess of proteids is taken in the food, it is broken down in the lining membrane of the gut, its nitrogenous part forming ammonia compounds. Its non-nitrogenous part may yield carbohydrates, since a proteid diet leads to the accumulation of glycogen in the liver. The ammonia compounds are carried to the liver and there changed to urea, and excreted as such, and thus the entrance of an excess of nitrogen to the tissues is prevented. It has been pointed out that gastric juice does not dissolve the phospho-proteids, but that they are dissolved by the pancreatic juice. The phosphorus is undoubtedly absorbed in organic combination, but the mode of absorption and the channels by which the blood-stream is reached have not been investigated. Though the chief monosaccharid formed in digestion is dextrose, others are also produced—from cane sugar lævulose, and from milk sugar galactose as well as dextrose. All these are absorbed in solution, and are carried away in the blood by the portal vein. It was for long thought that the fats are absorbed as a fine emulsion, but the most recent investigations seem to indicate that, after being split up into the component acids and glycerin, they pass, as soluble soaps or as the fatty acids soluble in the bile, through the borders of the intestinal epithelium. Here they appear to be again converted to fats by a synthesis of the acid with glycerin, and as fine fatty particles they are passed on from the cells, through the lymph tissue of the villus, into the central lymph vessels, and thus on through the thoracic duct to the blood-stream. Unlike the proteids and carbohydrates, they are not carried directly to the liver.

Fate of absorbed food.

The food thus absorbed may be used immediately as a source of energy, either for the construction or reconstruction of tissues, or for the production of mechanical work or heat. Or, on the other hand, it may be stored for future use in the body. Such storage takes place chiefly in three situations: (1) Fatty tissue; (2) Muscle; (3) Liver.

1. *Storage in Fatty Tissues.*—In most mammals the chief storage of surplus food is in the fatty tissues. That the fat of the food can be stored in them is shown by the fact that the administration of fats different from those of the body leads to their appearance in those tissues. Fats are also formed from the carbohydrates of the food. Feeding experiments upon pigs and other animals have definitely proved that sugary foods are changed to fat in the body and stored in that form. In fact, the conversion of cheap carbohydrates into the more expensive fats is the basis of the profits of the grazier. When it is remembered that as much energy is stored in a pound of fats as in two pounds of carbohydrates, the advantage of this conversion becomes manifest. There is good evidence that in excessive proteid feeding the non-nitrogenous part of the proteid molecule may be stored as fat. It has been maintained that the evidence in favour of the formation of fats directly from proteids is unsatisfactory; but since proteids do yield carbohydrates, and since carbohydrates form fats, it must be admitted that proteids may be a source of fats.

2. *Storage in Muscle.*—Some animals, as the salmon, store fats within their muscular fibres, but in mammals such a storage is limited in amount. The salmon also stores surplus proteid material in the muscles, and mammals too appear to do the same. How far a passive storage may occur is not known, but feeding experiments on mammals indicate that only a small amount of proteid can be accumulated. On the other hand, the experience of athletic training shows that the muscles may be enormously increased by building up the proteid of the food into their protoplasm.

3. *Storage in the Liver.*—The liver is the chief storehouse of carbohydrates in all animals, and of fat in some—*e.g.*, the cod.

Action of liver.

It is a matter of interest that the liver develops as a digestive gland—as a couple of diverticula from the embryonic gut. But early in fœtal life it comes to have important relationship with the blood going to nourish the body from the placenta. The vein bringing the blood breaks up into a series of capillaries in the young liver, and in these capillaries for a considerable time the development of the red cells of the blood goes on. Soon the liver begins to secrete bile, while animal starch and fat begin to accumulate in its cells. Gradually the formation of red cells stops, and the mass of liver cells become larger in proportion to the capillaries. As the fœtal intestine develops, the vein bringing blood from it—the portal vein—opens into the capillary network of the liver, so that, when at birth the supply of nourishment from the placenta is stopped, the liver is still associated with the blood bringing nutrient material to the tissues.

Claude Bernard discovered that there is a constant formation of sugar in the liver. Even when an animal undergoes a prolonged fast, the amount of sugar in the blood on account of this constant supply does not diminish. In starvation there are only two possible sources of this glucose—the fats and the proteids of the tissues. That fats can be changed to sugar in the liver was maintained by Seegen as a result of experiments *in vitro*, but his results have been questioned by subsequent investigators. That proteids are a source of sugary substances is shown by the accumulation of a starch in the liver in animals fed upon proteids; it is therefore probable that in starvation the proteids of the body are broken down and their non-nitrogenous part changed to sugar. Not only does the liver manufacture sugar for the tissues in starvation, but when the supply of sugar is in excess of the demands of the tissues, it stores it as a form of glycogen, and gives it out as sugar as this substance is required. On a carbohydrate diet the accumulation of glycogen in the liver is very great; but even on a proteid diet, in dogs at least, a smaller accumulation takes place. The observation that various monosaccharids are stored as the same form of glycogen, shows that they must first be assimilated by the liver protoplasm and then converted into glycogen. The mode in which glycogen is again changed to sugar is more doubtful. The fact that the liver after treatment with alcohol can change glycogen to glucose, has induced some physiologists to believe that it is by a zymin that this conversion goes on during life. But there is considerable evidence against this view; and it is possible that the conversion results from chemical changes in the liver protoplasm, which are controlled by the nerves of the liver. If too much sugar passes from the liver, or if the tissues do not use up the sugar produced, it appears in the urine, and *glycosuria* occurs.

Though the fats are not carried directly to the liver, like proteids and carbohydrates, they are stored in large amounts in the liver of some animals, *e.g.*, the cod among fishes and the cat among mammals. It appears that animals which have little power of storing fat generally throughout the muscles and other tissues, have a marked capacity for accumulating it in the liver. Even in starvation the fats do not disappear from the liver, and throughout all conditions of life a fairly constant amount of lecithin—a phosphorus and nitrogen containing fat—is present in the liver cells. There is good evidence that the lecithin is a stepping-stone in the formation of the more complex nuclein bodies of living cells; and it is possible that, in the formation of lecithin in the liver by the synthesis of glycerin, fatty acids, phosphoric acid and cholin, the first steps in the construction of the nuclein are carried out. If this is so, the fat of the liver may play an important part in retaining and fixing phosphorus in the body. There is some evidence, though not conclusive, that the liver fats may be formed from carbohydrates.

Along with the intestinal wall, the liver regulates the supply of proteids to the body. Study of the chemical changes in muscle has shown that the waste of proteid is normally small in amount, and that a great part of the nitrogen is capable of being used again if a supply of oxygen and carbonaceous material is forthcoming. Hence the demand for nitrogen in the muscles is small; and for this reason, apparently, any excess of proteid in the food is decomposed to ammonia compounds in the intestinal wall, and these are built into urea in the liver, to be thus excreted. After the splitting of the nitrogenous portion, the liver has the further power of turning the non-nitrogenous part into sugar, and either sending it to the tissues or storing it as glycogen. How far it is also able to perform the initial splitting of the proteid molecule has not been determined, but that it can manufacture urea from proteids without the co-operation of the digesting intestinal wall, is indicated by the constant production of urea in starvation. With one special proteid—hæmoglobin—the liver has important relations. The hæmoglobin breaks down, and the proteid part, which constitutes about 96 per cent. of its weight, is further decomposed, and its nitrogen excreted as urea, while the pigmented hæmatin portion is deprived of its iron and excreted as bilirubin.

The functions of the liver as regards the general metabolism may therefore be summarized thus:—(1) It regulates the supply of glucose to the body, (*a*) by manufacturing it from proteids when the supply of carbohydrates is cut off, and (*b*) by storing it as glycogen when the supply of carbohydrates is in excess, and afterwards giving it off as required. (2) It regulates the supply of proteids to the body, along with the intestinal wall, by decomposing any excess and giving off the nitrogen as urea, &c. (3) It regulates, in many animals at least, the supply of fat to the body by storing any excess. (4) It regulates the number of hæmocytes by getting rid of waste hæmoglobin and retaining the iron for further use.

D. *Excretion.*

Though our knowledge of the various stages of the catabolism of protoplasm is defective, the end products are fairly well known. These are excreted from the body, sometimes in the form in which they leave the tissue producing them, sometimes after further modification. The carbon dioxide and water formed in the tissues are excreted by the lungs (see RESPIRATION, below) and by the kidneys and skin without further change. The creatin of muscle is dehydrated to creatinin in the kidney before being excreted in the urine. As already pointed out, the various ammonia compounds are in the liver built up into urea or into diureides. That ammonia is a source of these diureides in birds, is shown by the fact that exclusion of the liver from the circulation in these animals leads to their disappearance from the urine, and to the appearance of lactate of ammonia in their place. How far in mammals the diureide molecule is derived solely from the splitting of nucleic acid, is not yet definitely known.

Kidneys.

The chief channel of the excretion of the nitrogenous waste products is the kidneys (see ANATOMY). In spite of many investigations, the difficulty of fully and satisfactorily explaining the way in which urine is produced in them has proved insurmountable. What is actually known may be briefly summarized:—(1) The watery part of the urine is produced by a process of filtration from the glomerular tufts. (2) Solids are also excreted from the glomerular tufts, since the fluid in the capsules is *alkaline*, and since such a pigment as sulph-indigotate of soda has been found in the epithelium covering the glomeruli. (3) The specific constituents of the urine are secreted by the epithelium of the convoluted tubules. (4) The convoluted tubules can also secrete water to a very considerable extent. This has been demonstrated by Munk's experiments of stopping the secretion of urine from the glomeruli by section of the cord, and then injecting caffeine, urea, &c., and producing a flow of urine from the tubules. But the old problem, whether any water or solids are reabsorbed in the tubules remains unsolved, though it must be admitted that nearly all the evidence which appears to support this view equally supports the other view, that the urine is changed in the tubules by the addition of solids. The very high osmotic equivalent of the urine as compared with that of the blood plasma is certainly opposed to the view that there is a passage of water from the urine to the plasma, for to bring about such an absorption the cells would have to do an amount of work so enormous that it is impossible to conceive that they accomplish it.

The acid reaction given to the urine in its passage through the tubules may equally well be explained by the absorption of its alkaline constituents, or by the addition of such acids as phosphoric and sulphuric acid. Perhaps the only experimental support for this idea of absorption is to be found in the observation of Ribbert, that removal of the medulla leads to the production of a more watery urine. But some experiments by Francis Boyd have yielded results which do not corroborate those of Ribbert.

In connexion with the action of the kidneys, a very curious observation has been made by Rose Bradford: that if, after one kidney has been removed from the dog, portions of the second are cut out, an increased flow of urine takes place; while if only about one-sixth of the total kidney substance is left, not only polyuria but an increased excretion of nitrogen, resulting from a rapid dissolution of the proteids of the body, chiefly of the muscles, occurs, and the animal dies in a short time. In all probability this is due to the accumulation of some toxic substance in the blood, and not, as has been suggested, to the formation of an internal secretion by the kidney.

Other organs of excretion.

The *Skin* is a channel of excretion of secondary importance compared with the lungs or the kidneys. By it are excreted in the sweat:—(1) Water. (2) Sodium chloride. (3) Nitrogen. (4) Carbon dioxide. (5) Various other substances in small quantities. The excretion of water varies with the temperature, from less than 500 to probably over 3000 c.c. per diem. Of the nitrogen excreted in the sweat, about 68 per cent. is in the form of urea, the rest being in the form of ammonia. The cutaneous excretion of nitrogen may amount to between 4 and 5 per cent. of the renal excretion. The carbon dioxide varies in amount; it probably does not usually exceed 9 grms. per diem, but under the influence of high temperature may rise to over 20 grms. One special modification of cutaneous excretion is the production of *milk*. In the 9th edition of this Encyclopædia the mode of secretion and the composition of milk are dealt with. The mode of secretion has not recently been investigated, but our knowledge of the composition of milk has been considerably extended. The chief proteid, caseinogen, is a pseudo-nucleo-proteid of marked acid character, occurring in a neutral lime combination which is not precipitated on boiling. But whenever the lime combination is split up by an acid, the free caseinogen becomes precipitated. When acted on by the rennet-zymin, caseinogen is split up into whey albumen and into para-caseinogen, which latter combines with the soluble lime salts of the milk to form an insoluble casein. This, with the entangled fats, constitutes the curd. The amount of phosphorus in caseinogen is small—only about ·8 per cent. After separation of the caseinogen, milk is found to contain traces of an albumen and of a globulin. Phosphorus occurs in milk in two organic combinations other than caseinogen: (1) Phosphocarnic acid, a substance which splits into phosphoric acid and carnic acid, which, according to Siegfried, is identical with antipeptone; and (2) Lecithin. It also occurs as inorganic salts of potassium, sodium, and calcium. The proportions of phosphorus in these different combinations vary much in different animals. The subjoined table shows that in human milk the greater amount of the phosphorus is organically combined:—

Per Centage of Phosphorus as P_2O_5.

	Organic.	Inorganic.	Total.	Per Cent. of Organic.
	P_2O_5.	P_2O_5.	P_2O_5.	P_2O_5.
Human . .	0·04	0·007	0·047	85
Cow . .	0·076	0·074	0·150	50
Goat . .	0·13	0·16	0·290	41

From the various *mucous membranes*, but chiefly from the mucous membrane of the bowel, a certain excretion of water, mucus, and various salts takes place. In some herbivora the excretion of phosphates by this channel occurs, to the exclusion of their excretion by the kidneys. Certain salines given as drugs are also got rid of by the lining membrane of the bowel.

The *Liver* as a channel of excretion has been already considered.

(D. N. P.)

Chemistry of Animal Body.

The following is an account of the chemistry of some of the more important substances that occur in the animal body:—

A. Anastates. — Substances which take part in the constructive (anabolic) processes in protoplasm:—

1. *Carbohydrates.*—These are aldehydes or ketones, and derivatives of these formed by polymerization and dehydration. They are for the most part derived from the members of the paraffin series, containing six carbon atoms (hexoses); but derivatives of the pentatomic alcohol (pentoses) have been derived from nucleins. The hexoses are derived from three hexacid alcohols isomeric with one another—mannitol, dulcitol, and sorbitol, $C_6H_{14}O_6$. From the first the sugar mannose is formed; from the second, galactose; and from the third, dextrose. The ketone of mannite is lævulose. Dextrose, or a body closely resembling it, has been prepared synthetically by the polymerization of formaldehyde.

The simplest carbohydrates constitute the group of monosaccharids, of which dextrose, *the* sugar of the animal body, is the most important. They are crystalline substances, readily soluble in water and in hot alcohol, and are fermented by ordinary yeast, yielding alcohol and carbonic acid, and by various micro-organisms, *e.g.*, the *Bacillus lactis*, giving lactic acids. They are readily oxidized in alkaline media; when boiled with caustic potash, they take up oxygen from the air and become brown from the development of acids (Moore's test). If cupric oxide is present, the oxygen is taken from this, and it is reduced to cuprous hydrate (Trommer's and Fehling's test). With phenyl-hydrazin they each form a crystalline compound, an osazone, by which their presence is readily recognized.

Glycuronic acid, $COH-(CH\cdot OH)_4-COOH$, is closely related to dextrose, and on oxidation yields the same acid, saccharic acid, and may be prepared from this by reduction. It does not occur free in the body, but is formed under the administration of various drugs, with which it combines, *e.g.*, camphor, and a large number of aromatic bodies like benzoic acid. These compounds appear in the urine; and since many of them are oxidized when boiled with caustic potash, they reduce Fehling's solution.

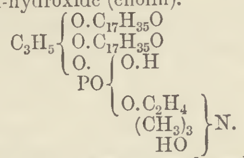
The monosaccharids polymerize with the loss of water, thus—$C_6H_{12}O_6+C_6H_{12}O_6=C_{12}H_{22}O_{11}+H_2O$, and disaccharides are produced. The most important of these are cane sugar (dextrose and lævulose), lactose (dextrose and galactose), and maltose (dextrose and dextrose). These rotate the plane of polarized light to the right, and break up into their component monosaccharids when boiled with an acid. Maltose and lactose are readily oxidized when boiled with an alkali, but cane sugar is not so oxidized.

By further polymerization and loss of water the group of polysaccharids n $(C_6H_{10}O_5)$ is produced, which form a series of bodies commencing with substances of very slightly higher molecular weight than the disaccharids, and extending up to the various starches, &c., which have probably a very large molecule. These most complex molecules are readily broken down by the action of acids, &c., and the series of bodies intermediate between them and the sugars are the dextrins, formed from starch, and the lævulins, formed from inulin. In physiology the most important members of this group are animal starch or glycogen, and vegetable starches and cellulose.

2. *Fats.*—These are ethers, formed by replacing the H of the HO molecule, usually of the triatomic alcohol glycerin, by the radicals of the fatty acids, which are derived by the oxidation of the various alcohols of the paraffin series. The acid with 16 atoms of carbon (palmitic$=C_{16}H_{32}O_2$) and the acid with 18 atoms of carbon (stearic$=C_{18}H_{36}O_2$) enter into the formation of the fat of mammals. Oleic acid ($=C_{18}H_{34}O_2$), a member of the less saturated acid series, is the most abundant acid in the fat. The fats all give a peculiar "oily" sensation, and leave a characteristic stain on various textures. They are insoluble in water, soluble in ether, chloroform, benzene, &c., also in hot alcohol. When dissolved in hot alcohol, palmitin and stearin crystallize out as the alcohol cools in the so-called margarin crystals. The melting-point varies according to the fatty acid which is present; thus olein melts at 5° C., palmitin at 45° C., and stearin at about 60° C. The olein at the temperature of the human body holds the two other fats in solution. They are readily split into glycerin and the characteristic fatty acid, and these may be broken down into fatty acids lower in the series under the action of putrefactive organisms, thus:—

$$\underset{\text{Propionic acid.}}{C_3H_6O_2}+O_3 \;=\; \underset{\text{Acetic acid.}}{C_2H_4O_2}+CO_2+H_2O.$$

In the body of man and other animals certain fats occur which are ethers of other alcohols than glycerin. Thus lanolin is the ether of the monatomic alcohol cholesterin ($C_{26}H_{43}OH$), which is soluble in ether and in hot alcohol, and crystallizes from the latter in characteristic rhombic plates. Lanolin, which occurs in the secretion of the sebaceous glands, combines with water and resists putrefaction in a marked manner. Spermaceti is the palmitate of cetyl alcohol, and beeswax the ether of cerotyl alcohol with cerotic acid. Lecithin is a fat in which one molecule of the radical of the fatty acid is replaced by phosphoric acid linked to trimethyl-oxyethyl-ammonium-hydroxide (cholin).



It is soluble in alcohol and ether, and swells up in water. It readily splits up into glycero-phosphoric acid, fatty acids, and cholin.

3. *Proteids.*—These bodies are of unknown constitution, but they contain the elements carbon, hydrogen, oxygen, nitrogen, and usually sulphur (sometimes also phosphorus in about the same percentage amounts), and give certain characteristic reactions. They constitute by far the greater part of the solids of all matter which has been living, and it is for this reason that they are named Proteids, or first substances. Drechsel gives the percentage composition thus:—

C	50·0 to 55·0
H	6·8 ,, 7·3
N	15·4 ,, 18·2
O	22·8 ,, 24·0
S	0·4 ,, 5·0

The nature of the compounds formed with metals, and the difficulty with which they dialyse through animal membranes, indicate that the proteid molecule is very large. Drechsel studied the magnesia compound of one of the vegetable proteids, and puts the *molecular weight* at 2757, while another investigation of a similar compound of ordinary albumen indicated a molecular weight of 1496. All that is known of the empirical formula is that in albumen it is not smaller than $C_{72}H_{112}N_{18}O_{22}S$, and very possibly the molecule is three times as large. What the constitution of the simplest possible proteid molecule may be has not been determined. We know that when the molecule is broken down, certain products are constantly formed. Among these are: Amido-acids of the fatty acid series, *e.g.*, leucin (amido-caproic acid); amido acids of the benzene series, *e.g.*, tyrosin; and certain ureides, having six carbon atoms, *e.g.*, lysatinin. According to Kossel, the simplest type of proteid is to be found in a series of bodies which are linked with nucleic acid in spermatozoa. These Protamins, when decomposed, take up water and yield the bases above referred to. They do not, however, yield the amido acids which are derived from ordinary proteids, and Kossel regards these as existing in "side chains" to the elementary protamin molecule. The proteids may be recognized by a number of *tests*, of which the most generally useful is the Xanthoproteic reaction. When boiled with nitric acid they decompose, with the formation of certain aromatic bodies, which give a brilliant orange colour with ammonia.

The proteids form a series of polymerization products of their *simplest molecule*, and the various members of the series differ from one another in their solubility and in their rate of diffusion.

Of the "simple proteids," (*a*) *peptones* are the lowest members in the series. They are very soluble, dialyse readily, are not coagulated by heat, and are not precipitated from their solution by saturation with ammonium sulphate. They polymerize, to form a series of (*b*) *proteoses*, which are not coagulated by heat and are precipitated in a saturated solution of ammonium sulphate. The lower members of the series, those most near the peptones, which are not precipitated by sodium chloride, are called the *deutero-proteoses*. The higher members, which are precipitated by that salt, are the *protoproteoses*. (*c*) *Native proteids*, on coagulation by heat, form *coagulated proteids*, and are precipitated by saturated ammonium sulphate. They do not readily dialyse through an animal membrane. When acted upon by acids or by digestive juices, they break down into proteoses, and finally into peptones. Two varieties are known: *Albumens*, which are soluble in distilled water, and are not so readily precipitated by neutral salts as the second variety; and *Globulins*, insoluble in distilled water, soluble in weak solution of neutral salts, and readily precipitated by stronger solutions.

The members of these various groups of proteids tend to link to various other bodies, to form what may be called the "combined proteids." According to the nature of the molecule with which they are linked, these may be classified into the following groups:—(*a*) *Glycoproteids*—a number of proteids, on treatment with acid, yield various sugar-like bodies, and some investigators have thought that there is a carbohydrate element in the proteid molecule. But since from many of the proteids no sugary substance can be prepared, we must consider that the carbohydrate molecule is simply linked to the proteid, possibly forming what Kossel has called a side chain. One of the best marked of this group is Mucin, the substance which gives viscosity to the saliva. (*b*) *Ferro-proteids*—proteids combined with an iron-containing molecule. The best-known of these is the colouring matter of the blood, hæmoglobin, which consists of about 96 per cent. of a globulin linked with about 4 per cent. of hæmatin. (For the chemistry of hæmoglobin see PIGMENTS, below.) (*c*) *Phospho-proteids*—proteids combining with a phosphorus-containing molecule—may be divided into two classes: *Nucleins*, where the proteid is linked to nucleic acid, which on decomposition yields phosphoric acid and the purin bases; and *Pseudo-nucleins*, which on decomposing yield a proteid and a phosphorus-containing acid, the latter readily splitting, to yield phosphoric acid but no purin bases. (*d*) *Phospho-ferro-proteids*, in which the proteid is linked to both a phosphorus and an iron-containing molecule, are illustrated by the vitellin of the yolk of egg. (*e*) *Sulpho-proteids* are proteids to which a considerable amount of sulphur—3 to 5 per cent.—in loose combination is attached. Keratin, the substance composing horn and the outer layer of the skin, is of this nature. (*f*) *Acid and Alkaline Proteids*—Acids and alkalis form combinations with proteids, which are of importance in the process of digestion.

Two peculiar modifications of this proteid group do not find a definite place in this classification:—(*α*) *Elastin*, the substance composing elastic fibrous tissue, which has all the characters of an insoluble proteid, but is free from sulphur; and (*β*) *Collagen*, the substance composing white fibrous tissue, which may be regarded as a combination between a proteid and amido-acetic acid (glycocoll). It yields this latter substance in large amount when heated with an acid. Collagen readily combines with water, to form the well-known gelatin, and with chondroitinsulphuric acid, to form chondrin, the substance of cartilage. This acid is a compound of sulphuric acid with chondroitin, $C_{18}H_{27}NO_{14}$, which decomposes into acetic acid and chondrosin, and which yields, on further decomposition, glycuronic acid and glycosamin.

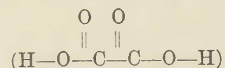
B. Catastates, the substances formed by catabolism of protoplasm in the body, and not further used by it as sources of energy.

I. *Non-Nitrogenous Bodies of the Fatty Acid Series.*

1. *Carbon di-oxide* ($O=C=O$), the substance in which the greater part of the carbon is excreted in the expired air.

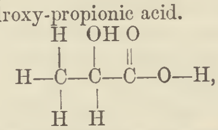
2. *Fatty acids.*—

Oxalic acid,



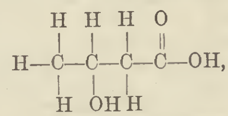
is found in urine as the oxalate of lime. It is chiefly derived from the oxalates in the food, but there is some evidence that it is formed in proteid catabolism.

Lactic acid is a hydroxy-propionic acid.



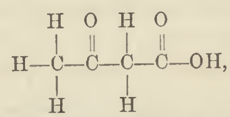
It occurs in the animal body in two isomeric forms. Ordinary lactic acid is obtained by the lactic acid fermentation of sugars, as in the souring of milk. It is a fluid of syrupy consistence, and is optically inactive. Sarcolactic acid is the acid formed in muscle. It is a syrupy fluid, which rotates the plane of polarized light to the right.

β Oxybutyric acid,



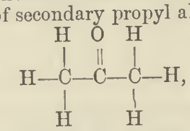
is found in the urine in starvation, in diabetes, and in certain other pathological conditions. It is derived from the decomposition of proteids.

Aceto-acetic acid,



occurs in the urine in the same condition as oxybutyric acid.

Aceton (the ketone of secondary propyl alcohol),



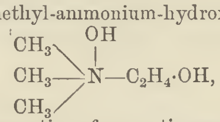
occurs in the urine along with the last two in the same circumstances.

II. *Nitrogenous Substances not of the Benzene Series.*

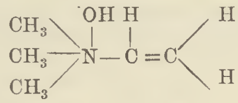
(1) *Ammonia and the Amines.*—

Ammonia (NH_3) is formed in the tissues and in the intestine, probably as the lactate. It is constantly present in the urine in small quantities, and its amount is increased under various pathological conditions of the metabolism.

Hydroxy-ethyl-trimethyl-ammonium-hydroxide (cholin),

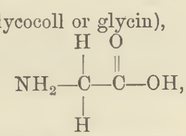


is formed in the disintegration of nerve tissues, being liberated from the lecithin molecule. It is a toxic substance. Neurine appears also to be formed.



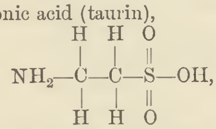
(2) *Amido Acids.*—

Amido-acetic acid (glycocoll or glycin),



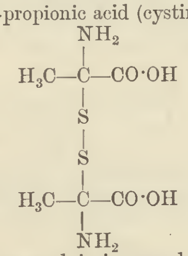
occurs in combination with cholic acid, forming the glycocholic acid of the bile.

Amido-ethyl-sulphonic acid (taurin),



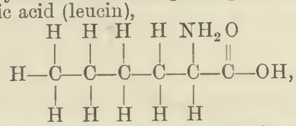
occurs in combination with cholic acid, forming the taurocholic acid of the bile. In the bile acids these are linked with cholic acid, $C_{24}H_{40}O_5$, a substance of unknown constitution.

Disulphide of amido-propionic acid (cystin),



occurs in traces in urine, and is increased in certain pathological conditions. It crystallizes in hexagonal plates.

α Amido-caproic acid (leucin),

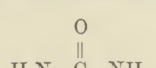


is formed in the pancreatic digestion of proteids, and appears in the urine in certain conditions. It crystallizes in characteristic oily-looking spheres.

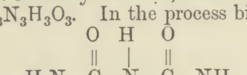
Di-amido-caproic acid (lysin) is a basic substance, also formed in the decomposition of proteids by pancreatic juice.

(3) *Amides.*—

Carbamide (urea),

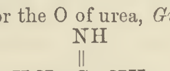


is the chief substance in which nitrogen is excreted in all vertebrates except the sauropsida. It crystallizes in long prisms, and is very soluble in water and alcohol. With nitric and oxalic acid it forms insoluble salts. It readily takes up water, to form carbonate of ammonia. When heated dry it forms cyanic acid, CN·OH, which polymerizes to cyanuric acid, $C_3N_3H_3O_3$. In the process biuret is formed.



With caustic potash and sulphate of copper this strikes a pink colour. With sodium hypobromite in excess of alkali, or under the action of nitrous acid, urea splits into nitrogen, carbonic acid, and water.

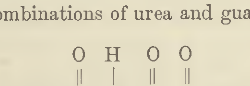
By substituting NH for the O of urea, *Guanidin* is formed.



It does not occur in the body, but is the basis of various important substances.

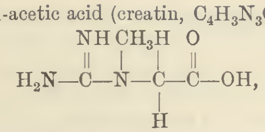
(4) *Ureides* are combinations of urea and guanidin with acids.

Oxaluric acid,

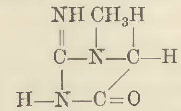


occurs in small traces in urine.

Methyl-guanidin-acetic acid (creatin, $C_4H_3N_3O_2$),



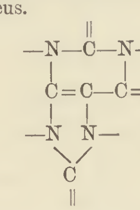
is a constant constituent of muscle. Creatinin is creatin which has lost a molecule of water and assumed a ring structure—



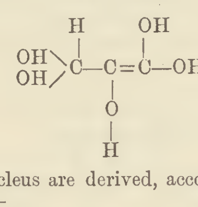
It is a normal constituent of the urine, and is crystalline and a powerful base.

Methyl - guanidin - propionic acid (lysatin) and lysatinin, $C_6H_{13}N_3O_2$, are homologues of creatin and creatinin, formed from proteids in pancreatic digestion.

(5) *Diureides* are formed of two molecules of urea linked through an acid chain. The most important are the Purin bases, derived from a double ring of five carbon and four nitrogen atoms, called by Fischer the Purin Nucleus.

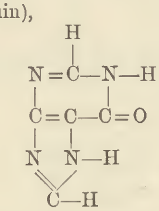


The hypothetical bond here is acrylic acid—an unsaturated propionic acid,

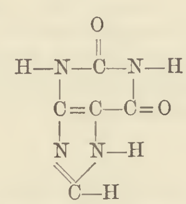


From the Purin Nucleus are derived, according to the degree of oxidation of the acid—

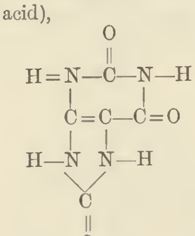
Oxypurin (hypoxanthin),



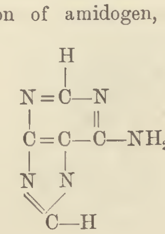
dioxypurin (xanthin),



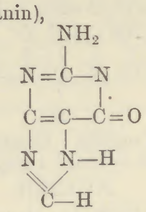
and trioxypurin (uric acid),



By the introduction of amidogen, amino-purin (adenin) is formed,

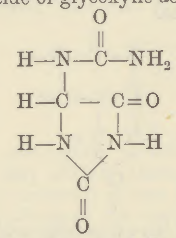


and amino-oxypurin (guanin),



Hypoxanthin and xanthin occur in small quantities in urine and in various organs. Uric acid, a dibasic acid ($NaH\bar{U}\cdot H_2\bar{U}$), is a soluble crystalline substance which occurs in small quantities, probably as sodium quadrurates, in the urine of mammals, and in large quantities in the urine of birds and reptiles. In birds, at least, it is in part formed in the liver from lactate of ammonia. In part it may be derived from the decomposites of nucleic acid. In mammals this is probably its chief source. Adenin was obtained by Kossel from the pancreas. Guanin is very widely distributed throughout the animal kingdom, occurring in the urine of birds, in the scales of fishes, and in many tissues, as the pancreas, liver, &c.

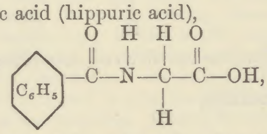
Allantoin is the diureide of glycoxylic acid.



It is a characteristic constituent of the allantoic and amniotic fluids and of fœtal urine, occurring also in the urine of the dog after the administration of uric acid and of nuclein. It crystallizes in small hexagonal prisms.

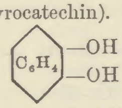
III. *Benzene Derivatives.*

Benzamido-acetic acid (hippuric acid),



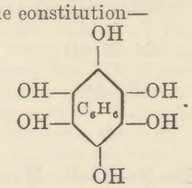
is formed by the union of benzoic acid and amido-acetic acid in the body. The former is derived from the food, the latter is formed in the body from proteids.

Ortho-dioxy-benzene (pyrocatechin).

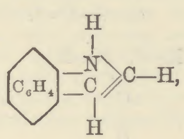


occurs as an ethereal compound with sulphate of potassium, $OH\cdot C_6H_4\cdot O\cdot SO_2OK$. Urine containing this, if exposed to air, especially if it be alkaline, becomes greenish brown or almost black. When boiled with an alkali, it reduces cupric hydrate.

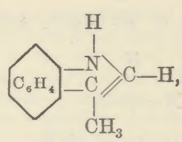
Inosite is a substance which used to be called muscle sugar, but which has probably the constitution—



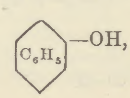
Indol,



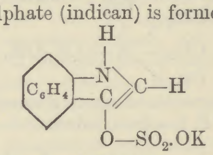
scatol (methyl indol),



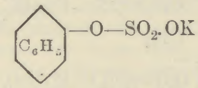
and phenol,



are substances formed by the action of putrefactive organisms upon proteids in the intestine. When absorbed, each is linked to sulphate of potassium, the two former after oxidation. Thus from indol, potassium indoxyl sulphate (indican) is formed—

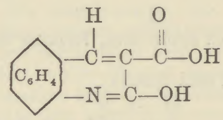


From scatol the scatoxyl sulphate of potassium is similarly produced; and from phenol, potassium phenyl sulphate—

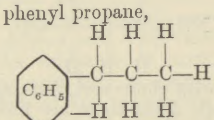


These are excreted in the urine. Indican when oxidized yields indigo blue, while the scatoxyl sulphate yields a reddish pigment.

Oxy-quinoline-carboxylic acid (kynurenic acid) has probably the formula—

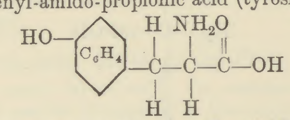


and is a derivative of phenyl propane,



It occurs in the urine of the dog, from which it may be crystallized in long white needles by evaporating and acidulating.

a Hydroxy-phenyl-amido-propionic acid (tyrosin),



is a product of the pancreatic digestion of proteids which crystallizes in sheaves of small acicular crystals, which are found in the urine in certain pathological conditions of the liver.

Pigments.

In this class are grouped, somewhat artificially, a number of substances, characterized by giving, even when present in very small quantities, to the tissue or fluid in which they occur a more or less marked colour. Their chemical nature is, generally speaking, little understood. They may be divided into lipochromes, blood pigments, and the waste pigments of the urine, fæces, and bile.

Lipochromes form a large group of pigments, varying from yellow to red in colour, and very widely distributed in plants and animals. Their name is due to their frequent association with fat. Their chemistry has been most carefully investigated in the carotin of the carrot; and, according to Ehring, they are of the nature of cholesterin fats, but it is very probable that other members of the series have a different chemical nature. Many of these pigments are readily bleached by light, and it is probable that the visual purple (rhodopsin) which occurs in the outer segments of the rods of the retina belongs to this class.

Blood Pigments.—The pigment of the blood, hæmoglobin, is a compound of about 96 per cent. of a globulin with about 4 per cent. of a brown pigment, Hæmatin. The latter contains iron, and has the formula $C_{34}H_{35}N_4FeO_5$. It gives a different spectrum in acid and in alkaline solutions, and in alkaline solution it can take up and give off oxygen. By mineral acids the iron may be removed, leaving a purplish pigment, Hæmatoporphyrin, which has no power of taking up or giving off oxygen. This pigment is, under certain conditions, formed in the body and excreted in the urine. It is closely allied to the bile pigments. Hæmoglobin, as pointed out in the section on RESPIRATION, readily takes up oxygen, to form two compounds: one—very unstable—Oxy-hæmoglobin, of a bright red colour; the other, very stable, of a brown colour, Methæmoglobin. It also forms compounds with other gases, most notably with carbon monoxide.

Waste Pigments.—A. *Of Bile.*—The bile contains a set of pigments closely allied to hæmatoporphyrin, of which the best known is Bilirubin, the probable formula of which is $C_{16}H_{18}N_2O_3$, but the constitution of which is unknown. It is an orange-brown substance which crystallizes in rhombic plates, and is very readily oxidized, forming a series of pigments. One of these, Biliverdin, $C_{16}H_{18}N_2O_4$, has a green colour and gives the characteristic hue to the bile of herbivora.

B. *Of Urine.*—Our knowledge of the chemical affinities of most of these pigments is very deficient. We know that normal yellow urine may undergo changes in colour on standing, and we know that in the fresh condition it does not give any definite bands in the spectrum. From this fresh urine a pigment, Urochrome, may be extracted, a brown hygroscopic substance which gives no definite spectral bands. By treating pure urochrome with a mild reducing agent, such as aldehyde, another colouring matter is developed, which gives a very definite band near Fraunhofer's line F in the spectrum. This is Urobilin, a pigment which, either in the coloured form or as a colourless material capable of yielding the coloured form, is present in the urine in health in small quantities, and in certain pathological conditions in larger amounts. It is probably identical with the pigment of the fæces, and with the Hydrobilirubin (probable formula $C_{32}H_{40}N_4O_7$) which Maly prepared from bilirubin. Uroerythrin is the pink pigment which gives the characteristic colour to deposits of urates. It is extremely unstable, and its chemical nature is unknown. Hæmatoporphyrin is normally excreted in very small quantities in the urine, but in certain pathological conditions it is increased, and gives to the urine a dark brown colour. Its chemical affinities have been already indicated.

The following table of the pigments of the blood, bile, urine, and fæces, shows their relations :—

Methæmoglobin. Oxy-hæmoglobin. Carbon-monoxide-hæmoglobin.

Globin. Alkaline—Hæmatin—Acid.

Oxidized. Reduced.

Iron-containing.

Hæmatoporphyrin. Bilirubin. Hydrobilirubin.
Biliverdin. Urobilin.
&c. Urochrome.

Iron-free.

(D. N. P.)

III. Animal Heat.

Experience has long taught mankind that animals can be divided into two classes, the "warm-blooded" and the "cold-blooded." The first group, composed of the higher animals, mammals and birds, is characterized by the possession of a high bodily temperature; whereas the members of the second class, which consists of the lower animals, reptiles, amphibians, fishes, and invertebrate animals, have a temperature practically the same as that of their surroundings. This difference is one that can be recognized by our sensations of heat and cold, and we are conscious that we belong to the warm-blooded class. Our sensations, however, are not an exact guide; we judge our own bodily temperature and that of other objects from the impression of heat or cold imparted to the nerves of our skin. The temperature of the skin may be low, owing to the presence of a smaller quantity of blood than usual; and hence will arise the impression of cold. We feel cold although the general heat of our body may be perfectly normal. A patient in the shivering stage of a fever looks cold and feels cold, although his internal temperature is at fever heat; on the other hand, in the sweating stage he perspires profusely and complains of feeling hot at a time when his internal temperature may be even below the normal point. In the former case the skin is cold and bloodless, owing to the contracted blood-vessels; in the latter the skin is very hot and red, with distended blood-vessels. We need therefore a much more exact measure of heat, and such we have in the thermometer (Thermometry). With that instrument we can compare accurately the temperatures of different animals and of man in health and disease, but it is necessary that care be taken in the selection of the part of the body in which the observation is to be made. The most suitable parts are those which afford a measure of the heat of the internal portions of the body, such as the bowel (*rectum*), the urine as it issues from the body, the arm-pit (*axilla*), the groin, and the mouth. The thermometer should be retained until the column of mercury becomes stationary. By numerous observations upon men and animals, John Hunter showed that the essential difference between the so-called warm-blooded and cold-blooded animals lies in the constancy of the temperature of the former, and in the inconstancy of the temperature of the latter. He defined the two groups as "animals of a permanent heat in all atmospheres" and "animals of a heat variable with every atmosphere."

In the following table are compared the internal temperatures of man and some of the warm-blooded animals :—

Animal.		Average Rectal Temperature. Deg. C.	(Deg. F.)	Range of Temperature in Health. Deg. C.	(Deg. F.)
Mammals	Man	37·0	(98·60)	36·2–37·8	(97·1–100)
	Horse	37·9	(100·2)	36·1–38·6	(97 –101·5)
	Cow	38·6	(101·5)	37·7–39·6	(99·8–103·3)
	Sheep	40·0	(104·0)	38·5–41·8	(101·3–107·2)
	Dog	38·6	(101·5)	37·1–39·9	(98·8–103·8)
	Cat	38·7	(101·7)	37·9–39·7	(100·2–103·4)
	Rabbit	39·2	(102·5)	37·0–40·8	(98·6–105·4)
	Mouse	37·4	(99·3)	36·1–38·6	(97 –101·5)
	Monkey	38·4	(101·1)	36·9–39·7	(98·4–103·4)
Birds	Common Fowl	41·6	(106·9)	40·6–43·0	(105·1–109·4)
	Pigeon	40·9	(105·6)	40·0–42·5	(104·0–108·5)
	Sparrow	42·1	(107·8)	...	

Lower Animals.—Since the temperature of cold-blooded animals varies with and in the same direction as that of their surroundings, its determination would be incomplete without a simultaneous observation of the air or water in which they live.

Animal.	Temperature of Animal. Deg. C.	(Deg. F.)	Temperature of Surroundings. Deg. C.	(Deg. F.)
Python	24·4	(76·0)	15·6	(60·1)
Frog	17·2	(63·0)	16·7	(62·0)
	8·9	(48·0)	6·7	(44·0)
Trout	14·4	(58·0)	13·3	(55·9)
	5·6	(42·0)	4·4	(39·9)
Shark	25·0	(77·0)	23·7	(74·6)
Crab	22·2	(72·0)	22·2	(72·0)
Leech	13·9	(57·0)	13·3	(55·9)
Locust	22·2	(72·0)	16·7	(62·0)

The data contained in this table show that there is no constant temperature for the cold-blooded animals, and that some members of the group often possess an internal heat considerably above that of their surroundings. The temperature of bees in their hives is often many degrees above that of the air outside; a female python maintains a high temperature when she is coiled round her eggs during the period of incubation. In fact, it is now known that there is no hard and fast line between the cold-blooded and warm-blooded animals. As the Darwinian theory of evolution would suggest, there has been a gradual development of the power of maintaining a constant temperature. The lowest mammals, such as the marsupials, possess a temperature much below that of the higher members of the group; thus the echidna has an internal temperature of 27·5° C. (81·5° F.), the duck-billed platypus (*Ornithorhynchus*) one of 32·0° C. (89·6° F.). Hibernating mammals, such as the marmot, hedgehog, and dormouse, during their winter sleep resemble cold-blooded animals; mammals born in a state of immaturity, naked, blind, and helpless—as are rats and rabbits—resemble cold-blooded animals in many respects, and on exposure to even moderate cold cannot maintain their temperature at the constant level characteristic of the adult. The chick, a warm-blooded animal, passes through a cold-blooded stage during its development within the egg.

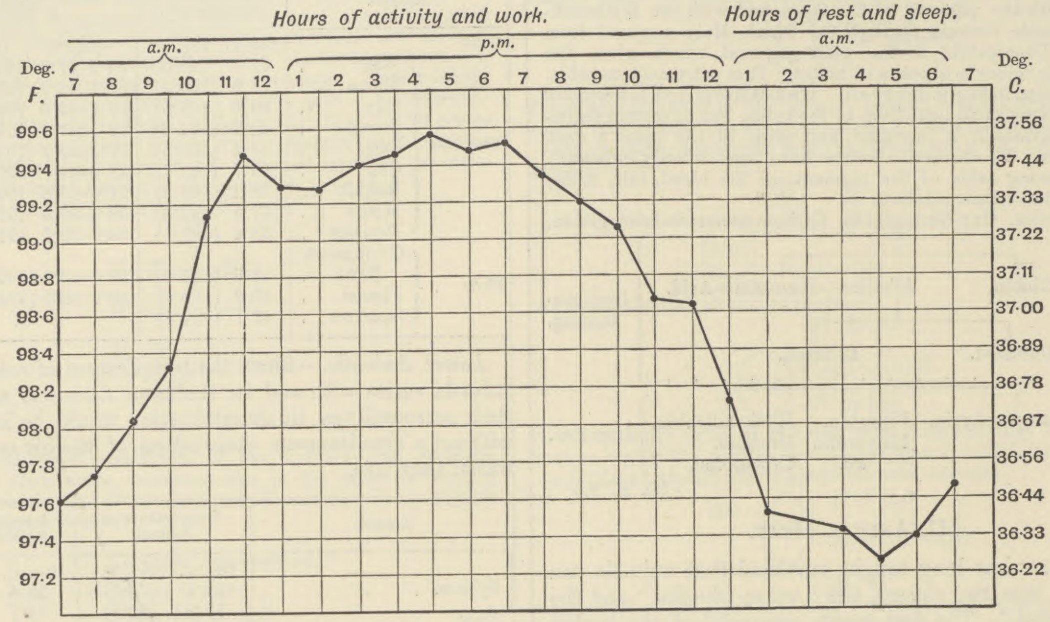
Variations in the Temperature of Man.—A careful study of the internal temperature of man and of other warm-blooded animals shows that the heat of the human body is not absolutely constant even in health, but undergoes slight changes. These fluctuations are caused by various conditions. There is a daily variation in temperature; during the day—the period of activity and work—the heat of the body rises; during the night—the hours of inactivity and sleep—the temperature falls. The range of this variation is about 1·2° C. (2·2° F.), the maximum being generally reached about five o'clock in the afternoon, the minimum about two or three o'clock in the early morning.

Curve of the Daily Variation in the Temperature of a Healthy Man.

Breakfast between	8 a.m. and 9 a.m.	Average mean, 37·01°.
Lunch ,,	1 p.m. and 2 p.m.	Highest mean, 37·54°.
Dinner ,,	7 p.m. and 8 p.m.	Lowest mean, 36·25°.

Tea (about 5 p.m.) not regularly taken.

The causes of this daily variation are to be sought in the greater activity of the body during the day, for if the temperature be observed in men who constantly work by



night and sleep by day, a reversal of the fluctuation is found. This fact alone would suggest that muscular exercise is the important factor in increasing the heat of the body. This source of heat is generally recognized by mankind: in cold weather the body is kept warm by a more energetic walk, by more rapid and more forcible contractions of the muscles than obtain in summer. If this natural safeguard against cold be resisted by an effort of the will, the sensation of cold may become so great and imperative that involuntary contractions of the muscles begin, the teeth chatter, and the body shivers and shakes. This increased muscular activity is accompanied by increased chemical changes and a greater production of heat in the muscles. Thus the injurious effect of cold is resisted. On the other hand, the athlete knows that prolonged and violent muscular effort would raise the temperature of the body so much as to cause great discomfort or actual injury, if he did not increase greatly the loss of heat from his body by discarding much of his ordinary clothing. Muscular exercise even under these conditions increases the internal heat of the body; the rectal temperature rises to 38° C. (100·4° F.) without causing any distress or discomfort. This increased heat from muscular work is most important, although often overlooked. It is responsible for much of the "falling out" and so-called "sunstroke" in soldiers marching in close order and unsuitable clothing on a hot day. The immediate effect of food is a slight rise in the internal temperature of the body. Mental work is accompanied by a slight fall in temperature, owing probably to the concomitant decrease in muscular activity. The temperature of the air has little or no effect upon the internal heat of the body; in the height of summer and the depth of winter, in the tropics with a temperature of 40° C. (104° F.) in the shade, and in the Arctic regions with the thermometer indicating fifty degrees of frost, the temperature of healthy men is practically the same.

Limits compatible with Life.—Although the temperature of warm-blooded animals is so constant during health, in disease great variations above and below the normal occur. In men poisoned by "drink" and exposed to cold, the internal heat of the body may fall as low as 24° C. (75·2° F.), and yet recovery from this unconscious condition may follow careful treatment and nursing. In severe fever the temperature may rise to 45° C. (113° F.) without a fatal result, but above this point death almost invariably occurs. In cold-blooded animals, however, the limits of temperature compatible with life are wider. Fishes and frogs may be frozen and still live if they are carefully thawed. During Franklin's explorations in the Arctic regions, it was observed that a carp, which had been frozen for thirty-six hours, was able after it was thawed to leap about with much vigour.

Regulation of Temperature.—The warm-blooded animals maintain so constant a temperature under such diverse conditions of external heat and cold, that they must possess some power of regulating the internal heat of their bodies. Two processes are comprised, regulation of the production and of the loss of heat. In cold weather the production of heat within the body is increased by greater muscular activity and the consumption of a larger quantity of food; the loss of heat is diminished by a contraction of the cutaneous blood-vessels, the skin becomes pale, and thus less blood is exposed to the cold surroundings. On the other hand, in hot weather muscular activity is less marked, less food is taken, and the body is cooled by the evaporation of sweat and the exposure of more blood in the dilated blood-vessels of the skin. In man the loss of heat is regulated also by the amount and nature of the clothes, and many animals develop special coats of fur for their protection against cold, and shed part of these coats on the approach of warm weather. The perfection of this regulation is shown by the fact already mentioned, that the temperature of man and of other warm-blooded animals is practically the same, whether they are living in the Arctic regions with such severe cold as 55° C. (−67° F.) below zero, or in the tropics with the temperature of the air 59° C. (138° F.). The experiments of Blagden and Fordyce show that even greater heat can be borne for a short time, if the air be dry: they remained fifteen minutes in a dry room heated to 115°–126° C. (239°–259° F.), in which beefsteaks were being cooked by the hot air; they sweated profusely, but their temperature was not raised above the normal.

Nervous Control.—The regulation of temperature is controlled by the nervous system, apparently by the cortical portions of the brain. Drugs, such as alcohol, morphia, chloroform, and ether, which in large doses paralyse or depress the activity of the nervous and muscular systems, disturb the regulation of temperature so much that in some cases the warm-blooded man or animal is reduced to a cold-blooded condition, cannot maintain a constant temperature, and soon dies. The nervous system controls not only the production of heat by impulses carried down the motor nerves to the muscles, but also the loss of heat, regulating through the vaso-motor nerves the diameter of the small blood-vessels, and consequently the distribution of blood to the superficial and deep portions of the body. Further, it controls the discharge of sweat, the evaporation of which cools the body; it adjusts the rapidity and depth of breathing—an important process in the regulation of the loss of heat, for the air driven out of the lungs has been raised almost to the temperature of the body, and is saturated with moisture which has evaporated from the respiratory tract. In some animals this factor is the essential one. Dogs breathe very rapidly, with open mouth and lolling tongue, when they suffer from heat; and if this natural means of cooling be prevented, as by a tight muzzle, their temperature rises much above the normal, and they suffer great discomfort and actual injury.

Sources of Animal Heat.—The real source of animal heat is now known to be a combustion or oxidation within the tissues of the body. The animal takes in food, which on combustion within the tissues of the body manifests its energy chiefly in two forms, heat and motion. Different foods have different values as producers of heat; thus one gramme (15·4 grains) of dry meat produces in the body about 4000 calories, or sufficient heat to raise 4000 cubic centimetres (7 pints) of water one degree; similar weights of dry sugar and fat yield on combustion about 4180 and 9400 calories respectively (see the section on RESPIRATION and the article on DIETETICS). A consideration of the law of conservation of energy would lead to the conclusion that the sole cause of animal heat is a chemical process, a combustion of food substances by the oxygen taken in by the animal. Rubner has shown by prolonged and careful experiments that in animal heat this great law is true. The following values may be given for the heat value of the daily diet of an adult man:—

120 grammes	proteid	× 4000 calories	= 480,000
90 ,,	fat	× 9423 ,,	= 848,070
330 ,,	carbohydrate	× 4182 ,,	= 1,380,060
			2,708,130 calories.

Calculations and experiments show that an adult man produces in twenty-four hours nearly 3,000,000 calories, or enough heat to boil about five or six pints of water; at the same time there is a continuous loss of heat, so carefully regulated that the internal temperature of the body remains constant.

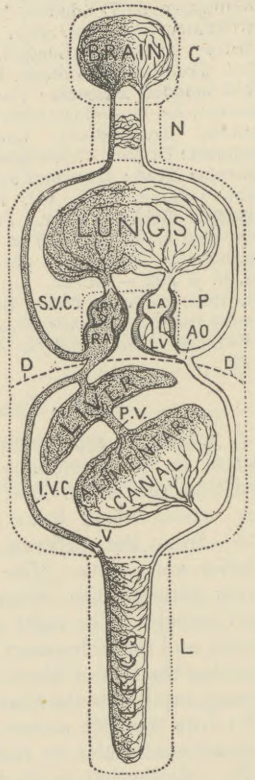
IV. VASCULAR SYSTEM.

General principles of the circulation.

A schematic representation is given of the circulatory system in the accompanying diagram. (For the detailed structure see *Ency. Brit.*, 9th ed., vol. xxiv.) The venous blood flows into the right auricle (RA) from the superior vena cava and the inferior vena cava. The right ventricle (RV) drives through the lungs the blood received from the right auricle. The right auriculo-ventricular valve, or tricuspid, and the pulmonary semi-lunar valve are represented directing the flow of blood in this direction. From the pulmonary capillaries the blood returns by the pulmonary veins (PV) into the left auricle (LA), and so through the left auriculo-ventricular or mitral valve into the left ventricle (LV). By the left ventricle the blood is driven through the aortic semi-lunar valve, and is distributed to the systemic arteries, and so to the capillaries of the various organs and back to the veins. The muscular wall of the auricles and that of the right ventricle are, as represented in the diagram, much thinner than that of the left ventricle. This is so, because the energy required of the left ventricle must exceed that of the right ventricle, inasmuch as the resistance in the systemic system exceeds that in the pulmonary circuit. The pulmonary vessels are of greater diameter, and the circulation through them is aided by the respiratory movements. The large arteries are of less capacity than the corresponding veins, and their walls are essentially extensile and elastic. The pulmonary arteries are especially extensile.

The elastic coefficients of the several layers of the coat of an artery increase from within out, and thus great strength is obtained with the use of a small amount of material. Over-expansion of the arteries is checked by an external coat of inextensile connective tissue. The elasticity of a healthy artery is almost perfect, while the breaking strain is very great and far above that exerted by the blood pressure. The small arteries and arterioles are essentially muscular tubes, and can, under the influence of the central nervous system, vary considerably in diameter. The "tone" of these vessels also directly depends on the quality and pressure of the blood. The arterioles open into the capillaries, and these are so numerous that each organ may be regarded as a sponge full of blood. The skeletal muscles and the muscular walls of the viscera at each contraction express the blood within them, and materially influence the circulation. The whole muscular system, as well as the heart, must therefore be regarded as a pump to the vascular system. The capillary wall is composed of a single layer of flattened cells, separating the blood within from the tissues without. Through this layer, which is of extraordinary tenuity, there takes place an exchange of material between the blood and the tissues, an exchange which does not exactly follow any of the known laws of filtration, osmosis, or diffusion, but depends on the physico-chemical conditions which characterize the living state of the cells. These conditions still await elucidation. The capillaries, in spite of the extreme tenuity of their walls, can, owing to their small diameter ($\frac{1}{100}$ mm.), withstand more than double the blood-pressure produced by the systole of the heart. (The circular tension equals the lateral pressure multiplied by the radius; the longitudinal tension is equal to half this product.) The veins are of larger calibre than the corresponding arteries, and have tough and inextensile walls. Their walls are muscular, and contract on local stimulation. There is no clear evidence, except in the case of the portal vein, that the veins are directly controlled by the central nervous system. The veins are not, as a rule, distended with blood to their full potential capacity. The latter is so great that the whole blood of the body can collect within the veins.



Scheme of the circulation of the blood in man, standing erect. The venous system is stippled. C, rigid cranial wall; N, muscles and cutaneous wall of neck; T, thoracic wall; A, muscular and cutaneous wall of abdomen; D, diaphragm; L, muscles and cutaneous wall of limbs; P, pericardium; AO, aorta; S.V.C, I.V.C, venae cavae; P.V, portal vein; V, valves in veins of neck, or legs; RA, LA, right and left auricles; RV, LV, right and left ventricles.

The heart and lungs are placed within the thoracic cavity (T), the floor of which is formed by the muscular diaphragm (D); the heart is itself enclosed in a tough inextensile bag, *the pericardium* (P), the function of which is to check over-dilatation of the heart. The pericardium bears to the muscular wall of the heart the same relation as the leather case of a football does to the bag within. The abdominal organs and blood-vessels are encompassed by the muscular wall of the abdomen (A), and may be regarded as enclosed in a sphere of muscle. Above is the dome of the diaphragm (T), and below the basin-like levator ani, closing the outlet of the pelvis; in front are the recti muscles, behind the quadrati lumborum and the spine; while the oblique and transverse muscles complete the wall at either side. The brain is enclosed in a rigid and unyielding box of bone—*the cranium*, while the limbs are encompassed by the extensile and, in health, taut and elastic skin.

If the vascular system were formed of wide tubes, free from constrictions, each systolic pulse-wave would travel with so great a velocity that the whole system would reach the same pressure before the next systole of the heart occurred. This is not so, for the friction of the blood flowing through the arterioles prevents it from passing through with anything like the velocity of the pulse-wave. The pulse-wave travels, in fact, 8 metres per second, while the blood in the arteries travels $\frac{1}{3}$ metre. The resistance to flow is chiefly situated, not in the capillaries, but in the small arteries, where the velocity is high; for "skin friction"—that is, the friction of the moving concentric layers of blood against one another and against the layer which wets the wall of these blood-vessels is proportional to the surface area and to the viscosity of the blood—is nearly proportional to the square of the velocity of flow, and is inversely proportional to the sectional area of the vessels. Owing to the resistance to the capillary outflow, the large arteries are expanded by each systolic output of the heart, and the elasticity of their walls comes into play, causing the outflow to continue during the succeeding diastole of the heart. The conditions are such that the intermittent flow from the heart is converted into a continuous flow through the capillaries. If the arteries were rigid tubes, it would be necessary for the heart to force on the whole column of blood at one and the same time; but, owing to the elasticity of these vessels, the heart is saved from such a prolonged and jarring strain, and can pass into diastolic rest, leaving the elasticity of the distended arteries to maintain the flow. As a result of disease, the elastic tissue may degenerate and the arteries become rigid. It has been well said that "a man is as old as his arteries." Besides the saving of heart-strain, there are other advantages in the elasticity of the arteries. It has been found that an intermittently acting pump maintains a greater outflow through an elastic than through a rigid tube; that is to say, if the tubes be of equal bore. Œdema and obstruction to the circulation quickly arise if the blood be delivered to an organ from a constant head of pressure in place of an intermittently acting pump. To maintain an efficient artificial circulation through a "surviving organ," the period of systole must be made, as in nature, half as short as the period of diastole, so delicately attuned are the finer vessels to this periodic wave motion.

Suppose, in an animal lying in the horizontal posture, the heart be arrested, *e.g.*, by stimulation of the vagus nerve, then the arteries, owing to their elastic resilience and contractility, continue to drive the blood through the capillaries. The blood, under the influence of gravity, collects in the venous system, fills the right side of the heart, and congests in the capillaries in the most dependent parts of the body. So soon as the heart starts again to beat, the blood is taken from the venous system and piled up in the arteries, for at each systole of the heart a greater quantity of blood is driven into the arteries than can escape through the capillaries. With each succeeding systole, therefore, the blood-pressure mounts in the arteries, while the venous pressure cannot sink below the atmospheric pressure, in spite of the continued abstraction of blood, for the flaccid walls of the veins collapse. After the first few strokes of the heart, a condition of equilibrium is established as the outflow through the capillaries, during the period of each cardiac cycle, becomes equal to the volume of blood expelled by the heart at each systole. The continuous flow of blood thus established through the capillaries is due to the difference between the blood-pressure in the arteries and that in the veins. The energy imparted to the mass of blood expelled at each systole is spent in overcoming the resistance and is dissipated into heat. The potential energy of the blood is indicated by the lateral pressure; the kinetic energy varies as the square of the velocity of flow. The lateral pressure is reduced from 110 mm. of mercury in the arteries to 30–40 mm. in the capillaries, while the velocity of flow diminishes from 300 mm. per second in the arteries to 1 mm. per second in the capillaries. The kinetic energy of the systolic output is thus reduced to $(\frac{1}{300})^2$ of its value in the aorta. In the veins the lateral pressure continues to fall, while the velocity increases until in the venæ cavæ it reaches a value not less than half that in the aorta. The increase of kinetic energy in the veins is due partly to the change of potential into kinetic energy, but chiefly results from other sources of energy, such as the compressive action of the skeletal muscles, the influence of gravity, and the action of the respiratory pump.

In each unit of time the same quantity of blood must, on the average, flow through the lesser and greater circuit, for otherwise the circulation would not continue. Likewise, the average velocity at any part of the vascular system must be inversely proportional to the total cross-section at that part. In other words, where the bed is wider, the stream is slower; the total sectional area of the capillaries is roughly estimated to be 700 times greater than that of the aorta or venæ cavæ. Any general change in velocity at any section of this circuit tells both backwards and forwards on the velocity in all other sections, for the average velocity in the arteries, veins, and capillaries, these vessels being taken respectively as a whole, depends always on the relative areas of their total cross-sections.

The velocity of flow can be determined in any organ by injecting salt solution into an artery, and observing, with the aid of a Wheatstone's bridge arrangement, the galvanometric change in electrical resistance which occurs in the corresponding vein when the salt solution reaches it. The moment of injection and that of the alteration in resistance are observed with a stop-watch (Stewart).

The venous side of the vascular system, owing to the great capacity of the veins, is not filled to distension, while many of the capillaries in each organ are empty and collapsed, except at those periods of vaso-dilatation and hyperæmia which accompany extreme activity of function. The vascular system cannot be regarded as a closed system, for the blood-plasma, whenever the capillary pressure is increased, transudes through the capillary wall into the tissue-spaces and enters the lymphatics. Thus, if fluid be transfused into the circulatory system, it not only collects in the capacious reservoirs of the veins and capillaries—especially in the lungs, liver, and abdominal organs—but leaks into the tissue-spaces. Hence the pressure in the vascular system cannot be raised above the normal for any length of time by the injection of even enormous quantities of fluid. The lymphatics of tissue-spaces must be regarded as part of the vascular system. There is a constant give and take between the blood-plasma and the tissue lymph. If the fluid part of the blood be increased, then the capillary transudation becomes greater, and the excess of fluid is excreted from the kidneys and glands of the alimentary canal. If the fluid part of the blood diminish, then fluid passes from the tissue-spaces into the blood, and the sensation of thirst arises, and more drink is taken. The vascular system is especially constructed so that considerable changes of pressure may be brought about in the arterial section, without any (or scarcely any) alteration of the pressures in the venous or pulmonary sections of the circulatory system. A high-pressure main (the arteries) runs to all the organs, and this is supplied with taps; for by means of the vaso-motor nerves which control the diameter of the arterioles, the stream can be turned on here or there, and any part flushed with the blood, while the supply to the remaining parts is kept under control. Normally, the sum of the resistances which at any moment opposes the outflow through the capillaries is maintained at the same value, for the vascular system is so co-ordinated by the nervous system that dilatation of the arterioles in any one organ is compensated for by constriction in another. Thus the arterial pressure remains constant, except at times of great activity.

The mean arterial pressure can be measured in man with considerable accuracy by means of the sphygmometer of Hill and Barnard. Fluid pressure is applied to the radial or brachial artery by an apparatus which indicates on a scale the size of the pulse-oscillations and the pressure employed to compress the artery. The pressure is read on the scale at the point where the pulse-oscillations appear to be maximal, for the wall of the artery oscillates most freely when the mean pressure within and without the artery are the same. The measurements are made with the arm on the same level as the heart, in order to avoid the influence which gravity exerts on the blood pressure. The normal mean arterial pressure is 100–110 mm. Hg. In a healthy man it is slightly higher in the erect than in the recumbent posture. The pressure rises to 120–150 mm. of mercury during bodily exertion or mental excitement, and falls to 95–100 mm. during rest in the recumbent posture or during sleep. By the same instrument the venous pressure can be ascertained. The instrument is applied to one of the veins at the back of the hand, the vein emptied, and the pressure noted at which the vein fills with blood.

The Circulation during Muscular Activity.—The great splanchnic area of arterioles acts as "the resistance box" of the arterial system. By the constriction of these arterioles during mental or muscular activity the blood-current is switched off the abdominal organs on to the brain and muscles, while by dilating during rest and digestion they produce the contrary effect. The constriction of the splanchnic vessels does not sensibly diminish the capacity of the total vascular system, for the veins possess little elasticity. Thus variations of arterial pressure, brought about by constriction or dilatation of the arterial system, produce little or no effect on the pressure in the great veins or pulmonary circuit. Owing to this fact, the diastolic, or filling, pressure of the heart varies but slightly, while the arterial pressure is, at times of great effort, considerably raised, both by the increased energy of the heart and by vaso-constriction. It is obviously of the utmost importance that the heart should not be over-dilated by an increased filling pressure during the period of diastole.

When a man strains to lift a heavy weight he closes the glottis, and by contracting the muscles which are attached to the thorax, raises the intrathoracic pressure. The rise of intrathoracic pressure aids the pericardium in supporting the heart, and prevents over-dilatation by resisting the increase in blood pressure. This increase results from the powerful and sustained contraction of the abdominal and other skeletal muscles. In the diagram it is clear that the contraction of T will counteract the contraction of A. At the same time the rise of intrathoracic pressure supports the lungs, and prevents the blood, driven out from the veins, from congesting within the pulmonary vessels. Over-dilatation both of the heart and lungs being thus prevented, the blood expressed from the abdomen is driven through the lungs into the left ventricle, and so into the arteries. So long as the general and intense muscular spasms continue, there is increased resistance to the outflow of the blood through the capillaries both of the abdominal viscera and the limbs. The arterial pressure rises, therefore, and the flow of blood to the central nervous system is at first greatly increased. The rise of the intrathoracic and intra-abdominal pressures, and the sustained contraction of the skeletal muscles, alike hinder the return of venous blood from the capillaries to the heart, and, owing to this, the face and limbs become congested until the veins stand out as knotted cords. It is obvious that at this stage the total capacity of the vascular system is greatly diminished, and the pressure in all parts of the system is raised. It is during such a muscular effort that a degenerated vessel in the brain is prone to rupture and occasion apoplexy. The venous obstruction quickly leads to diminished diastolic filling of the heart, and to such a decreased velocity of blood-flow that the effort is terminated by the lack of oxygen in the brain. During any violent exercise, such as running, the skeletal muscles alternately contract and expand, and the full flood of the circulation flows through the locomotor organs. The stroke of the heart is then both more energetic and more frequent, and the blood circulates with increased velocity. Under these conditions the filling of the heart is maintained by the pumping action of the skeletal and respiratory muscles. The abdominal wall is tonically contracted, and the reserve of blood is driven from the splanchnic vessels to fill the dilated vessels of the locomotor organs. The thorax is tonically elevated and the thoracic cavity enlarged, so that the pulmonary vessels are dilated. At each respiration the pressure within the thoracic cavity becomes less than that of the atmosphere, and the blood is aspirated from the veins into the right side of the heart and lungs; conversely, at each expiration the thoracic pressure increases, and the blood is expressed from the lungs into the left side of the heart. While the respiratory pump at all times renders important aid to the circulation of the blood, its action becomes of supreme importance during such an exercise as running. The runner pants for breath, and this not only increases the intake of oxygen, but maintains the diastolic filling of the heart. It is of the utmost importance that man should grasp the fact that the circulation of the blood depends not only on the heart, but on the vigour of the respiration and the activity of the skeletal muscles. Muscular exercise is for this reason a *sine quâ non* for the maintenance of vigorous mental and bodily health. Under the influence of the muscular system comes not only the blood but the lymph. The lymphatics form a subsidiary system of small valved vessels, and drain the tissues of the excess of lymph, which transudes from the capillaries of the organs during functional activity, or in consequence of venous obstruction. The larger lymphatics open into the veins at the root of the neck. It is chiefly by the compressive action of the skeletal and visceral muscles, and the aspirating action of the respiratory pump, that the lymph is propelled onwards. It must be borne in mind that the descent of the diaphragm during inspiration compresses the abdominal organs, and thus aids the aspirating action of the thorax in furthering the return to the heart both of venous blood and of lymph.

Influence of Posture on the Circulation.—The circulation remains efficient not only in the horizontal but also in the erect position, and just as much so when a man, like a gymnast, is ceaselessly shifting the position of his body. Yet in a man standing six feet the hydrostatic pressure of a column of blood reaching from the vertex to the soles of the feet is equal to 14 cm. of mercury. The blood, owing to its weight, continually presses downwards, and under the influence of gravity would sink if the veins and capillaries of the lower parts were sufficiently extensile to contain it. Such is actually the case in the snake or eel, for the heart empties so soon as one of these animals is immobilized in the vertical posture. This does not occur in an eel or snake immersed in water, for the hydrostatic pressure of the column of water outside balances that of the blood within. During the evolution of man there have been developed special mechanisms by which the determination of the blood to the lower parts is prevented, and the assumption of the erect posture rendered possible. The pericardium is suspended above by the deep cervical fascia, while below it is attached to the central tendon of the diaphragm. Almost all displacement of the heart is thus prevented. The pericardium supports the right heart when the weight of a long column of venous blood suddenly bears upon it, as, for example, when a man stands on his head. The abdominal viscera are slung upwards to the spine, while below they are supported by the pelvic basin and the wall of the abdomen, the muscles of which are arranged so as to act as a natural waist-band. In tame hutch rabbits, with large patulous abdomens, death may result in from 15 to 30 minutes if the animals are suspended and immobilized in the erect posture, for the circulation through the brain ceases and the heart soon becomes emptied of blood. If, however, the capacious veins of the abdomen be confined by an abdominal bandage, no such result occurs. Man is naturally provided with an efficient abdominal belt, although this in many is rendered toneless by neglect of exercise and gross or indolent living. The splanchnic arterioles are maintained in tonic contraction by the vaso-motor centre, and thus the flow of blood to the abdominal viscera is confined within due limits. The veins of the limbs are broken into short segments by valves, and these support the weight of the blood in the erect posture. The brain is confined within the rigid wall of the skull, and by this wall are the cerebral vessels supported and confined when the pressure is increased by the head-down posture. Every contraction of the skeletal muscles compresses the veins of the body and limbs, for these are confined beneath the taut and elastic skin. The pressure of the body against external objects has a like result. Guided by the valves of the veins, the blood is by such means continually driven upwards into the venæ cavæ. If the reader hangs one arm motionless, until the veins at the back of the hand become congested, and then either elevates the limb or forcibly clenches the fist, he will recognize the enormous influence which muscular exercise, and continual change of posture, has on the return of blood to the heart. It becomes wearisome and soon impossible for a man to stand motionless. When a man is crucified—that is to say, immobilized in the erect posture—the blood slowly sinks to the most dependent parts, œdema and thirst result, and finally death from cerebral anæmia ensues. In man, standing erect, the heart is situated above its chief reservoir—the abdominal veins. The blood is raised by the action of the respiratory movements, which act both as a suction and as a force pump, for the blood is not only aspirated into the right ventricle by the expansion of the thoracic cavity, but is expressed from the abdomen by the descent of the diaphragm. When a man faints from fear, his muscular system is relaxed and respiration inhibited. The blood in consequence sinks into the abdomen, the face blanches, and the heart fails to fill. He is resuscitated either by compression of the abdomen, or by being placed in the head-down posture. To prevent faintness and drive the blood-stream to his brain and muscles, a soldier tightens his belt before entering into action. Similarly, men and women with lax abdominal wall and toneless muscles take refuge in the wearing of abdominal belts, and find comfort in prolonged immersion in baths. It would be more rational if they practised rope-hauling, and, like fishermen, hardened their abdominal muscles.

The Heart-Beat.—The rhythmic systole and diastoles of the heart are the result of oscillations between processes of catabolism and anabolism, which take place in its chemical structure. The function of the heart is fundamentally an automatic one. The rhythmic beat is not excited by stimulation from without, but is provoked by the chemical condition of the sarcoplasm of the cardiac muscle itself, and this in its turn ultimately, but not immediately, depends on the rate of flow and the quality of the blood which circulates through the coronary vessels. During diastole the production of synthetic compounds—the hypothetical "inogens" of Hermann—is, it is supposed, pushed to the maximal limit of instability until there results, in the ensuing systole, an explosive liberation of energy. The autonomy of the heart is shown by the fact that the mammalian heart continues to beat for hours if fed through the coronary vessels with warm oxygenated defibrinated blood. If oxygen be supplied to the excised heart, at a tension of two atmospheres, a very small quantity of blood is sufficient to maintain activity (Porter). It is clear, therefore, that there is in the heart a large reserve supply of explosive material. Similarly, the excised and bloodless heart of the cold-blooded animal, if merely kept cool and moist, continues to beat for hours and even days. The beat of the heart does not, therefore, depend on excitations received from the central nervous system, and neither does it emanate from a rhythmic activity of these ganglion cells which lie scattered in the cardiac muscle at the base of the heart. That this is so is shown by the fact that every bit of the heart muscle, whether free of ganglion-cells or not, is capable, under suitable conditions, of rhythmic activity (Gaskell, Engelmann, Porter). The inherent power of rhythmic contraction is most clearly seen in the embryonic heart, for the pulsation of the chick's heart becomes visible by the twenty-fourth to the forty-eighth hour of incubation, while the migration of ganglion-cells into the heart from the sympathic system does not take place until the sixth day (His, jun.). In an automatic organ, such as the heart, it is the accumulation of the explosive bioplasm which, in itself, unassisted by any external stimulus, provokes explosion. The anatomical elements of the heart are singly- or doubly-nucleated, branched, and cross-striated muscle-cells. In contradistinction to cross-striated muscle, the structural unit of the heart is not also a functional unit, for the heart-cells are, from the earliest stage of development, joined together by branches into networks and bands so as to form one functional whole, and hence excitation of any one part leads to the contraction of the whole. The first part to begin to functionate in the embryo is the venous end, and the waves of contraction passing thence spread over the developing ventricular segment. The muscle-cells of the ventricles are thicker, less sarcoplasmic, and more clearly striated than the auricular muscle, which is more embryonic in structure. The contraction lasts longer in the ventricular than in the auricular muscle, while the automatic rhythm not only persists longer in the auricles, but is of a greater frequency, as is clearly seen when the cavities of the heart are divided from each other. The venous orifices of the heart are least sensitive to injury, beat longest after death, and are the first to recover after arrest. Owing to the more powerful automatism of the venous extremity, the contraction normally proceeds thence, and, passing as a peristaltic wave over the auricles and ventricles, finally reaches the arterial orifices. This peristaltic form of contraction is invariable in all periods of development and in all hearts both of invertebrate and vertebrate animals. The peristalsis may, with difficulty, be artificially reversed by the application of a powerful rhythmic stimulus to the ventricular end. Antiperistalsis does not, however, take place easily, because the comparatively slow excitation process in the ventricle has little effect on the auricular muscle. The latter, by initiating more rapid contraction-waves, over-dominates the former. The frequency of the whole heart is accelerated by warming the auricles, while the period of systole is alone shortened on warming the ventricles. The segmentation of the cardiac contraction into auricular and ventricular systole depends upon certain muscle-cells, of embryonic type, which bridge the otherwise complete septum of connective tissue that divides the auricles from the ventricles (Kent, His). These fibres are endowed with a sluggish power of conductivity, and hence the peristaltic wave is at this point resisted and retarded. There is no convincing evidence in support of the view that the excitation is transmitted through the heart, and the contraction regulated in sequence, by the nerve ganglia of the heart. The velocity of conduction of the excitation wave (5 metres per second) speaks against this hypothesis, for the rate is six times less rapid than in nerve (Engelmann). By the study of the electrical current—*i.e.*, the current of action which accompanies the systole—with the aid of the capillary electrometer, it has been determined that the contraction of the heart is a simple twitch and not a tetanus (Sanderson and Page, Waller and Reid).

The heart during the period of systole is refractive to artificial excitation, but its susceptibility returns with diastole. The force and amplitude of any cardiac contraction depend on the previous activity of the heart and on such physical conditions as the degree of diastolic filling, the resistance to systolic outflow, temperature, &c., but are independent of the strength of the artificial stimulus so long as the latter is efficient. Owing to the refractory period, the slow rate of contraction, and the independence of the amplitude of contraction on the strength of stimulus, the heart cannot be thrown, by rapidly-repeated excitation, into a complete state of tetanic spasm. The cardiac muscle is rich in sarcoplasm, and on this depends its power of slow, sustained contraction. The heart-muscle besides rhythmically contracting possesses "tone," and this tone varies with the conditions of metabolism, temperature, &c. Chloroform, for example, produces a soft dilated, and strychnine or ammonia a tonically contracted, heart. The auricular muscle in some animals undergoes rhythmic oscillations of tone. The ganglion-cells, which first wander into the embryonic heart several hours after it has started beating, can be removed without disturbing the cardiac rhythm. Extra-cardiac nerves from the vagus and from the sympathetic system end in these ganglia. From these ganglion-cells there pass non-medullated, intracardiac nerve-fibres, which spin a fine-meshed network through all parts of the cardiac muscle. The study of development, and of comparative anatomy, alike show that the nervous system of the heart becomes more complicated with increasing complication of structure. A great many of the cardiac nerve-fibres are centripetal. These fibres pass in the vagus nerves up to the spinal bulb, and reflexly regulate the heart-frequency, the breathing, and the tonus of the blood-vessels. For example, the stimulation of certain fibres, termed *depressor*, causes dilatation of the arterioles and a fall of arterial pressure by inhibiting the tonic action of the vaso-motor centre in the spinal bulb. The depressor fibres come into action when the systolic output is resisted by over-constriction of the arterioles. The centripetal impulses which proceed from the normal heart do not enter into consciousness. The centrifugal cardiac nerves influence the frequency, the force of contraction, and the conductivity of the excitatory wave (chrono-, ino-, and dromo-tropism of Engelmann). The inhibitory fibres running in the vagi arise from a centre in the spinal bulb which is in tonic action and constantly curbs the heart. The function of the vagi is to decrease the frequency, force, and conductivity. The acceleratory and augmentory fibres are likewise in tonic action and antagonize the action of the vagi. These fibres arise from the anterior spinal roots in the upper thoracic region, and form synapses with the ganglion-cells in the first thoracic sympathetic ganglia. The vagus nerve works directly on the cardiac muscle-fibre, and produces, it is supposed, a chemical change whereby the conductivity, the excitability, and force are lowered. After a period of arrest, produced by vagal excitation, the heart beats more strongly, for the process of anabolism is increased thereby. The converse occurs after excitation of the sympathetic fibres. The function of the cardiac nerves is to co-ordinate the beat of the heart with the needs of the body and to co-ordinate the functions of other organs with the needs of the heart. For example, an undue rise of arterial pressure, induced, let us say, by compression of the abdomen, excites the centre of the vagus and produces slowing of the heart and a consequent lowering of arterial pressure. The heart of a mammal, however, continues to functionate after a section of all the branches of the cardiac plexus has been made, so that the nervous control and co-ordination of the heart are not absolutely essential to the continuance of life (Krehl).

The work of the heart, attained by multiplying the volume of the systolic output by the arterial pressure, *i.e.*, the height of the lift, has hitherto been reckoned at too high a rate. The output is not greater than 60–100 c.c. (3 oz.) (Tigerstedt, Zuntz), and the mean arterial pressure in a healthy man, determined by the sphygmometer, is not more than 110 mm. of mercury (L. Hill). The work of the right heart can be reckoned to be $\frac{1}{3}$ that of the left, for the pressure in the pulmonary artery does not exceed 40 mm. The total work of the heart during the day may be taken as equal to 20,000 kilogrm.-metres, and this would be equivalent to 50 Calories out of the total 2500 Calories which a man takes in as food. The total work is increased two or three times over by very severe muscular labour. It has been estimated that the heart requires per diem, to maintain its energy, an amount of solid food (water-free) equal to the weight of solids in the heart itself, *i.e.*, about 60 grms. of sugar or proteid (Stewart). 30 c.c. of blood must be circulated per minute through the coronary arteries of a dog to maintain the vigour of the heart.

Changes of Pressure in the Heart during the Cardiac Cycle.—Much labour has been spent in the contrivance of rapidly-acting spring pressure gauges, freed as far as possible from inertia, in order to investigate the changes of intracardiac pressure, which were first described by Chauveau and Marey (cf. *Ency. Brit.* vol. xxiv. VASCULAR SYSTEM). As the intraventricular pressure may rise 150 mm. of mercury in $\frac{1}{10}$ of a second, it is no easy matter to contrive an instrument which will respond as rapidly and yet yield an accurate result without overshooting the mark. The final result of a most careful inquiry is the confirmation in almost every point of Chauveau and Marey's pressure curves. Hürthle's differential manometer has proved to be an instrument of great value and precision. A double-bored tube cannula is introduced so that one tube reaches the right auricle and the other the right ventricle. In observations on the left side of the heart, one tube is placed in the left ventricle and the other in the aorta, and each of these tubes is brought in connexion with a tambour. The two tambours are placed, one on either side of the fulcrum of a lever. This lever works against a light spring, which in its turn sets in motion a writing-style. The style records the pressure changes on a drum covered with smoked paper. By this means there can be recorded the exact moment at which the auricular pressure exceeds that in the ventricle, that is to say, the moment when the auriculo-ventricular valves open; likewise the moment when the ventricular pressure becomes greater than that in the auricles, and the auriculo-ventricular valves shut. Similarly, there can be recorded the moment when the intraventricular pressure exceeds that in the aorta and the semilunar valves open, and the moment at which the diastole of the ventricle begins, when the aortic pressure becomes the greater, and the semilunar valves shut. The smoothness with which the heart works is shown by the fact that neither the opening nor the closing of the valves is marked by any peak or point on the pressure curves. The first part of the period of ventricular systole is spent in raising the tension of the blood up to and above that in the aorta. All the valves are closed during this period, and the contraction of the ventricular muscle is at this time isometric, for the volume of the ventricle does not alter. The period of rising tension lasts in the dog ·02″–·04″, and varies very little when the output is resisted by a rise in arterial pressure. In other words, the heart can meet greater demands on its power without appreciable loss of time. The period of systolic output lasts from the moment when the semilunar valves open to the moment when they close. This period equals ·178″ to ·195″, and is but slightly altered by variations in arterial pressure or the frequency of the heart. The intraventricular pressure continues to rise during the period of output if the outflow be resisted; on the other hand, it falls if the arterioles are dilated and the outflow unimpeded. When the heart becomes more frequent, as in fever, it is the diastolic or resting period which is especially shortened. A negative pressure (–10 to –30 mm.) appears in the auricles during the period of systolic output, and this is of no little importance, for it materially aids in the filling of the auricles. It is mainly produced by the expulsion of the blood by the left ventricle into the arteries, and so out of the thorax. To take the place of the arterial blood which leaves the thoracic cavity, air passes into the lungs and blood into the auricles. The maximal and minimal pressures have been accurately recorded in the heart by a manometer fitted with a valve arranged so that either only a rise or a fall of pressure is recorded. In the right ventricle of the dog the maximal pressures recorded equalled 35–62 mm. of mercury, in the left ventricle 114–135 mm., in the auricles 2–20 mm. (de Jäger). A negative pressure, of considerable amount but of very fleeting duration, sometimes occurs in the ventricles at the beginning of diastole. This is produced by the elastic rebound of the fleshy columns of the inner wall of the heart, which become pressed together as the blood is wrung out of the ventricular cavities. The entry of the first few drops of blood from the auricles abolishes this negative pressure, and it has no important influence on the filling of the heart.

Valves and Papillary Muscles.—The muscular columns to be seen on the inner walls of the ventricles are attached by inextensile cords (the chordæ tendineæ) to the auriculo-ventricular valve flaps. It has experimentally been determined that the cords are pulled taut synchronously with the ventricular contraction, and so prevent the ballooning out of the valves into the auricles (Roy, Haycraft). The edges of these valves are thin and delicate membranes, and when in apposition are pressed together by the blood in the ventricles. Regurgitation of blood is thus completely prevented. The outer parts of the valves bear the full strain of the intraventricular pressure, and are therefore tough and strong. These parts are supported by the chordæ tendineæ, just as an umbrella is supported by its ribs. A ring of muscle surrounds the auriculo-ventricular orifices, and confines the size of these openings during systole. The auriculo-ventricular valves are floated up and brought into apposition by eddies set up in the blood which streams into the ventricles during the auricular systole. They close without noise or jar at the moment when the intraventricular pressure exceeds in the least degree that in the auricles. The semilunar valves are similarly brought into apposition by eddies, and close without noise or jar at the moment when the intraventricular pressure becomes less than that in the aorta. The arterial orifices are confined by the contraction of the muscle bands which surround them. During the period of systolic output the aortic valve-flaps assume a vertical position in mid-stream, and do not swing back against the orifices of the coronary arteries which lie at the root of the aorta. At the height of systole the flow through the coronary vessels is momentarily checked, for the pressure of the ventricular muscle becomes greater than that in the aorta. The capillaries of the heart muscle become filled with blood during diastole, and this blood is partly expressed into the coronary veins during systole.

The Cardiac Impulse.—The impulse is synchronous with the period of rising tension in the ventricle. It occurs at the point where the ventricular wall touches the parietes of the chest, and is thus felt at a slightly different spot in each position of the body, for, owing to the influence of gravity, different parts of the heart come in contact with the chest-wall in different postures. The cause of the impulse is the sudden hardening of the ventricular muscle. Where the heart touches the chest-wall the latter is driven outwards; at all other points it is sucked inwards, owing to the diminution in the size of the ventricles during the period of systolic output. To obtain a typical cardiogram, the cardiograph must be applied to the exact seat of the impulse. An excellent form of cardiograph has been contrived by Edgren (see Schäfer's *Physiology*, vol. ii. p. 35). The cardiogram is partly a pressure and partly a volume curve. The form of the typical curve resembles that of intraventricular pressure, but it can be endlessly varied by altering the position and pressure of the instrument, and the cardiograph is not therefore a sure or trustworthy guide to any facts concerning the force or extent of the cardiac contraction. By simultaneously recording the impulse curve, the heart sounds, and the pulse curve in the carotid artery, the time relations of the various acts which go to make up the cardiac cycle can be measured in man. The beginning of the impulse curve marks the beginning of the period of rising pressure in the ventricles. The beginning of the ascent of the pulse curve marks the beginning of the period of systolic output. The beginning of the dicrotic notch on the pulse curve marks the end of the period of output and the commencement of ventricular diastole. In making such calculations, a deduction must be made for the time spent in the transmission of the pulse-wave.

The Sounds of the Heart.—The sounds of the heart have been successfully recorded by means of the microphone. Hürthle inserted the microphone in the primary circuit of a Du Bois Raymond induction coil, and placed the nerve of a frog-muscle preparation in the secondary circuit. The muscle, being attached to a lever, recorded its contraction on a revolving drum at the moment when the sound of the heart reached the microphone and closed the primary circuit. A capillary electrometer can be inserted in place of the frog-muscle indicator, and the movements of the electrometer photographed on a sensitized plate moved by clockwork (Einthoven). Each sound gives rise to a succession of vibrations of the mercury meniscus of the capillary electrometer. The first sound is formed of many component tones derived from the sudden tension, and consequent vibration, of the ventricular muscle, and of the auricular-ventricular valves with their chordæ tendineæ. The first sound can be resolved by a trained musical ear into two tones, one deep and the other high. The deeper tone alone is heard on the contraction of the excised and bloodless heart, while the higher tone is produced by throwing the auriculo-ventricular valves into tension (Haycraft). In the cold-blooded animal, such as the turtle, the heart muscle does not become tense rapidly enough to produce a sound (Allen). This sound is not produced by fluid friction as the blood rushes through the arterial orifices, for the velocity of outflow is too small to produce in this way any noise. Nor is it produced by sudden opening of the semilunar valves, for these open quietly and without jar at the moment when the intraventricular pressure rises above that in the aorta.

The second sound of the heart is produced by the tension of the semilunar valves in the aorta and pulmonary artery at the moment when the ventricles pass into diastole. These valves close without any jar or shock so soon as the arterial pressures rise to the slightest degree above that in the ventricles. In the next moment the ventricles dilate, and the valves, no longer supported on one side, become taut. The elastic vibrations of the walls of the distended arteries probably share in the production of this sound.

Vaso-motor System.—The tone of the arteries and veins, just as the permeability of the capillaries, depends on the chemical quality, the pressure, and the velocity of flow of the circulating blood. The tone of the arterioles is secondarily controlled by the vaso-motor nerves, which are in their turn dominated by the vaso-motor centre in the medulla oblongata. The portal venous system is also controlled by vaso-motor nerves, while, as to the rest of the venous system, there is no definite evidence of the existence of any such control. The vaso-motor nerves are of two kinds, vaso-constrictor and vaso-dilator. The vaso-constrictor fibres issue in the anterior spinal roots, from the second thoracic to the second lumbar root, and pass to the sympathetic chain of ganglia. The fibres are of small diameter, and probably arise from cells situated in the lateral horn of the grey matter of the spinal cord. Nicotine paralyses ganglion cells, and by applying this test to the various ganglia, the cell stations of the vaso-constrictor fibres supplying each organ have been mapped out. The vaso-dilator fibres have not so restricted an origin, for they issue in the efferent roots in all parts of the neural axis. The two kinds of nerves, although antagonistic in action, end in the same terminal plexus which surrounds the vessels. The presence of vaso-dilator fibres in the common nerve trunks is masked, on excitation, by the overpowering action of the vaso-constrictor nerves. The latter are, however, more rapidly fatigued than the former, and by this and other means the presence of vaso-dilator fibres can be demonstrated in almost all parts of the body. The nervi-erigentes to the penis and the chorda tympani supplying the salivary glands are the most striking examples of vaso-dilator nerves. The vaso-motor centre exerts a tonic influence over the calibre of the arterial and portal venous systems, and, influenced as it is by afferent impulses received from all parts, reflexly regulates the supply of blood to the organs. Functional activity is accompanied by vaso-dilatation. Stimulation of the afferent nerves of any part excites reflexly vaso-dilatation in that part and constriction in other vascular areas. Paralytic dilatation results on cutting off any part from the influence of the vaso-motor centre, but after a few days local tone returns.

AUTHORITIES.—An exhaustive account of the literature on the circulation of the blood will be found in Tigerstedt's *Lehrbuch der Physiologie des Kreislaufes*, 1893. The following may also be consulted:—Porter's article on the "Circulation" in Howell's *American Text-Book of Physiology*, 1896; Gaskell's article on "Cardiac Muscle," and Leonard Hill's article on the "Vascular Mechanism," in Schäfer's *Text-Book of Physiology*, vol. ii.; and the articles "Circulation," "Cœur," &c., in Richet's *Dictionnaire de Physiologie*. For a general account of the vascular system, Foster's *Text-Book of Physiology*, 6th ed., may be consulted.

(L. E. H.)

V. RESPIRATION.

So far as is known, the intake of oxygen, either free or in combination, and the output of carbonic acid, are an essential part of the life of all organisms. The two processes are so closely associated with one another that they are always included together under the designation of Respiration, which may thus be defined as that part of organic activity which is concerned in the intake of oxygen and output of carbonic acid. According to the evidence at present available, it is only within living cells that the respiratory oxygen is consumed and the carbonic acid formed. The mere conveying of oxygen from the air to these cells, and of carbonic acid from them to the air, is, however, in itself a complex process in the higher animals; and accordingly an account of animal respiration naturally falls into two divisions, the first of which (I.) is concerned with the manner in which oxygen and carbonic acid are conveyed to and from the living tissues, and the second (II.) with the consumption of oxygen and production of carbonic acid by the living tissues themselves. Of these two divisions, the second is in reality the more important; for the conveyance of oxygen and carbonic acid between the air and the tissues is essentially a subsidiary process, the rate of which, as will be shown below, is regulated in accordance with the requirements of the tissues.

I. In the higher vertebrates air is brought into the lungs by the respiratory movements. Oxygen from this air passes through the delicate lining membrane of the air-cells of the lungs into the blood, where it enters into loose chemical combination with the hæmoglobin of the red corpuscles. In this form it is conveyed onwards to the heart, and thence through the arteries to the capillaries, where it again parts from the hæmoglobin, and passes through the capillary walls to the tissues, where it is consumed. Carbonic acid passes out from the tissues into the blood in a corresponding manner, enters into loose combination as bicarbonate, and possibly in other ways, in the blood, and is conveyed by the veins to the lungs, whence it passes out in the expired air. A detailed account of this complex process, together with a sketch of the corresponding processes in lower animals, is given in the article on RESPIRATION in the ninth edition of this work, which need only be supplemented here as regards points which have been further elucidated by recent research.

In certain circumstances the consumption of oxygen and production of carbonic acid by the body are temporarily much increased. Thus during hard muscular work this increase may amount to ten times the normal, or more. It is evident that to meet this increase there must be (1) a large increase in the volume of air breathed, and (2) a similar increase in the rate of circulation of the blood. As regards the first point, we know from analyses that the deficiency of oxygen and excess of carbonic acid in the expired air are nearly the same during muscular exercise as during rest; so that the volume of air breathed is increased about proportionally to the increased respiratory exchange of oxygen and carbonic acid. The increased volume of air breathed is due partly to greater frequency, and partly to greater depth, of the respirations. It has been shown that this alteration in the breathing is brought about by an altered state of the blood reaching the respiratory centre; and formerly it was believed that deficiency of oxygen in this blood is the cause. Deficiency of oxygen does undoubtedly stimulate the respiratory centre, but a study of the effects in man of deficiency of oxygen due to the breathing of air poor in oxygen is sufficient to negative the idea that this is the normal stimulus to the respiratory centre. Simultaneously with the stimulation (which is, moreover, sometimes so feeble as to be scarcely noticeable) there is more or less of mental confusion, impairment of the senses, loss of muscular power, and other alarming symptoms, which certainly do not accompany the normal stimulation of the respiratory centre. Excess of carbonic acid in the air breathed acts far more powerfully and persistently on the respiratory centre than deficiency of oxygen. The phenomena experienced on breathing air containing a sufficient excess to cause panting are, moreover, identical with those observed during panting produced by muscular exercise, so that it seems probable that excess of carbonic acid in the blood bathing the respiratory centre is the real stimulus. It is only, however, *free* carbonic acid that affects the centre. As only a small part of the carbonic acid in the blood is in the free state, the rest being combined with alkalies, the available proportion of which varies greatly at different times, mere determinations of the total proportion of carbonic acid in the arterial blood during rest and during exercise cannot decide the question whether it is the actual stimulus. Some physiologists maintain, on grounds which seem to the present writer insufficient, that the normal stimulus to the respiratory centre is some unknown "product of metabolism." If, either voluntarily or by artificial means, the respiratory movements are increased for a short time, the condition known as *apnœa* follows, the action of the respiratory centre being temporarily suspended. During apnœa the arterial blood contains much less carbonic acid than before, an abnormal amount having been washed out in the lungs by the excessive breathing. The amount of oxygen is, however, practically the same, the arterial blood being saturated under normal conditions, so that with excessive breathing it can take up no more. The main, though not the only, factor in producing apnœa seems to be the deficiency of carbonic acid in the blood. Although the respiratory centre tends to act in the normal rhythmic manner apart from all stimuli through nerves, yet researches have shown that afferent impulses conveyed from the lungs by the vagus nerve play a most important part in regulating the rhythm of the centre. Distension of the lungs arrests inspiration, while collapse of the lungs stimulates it, and this is brought about by stimuli conveyed by the vagus fibres, and caused by the stretching and relaxation of the lungs. When the vagus nerves are severed, the effect is absent, and the respirations are diminished in frequency and are deeper.

As regards the causes of the increased flow of blood which compensates for increased oxygen consumption in the muscles and other tissues, our knowledge is somewhat scanty. It appears that, along with the motor impulses which cause a muscle to contract, there proceed to the arterioles of the muscle vaso-motor impulses, leading to a greatly increased circulation through the muscle. The rush of blood through the working muscles must be compensated for by a corresponding increase in the work of the heart, as there is no fall in blood pressure; but by what means the compensation is brought about is not yet clear.

Until recently it was assumed that practically the whole of the carbonic acid discharged in the breath is brought to the lungs by the venous blood. Experiments made to test this question seem to show, however, that there is a very considerable production of carbonic acid and disappearance of oxygen in the lungs themselves, as much as a third or even half the total carbonic acid produced being under certain conditions formed there. On account of the unpleasant effects produced by the air of crowded rooms, and for other reasons, it was believed that expired air contains, besides carbonic acid, some poisonous substance. A careful investigation of the question has shown that no such substance exists.

Hæmoglobin.—The law according to which the hæmoglobin of the red blood corpuscles enters into combination with, or parts from, oxygen, has recently been more clearly determined. It has been shown that at a constant temperature the *relative* proportion of the hæmoglobin present which will enter into combination, or remain in combination, with oxygen, varies with the partial pressure of the oxygen present. If blood or hæmoglobin solution at a temperature of 37·4° C. (which is about that of the body) be shaken to saturation with pure oxygen at a pressure of 1·2 per cent. of an atmosphere (or at ordinary atmospheric pressure with nitrogen containing 1·2 per cent. of oxygen), half of the hæmoglobin will combine with oxygen, the relative proportions of combined and uncombined hæmoglobin being thus equal, or $\frac{1}{1}$. At a pressure of 2·4 per cent. of an atmosphere the proportion of combined to uncombined hæmoglobin will be $\frac{2}{1}$, so that the hæmoglobin will be two-thirds saturated with oxygen, and so on. In dry air at normal atmospheric pressure the pressure of oxygen is 20·94 per cent. of an atmosphere, so that in blood saturated with air the ratio of combined to uncombined hæmoglobin will be $\frac{17 \cdot 5}{1}$, and the hæmoglobin will thus be 94·6 per cent. saturated. It is evident from these data that, provided that the blood in passing through the lungs is saturated with oxygen at a pressure of 5 or 6 per cent. of an atmosphere of oxygen, the amount of oxygen taken up by the hæmoglobin of the blood will vary but little either with variations of atmospheric pressure or with variations in the percentage of oxygen in the air breathed. Hæmoglobin not only combines with oxygen, but also forms an analogous compound with carbonic oxide. The affinity of the latter gas for hæmoglobin is, however, much more powerful than that of oxygen. When blood is saturated with air containing 0·07 per cent. of carbonic oxide, the hæmoglobin is shared equally between the two gases, and increase of the percentage or partial pressure of either of the gases increases correspondingly its relative share of the hæmoglobin. When carbonic oxide is breathed it passes into the blood, which continues to absorb it until the point is reached at which the pressure of oxygen in the blood passing through the lungs suffices to prevent further absorption. As, however, the hæmoglobin combined with carbonic oxide is useless for the time as an oxygen-carrier, symptoms of lack of oxygen, or death from want of oxygen, may easily be caused by carbonic oxide. When death occurs the blood is usually about 80 per cent. saturated with carbonic oxide, which is the poisonous constituent of lighting-gas, smoke, and the after-damp which causes most of the deaths in colliery explosions. Besides the ordinary oxygen compound of hæmoglobin, there is another oxygen compound known as *Methæmoglobin*, containing the same amount of oxygen, but combined in a different manner. Methæmoglobin has a brown colour, and does not yield its oxygen to a vacuum. It is readily formed by the action of various oxidizing agents, such as ferricyanide of potassium, on hæmoglobin. When the hæmoglobin acted on is already combined in the ordinary way with oxygen or carbonic oxide, the whole of the gas thus combined is set free, and this reaction affords an easy and accurate means of determining the proportion of hæmoglobin in a sample of blood. Methæmoglobin is formed in the living body by the action of various poisons, such as chlorate of potash, amylnitrite, or dinitrobenzol (the chief constituent of the explosive roburite). Since the methæmoglobin thus formed is useless as an oxygen-carrier, symptoms similar to those of carbonic oxide poisoning are produced.

Between the air in the air-cells of the lungs and the blood of the lung-capillaries there intervenes nothing but a layer of very thin, flattened cells, and until recently it was very generally believed that it was by diffusion alone that oxygen passes inwards and carbonic acid outwards through this layer. Similar simple physical explanations of processes of secretion and absorption through living cells have, however, turned out to be incorrect in the case of other organs. It is known, moreover, that in the case of the swimming-bladder of fishes oxygen is secreted into the interior against enormous pressure. Thus, in the case of a fish caught at a depth of 4500 feet, the partial pressure of the oxygen present in the swimming-bladder at this depth was 127 atmospheres, whereas the partial pressure of oxygen in sea water is only about 0·2 atmosphere. Diffusion can therefore have nothing to do with the passage of gas inwards, which is known to be under the control of the nervous system. The cells lining the interior of the swimming-bladder are developed from the same part of the alimentary tract as those lining the air-cells of the lungs, so that it seems not unlikely that the lungs should possess the power of actively secreting or excreting gases. The question whether such a power exists, and is normally exercised, has been investigated by more than one method; and although it is not possible to go into the details of the experiments, there can be no doubt that the balance of the evidence at present available is in favour of the view that diffusion alone is incapable of explaining either the absorption of oxygen or the excretion of carbonic acid through the lining cells of the lungs. The partial pressure of oxygen appears to be always higher, and of carbonic acid often lower, in the blood leaving the lungs than in the air of the air-cells; and this result is inconsistent with the diffusion theory. As to the causes of the passage of oxygen and carbonic acid through the walls of the capillaries of the general circulation, we are at present in the dark. Possibly diffusion may explain this process.

II. Although we cannot trace the exact changes which occur when oxygen passes into living cells, and although, indeed, we have the clearest reasons for believing that it would be impossible to express these changes fully in chemical terms, yet it is possible to obtain a clear general view of both the ultimate destiny of the oxygen and the origin of the carbonic acid. The oxidizable material within the body consists, practically speaking, of proteids (albumen-like substances, with which the collagen of connective tissue may be included), fats, and carbohydrates (sugars and glycogen). All of these substances contain carbon, hydrogen, and oxygen in known, though different proportions, and the former also contains a known amount of nitrogen and a little sulphur. Nitrogen is constantly leaving the body as urea and other substances in the urine and faeces; and a small but easily measurable proportion of carbon passes off in the same manner. The rest of the carbon passes out as carbonic acid in respiration. Now carbohydrates and fats are oxidized completely in the body to carbonic acid and water. This follows from the fact that, practically speaking, no other products into which they might have been converted leave the body except carbonic acid and water. Moreover, a given weight of carbohydrate requires for its oxidation a definite weight of oxygen, and produces a definite weight of carbonic acid. There is thus a definite relation between the weight of oxygen used up and the weight of carbonic acid formed in this oxidation. The same is true for the oxidation of fat, and of proteid, allowing in the latter case for the fact that the nitrogen, together with part of the carbon and hydrogen, passes out as urea, &c., in an incompletely oxidized form. From all this it follows that if we measure over a given period (1) the discharge of nitrogen from the body, (2) the intake of oxygen, and (3) the output of carbonic acid, we can easily calculate exactly what the ultimate destiny of the oxygen has been, and at the ultimate expense of what material the carbonic acid has been formed. What the intermediate stages may have been we cannot say, but this in no way affects the validity of the calculation. If, during the period of measurement, food is taken, the basis of the calculation is still substantially the same, as the oxidizable material in food consists of practically nothing else except proteids, carbohydrates, and fats.

Liberation of Energy.—From experiments made outside the body, we know that in the oxidation of a given weight of proteid, carbohydrate, or fat, a definite amount of energy is liberated. In the article on DIETETICS it has been shown that precisely the same liberation of energy occurs in the living body, due allowance being made for the fact that the oxidation of proteid is not quite complete. The following table shows the respiratory quotients (see RESPIRATION, 9th edition) and energy expressed in units of heat (Calories) liberated per gramme of carbonic acid produced and oxygen consumed in the living body during the oxidation of proteid, fat, and a typical carbohydrate.

Substance oxidized.	Respiratory Quotient.	Calories per gramme of CO_2 produced.	Calories per gramme of oxygen consumed.
Proteid . .	·78	2·78	3·00
Fat . . .	·71	3·35	3·27
Cane-sugar .	1·00	2·59	3·56

In the oxidation of non-living substances the rate varies, within wide limits, according to that at which oxygen is supplied. Thus a fire burns the faster the more air is supplied, and the higher the percentage of oxygen in the air. It was for long believed that in the living body also the rate of oxidation must vary according to the oxygen supply. It has been found, however, that this is not the case. Provided that a certain minimum of oxygen is present in the air breathed, or in the blood supplied to the tissues, it is, practically speaking, indifferent whether the oxygen supply be increased or diminished : only a certain amount is consumed. It might be supposed that the reason for this is that the available oxidizable material in the body is limited, and that if the food supply were increased there would be a corresponding increase in the rate of oxidation. This hypothesis is apparently supported by the fact that, when an increased supply of proteid is given as food, the amount of nitrogen discharged in the urine is almost exactly correspondingly increased, so that evidently the oxidation of proteid increases correspondingly with the supply. Similarly, when carbohydrate food is given, the alteration in the respiratory quotient shows that more carbohydrate than before is being oxidized. Closer investigation in recent times has, however, brought out the very striking fact that, if oxidation be measured in terms of energy liberated by it in the body, it makes but little difference whether the animal is fasting or not. If more proteid or carbohydrate is oxidized at one time, correspondingly less fat is oxidized, but the total energy liberated as heat, &c., in the body is about the same, unless the diet is very excessive, when there is a slight increase of oxidation. Even after many days of starvation, the rate of oxidation per unit of body weight has been found to remain sensibly the same in man. When more food is taken than is required, the excess is stored up, chiefly in the form of fat, into which carbohydrate and possibly also proteid are readily converted in the body. When less food is taken than is needed, the stock of fat is drawn upon, and supplies by far the greater proportion of the energy requirements of the body.

During the performance of muscular work oxidation is greatly increased, and may amount to ten times the normal or more. Even the slight exertion of walking increases oxidation to three times. When the energy represented by the external work done in muscular exertion is compared with the extra energy liberated by oxidation in the body, it is found, as would be expected, that the latter value largely exceeds the former. In other words, much of the energy liberated is wasted as heat. Nevertheless the muscles are capable of working with far less waste than any steam or gas engine. In the work of climbing, for instance, it has been found in the case of man that 35 per cent. of the energy liberated is represented in the work done in raising the body. Muscular work, if at all excessive, leads to fatigue, and consequent rest. On the other hand, unnatural abstinence from muscular activity leads to restlessness and consequent muscular work. Hence on an average of the 24 hours the expenditure of energy by different individuals, with different modes of life, does not as a rule differ greatly.

The rate of oxidation per unit of body-weight varies considerably according to size and age. If we compare different warm-blooded animals, we find that the rate of oxidation is relatively to their weight far higher in the smaller ones. In a mouse or small bird, for instance, the rate is about twenty times as great as in a man. The difference is in part due to the fact that the smaller an animal is the greater is its surface relatively to its mass, and consequently the more heat does it require to keep up its temperature. The smaller animal must therefore produce more heat. Even in cold-blooded animals, however, oxidation appears to be more rapid the smaller the animal. In the case of man oxidation is relatively more than twice as rapid in children as in adults, and the difference is greater than would be accounted for by the difference in the ratio of surface to mass. Allowing for differences in size, oxidation is about equally rapid in men and women.

It was for long believed that the special function of respiratory oxidation was (1) the production of heat, and (2) the destruction of the supposed "waste products." Further investigation has, however, tended to show more and more clearly that in reality respiratory oxidation is an essential and intimate accompaniment of all vital activity. To take one example, secretion and absorption, which were formerly explained as simple processes of filtration and diffusion, are now known to be accompanied, and necessarily so, by respiratory oxidation in the tissues concerned. The respiratory oxidation of an animal is thus a very direct index of the activity of its vital processes as a whole. Looking at what is known with regard to respiratory oxidation, we see that what is most striking and most characteristic in it is its tendency to persist—to remain on the whole at about a normal level for each animal, or each stage of development of an animal. The significance of this cannot be over-estimated. It indicates clearly that just as an organism differentiates itself from any non-living material system by the manner in which it actually asserts and maintains its specific anatomical structure, so does it differentiate itself from any mere mechanism by the manner in which it asserts and maintains its specific physiological activities. This points to a fundamental difference in kind between the two aspects (and they are both of them only abstract aspects) of experience which are respectively represented in the Biological and Physico-chemical sciences, and to the necessity for a clear recognition of the corresponding differences in what are the only practical aims which each of the two groups of sciences can set before itself.

VI. Muscle and Nerve.

Muscle.—Among the properties of living material there is one, widely though not universally present in it, which forms the pre-eminent characteristic of muscular cells. This property is the liberation of some of the energy contained in the chemical compounds of the cells in such a way as to give mechanical work. The mechanical work is obtained by movement resulting from a change in, it is supposed, the elastic tension of the living framework of the cell. In the fibrils existing in the cell a sudden alteration of elasticity occurs, resulting in an increased tension on the points of attachment of the cell to the neighbouring elements of the tissue in which the cell is placed. These yield under the strain, and the cell shortens between those points of its attachment. This shortening is called *contraction*. But the volume of the cell is not appreciably altered, despite the change of its shape, for its one diameter increases in proportion as its other is diminished. The manifestations of contractility by muscle are various in mode. By *tonic* contraction is meant a prolonged and equable state of tension which yields under analysis no element of intermittent character. This is manifested by the muscular walls of the hollow viscera and of the heart, where it is the expression of a continuous liberation of energy in process in the muscular tissue, the outcome of the latter's own intrinsic life, and largely independent of any connexion with the nervous system. The muscular wall of the blood-vessels also exhibits tonic contraction, which, however, seems to be mainly traceable to a continual excitation of the muscle cells by nervous influence conveyed to them along their nerves, and originating in the great *vaso-motor centre* in the bulb. In the ordinary striped muscle tissue of the skeletal musculature, *e.g.*, *gastrocnemius*, tonic contraction obtains; but this, like the last mentioned, is not of autochthonous origin in the muscles themselves; it is indirect and *neural*, and appears to be chiefly maintained reflexly. The sensifacient organs of the muscular sense and of the semicircular canals are to be regarded as the sites of origin of this *reflex* tonus of the skeletal muscles. Striped muscles possessing an autochthonous tonus appear to be the various sphincter muscles.

Contractility.

Another mode of manifestation of contractility by muscles is the *rhythmic*. A tendency to rhythmic contraction seems discoverable in almost all muscles. In some it is very marked, for example, in some viscera, the spleen, the bladder, the ureter, the uterus, the intestine, and especially in the heart. In several of these it appears proven that the recurrent explosive liberations of energy in the muscle tissue are not secondary to recurrent explosions in nerve cells, but are attributable to decompositions arising *suâ sponte* in the chemical substances of the muscle cells themselves in the course of their living. Even small strips of the muscle of the heart, if taken immediately after the death of the animal, continue, when kept moist and warm and supplied with oxygen, to "beat" rhythmically for hours. Rhythmic contraction is also characteristic of certain groups of skeletal muscles, *e.g.*, the respiratory. In these the rhythmic activity is, however, clearly secondary to rhythmic discharges of the nerve cells constituting the respiratory centre in the bulb. Such discharges descend the nerve fibres of the spinal cord, and through the intermediation of various spinal nerve cells excite the respiratory muscles through their motor nerves. A form of contraction intermediate in character between the tonic and the rhythmic is met in the auricle of the heart of the toad. These slowly successive phases of increased and of diminished tonus regularly alternate, and upon them are superposed the rhythmic "beats" of the pulsating heart.

The "beat," *i.e.*, the short-lasting explosive contraction, of the heart muscle can be elicited by a single, even momentary, application of a stimulus, *e.g.*, by an induction shock. Similarly, such a single stimulus elicits from a skeletal muscle a single "beat," or, as it is termed, a "twitch." In the heart muscle during a brief period after each beat, that is, after each single contraction of the rhythmic series, the muscle becomes "*inexcitable.*" It cannot then be excited to contract by any agent, though the inexcitable period is more brief for strong than for weak stimuli. But in the great group of the skeletal, voluntary, or striped muscles, a second stimulus succeeding a previous so quickly as to fall even during the continuance of the contraction excited by a first, elicits a second contraction. This second contraction starts from whatever phase of previous contraction the muscle may have reached at the time. A third stimulus excites a third additional contraction, a fourth a fourth, and so on. The increments of contraction become, however, less and less, until the succeeding stimuli serve merely to maintain, not to augment, the existing degree of contraction. We arrive thus by analysis at a summation of "beats" or of simple contractions in the compound, or "tetanic," or summed contraction of the skeletal muscles. The tetanic or summed contractions are more extensive than the simple, both in space and time, and liberate more energy, both as mechanical work and heat. The tension developed by their means in the muscle is many times greater than that developed by a simple twitch.

Muscle cells respond by changes in their activity to changes in their environment, and thus are said to be "excitable." They are, however, less excitable than are the nerve cells which innervate them. The change which excites them is termed a *stimulus*. The least stimulus which suffices to excite is known as the *stimulus of threshold value*. In the case of the heart muscle this threshold stimulus evokes a beat as extensive as does the strongest stimulus; that is, the intensity of the stimulus, so long as it is above threshold value, is not a function of the amount of the muscular response. But in the ordinary skeletal muscles the amount of the muscular contraction is for a short range of quantities of stimulus (of above threshold value) proportioned to the intensity of the stimulus and increases with it. A value of stimulus is, however, soon reached which evokes a *maximal* contraction. Further increase of contraction does not follow further increase of the intensity of the stimulus above that point. Just as in a nerve fibre, when excited by a localized stimulus, the excited state spreads from the excited point to the adjacent unexcited ones, so in muscle the "contraction," when excited at a point, spreads to the adjacent uncontracted parts. Both in muscle and in nerve this spread is termed "*conduction.*" It is propagated along the muscle fibres of the skeletal muscles at a rate of about 3 metres per second. In the heart muscle it travels much more slowly. The disturbance travels as a *wave* of contraction, and the whole extent of the wave-like disturbance measures in ordinary muscles much more than the whole length of any single muscle fibre. That the excited state spreads only to previously unexcited portions of the muscle fibre, shows that even in the skeletal variety of muscle there exists, though only for a very brief time, a period of inexcitability. The duration of this period is about $\frac{1}{500}$ of a second in skeletal muscle.

Excitability.

When muscle that has remained inactive for some time is excited by a series of single and equal stimuli succeeding at intervals too prolonged to cause summation, the succeeding contractions exhibit progressive increase up to a certain degree. The tenth contraction usually exhibits the culmination of this so-called "staircase effect." The explanation may lie in the production of CO_2 in the muscle. That substance, in small doses, favours the contractile power of muscle. The muscle is a machine for utilizing the energy contained in its own chemical compounds. It is not surprising that the chemical substances produced in it by the decomposition of its living material should not be of a nature indifferent for muscular life. We find that if the series of excitations of the muscle be prolonged beyond the short stage of initial improvement, the contractions, after being well maintained for a time, later decline in force and speed, and ultimately dwindle even to vanishing point. This decline is said to be due to *muscular fatigue.* The muscle recovers on being allowed to rest unstimulated for a while, and more quickly on being washed with an innocuous but non-nutritious solution, such as ·6 per cent. NaCl in water. The washing seems to remove excreta of the muscle's own production, and the period of repose removes them perhaps by diffusion, perhaps by breaking them down into innocuous material. Since the muscle produces lactic acids during activity, it has been suggested that acids are among the "fatigue substances" with which muscle poisons itself when deprived of circulating blood. Muscles when active seem to pour into the circulation substances which, of unknown chemical composition, are physiologically recognizable by their stimulant action on the respiratory nervous centre. The effect of the fatigue substances upon the contraction of the tissue is manifest especially in the relaxation process. The contracted state, instead of rapidly subsiding after discontinuance of the stimulus, slowly and only partially wears off, the muscle remaining in a condition of physiological "contracture." The alkaloid veratrin has a similar effect upon the contraction of muscle; it enormously delays the return from the contracted state, as also does epinephrin, an alkaloid extracted from the suprarenal gland.

NERVOUS SYSTEM.—The work of Golgi (Pavia, 1885 and onwards) on the minute structure of the nervous system has led to great alteration of doctrine in neural physiology. It had been held that the branches of the nerve cells, that is to say, the fine nerve fibres—since all nerve fibres are nerve cell branches, and all nerve cell branches are nerve fibres—which form a close felt-work in the nervous centres, there combined into a network actually continuous throughout. This *continuum* was held to render possible conduction in all directions throughout the grey matter of the whole nervous system. The fact that conduction occurred preponderantly in certain directions, was explained by appeal to a hypothetical resistance to conduction which, for reasons unascertained, lay less in some directions than in others. The intricate felt-work has by Golgi been ascertained to be a mere interlacement, not an actual anastomosis network; the branches springing from the various cells remain life-long unattached and unjoined to any other than their own individual cell. Each neuron or nerve cell is a morphologically distinct and discrete unit connected functionally but not structurally with its neighbours, and with its own life and death independently of the destiny of its neighbours. Among the properties of the neuron is conductivity in all directions. But when neurons are linked together it is found that nerve impulses will only pass from neuron A to neuron B, and not from neuron B to neuron A; that is, the transmission of the excited state or nervous impulse, although possible in each neuron both up and down its own cell branches, is only possible from one nerve cell to another in one direction.

Neuron theory.

That direction is the direction in which the nerve impulses flow under the conditions of natural life. The *synapse,* therefore, as the place of meeting of one neuron with the next is called, is said to valve the nerve circuits. This determinate sense of the spread is expressed as *the law of forward direction.* The synapse appears to be a weak spot in the chain of conduction, or rather to be a place which breaks down with comparative ease under stress, *e.g.,* under effect of poisons. The axons of the motor neurons are, inasmuch as they are nerve fibres in nerve trunks, easily accessible to artificial stimuli. It can be demonstrated that they are practically indefatigable—repeatedly stimulated by electrical currents, even through many hours, they, unlike muscle, continue to respond with unimpaired reaction. Yet when the muscular contraction is taken as index of the response of the nerve, it is found that unmistakable signs of fatigue appear even a very brief period after commencement of the excitation of the nerve, and the muscle soon ceases to give any contraction whatever in response to stimuli applied indirectly to it through its nerve. But the muscle will, when excited directly, *e.g.,* by direct application of electric currents, contract vigorously after all response on its part to the stimuli (nerve impulses) applied to it indirectly through its nerve has failed. The inference is that the "fatigue substances" generated in the muscle fibres in the course of their prolonged contraction injure and paralyse the motor end plates, which are places of synapses between nerve cell and muscle cell, even earlier than they harm the contractility of the muscle fibres themselves. The alkaloid curarin causes motor paralysis by attacking in a selective way this junction of motor nerve cell and striped muscular fibre. It seems probable that the practical immunity of nerve fibres from fatigue is associated with their possession of a myelin sheath, for nerve fibres of the non-myelinate kind do not exhibit this immunity. Now, there is a difference between the axon in its course and at its termination, for at the latter it is naked and unsheathed in myelin. It may be that the rapidly fatigable character of the motor end plate is due to the naked non-myelinate condition of the nerve fibre there. The myelin sheath probably prevents fatigue more by ensuring rapid renewal of nerve-conducting material than by mechanical protection; it may be looked on as a nutrient bath in which the core conductor lies immersed.

Peripheral fatigue.

The neuron is described as having a cell body or *perikaryon* from which the cell branches—dendrites and axon—extend, and it is this perikaryon which, as its name implies, contains the nucleus. It forms the trophic centre of the cell, just as the nucleus-containing part of every cell is the trophic centre of the whole cell. Any part of the cell cut off from the nucleus-containing part dies down: this is as true of nerve cells as of amœba, and in regard to the neuron it constitutes what is known as the *Wallerian degeneration.* On the other hand, in some neurons, after severance of the axon from the rest of the cell (spinal motor cell), the whole nerve cell as well as the severed axon degenerates, and may eventually die and be removed. In the severed axon the degeneration is first evident in a breaking down of the naked nerve filaments of the motor end plate. A little later the breaking down of the whole axon, both axis cylinder and myelin sheath alike, seems to occur simultaneously throughout its entire length distal to the place of severance. The complex fat of the myelin becomes altered chemically, while the other components of the sheath break down. This death of the sheath as well as of the axis cylinder shows that it, like the axis cylinder, is a part of the nerve cell itself.

Solidarity of neuron.

In addition to the trophic influence exerted by each part of the neuron on its other parts, notably by the perikaryon on the cell branches, one neuron also in many instances influences the nutrition of other neurons. When, for instance, the axons of the ganglion cells of the retina are severed by section of the optic nerve, and thus their influence upon the nerve cells of the visual cerebral centres is set aside, the nerve cells of those centres undergo secondary atrophy (*Gadden's atrophy*). They dwindle in size; they do not, however, die. Similarly, when the axons of the motor spinal cells are by severance of the nerve trunk of a muscle broken through, the muscle cells undergo "degeneration"—dwindle, become fatty, and alter almost beyond recognition. This trophic influence which one neuron exerts upon others, or upon the cells of an extrinsic tissue, such as muscle, is exerted in that direction which is the one normally taken by the natural nerve impulses. It seems, especially in the case of the nexus between certain neurons, that the influence, loss of which endangers nutrition, is associated with the occurrence of something more than merely the nervous impulses awakened from time to time in the leading nerve cell. The wave of change (nervous impulse) induced in a neuron by advent of a stimulus is after all only a sudden augmentation of an activity continuous within the neuron—a transient accentuation of one (the disintegrative) phase of the metabolism inherent in and inseparable from its life. The nervous impulse is, so to say, the sudden evanescent glow of an ember continuously black-hot. A continuous lesser "change" or stream of changes sets through the neuron, and is distributed by it to other neurons in the same direction and by the same synapses as are its nerve impulses. This gentle continuous activity of the neuron is called its *tonus*. In tracing the tonus of neurons to a source, one is always led link by link against the current of nerve force—so to say, "up stream"—to the first beginnings of the chain of neurons in the sensifacient surfaces of the body. From these, as in the eye, ear, and other sense organs, tonus is constantly initiated. Hence, when cut off from these sources, the nutrition of the neurons of various central mechanisms suffers. Thus the tonus of the motor neurons of the spinal cord is much lessened by rupture of the great afferent root cells which normally play upon them. A prominent and practically important illustration of neural tonus is given by the skeletal muscles. These muscles exhibit a certain constant condition of slight contraction, which disappears on severance of the nerve that innervates the muscle. It is a muscular tonus of central source consequent on the continual glow of excitement in the spinal motor neuron, whose outgoing end plays upon the muscle cells, whose ingoing end is played upon by other neurons—spinal, cerebral, and cerebellar.

Tonic activity of neurons.

It is with the neural element of muscle tonus that *tendon phenomena* are intimately associated. The earliest-studied of these, the "*knee-jerk*," may serve as example of the class. It is a brief extension of the limb at the knee-joint, due to a simple contraction of the extensor muscle, elicited by a tap or other short mechanical stimulus applied to the muscle fibres through the tendon of the muscle. The jerk is obtainable only from muscle fibres possessed of neural tonus. If the sensory nerves of the extensor muscle be severed, the "jerk" is lost. The brevity of the interval between the tap on the knee and the beginning of the resultant contraction of the muscle excludes the possibility of reflex development. A little experience in observations on the knee-jerk imparts a notion of the average strength of the "jerk." Wide departures from the normal standard are met with and are symptomatic of certain nervous conditions. Stretching of the muscles antagonistic to the extensors—namely, of the flexor muscles—reduces the jerk by inhibiting the extensor spinal nerve cells through the nervous impulses generated by the tense flexor muscles. Hence a favourable posture of the limb for eliciting the jerk is one ensuring relaxation of the hamstring muscles, as when the leg has been crossed upon the other. In sleep the jerk is diminished, in deep sleep quite abolished. Extreme bodily fatigue diminishes it. Conversely, a cold bath increases it. The turning of attention towards the knee interferes with the jerk; hence the device of directing the person to perform vigorously some movement, which does not involve the muscles of the lower limb, at the moment when the light blow is dealt upon the tendon. A slight degree of contraction of muscle seems the *substratum* of all attention. The direction of attention to the performance of some movement by the arm ensures that looseness and freedom from tension in the thigh muscles which is essential for the provocation of the jerk. The motor cells of the extensor muscles, when preoccupied by cerebral influence, appear refractory. Ziehen has noted exaltation of the jerk to follow extirpation of a cortical centre.

Although the cell body or perikaryon of the neuron, with its contained nucleus, is essential for the maintenance of the life of the cell branches, it has become recognized that the actual process and function of "conduction" in many neurons can, and does, go on without the cell body being directly concerned in the conduction. Wundt first showed, many years ago, that the nerve impulse travels through the spinal ganglion at the same speed as along the other parts of the nerve trunk—that is, that it suffers no delay in transit through the perikarya of the afferent root-neurons. Bethe has succeeded in isolating their perikarya from certain of the afferent neurons of the antenna of *Carcinus*. The conduction through the amputated cell branches continues unimpaired for many hours. This indicates that the conjunction between the conducting substance of the dendrons and that of the axon can be effected without the intermediation of the cell body. But the proper nutrition of the conducting substance is indissolubly dependent on the cell branches being in continuity with the cell body and nucleus it contains. Evidence illustrating this nexus is found in the visible changes produced in the perikaryon by prolonged activity induced and maintained in the conducting branches of the cell. As a result, the fatigued cells appear shrunken, and their reaction to staining reagents alters, thus showing chemical alteration. Most marked is the decrease in the volume of the nucleus, amounting even to 44 per cent. of the initial volume. In the myelinated cell branches of the neuron, that is, in the ordinary nerve fibres, no visible change has ever been demonstrated as the result of any normal activity, however great—a striking contrast to the observations obtained on the perikarya. The chemical changes that accompany activity in the nerve fibre must be very small, for no measurable production of CO_2 or of heat is observable as the result of the most forced tetanic activity.

Conduction in neurons.

The nerve cells of the higher vertebrata, unlike their blood cells, their connective tissue cells, and even their muscle cells, early, and indeed in embryonic life, lose power of multiplication. The number of them formed is definitely closed at an early period of the individual life; they are like a committee given definite work to do and without power to add to their number. The nerve cells of a centenarian are themselves each individually a hundred years of age. Although, unlike so many other cells, thus early sterile for reproduction of their kind, they retain for longer than most cells a high power of individual growth. They continue to grow, and to thrust out new branches and to lengthen existing branches, for many years far into adult life. They similarly possess power to repair and to regenerate their cell branches where these are injured or destroyed by trauma or disease. This is the explanation of the repair of nerve trunks that have been severed, with consequent degeneration of the peripheral nerve fibres. As a rule, a longer time is required to restore the motor than the sensory functions of a nerve trunk.

Growth in nervous system.

Whether examined by functional or by structural features, the conducting paths of the nervous system, traced from beginning to end, never terminate in the centres of that system, but pass through them. All ultimately emerge as efferent channels. Every afferent channel, after entrance in the central nervous system, subdivides into several; of these some pass to efferent channels soon, others pass farther and farther within the cord and brain before they finally reach channels of outlet. All the longest routes thus formed traverse late in their course the cortex of the cerebral hemisphere. It is this relatively huge development of cortex cerebri which is the pre-eminent structural character of man. This means that the number of "longest routes" in man is, as compared with lower animals, disproportionately great. In the lower animal forms there is no such nervous structure at all as the cortex cerebri. In the frog, lizard, and even bird, it is a thin and poorly developed thing. In the marsupials it is more evident, and its excitation by electric currents evokes movements in the musculature of the crossed side of the body. Larger and thicker in the rabbit, when excited it gives rise in that animal to movements of the eyes and of the fore-limbs and neck; but it is only in much higher types, such as the dog, that the cortex yields, under experimental excitation, definitely localized foci, whence can be evoked movements of the fore-limb, hind-limb, neck, eyes, ears, and face. In the monkey the proportions it assumes are vastly greater, and the number of foci, for distinct movements of this and that member, indeed for the individual joints of each limb, are much more numerous, and together occupy a more extensive surface, though relatively to the total surface of the brain a smaller one.

Cerebral cortex.

Experiment shows that in the manlike (anthropoid) apes the differentiation of the foci or "centres" of movement in the motor field of the cortex is more minute still. In them areas are found whence stimuli excite movements even of this or that finger alone, of the upper lip without the lower, of the tip only of the tongue, or of one upper eyelid by itself. The movement evoked from a point of cortex is not always the same; its character is determined by movements evoked from neighbouring points of cortex immediately antecedently. Thus a point A will, when excited soon subsequent to point B, which latter yields protrusion of lips, itself yield lip-protrusion, whereas if excited after C, which yields lip-retraction, it will itself yield lip-retraction. The movements obtained by point-to-point excitation of the cortex are often evidently imperfect as compared with natural movements—that is, are only portions of complete normal movements. Thus among the tongue movements evoked by stigmatic stimulation of the cortex undeviated protrusion or retraction of the organ is not found. Again, from different points of the cortex the assumption of the requisite positions of the tongue, lips, cheeks, palate, and epiglottis, as components in the act of sucking, can be provoked singly. Rarely can the whole action be provoked, and then only gradually, by prolonged and strong excitation of one of the requisite points, *e.g.*, that for the tongue, with which the other points are functionally connected. Again, no single point in the cortex evokes the act of ocular convergence and fixation. All this means that the execution of natural movements employs simultaneous co-operative activity of a number of points in the motor fields on both sides of the brain together.

The accompanying simple figure indicates better than any verbal description the topography of the main groups of foci in the motor field of a manlike ape (chimpanzee). It will be noted from it that there is no direct relation between the extent of a cortical area and the mass of muscles which it controls. The mass of muscles in the trunk is greater than in the leg, and in the leg is greater than in the arm, and in the arm is many times greater than in the face and head; yet for the last the cortical area is the most extensive of all, and for the first-named is the least extensive of all.

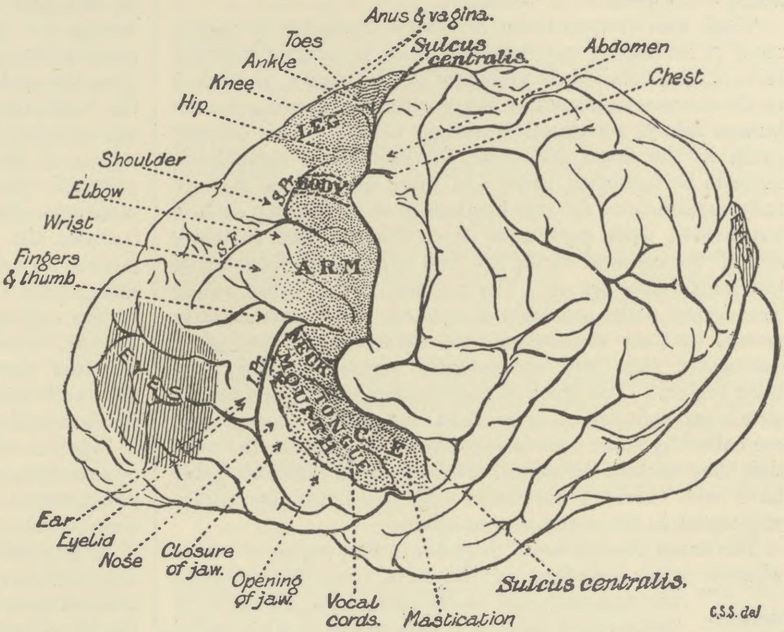

Diagram of the Topography of the Main Groups of Foci in the Motor Field of Chimpanzee.

The motor field of the cortex is, taken altogether, relatively to the size of the lower parts of the brain, larger in the anthropoid than in the inferior monkey brains. But in the anthropoid brain still more increased even than the motor field are the great regions of the cortex outside that field, which yields in definite movements under electric excitation, and are for that reason known as "inexcitable." The motor field, therefore, though absolutely larger, forms nevertheless a smaller fraction of the whole cortex of the brain than in the lower forms. The statement that in the anthropoid (orang-outan) brain the groups of foci in the motor fields of the cortex are themselves separated one from another by surrounding inexcitable cortex, has been made and was one of great interest, but has not been confirmed by subsequent observation. That in man the excitable foci of the motor field are islanded in inexcitable surface similarly and even more extensively, was a natural inference, but it had its chief basis in the observations on the orang, now known to be erroneous; unless direct confirmatory evidence is forthcoming from observations on the human brain itself, the supposition must be abandoned.

In the diagram there is indicated the situation of the cortical centres for movement of the vocal cords. Their situation is at the lower end of the motor field. That they should lie there is interesting, because that place is close to one known in man to be associated with management of the movements concerned in speech. When that area in man is injured, the ability to utter words is impaired. Not that there is paralysis of the muscles of speech, since these muscles can be used perfectly for all acts other than speech. The area in man is known as the motor centre for speech; in most persons it exists only in the left half of the brain and not in the right. In a similar way damage of a certain small portion of the temporal lobe of the brain produces loss of intelligent apprehension of words spoken, although there is no deafness and although words seen are perfectly apprehended. Another region, "the angular region," is similarly related to intelligent apprehension of words seen, though words heard are apprehended perfectly.

When this differentiation of cortex, traceable by experiment to its highest expression in man, is collated with the facts of the detailed development of the cortex as studied in the successive phases of its growth and ripening in the human infant, a suggestive analogy is seen. The nervous paths in the brain and cord, as they attain completion, come to be furnished more and more with fibres that are fully myelinate. At the beginning of its history each is unprovided with myelinate nerve fibres. The excitable foci of the cerebral cortex are well myelinated long before the unexcitable are so. The regions of the cortex, whose conduction paths are early completed, may be arranged in groups by their connexions with sense-organs: eye-region, ear-region, skin and somæsthetic region, olfactory and taste region. The areas of intervening cortex, arriving at structural completion later than the above *sense-spheres*, are called by some *association-spheres*, to indicate the view that they contain the neural mechanisms of reactions (some have said "ideas") associated with the sense perceptions elaborated in the several sense-spheres.

Sensori-motor centres.

The name "motor area" is given to that region of cortex whence motor reactions of the facial and limb muscles are regularly and easily evoked, as Ferrier's investigations showed. This region is often called the *sensori-motor cortex*, and the term *somæsthetic* has also been used and seems very appropriate. It has been found that disturbance of sensation, as well as disturbance of movement, is often incurred by its injury. Patients in whom, for purposes of diagnosis, it has been electrically excited, describe, as the initial effect of the stimulation, tingling and obscure but locally-limited sensations, referred to the part whose muscles a moment later are thrown into co-ordinate activity. The distinction, therefore, between the movement of the eyeballs, elicited from the occipital (visual) cortex, and that of the hand, elicited from the cortex in the region of the central sulcus (somæsthetic), is not a difference between motor and sensory, for both are sensori-motor in the nature of their reactions; the difference is only a difference between the kind of sense and sense-organ in the two cases, the muscular apparatus in each case being an appanage of the sensual.

That the lower types of vertebrate, such as fish, *e.g.*, carp, possess practically no cortex cerebri, and nevertheless execute "volitional" acts involving high co-ordination and suggesting the possession by them of *associative memory*, shows that for the existence of these phenomena the cortex cerebri is in them not essential. In the dog it has been proved that after removal from the animal of every vestige of its cortex cerebri, it still executes habitual acts of great motor complexity requiring extraordinarily delicate adjustment of muscular contraction. It can walk, run, and feed; such an animal, on wounding its foot, will run on three legs, as will a normal dog under similar mischance. But signs of associative memory are almost, if not entirely, wanting. Throughout three years such a dog failed to learn that the attendant's lifting it from the cage at a certain hour was the preliminary circumstance of the feeding-hour; yet it did exhibit hunger, and would refuse further food when a sufficiency had been taken. In man, actually gross sensory defects follow even limited lesions of the cortex. Thus the rabbit and dog are not absolutely blinded by removal of the entire cortex, but in man destruction of the occipital cortex produces total blindness, even to the extent that the pupil of the eye does not respond when light is flashed into the eye.

Cerebellum.

Examination of the cerebellum by the method of Wallerian degeneration has shown that a large number of spinal and bulbar nerve cells send branches up into it. These seem to end, for the most part, in the grey cortex of the median lobe, some, though not the majority, of them decussating across the median line. The organ seems also to receive many fibres from the parietal region of the cerebral hemisphere. From the organ there emerge fibres which cross to the opposite red nucleus, and directly or indirectly reach the thalamic region of the crossed hemisphere. The pons or middle peduncle, which was regarded, on the uncertain ground of naked-eye dissection of human anatomy, as commissural between the two lateral lobes of the cerebellum, is now known as constituting chiefly a cerebro-cerebellar decussating path. Certain cerebellar cells send processes down to the cell-group in the bulb known as the nucleus of Deiters, which latter projects fibres down the spinal cord. Whether there is any other or direct emergent path from the cerebellum into the spinal cord is a matter on which opinion is divided.

Injuries of the cerebellum, if large, derange the power of executing movements, without producing any detectable derangement of sensation. The derangement gradually disappears, unless the damage to the organ be very wide. A reeling gait, oscillations of the body which impart a zigzag direction to the walk, difficulty in standing, owing to unsteadiness of limb, are common in cerebellar disease. On the other hand, congenital defect amounting to absence of one cerebellar hemisphere has been found to occasion practically no symptoms whatsoever. Not a hundredth part of the cerebellum has remained, and yet there has existed ability to stand, to walk, to handle and lift objects in a fairly normal way, without any trace of impairment of cutaneous or muscular sensitivity. The damage to the cerebellum must, it would seem, occur not very slowly in order to occasion marked derangement of function, and then the derangement falls on the execution of movements. One aspect of this derangement, named by Luciani *astasia*, is a tremor heightened by or only appearing when the muscles enter upon action—"intention tremor." Vertigo is a frequent result of cerebellar injury: animals indicate it by their actions; patients describe it. To interpret this vertigo, appeal must be made to disturbances, other than cerebellar, which likewise occasion vertigo. These include, besides ocular squint, many spatial positions and movements unwonted to the body: the looking from a height, the gliding over ice, sea-travel, to some persons even travelling by train, or the covering of one eye. Common to all these conditions is the synchronous rise of perceptions of spatial relations between the self and the environment which have not, or have rarely, before arisen in synchronous combination. The tactual organs of the soles, and the muscular sense organs of limbs and trunk, are originating perceptions that indicate that the self is standing on the solid earth, yet the eyes are at the same time originating perceptions that indicate that the solid earth is far away below the standing self. The combination is hard to harmonize at first; it is at least not given as *innately* harmonized. Perceptions regarding the "me" are notoriously highly charged with "feeling," and the conflict occasions the feeling insufficiently described as "giddiness." The cerebellum receives paths from most, if not from all, the afferent roots. With certain of these it stands associated most closely, namely, with the vestibular, representing the sense organs which furnish data for appreciation of positions and movements of the head, and with the channels, conveying centripetal impressions from the apparatus of skeletal movement. Disorder of the cerebellum sets at variance, brings discord into, the space-perceptions contributory to the movement. The body's movement becomes thus imperfectly adjusted to the spatial requirements of the act it would perform.

In the physiological basis of sense exist many impressions which, apart from and devoid of psychical accompaniment, reflexly influence motor (muscular) innervation. It is with this sort of habitually apsychical reaction that the cerebellum is, it would seem, employed. That it is apparently devoid of psychical concomitant need not imply that the impressions concerned in it are crude and inelaborate. The seeming want of reaction of so much of the cerebellar structure under artificial stimulation, and the complex relay system revealed in the histology of the cerebellum, suggest that the impressions are elaborate. Its reaction preponderantly helps to secure co-ordinate innervation of the skeletal musculature, both for maintenance of attitude and for execution of movements. So far as the geotropism and stereotropism of the animal can be "centred" at any one limited field of the central nervous system, that field is cerebellar.

Sleep.—The more obvious of the characters of sleep are essentially nervous. In deep sleep the threshold-value of the stimuli for the various senses is very greatly raised, rising rapidly during the first hour and a half of sleep, and then declining with gradually decreasing decrements. The muscles become less tense than in their waking state: their tonus is diminished, the upper eyelid falls, and the knee-jerk is in abeyance. The respiratory rhythm is less frequent and the breathing less deep; the heart-beat is less frequent; the secretions are less copious; the pupil is narrow; in the brain there exists arterial anæmia with venous congestion, so that the blood-flow there is less than in the waking state.

Theories of sleep.

It has been suggested that the gradual cumulative result of the activity of the nerve cells during the waking day is to load the brain tissue with "fatigue-substances" which clog the action of the cells, and thus periodically produce that loss of consciousness, &c., which is sleep. Such a drugging of tissue by its own excreta is known in muscular fatigue, but the fact that the depth of sleep progressively increases for an hour and more after its onset prevents complete explanation of sleep on similar lines. It has been urged that the neurons retract during sleep, and that thus at the synapses the gap between nerve cell and nerve cell becomes wider, or that the supporting cells expand between the nerve cells and tend to isolate the latter one from other. Certain it is that in the course of the waking day a great number of stimuli play on the sense organs, and through these produce disintegration of the living molecules of the central nervous system. Hence during the day the assimilatory processes of these cells are overbalanced by their wear and tear, and the end-result is that the cell attains an atomic condition less favourable to further disintegration than to reintegration. That phase of cell life which we are accustomed to call "active" is accompanied always by disintegration. When in the cell the assimilative processes exceed dissimilative, the external manifestations of energy are liable to cease or diminish. Sleep is not exhaustion of the neuron in the sense that prolonged activity has reduced its excitability to zero. The nerve cell just prior to sleep is still well capable of response to stimuli, although perhaps the threshold-value of the stimulus has become rather high, whereas after entrance upon sleep and continuance of sleep for several hours, and more, when all spur to the dissimilation process has been long withheld, the threshold-value of the sensory stimulus becomes enormously higher than before. The exciting cause of sleep is therefore no complete exhaustion of the available material of the cells, nor is it entirely any paralysing of them by their excreta. It is more probably abeyance of external function during a periodic internal assimilatory phase.

Two processes conjoin to initiate the assimilatory phase. There is close interconnexion between the two aspects of the double activity that in physiological theory constitute the chemical life of protoplasm, between dissimilation and assimilation. Hering has long insisted on a self-regulative adjustment of the cell metabolism, so that action involves reaction, increased catabolism necessitates after-increase of anabolism. The long-continued incitement to catabolism of the waking day thus of itself predisposes the nerve cells towards rebound into the opposite phase; the increased catabolism due to the day's stimuli induces increase of anabolism, and though recuperation goes on to a large extent during the day itself, the recuperative process is slower than, and lags behind, the disintegrative. Hence there occurs a cumulative effect, progressively increasing from the opening till the closing hours. The second factor inducing the assimilative change is the withdrawal of the nervous system from sensual stimulation. The eyes are closed, the maintenance of posture by active contraction is replaced by the recumbent pose which can be maintained by static action and the mere mechanical consistence of the body, the ears are screened from noise in the quiet chamber, the skin from localized pressure by a soft, yielding couch. The effect of thus reducing the excitant action of the environment is to give consciousness over more to mere revivals by memory, and gradually consciousness lapses. A remarkable case is well authenticated, where, owing to disease, a young man had lost the use of all the senses save of one eye and of one ear. If these last channels were sealed, in two or three minutes' time he invariably fell asleep.

Narcotics.

If natural sleep is the expression of a phase of decreased excitability due to the setting in of a tide of anabolism in the cells of the nervous system, what is the action of narcotics? They lower the external activities of the cells, but do they not at the same time lower the internal, reparative, assimilative activity of the cell that in natural sleep goes vigorously forward preparing the system for the next day's drain on energy? In most cases they seem to lower both the internal and the external activity of the nerve cells, to lessen the cell's entire metabolism, to reduce the speed of its whole chemical movement and life. Hence it is not surprising that often the refreshment, the recuperation, obtained from and felt after sleep induced by a drug amounts to nothing, or to worse than nothing. But very often refreshment is undoubtedly obtained from such narcotic sleep. It may be supposed that in the latter case the effect of the drug has been to ensure occurrence of that second predisposing factor mentioned above, of that withdrawal of sense impulses from the nerve centres that serves to usher in the state of sleep. In certain conditions it may be well worth while by means of narcotic drugs to close the portals of the senses for the sake of thus obtaining stillness in the chambers of the mind; their enforced quietude may induce a period in which natural rest and repair continue long after the initial unnatural arrest of vitality due to the drug itself has passed away.

Hypnotism.—The physiology of this group of "states" is, as regards the real understanding of their production, eminently vague. The conditions which tend to induce them contain generally, as one element, constrained visual attention prolonged beyond ordinary duration. Symptoms attendant on the *hypnotic* state are closure of the eyelids by the hypnotizer without subsequent attempt to open them by the hypnotized subject; the pupils, instead of being constricted, as for near vision, dilate, and there sets in a condition superficially resembling sleep. But in natural sleep the action of all parts of the nervous system is subdued, whereas in the hypnotic the reactions of the lower, and some even of the higher, parts are exalted. Moreover, the reactions seem to follow the sense impressions with such fatality, that, as an inference, absence of will-power to control them or suppress them is suggested. This reflex activity with "paralysis of will" is characteristic of the *somnambulistic* state. The threshold-value of the stimuli adequate for the various senses may be extraordinarily lowered. Print of microscopic size may be read; a watch ticking in another room can be heard. Judgment of weight and texture of surface is exalted; thus a card can in a dark room be felt and then re-selected from the re-shuffled pack. Akin to this condition is that in which the power of maintaining muscular effort is in creased; the individual may lie stiff with merely head and feet supported on two chairs; the limbs can be held outstretched for hours at a time. This is the *cataleptic* state, the phase of hypnotism which the phenomena of so-called "animal hypnotism" resemble most. A frog or fowl or guinea-pig held in some unnatural pose, and retained so forcibly for a time, becomes "set" in that pose, or rather in a posture of partial recovery of the normal posture. In this state it remains motionless for various periods. This condition is more than usually readily induced when the cerebral hemispheres have been removed. The decerebrate monkey exhibits "cataleptoid" reflexes. Father Kircher's *experimentum mirabile* with the fowl and the chalk line succeeds best with the decerebrate hen. The attitude may be described as due to prolonged, not very intense, discharge from reflex centres that regulate posture and are probably intimately connected with the cerebellum. A sudden intense sense stimulus usually suffices to end this tonic discharge. It completes the movement that has already set in but had been checked, as it were, half-way, though tonically maintained. Coincidently with the persistence of the tonic contraction, the higher and volitional centres seem to lie under a spell of inhibition; their action, which would complete or cut short the posture-spasm, rests in abeyance. Suspension of cerebral influence exists even more markedly, of course, when the cerebral hemispheres have been ablated.

But a potent—according to some, the most potent—factor in hypnotism, namely, *suggestion*, is unrepresented in the production of so-called animal hypnotism. We know that one idea suggests another, and that volitional movements are the outcome of ideation. If we assume that there is a material process at the basis of ideation, we may take the analogy of the concomitance between a spinal reflex movement and a skin sensation. The physical "touch" that initiates the psychical "touch" initiates, through the very same nerve channels, a reflex movement responsive to the physical "touch," just as the psychical "touch" may be considered also a response to the same physical event. But in the decapitated animal we get, we have good arguments for belief, the reflex movement alone as response; the psychical touch drops out. Could we assume that there is in the adult man reflex machinery which is of higher order than the merely spinal, which employs much more complex motor mechanisms than they, and is connected with a much wider range of sense organs; and could we assume that this reflex machinery, although usually associated in its action with memorial and volitional processes, may in certain circumstances be sundered from these latter and unattendant on them—may in fact continue in work when the higher processes are at a standstill—then we might imagine a condition resembling that of the somnambulistic and cataleptic states of hypnotism.

Such assumptions are not wholly unjustified. Actions of great complexity and delicacy of adjustment are daily executed by each of us without what is ordinarily understood as volition, and without more than a mere shred of memory attached thereto. To take one's watch from the pocket and look at it when from a familiar clock-tower a familiar bell strikes a familiar hour, is an instance of a habitual action initiated by a sense perception outside attentive consciousness. We may suddenly remember dimly afterwards that we have done so, and we quite fail to recall the difference between the watch time and the clock time. In many instances hypnotism seems to establish quickly reactions similar to such as usually result only from long and closely attentive practice. The sleeping mother rests undisturbed by the various noises of the house and street, but wakes at a slight murmur from her child. The ship's engineer, engaged in conversation with some visitor to the engine-room, talks apparently undisturbed by all the multifold noise and rattle of the machinery, but let the noise alter in some item which, though unnoticeable to the visitor, betokens importance to the trained ear, and his passive attention is in a moment caught. The warders at an asylum have been hypnotized to sleep by the bedside of dangerous patients, and "suggested" to awake the instant the patients attempt to get out of bed, sounds which had no import for them being inhibited by suggestion. Warders in this way worked all day and performed night duty also for months without showing fatigue. This is akin to the "repetition" which, read by the schoolboy last thing overnight, is on waking "known by heart." Most of us can wake somewhere about a desired although unusually early hour, if overnight we desire much to do so.

Two theories of a physiological nature have been proposed to account for the separation of the complex reactions of these conditions of hypnotism from volition and from memory. Heidenhain's view is that the cortical centres of the hemisphere are inhibited by peculiar conditions attaching to the initiatory sense stimuli. Preyer's view is that the essential condition for initiation is fatigue of the will-power under a prolonged effort of undivided attention.

Hypnotic somnambulism and hypnotic catalepsy are not the only or the most profound changes of nervous condition that hypnosis can induce. The physiological derangement which is the basis of the abeyance of volition may, if hypnotism be profound, pass into more widespread derangement, exhibiting itself as the *hypnotic lethargy*. This is associated not only with paralysis of will but with profound anæsthesia. Proposals have been made to employ hypnotism as a method of producing anæsthesia for surgical purposes, but there are two grave objections to such employment. In order to produce a sufficient degree of hypnotic lethargy the subject must be made extremely susceptible, and this can only be done by repeated hypnotization. It is necessary to hypnotize patients every day for several weeks before they can be got into a degree of stupor sufficient to allow of the safe execution of a surgical operation. But the state itself, when reached, is at least as dangerous to life as is that produced by inhalation of ether, and it is more difficult to recover from. Moreover, by the processes the subject has gone through he has had those physiological activities upon which his volitional power depends excessively deranged, and not improbably permanently enfeebled.

(C. S. S.)

VII. Special Senses.

Touch.—The sense of touch depends upon pressure. When we touch a body, a pressure is exerted. This pressure reacts on nerve-endings in the epidermis or skin, nervous impulses are generated, and when these react, the brain sensations of "touch" are the result (see 9th edition, article Touch, vol. xxiii. p. 478). Research shows that the sensation may be referred to parts of the skin which do not contain the special end organs associated with this sense, and that filaments in the Malpighian layer (the layer immediately above the papillæ of the true skin) may form the anatomical basis of the sense. The skin may be regarded, also, as an extensive surface containing nervous arrangements by which we are brought into relation with the outer world. Accordingly, touch is not the only sensation referred to the skin, but we also refer sensations of temperature (heat and cold), and often those peculiar sensations which we call pain.

Temperature sensations.

Sensations of heat and cold are chiefly referred to the skin, and only partially to some mucous membranes, such as those of the alimentary canal. Direct irritation of a nerve does not give rise to these sensations. Thus, if we plunge the elbow into hot water, or into ice-cold water, we may have feelings of heat or of cold referred to the parts immersed, but we do not experience heat or cold by irritating the ulnar nerve, which lies here just below the skin. When the change of temperature affects the nerve, there is a painful sensation referred to the extremities of the nerve on the ulnar side of the arm and hand. The exposed pulp of a diseased tooth, when irritated by hot or cold fluids, gives rise to pain, not to sensations of temperature. It has now been ascertained that there are minute areas on the skin in which sensations of heat and cold may be more acutely felt than in adjoining areas; and, further, that there are points stimulated by addition of heat, hot spots, while others are stimulated by withdrawal of heat, cold spots.

A simple method of demonstrating this phenomenon is to use a solid cylinder of copper, eight inches in length by half an inch in thickness, and sharpened at one end to a fine pencil-like point. Dip the pointed end into very hot water, close the eyes, and touch parts of the skin. When a hot spot is touched, there is an acute sensation of burning. Such a spot is often near a hair. Again, in another set of experiments, dip the copper pencil into ice-cold water and search for cold spots. When one of these is touched, a sensation of cold, as if concentrated on a point, is experienced. Thus it may be demonstrated that in a given area of skin there may be hot spots, cold spots, and touch spots.

Cold spots are more abundant than hot spots. The spots are arranged in curved lines, but the curve uniting a number of cold spots does not coincide with the curve forming a chain of hot spots. By Weber's method (see TOUCH, 9th edition, vol. xxiii. p. 480) it will be found that we can discriminate cold spots at a shorter distance from each other than hot spots. Thus on the forehead cold spots have a minimum distance of 8 mm., and hot spots 4 mm.; on the skin of the breast, cold spots 2 mm., and hot spots 5 mm.; on the back, cold spots 1·5 mm., and hot spots 4 to 6 mm.; on the back of the hand, cold spots 3 mm., and hots spots 4 mm.; on the palm, cold spots 8 mm., and hot spots 2 mm.; and on the thigh and leg, cold spots 3 mm., and hot spots 3·5 mm. Electrical and mechanical stimulation of the hot or cold spots call forth the corresponding sensation. No terminal organ for discrimination of temperature has yet been found. It will be observed that the sensation of heat or cold is excited by *change* of temperature, and that it is more acute and definite the more sudden the change. Thus discrimination of temperature is similar to discrimination of touch, which depends on more or less sudden change of pressure. The term cold means, physiologically, the sensation we experience when heat is abstracted, and the term heat, the sensation felt when heat is added to the part. Thus we are led to consider that the skin contains at least two kinds of specific terminal organs for sensations of touch and temperature, and two sets of nerve fibres which carry the nervous impulses to the brain. In all probability, also, these fibres have different central endings, and in their course to the brain run in different tracts in the spinal cord. This will explain cases of disease of the central nervous system in which, over certain areas of skin, sensations of touch have been lost while sensations of temperature and pain remain, or *vice versâ*. Tactile and thermal impressions may influence each other. Thus a leg sent to "sleep" by pressure on the sciatic nerve will be found to be less sensitive to heat, but distinctly sensitive to cold. In some cases of disease it has been noticed that the skin is sensitive to a temperature above that of the limb, but insensitive to cold. Again, a weight is always felt to be heavier when it is cold than when it is hot, and the minimum distance at which two compass points are felt is diminished when *one* point is warmer than the other. It is highly probable that, just as we found in the case of touch (pressure), the terminal organs connected with the sense of temperature are the fine nerve filaments that have been detected in the deeper strata of the Malpighian region of the epidermis, immediately above the true skin, and it is also probable that certain epidermic (epithelial) cells in that region play their part in the mechanism.

Sensations of touch (pressure) and of temperature are not, however, the only sensations referred to the skin. We may also experience in that organ the peculiar class of sensations called pain. Sensations of a painful character may also, in certain circumstances, be referred to the viscera, and to mucous and serous surfaces. Pain is not a sensation excited by irritating the end organs either of touch or of temperature, nor even by irritating directly the filaments of a sensory nerve. Even if sensory nerves are cut or bruised, as in surgical operations, there may be no sensations of pain; and it has been found that muscles, vessels, and even the viscera, such as the heart, stomach, liver, or kidneys, may be freely handled without giving rise to any feeling of pain, or indeed to any kind of sensation. These parts, in ordinary circumstances, appear to be insensitive, and yet they contain afferent nerves. If the sensibility of these nerves is heightened, or possibly if the sensitiveness of the central terminations of the nerves is raised, then we may have sensations to which we give the name of pain. In like manner the skin is endowed with afferent nerves, distinct from these ministering to touch and to temperature, along which nervous impulses are constantly flowing. When these nervous impulses reach the central nervous system, in ordinary circumstances they do not give rise to changes that reach the level of consciousness, but they form, as it were, the warp and woof of our mental life, and they also affect metabolisms, that is to say, nutritive changes in many parts of the body. They may also, as is well known, affect unconsciously such mechanisms as those of the action of the heart, the calibre of the blood-vessels, and the movements of respiration. If, however, their plane of activity is raised, as by intermittent pressure, or by inflammatory action, or by sudden changes of temperature, as in burning, scalding, &c., such nervous impulses give rise to pain. Sometimes pain is distinctly located, and in other cases it may be irradiated in the nerve centres, and referred to areas of skin or to regions of the body which are not really the seat of the irritation. Thus irritation of the liver may cause pain in the shoulder; disease of the hip-joint often gives rise to pain in the knee; and renal colic, due to the passage of a calculus down the ureter, to severe pain even in the abdominal walls. It is also noticeable that a sensation of pain gives us no information as to its cause; we simply have an agonizing sensation in a part to which, hitherto, we probably referred no sensations. The acuteness or intensity of pain depends partly on the intensity of the irritation, and partly on the degree of excitability of the sensory nerves at the time. Sometimes, for example, the excitability of sensory nerves may be so high that a whiff of air may cause acute distress. If only a few nerves are affected, the pain is acute and piercing; but if many nerves are involved, it may be more massive and diffuse in character. The quality of pain, whether it is gnawing, dull, boring, piercing, shooting, depends on the nature of the irritation, and on whether the irritation is constant or intermittent (see TOUCH, vol. xxiii. p. 482).

Pain.

Smell.—It has not yet been decided whether the sense of smell depends, in the first instance, on a chemical or on a physical process. All that can be said is that sensory impulses are excited when odoriferous particles come into contact with the free ends of peculiar rod-like cells found in the olfactory mucous membrane (see ANATOMY, vol. i. p. 885; also SMELL, vol. xxii. p. 167). The free olfactory surface is always covered with a thin layer of fluid, and it is clear that all odoriferous matters must be dissolved in this fluid so as to reach the rod-cells. There is here an analogy with the conditions found in the sense of taste, where sapid substances must be soluble in the fluid of the mouth. The intensity of the sensation of smell depends on the size of the area of the olfactory membrane affected: the greater the area the more intense the sensation. On this principle an olfactometer may be constructed by which the intensities of different odours may be compared. Thus the odoriferous value of a substance may be expressed by the smallest superficial area, impregnated with the odoriferous matter, over which the air must pass to give rise to a distinct sensation. The minimal quantity of material, as in the case of musk, is extremely small.

No progress has been made in establishing any connexion between the chemical nature of a substance and the odour it may excite. There is a relation between the molecular weight of a gas and the presence or absence of odour. Gases of less than a certain molecular weight are odourless, and it is significant that to some persons hydrocyanic acid, which has a low molecular weight, gives rise to no sensation of smell. It has also been pointed out that chemical compounds of elements belonging to the same group, according to the well-known periodic law, have sometimes odours of a similar character (Foster's *Physiology*, part iv. p. 1505).

As a rule, we experience odours by the simultaneous use of both nostrils. Stimulation of either nostril would give rise to the sensation, while there is a fusion of sensations when both are affected. If, by means of a tube, an odour is conveyed into one nostril, while an odour of a different kind is directed into the other, there may be either a compound sensational effect, a sort of double-odour, or one odour may so predominate as entirely to destroy the other. The fusion of odours is not complete, and it is similar to the effect of combining, say blue and red, in stereoscopic vision. When one odour destroys the other, the obliteration must take place in the cerebral centre. It is not unlikely that when one odour predominates among many, this may be due not to any chemical action of one substance over another, but that the missing sensations may be accounted for by their failure to excite the olfactory region of the cerebrum in the presence of a stronger stimulus.

Taste.—The structure of the terminal organ of taste has already been fully described (see TASTE, 9th ed., vol. xxiii. p. 79). Evidence is accumulating that taste depends on nervous impulses excited by chemical change. Substances that have taste must be soluble, and they are brought into contact with delicate hair-like processes in the taste goblets (taste-buds), or with filaments ending on the free mucous surface between epithelial cells. Chemical changes are in all probability set up in these taste cells, or in the processes connected with them. Some progress has been made in the attempt to establish a connexion between the chemical composition of sapid substances and the different kinds of taste to which they may give rise. Thus acids are usually sour; alkaloids have a peculiar soapy taste; salts may be sweet, like sugar of lead, or bitter, like sulphate of magnesia; soluble alkaloids, such as quinine or strychnine, are usually bitter; and the higher alcohols are more or less sweet. Substances which taste sweet or bitter often contain definite groups in the molecule, especially the hydroxyl (HO) and amido (NH_2) groups. By altering the chemical composition of a substance having a characteristic taste (changing the position or relations of the radicles), the substance may become tasteless or intensely bitter. The sensation of taste may also be excited mechanically, as by smartly tapping the tongue, or by the stimulus of a continuous current (see art. TASTE, p. 80). In the latter case electrolytic change may be the exciting cause; but that the sense organs may be stimulated electrically is proved by the fact that very rapidly-interrupted induced currents, which produce little or no electrolysis, may also excite taste. Sensations of taste are heightened by increasing the area of the tongue affected, and by mechanical stimulation, as when the tongue is pressed against the lips, cheeks, or palate. A temperature of about 40° C. is most favourable, either extreme heat or cold apparently benumbing the sense for a time. Gustatory sensations affect each other: that is to say, a strong taste will affect the taste of another body taken immediately after it. Thus sweetness will modify bitterness, and sourness will modify both. Moreover, the application of a sapid substance to the tongue will affect taste in other parts. If the same taste is excited on each side of the tongue, although there are two sets of gustatory nerves, one for each lateral half, the sensations are blended into one; while if two different substances, say one sweet and the other bitter, are simultaneously applied, one to each side, there is not a blending of the sensation, but the observer can distinctly differentiate the one from the other.

As a general rule, bitter tastes are most acute at the back of the tongue, near the circumvallate papillæ, and sweet tastes at the lip, but there are considerable individual variations. Some persons taste both bitter and sweet substances best at the back, while others taste bitter things at the lip. Many experience salt tastes best at the tip, and acid tastes at the sides of the tongue. When we consider that there are three kinds of papillæ on the surface of the tongue, filiform, fungiform, and circumvallate (see ANATOMY), one would almost expect to meet with different degrees of sensitiveness to different tastes, even while we admit that the papillæ may also have to do with sensations of touch and of temperature. By experimenting with fine capillary tubes containing sapid substances, observations have been made with individual papillæ. Some are found to be sensitive to many tastes, others to two or three, others to only one, while others are insensitive to taste altogether. Again, it has been found that a mixture of sapid substances, say of quinine and sugar, may taste sweet when applied to one papilla and bitter when applied to another. The inference must be that there are special terminal organs for different tastes. This is supported by some interesting experiments made by Shore (*Journal of Physiology*, 1891). Assuming that there are different kinds of taste cells, it might be possible to paralyse some without affecting others, and thus different sensations of taste might be discriminated. This has been done by the use of the leaves of a common Indian plant, *Gymnema sylvestre.* If some of these be chewed, it has been found that bitters and sweets are paralysed (neither quinine nor sugar giving rise to sensation), while acids and salines are unaffected. Again, certain strengths of decoctions of the leaves appear to paralyse sweets sooner than bitters. These observations show the existence of different taste cells for sweets, bitters, acids, and salines; and it is clear that the region of the tongue most richly supplied with taste cells sensitive to sweets will respond best to sweet substances, while another region, supplied by taste cells sensitive to bitters, will respond best to bitter substances. In like manner the argument may be applied to other tastes. Suppose, again, a set of taste cells sensitive to bitter substances: it is conceivable that in whatever way these were irritated, a bitter taste would result. If so, a substance which, applied to one part of the tongue, would cause a sweet sensation, might cause a bitter if applied to a part of the tongue richly supplied with taste cells sensitive to bitters. This may explain why sulphate of magnesia excites at the root of the tongue a bitter taste, while applied to the lip it causes a sweet or an acid taste. Saccharine, a peculiar bromine derivative, in like manner is sweet to the lip and bitter to the back of the tongue. It has also been found that if the sweet and bitter taste cells are paralysed by *Gymnema*, electrical irritation of the lip by a weak interrupted current does not give rise to an acid taste mixed with sweet, as it usually does, but to sensations somewhat different, and which may be described as metallic or salt or acid. This experiment indicates that the action of the interrupted current on the terminal organ is analogous to the action of sweet or bitter substances. No direct observations of importance have yet been made on single circumvallate papillæ. Further experiments with capillary tubes show that fungiform papillæ destitute of taste buds, and areas of the surface of the tongue having neither papillæ nor taste buds, may still, when stimulated by sapid substances, give rise to tastes.

Nerves of the tongue.

The distribution of nerves to the tongue is very complicated. The motor nerve, that is, the nerve that excites and governs the movement of the tongue, is the ninth cranial, known as the hypoglossal. The sensory nerves are usually described as two in number, the anterior two-thirds of the tongue being supplied by the gustatory or lingual branches of the fifth cranial nerve, and the posterior third (the situation of the circumvallate papillæ) by the glosso-pharyngeal nerves. The lingual branch of the fifth nerve contains both ordinary sensory and gustatory filaments, and the glosso-pharyngeal supplies the circumvallate papillæ and taste buds. Another nerve, however, has to be considered, namely, the chorda tympani, a branch given off by the facial nerve during the passage of the latter through a canal in the petrous portion of the temporal bone known as the aqueduct of Fallopius. Loss of taste on one side of the tongue has been observed in cases of disease of the ear involving the chorda nerve. This, however, is not conclusive evidence that the chorda contains gustatory filaments, as the loss of taste following its injury may be due to the removal of its influence over the nutrition of the mucous membrane of the organ. If the mucous membrane deteriorated from faulty nutrition, then loss of taste might be due to that cause. On the other hand, there are good grounds for the view that the gustatory filaments, both of the lingual branch of the fifth and of the glosso-pharyngeal itself, come primarily from the roots of the fifth nerve. It is true that there is no direct evidence that irritation of the proximal end of the fifth nerve, after it had been divided, gives rise to sensations of taste. Clinical evidence, however, shows that disease of this nerve within the cranial cavity causes loss of taste in one lateral half of the tongue, both lip and back, but no case has been recorded of disease of the glosso-pharyngeal being followed by this result (M'Kendrick and Snodgrass, *Physiology of the Senses*, p. 78).

Mechanism of accommodation.

Vision.—The mechanism of vision has been described in the article Eye, 9th ed., vol. viii. p. 816. The mechanism by which the anterior surface of the lens becomes more convex when we look at objects within a range of say 70 yards to 10 inches, is usually described as consisting of a contraction of the fibres of the ciliary muscle by which the ciliary processes of the choroid are pulled forwards, thus releasing the tension of the anterior layer of the capsule of the lens (the layer in front of the lens), and allowing the lens to bulge forwards by its elasticity. Thus rays of light from an object within the range above indicated, becoming more and more divergent as the object approaches the eye, are brought to a focus on the retina, and distinct vision is secured. By this mechanism the radius of curvature of the anterior surface of the lens, as the eye accommodates from the far to the near point, may shorten from 10 mm. to 6 mm., as determined by Helmholtz. The ciliary muscle, however, contains two sets of fibres, the longitudinal or meridional, which run from before backwards, and the circular or equatorial (Müller's muscle), which run, as their name indicates, around the band of longitudinal fibres forming the muscle. Direct observation on the eye of an animal immediately after death shows that stimulation of the ciliary nerves actually causes a forward movement of the ciliary processes, and there can be little doubt that the explanation above given applies to man, probably most mammals, and to birds and most reptiles. In birds, which are remarkable for acuteness of vision, the mechanism is somewhat peculiar. In them the fibres of the ciliary muscle have a strong attachment posteriorly, and when these contract they pull back the inner posterior layers of the cornea, and thus relax that part of the ciliary zone called the ligamentum pectinatum. In a state of rest this structure in the bird's eye is tense, but in accommodation it becomes relaxed. Thus by a somewhat different mechanism in the bird, accommodation consists in allowing the anterior surface of the lens to become more and more convex. In reptiles generally the mechanism resembles that of the bird; but it is said that in snakes and amphibia there is a movement forwards of the lens as a whole, so as to catch rays at a less divergent angle. When the eye is directed to a distant object, such as a star, the mechanism of accommodation is at rest in mammals, birds, reptiles, and amphibia, but in fishes and cephalopods the eye at rest is normally adjusted for near vision. Consequently accommodation in the latter is brought about by a mechanism that carries the lens as a whole backwards. There is still some difficulty in explaining the action of the equatorial (circular) fibres. Some have found that the increased convexity of the anterior surface of the lens takes place only in the central portions of the lens, and that the circumferential part of the lens is actually flattened, presumably by the contraction of the equatorial fibres. Seeing, however, that the central part of the lens is the portion used in vision, as the pupil contracts during accommodation, a flattening of the margins of the lens can have no optical effect. Further, another explanation can be offered of the flattening. As just stated, during accommodation the pupil contracts, and the pupillary edge of the iris, thinned out, spreads over the anterior surface of the capsule of the lens, which it actually touches, and this part of the iris, along with the more convex central part of the lens, bulges into the anterior chamber, and must thus displace some of the aqueous humour. To make room for this, however, the circumferential part of the iris, related to the ligamentum pectinatum, moves backwards very slightly, while the flattening of the circumferential part of the lens facilitates this movement. Nor must we suppose that the longitudinal and equatorial fibres of the iris always act independently. It is more probable that the muscle acts as a whole. Thus, for man and the higher animals, the explanation of the mechanism of accommodation as propounded by Helmholtz is correct.

Sensations of colour.

Under Eye, 9th ed., vol. viii. p. 824, a short account is given of one theory by which an attempt is made to explain the perception of colour. This theory, originally proposed by Thomas Young and advocated by Helmholtz and Clerk Maxwell, is not, however, the only theory of colour vision. Another, enunciated by Hering, has received large support, more especially from physiologists. We shall here give a brief statement upon this important question. Colour, on the most likely hypothesis as to the physical nature of light, depends on the rate of vibration of the luminiferous ether, and white light is a compound of all the colours in definite proportion. When a surface reflects solar light into the eye without affecting this proportion, it is white, but if it absorbs all the light so as to reflect nothing, it appears to be black. If a body held between the eye and the sun transmits light unchanged, and is transparent, it is colourless, but if translucent it is white. If the medium transmits or reflects some rays and absorbs others, it is coloured. Thus, if a body absorbs all the rays of the spectrum but those which cause the sensation of green, we say the body is green in colour; but this green can only be perceived if the rays of light falling on the body contain rays having the special rate of vibration required for this special colour. For if the surface be illuminated by any other pure ray of the spectrum, say red, these red rays will be absorbed and the body will appear to be black. As a white surface reflects all the rays, in red light it will be seen to be red, and in a green light, green. Colour depends on the nature of the body and on the nature of the light falling on it, and a *sensation of colour* arises when the body reflects or transmits the special rays to the eye. If two rays of different rates of vibration, that is to say, of different colours, affect a surface of the retina at the same moment, the effects are fused together and we have the sensation of a third colour different from its cause. Thus, if red be removed from the solar spectrum, all the other colours combined cause a sensation of greenish yellow. Under the article EYE, vol. viii. p. 823, a table is given showing the result of mixing the pure colours of the spectrum. Thus red and violet give purple, and yellow and blue, white. Yellow and blue, however, only give white when pure spectral colours are mixed. It is well known that a mixture of yellow and blue *pigments* do not produce white, but green; but, as was explained by Helmholtz, this is because the blue pigment absorbs all the rays at the red end of the spectrum up to the green, while the yellow pigment absorbs all the rays at the violet end down to the green, and as the only rays reflected into the eye are the green rays, the substance appears green. Finally, if colours are painted on a disc in due proportions and in a proper order, the disc will, when quickly rotated, appear white, from the rapid fusion of colour effects.

When two colours produce a sensation of white, they are said to be complementary to each other. Thus red with blue-green will give white, but the whiteness so produced is not so intense as the white caused by the simultaneous action of all the spectral colours. The following list shows characteristic complementary colours, with their wave-lengths (λ) in millionths of a millimetre:—

Red, λ 656.	Blue-green, λ 492.
Orange, λ 608.	Blue, λ 490.
Gold-yellow, λ 574.	Blue, λ 482.
Yellow, λ 567.	Indigo-blue, λ 464.
Greenish yellow, λ 564.	Violet, λ 433.

By combining colours at opposite ends of the spectrum, the effect of the intermediate colours may be produced; but the lowest and the highest, red and violet, cannot thus be formed. These are therefore fundamental or primary colours, colours that cannot be produced by the fusion of other colours. If now to red and violet we add green, which has a rate of vibration about midway between red and violet, we obtain a sensation of white. Red, green, and violet are therefore the three fundamental colours.

Colour physiologically is a sensation, and it therefore does not depend only on the physical stimulus of light, but also on the part of the retina affected. The power of distinguishing colours is greatest when they fall on, or immediately around, the yellow spot, where the number of cones is greatest. In these regions more than two hundred different tints of colour may be distinguished. Outside of this area lies a middle zone, where fewer tints are perceived, mostly confined to shades of yellow and blue. If intense coloured stimuli are employed, colours may be perceived even to the margin of the periphery of the retina, but with weak stimuli coloured objects may seem to be black, or dark like shadows. In passing a colour from the periphery to the centre of the yellow spot, remarkable changes in hue may be observed. Orange is first grey, then yellow, and it only appears as orange when it enters the zone sensitive to red. Purple and bluish green are blue at the periphery, and only show the true tint in the central region. Four tints have been found which do not thus change: a red obtained by adding to the red of the spectrum a little blue (a purple), a yellow of 574·5 λ, a green of 495 λ, and a blue of 471 λ.

Every colour has three qualities: (1) *hue*, or tint, such as red, green, violet; (2) *degree of saturation*, or purity, according to the amount of white mixed with the tint, as when we recognize a red or green as pale or deep; and (3) *intensity*, or luminosity, or brightness, as when we designate the tint of a red rose as dark or bright. Two colours are identical when they agree as to these three qualities. Observation shows, however, that out of one hundred men ninety-six agree in identifying or in discriminating colours, while the remaining four show defective appreciation. These latter are called *colour-blind*. This defect is about ten times less frequent in women. Colour-blindness is congenital and incurable, and it is due to an unknown condition of the retina or nerve centres, or both, and must be distinguished from transient colour-blindness, sometimes caused by the excessive use of tobacco and by disease. When caused by tobacco, the sensation of blue is the last to disappear. Absolute inability to distinguish colour is rare, if it really exists; in some rare cases there is only one colour sensation; and in a few cases the colour-blind fails to distinguish blue from green, or there is insensibility to violet. Daltonism, or red-green blindness, of which there are two varieties, the red-blind and the green-blind, is the more common defect. Red appears to a red-blind person as a dark green or greenish yellow, yellow and orange as dirty green, and green is green and brighter than the green of the yellow and orange. To a green-blind person red appears as dark yellow, yellow is yellow, except a little lighter in shade than the red he calls dark yellow, and green is pale yellow.

"Seeing that green lights imply safety, and red lights danger, on our railways, and that in navigation a green or red light on the port or starboard side shows the course a vessel is taking, it is evident that no one who is red- or green-blind should be employed in the services, and accordingly various tests are now in use for the detection of such defects. The most efficient is the wool-test of Holmgren, which consists of three skeins of wool dyed with *standard test colours*, namely, a light green, a pale purple or pink, and a bright red. Other skeins of reds, oranges, yellows, yellowish greens, pure greens, blue greens, violets, purples, pinks, browns, and greys, all called *confusion colours*, are provided, and the examinee is requested to select one and match it with one of the test colours. Suppose the light green skein is shown first. If the examinee matches greys, brownish greys, yellows, orange, or faint pink with this, he is colour-blind. Then he is shown the purple skein. If he matches with this blue or violet he is red-blind, but if he selects only grey or green, he is green-blind. Finally, he may be shown the red skein, having a bright red colour, like the red flag used on railways. A red-blind person will then match with this, green or shades of brown, which to a normal eye seem darker than red; while, if he be green-blind, he will select shades of these colours which look lighter than red. Violet blindness is recognized by the examinee confusing red and orange with purple" (*Physiology of the Senses*, by M'Kendrick and Snodgrass, 1893, p. 160).

The question now arises, How can we perceive differences in colour? We might suppose a molecular vibration to be set up in the nerve-endings synchronous with the undulations of the luminiferous ether, without any change in the chemical constitution of the sensory surface, and we might suppose that where various series of waves in the ether corresponding to different colours act together, these may be fused together, or to interfere so as to give rise to a vibration of modified form or rate that corresponded in some way to the sensation. Or, to adopt another line of thought, we might suppose that the effect of different rays (rays differing in frequency of vibration and in physiological effect) is to promote or retard chemical changes in the sensory surface, "which again so affect the sensory nerves as to give rise to differing states in the nerves and the nerve centres, with differing concomitant sensations." The former of these thoughts is the foundation of the Young-Helmholtz theory (see EYE, vol. viii. p. 824), while the latter is applicable to the theory of Hering.

According to the Young-Helmholtz theory, there are three fundamental colour sensations, red, green, and violet, by the combination of which all other colours may be formed, and it is assumed that there exist in the retina three kinds of nerve elements, each of which is specially responsive to the stimulus of waves of a certain frequency corresponding to one colour, and much less so to waves of other frequencies and other colours. If waves corresponding to pure red alone act on the retina, only the corresponding nerve element for red would be excited, and so with green and violet. But if waves of different frequencies are mixed (corresponding to a mixture of colours), then the nerve elements will be set in action in proportion to the amount and intensity of the constituent excitant rays in the colour. Thus if all the nerve elements were simultaneously set in action, the sensation is that of white light; if that corresponding to red and green, the resultant sensation will be orange or yellow; if mainly the green and violet, the sensation will be blue and indigo. Then red-blindness may be explained by supposing that the elements corresponding to the sensation of red are absent; and green-blindness, to the absence of the elements sensitive to green. If to a red-blind person the green and violet are equal, and when to a green-blind person the red and violet are equal, they may have sensations which to them constitute white, while to the normal eye the sensation is not white, but bluish green in the one case and green in the other. In each case, to the normal eye, the sensation of green has been added to the sensations of red and blue. It will be evident, also, that whiteness to the colour-blind eye cannot be the same as whiteness to the normal eye. No doubt this theory explains certain phenomena of colour-blindness, of after-coloured images, and of contrast of colour, but it is open to various objections. It has no anatomical basis, as it has been found to be impossible to demonstrate the existence of three kinds of nerve elements, or retinal elements, corresponding to the three fundamental colour sensations. Why should red to a colour-blind person give rise to a sensation of something like green, or why should it give rise to a sensation at all? Again, and as already stated, in cases of colour-blindness due to tobacco or to disease, only blue may be seen, while it is said that the rest of the spectrum seems to be white. It is difficult to understand how *white* can be the sensation if the sensations of red and green are lost. On the other hand, it may be argued that such colour-blind eyes do not really see white as seen by a normal person, and that they only have a sensation which they have been accustomed to call white. According to this theory, we never actually experience the primary sensations. Thus we never see primary red, as the sensation is more or less mixed with primary green, and even with primary blue (violet). So with regard to primary green and primary violet. Helmholtz, in his last work on the subject, adopted as "the three primary colours a red bluer than spectral red, (*a*) a green lying between 540 λ and 560 λ (*b*, like the green of vegetation), and a blue at about 470 λ (*c*, like ultramarine), all, however, much more highly saturated than any colours existing in the spectrum" (Foster's *Physiology*, part iv. p. 1345).

In *Handbuch der Physiologischen Optik* (Hamburg and Leipzig, 1896) Helmholtz pointed out that luminosity or brightness plays a more important part in colour perception than has been supposed. Each spectral colour is composed of certain proportions of these fundamental colours, or, to put it in another way, a combination of two of them (*a* and *b*) added to a certain amount of white (*c*). Thus 100 parts of green are composed of 15 of *a*, 51 of *b*, and 34 of *c*; or, to take other examples, spectral red will contain, per cent., 42 of *a*, 7 of *b*, and 51 of white; yellow, 11 of *a*, 14 of *b*, and 75 of white; and blue, 2 of *a*, 11 of *c*, and 87 of white. The white gives brightness. "According to this view, it is not necessary to suppose that in the red-blind the red-perceiving elements are awanting, or that in the green-blind the green-perceiving elements are absent, but that these elements may be stimulated with intensities different from those affecting the normal eye. Suppose that in the eye of a colour-blind person the curves of intensity representing the red and green coincided, or, in other words, that the elements responsive to red and green in the abnormal eye were stimulated intensities equal to that of red in a normal eye, the sensation would be yellow, as we find to be the case in so-called green-blindness. Again, if in a similar way the red curve coincided as regards intensity with the green, the general effect would be that of a red-blind person, the red end of the spectrum would appear to be green and no red would be visible" (M'Kendrick and Snodgrass, *op. cit.* p. 169).

Hering's theory proceeds on the assumption of chemical changes in the retina under the influence of light. It also assumes that certain fundamental sensations are excited by light or occur during the absence of light. These fundamental sensations are white, black, red, yellow, green, and blue. They are arranged in pairs, the one colour in each pair being, in a sense, complementary to the other, as white to black, red to green, and yellow to blue. Hering also supposes that when rays of a certain wave-length fall on visual substances assumed to exist in the retina, destructive or, as it is termed, catabolic changes occur, while rays having other wave-lengths cause constructive or anabolic changes. Suppose that in a red-green substance catabolic and anabolic changes occur in equal amount, there may be no sensation, but when waves of a certain wave-length or frequency cause catabolic changes in excess, there will be a sensation of red, while shorter waves and of greater frequency, by exciting anabolic changes, will cause a sensation of green. In like manner, catabolism of a yellow-blue visual substance gives rise to a sensation we call yellow, while anabolism, by shorter waves acting on the same substance, causes the sensation of blue. Again, catabolism of a white-black visual substance gives white, while anabolism, in the dark, gives rise to the sensation of blackness. Thus blackness is a sensation as well as whiteness, and the members of each pair are antagonistic as well as complementary. In the red end of the spectrum the rays cause catabolism of the red-green substance, while they have no effect on the yellow-blue substance. Here the sensation is red. The shorter waves of the spectral yellow cause catabolism of the yellow-blue material, while catabolism and anabolism of the red-green substance are here equal. Here the sensation is yellow. Still shorter waves, corresponding to green, now cause anabolism of the red-green substance, while their influence on the yellow-blue substance, being equal in amount as regards catabolism and anabolism, is neutral. Here the sensation is green. Short waves of the blue of the spectrum cause anabolism of the yellow-blue material, and as their action on the red-green matter is neutral, the sensation is blue. The very short waves at the blue end of the spectrum excite catabolism of the red-green substance, and thus give violet by adding red to blue. The sensation orange is experienced when there is excess of catabolism, and greenish blue when there is excess of anabolism in both substances. Again, when all the rays of the spectrum fall on the retina, catabolism and anabolism in the red-green and yellow-blue matters are equal and neutralize each other, but catabolism is great in the white-black substance, and we call the sensation white. Lastly, when no light falls on the retina, anabolic changes are going on and there is the sensation of black.

Hering's theory accounts satisfactorily for the formation of coloured after-images. Thus, if we suppose the retina to be stimulated by red light, catabolism takes place, and if the effect continues after withdrawal of the red stimulus, we have a positive after-image. Then anabolic changes occur under the influence of nutrition, and the effect is assisted by the anabolic effect of shorter wave-lengths, with the result that the negative after-image, green, is perceived. Perhaps the distinctive feature of Hering's theory is that white is an independent sensation, and not the secondary result of a mixture of primary sensations, as held by the Young-Helmholtz view. The greatest difficulty in the way of the acceptance of Hering's theory is with reference to the sensation of black. Black is held to be due to anabolic changes occurring in the white-black substance. Suppose that anabolism and catabolism of the white-black substance are in equilibrium, unaccompanied by stimulation of either the red-green or yellow-blue substance, we find that we have a sensation of darkness, but not one of intense blackness. This "darkness" has still a certain amount of luminosity, and it has been termed the "intrinsic light" of the retina. Sensations of black differing from this darkness may be readily experienced, as when we expose the retina to bright sunshine for a few moments and then close the eye. We then have a sensation of intense blackness, which soon, however, is succeded by the darkness of the "intrinsic light." The various degrees of blackness, if it is truly a sensation, are small compared with the degrees in the intensity of whiteness. Another difficulty is thus stated by Ladd: "A light composed of red and green may be made to seem to the eye the same as a light composed of yellow and blue. If, then, the eye is fatigued to red, instead of the red-green mixture appearing greenish, and so distinguishable from the yellow-blue mixture, they both appear the same to the fatigued eye" (Ladd, *Outlines of Physiological Psychology*, p. 268). The application of both theories to the phenomena of colour-blindness is fully discussed in Foster's *Physiology*, part iv., 1900, p. 1352.

The movements of the eyes.

The movements of the eye are described in the article Eye, 9th ed. vol. viii. p. 825, but one or two points require further elucidation. It has been shown that the eye may rotate round three possible axes, a vertical, horizontal, and antero-posterior. These movements are effected by four straight muscles and two oblique. The four straight muscles arise from the back of the orbit, and pass forward to be inserted into the front part of the eyeball, or its equator, if we regard the anterior and posterior ends of the globe as the poles. The two obliques (one originating at the back of the orbit) come, as it were, from the nasal side—the one goes above the eyeball, the other below, while both are inserted into the eyeball on the temporal side, the superior oblique above, and the inferior oblique below. The six muscles work in pairs. The internal and external recti turn the eye round the vertical axis, so that the line of vision is directed to the right or left. The superior and inferior recti rotate the eye round the horizontal axis, and thus the line of vision is raised or lowered. The oblique muscles turn the eye round an axis passing through the centre of the eye to the back of the head, so that the superior oblique muscle lowers, while the inferior oblique raises, the visual line. It was also shown by Helmholtz that the oblique muscles sometimes cause a slight rotation of the eyeball round the visual axis itself. These movements are under the control of the will up to a certain point, but there are slighter movements that are altogether involuntary. Helmholtz studied these slighter movements by a method first suggested by Donders. By this method the apparent position of after-images produced by exhausting the retina, say with a red or green object, was compared with that of a line or fixed point gazed at with a new position of the eyeball. The ocular spectra soon vanish, but a quick observer can determine the coincidence of lines with the spectra. After producing an after-image with the head in the erect position, the head may be placed into any inclined position, and if the attention is then fixed on a diagram having vertical lines ruled upon it, it can easily be seen whether the after-image coincides with these lines. As the after-image must remain in the same position on the retina, it will be evident that if it coincides with the vertical lines there must have been a slight rotation of the eyeball. Such a coincidence always takes place, and thus it is proved that there is an involuntary rotation. This minute rotation enables us to judge more accurately of the position of external objects.

The *horopter* is the locus of those points of space which are projected on retinal points. While geometrically it may be conceived as simple, as a matter of fact it is generally a line of double curvature produced by the intersection of two hyperboloids, or, in other words, it is a twisted cubic curve formed by the intersection of two hyperboloids which have a common generator. The curves pass through the nodal point of both eyes. An infinite number of lines may be drawn from any point of the horopter, so that the point may be seen as a single point, and these lines lie on a cone of the second order, whose vertex is the point. When we gaze at the horizon, the horopter is really a horizontal plane passing through our feet. The horopter in this instance is the ground on which we stand. Experiments show "that the forms and the distances of these objects which are situated in, or very nearly in, the horopter, are perceived with a greater degree of accuracy than the same forms and distances would be when not situated in the horopter" (M'Kendrick, *Life of Helmholtz*, 1899, p. 172 *et seq.*).

Hearing.—The mechanism of hearing has been described in the article Ear, vol. vii. p. 591. (Details will be found in the article "Ear" by M'Kendrick in Schäfer's *Text-Book of Physiology*, vol. ii.)

The mechanism of transmission.

The special form of the drum-head attains a maximum of efficiency for tones of the feeblest intensity. When the effect of a sound-wave is transmitted from the drum-head to the internal ear, there is a change in the amount of force expended, and also a change in the amplitude of the movement. The mechanism of the chain of bones, malleus, incus, and stapes, serves the purpose of conveying periodical variations of pressure, occurring in the air, into a minute space or cavity full of fluid, in which we find the terminal structures connected with hearing, and this result is attained with a minimum loss of energy by the chain of bones. The chain is a lever in which the handle of the malleus forms the long arm, the fulcrum is where the short process of the incus abuts against the wall of the tympanum, while the long process of the incus, carrying the stapes, forms the short arm. The mechanism is a lever of the second order. Measurements show that the ratio of the lengths of the two arms is as 1·5 : 1; the ratio of the resulting force at the stapes is therefore as 1 : 1·5; while the amplitudes of the movements at the tip of the handle of the malleus and the stapes is as 1·5 : 1. Hence, while there is a diminution in amplitude there is a gain in power, and thus the pressures are conveyed with great efficiency from the membrana tympani to the labyrinth, while the amplitude of the oscillation is diminished so as to be adapted to the small capacity of the labyrinth. As the drum-head is nearly twenty times greater in area than the membrane covering the oval window, with which the base of the stapes is connected, the energy of the movements of the membrana tympani is concentrated on an area twenty times smaller; hence the pressure is increased thirty-fold ($1·5 \times 20$) when it acts at the base of the stapes. Experiments on the human ear have shown that the movement of greatest amplitude was at the tip of the handle of the malleus, 0·76 mm.; the movement of the tip of the long arm process of the incus was 0·21 mm.; while the greatest amplitude at the base of the stapes was only ·0714 mm. Other observations have shown the movements at the stapes to have a still smaller amplitude, varying from 0·001 to 0·032 mm. With tones of feeble intensity the movements must be almost infinitesimal.

The utricle and saccule.

The sacs of the internal ear, known as the utricle and saccule, receive the impulses of the base of the stapes. Considerable doubt still exists as to their functions. The simplest form of internal ear is a sac containing fluid in which an otolithic mass (ear-stones) is usually immersed, and having on the wall hair-like processes related to the terminations of a nerve. Such internal ears exist in some of the lower invertebrates. In the lower vertebrates (fish) there is a single sac, into which the semicircular canals open; still higher (amphibia), we find the beginning of the cochlear duct; and lastly (birds and mammals), a division of the sac into two, with a much greater development of the cochlear portion. These facts seem to point to the sacs being organs connected with the perception of sounds as sound, without reference to pitch or quality. For the *analysis* of tone a cochlea seems to be necessary. Even in mammals all the parts of the ear may be destroyed or affected by disease, except these sacs, without causing complete deafness. The evidence, however, is by no means satisfactory.

It has been suggested by Lee (*Amer. Jour. of Physiol.* vol. i. No. 1, p. 128) that in fishes the sac has nothing to do with hearing, but serves for the perception of movements, such as those of rotation and translation through space, movements much coarser than those that form the physical basis of sound. He considers, also, that as fishes, with few exceptions, are dumb, they are also deaf. In the fish there are peculiar organs along the lateral line which are known to be connected with the perception of movements of the body as a whole, and Beard (*Zool. Anz. Leipzig*, 1884, Bd. vii. S. 140) has attempted to trace a phylogenetic connexion between the sacs of the internal ear and the organs in the lateral line. According to this view, when animals became air-breathers, a part of the ear (the *papilla acustica basilaris*) was gradually evolved for the perception of delicate vibrations of sound. It may be assumed, however, that even in the higher vertebrates the nerve-endings in the saccule and utricle may still have to do with the perception of the grosser mass movements.

It is by means of the part of the internal ear known as the cochlea that we discriminate pitch, hear beats, and are affected by quality of tone.

The cochlea.

(*a*) *Pitch and Beats.*—The range of pitch appreciated by the human ear is from 30 to 40,000 vibrations per second. When two tones are in unison, they are heard as one sound; but if one is made a little flatter than the other, then a peculiar sensation is experienced, to which we give the name of a beat. The number of beats per second increases in proportion to the difference in frequencies of the two tones, so that beats may be heard so slow as to be only a waxing and waning of the auditory sensation, or they may be so rapid as to be individually indistinguishable, while they still give a feeling of harshness or roughness to the sound. If the number of beats per second is equal to the difference of the frequencies of the tones, and if, as is the case, an interval depends on the ratio of frequencies, it is evident that the number of beats given by two tones nearly in unison will be doubled if the two tones are sounded an octave higher. It is possible by means of beats to measure the sensitiveness of the ear by determining the smallest difference in pitch that may give rise to a beat. In no part of the scale can a difference smaller than 0·2 vibration per second be distinguished. The sensitiveness varies with pitch. Thus at 120 vibs. per second 0·4 vib. per second, at 500 about 0·3 vib. per second, and at 1000, 0·5 vib. per second can be distinguished. This is a remarkable illustration of the great sensitiveness of the ear. When tones of low pitch are produced that do not rapidly die away, as by sounding heavy tuning-forks, not only may the beats be perceived corresponding to the difference between the frequencies of the forks, but also other sets of beats. Thus, if the two tones have frequencies of 40 and 74, a two-order beat may be heard, one having a frequency of 34 and the other of 6, as $74 \div 40 = 1 +$ a positive remainder of 34, and $74 \div 40 = 2 - 6$, or $80 - 74$, a negative remainder of 6. The lower beat is heard most distinctly when the number is *less* than half the frequency of the lower primary, and the upper when the number is greater. The beats we have been considering are produced when two notes are sounded slightly differing in frequency, or at all events their frequencies are not so great as those of two notes separated by a musical interval, such as an octave or a fifth. But Lord Kelvin has shown that beats may also be produced on slightly inharmonious musical intervals (*Proc. Roy. Soc. Ed.* 1878, vol. ix. p. 602). Thus, take two tuning-forks, $ut_2=256$ and $ut_3=512$; slightly flatten ut_3 so as to make its frequency 510, and we hear, not a roughness corresponding to 254 beats, but a slow beat of 2 per second. The sensation also passes through a cycle, the beats now sounding loudly and fading away in intensity, again sounding loudly, and so on. One might suppose that the beat occurred between 510 (the frequency of ut_3 flattened) and 512, the first partial of ut_2, namely ut_3, but this is not so, as the beat is most audible when ut_2 is sounded feebly. In a similar way, beats may be produced on the approximate harmonies 2 : 3, 3 : 4, 4 : 5, 5 : 6, 6 : 7, 7 : 8, 1 : 3, 3 : 5, and beats may even be produced on the major chord 4 : 5 : 6 by sounding ut_3, mi_3, sol_3, with sol_3 or mi_3 slightly flattened, "when a peculiar beat will be heard as if a wheel were being turned against a surface, one small part of which was rougher than the rest" (article by author on the "Ear," in Schäfer's *Text-Book of Physiology*, vol. ii., 1900). These beats on imperfect harmonies appear to indicate that the ear does distinguish between an increase of pressure on the drum-head and a diminution, or between a push and a pull, or, in other words, that it is affected by phase.

(*b*) *Beat Tones.*—Considerable difference of opinion exists as to whether beats can blend so as to give a sensation of tone; but König, by using very pure tones of high pitch, appears to have settled the question. These tones were produced by large tuning-forks. Thus $ut_6=2048$ and $re_6=2304$. Then the beat tone is $ut_3=256$ $(2304-2048)$. If we strike the two forks, ut_3 sounds as a grave or lower beat tone. Again, $ut_6=2048$ and $si_6=3840$. Then $(2048)_2-3840=256$, a negative remainder, ut_3, as before, and when both forks are sounded ut_3 will be heard. Again, $ut_6=2048$ and $sol_6=3072$, and $3072-2048=1024$, or ut_6, which will be distinctly heard when ut_6 and sol_6 are sounded (König, *Quelques expériénces d'acoustique*, Paris, 1882, p. 87).

(*c*) *Analytical Power of the Ear.*—When we listen to a compound tone, we have the power of picking out these partials from the general mass of sound. It is known that the frequencies of the partials as compared with that of the fundamental tone are simple mutiples of the frequency of the fundamental, and also that physically the waves of the partials so blend with each other as to produce waves of very complicated forms. Yet the ear, or the ear and the brain together, can resolve this complicated wave-form into its constituents, and this is done more easily if we listen to the sound with resonators, the pitch of which corresponds, or nearly corresponds, to the frequencies of the partials (see article EAR, *Ency. Brit.* vol. vii. p. 593). Much discussion has taken place as to how the ear accomplishes this analysis. All are agreed that there is a complicated apparatus in the cochlea which presumably may serve this purpose; but while some are of opinion that this structure is probably quite sufficient, others hold that the analysis ultimately takes place in the brain. When a complicated wave falls on the drum-head, it must move out and in in a way corresponding to the variations of pressure, and these variations will, in a single vibration, depend on the greater or less degree of complexity of the wave. Thus a single tone will cause a movement like that of a pendulum, a simple pendular vibration, while a complex tone, although occurring in the same duration of time, will cause the drum-head to move out and in in a much more complicated manner. The complex movement will be conveyed to the base of the stapes, thence to the vestibule, and thence to the cochlea, in which we find the ductus cochlearis containing the organ of Corti, a highly complicated structure composed of epithelium and the nerve-endings of the cochlear nerve. It is to be noted also that the parts in the cochlea are so small as to constitute only a fraction of the wave-length of most tones audible to the human ear. Now it is evident that the cochlea must act either as a whole, all the nerve fibres being affected by any variations of pressure, or the nerve fibres may have a selective action, each fibre being excited by a wave of a definite period, or there may exist small vibratile bodies between the nerve filaments and the pressures sent into the organ. The last hypothesis gives the most rational explanation of the phenomena, and on it is founded a theory generally accepted and associated with the names of Thomas Young and Hermann Helmholtz. It may be shortly stated as follows:—

"(1) In the cochlea there are vibrators, tuned to frequencies within the limits of hearing, say from 30 to 40,000 or 50,000 vibs. per second. (2) Each vibrator is capable of exciting its appropriate nerve filament or filaments, so that a nervous impulse, corresponding to the frequency of the vibrator, is transmitted to the brain—not corresponding necessarily, as regards the number of nervous impulses, but in such a way that when the impulses along a particular nerve filament reach the brain, a state of consciousness is aroused which does correspond with the number of the physical stimuli and with the period of the auditory vibrator. (3) The mass of each vibrator is such that it will be easily set in motion, and after the stimulus has ceased it will readily come to rest. (4) Damping arrangements exist in the ear, so as quickly to extinguish movements of the vibrators. (5) If a simple tone falls on the ear, there is a pendular movement of the base of the stapes, which will affect all the parts, causing them to move; but any part whose natural period is nearly the same as that of the sound will respond on the principle of sympathetic resonance, a particular nerve filament or nerve filaments will be affected, and a sensation of a tone of definite pitch will be experienced, thus accounting for discrimination in pitch. (6) Intensity or loudness will depend on the amplitude of movement of the vibrating body, and consequently on the intensity of nerve stimulation. (7) If a compound wave of pressure be communicated by the base of the stapes, it will be resolved into its constituents by the vibrators corresponding to tones existing in it, each picking out its appropriate portion of the wave, and thus irritating corresponding nerve filaments, so that nervous impulses are transmitted to the brain, where they are fused in such a way as to give rise to a sensation of a particular quality or character, but still so imperfectly fused that each constituent, by a strong effort of attention, may be specially recognized" (article "Ear," by author, Schäfer's *Text-Book*, *loc. cit.*).

The structure of the ductus cochlearis meets the demands of this theory. It is highly differentiated, and it can be shown that in it there are a sufficient number of elements to account for the delicate appreciation of pitch possessed by the human ear, and on the basis that the highly trained ear of a violinist can detect a difference of $\frac{1}{64}$th of a semitone (M'Kendrick, *Trans. Roy. Soc. Ed.*, 1896, vol. xxxviii. p. 780; also Schäfer's *Text-Book*, *loc. cit.*). Measurements of the cochlea have also shown such differentiation as to make it difficult to imagine that it can act as a whole. A much less complex organ might have served this purpose (M'Kendrick, *op. cit.*). The following table, given by Retzius (*Das Gehörorgan der Wirbelthiere*, Bd. ii. S. 356), shows differentiations in the cochlea of man, the cat, and the rabbit, all of which no doubt hear tones, although in all probability they have very different powers of discrimination:—

	Man.	Cat.	Rabbit.
Ear-teeth	2490	2430	1550
Holes in habenula for nerves .	3985	2780	1650
Inner rods of Corti's organ .	5590	4700	2800
Outer rods of Corti's organ .	3848	3300	1900
Inner hair cells (one row) .	3487	2600	1600
Outer hair cells (several rows) .	11,750	9900	6100
Fibres in basilar membrane .	23,750	15,700	10,500

(*d*) *Dissonance.*—The theory can also be used to explain dissonance. When two tones sufficiently near in pitch are simultaneously sounded, beats are produced. If the beats are few in number they can be counted, because they give rise to separate and distinct sensations; but if they are very numerous they blend so as to give roughness or dissonance to the interval. The roughness or dissonance is most disagreeable with about 33 beats falling on the ear per second. When two compound tones are sounded, say a minor third on a harmonium in the lower part of the keyboard, then we have beats not only between the primaries, but also between the upper partials of each of the primaries. The beating distance may, for tones of medium pitch, be fixed at about a minor third, but this interval will expand for intervals on low tones and contract for intervals on high ones. This explains why the same interval in the lower part of the scale may give slow beats that are not disagreeable, while in the higher part it may cause harsh and unpleasant dissonance. The partials up to the seventh are beyond beating distance, but above this they come close together. Consequently instruments (such as tongues, or reeds) that abound in upper partials cause an intolerable dissonance if one of the primaries is slightly out of tune (Sedley Taylor, *Sound and Music*, London, 1873, p. 166 *et seq.*). Some intervals are pleasant and satisfying when produced on instruments having few partials in their tones. These are concords. Others are less so, and they may give rise to an uncomfortable sensation. These are discords. In this way unison, $\frac{1}{1}$, minor third $\frac{6}{5}$, major third $\frac{5}{4}$, fourth $\frac{4}{3}$, fifth $\frac{3}{2}$, minor sixth $\frac{8}{5}$, major sixth $\frac{5}{3}$, and octave $\frac{2}{1}$, are all concords; while a second $\frac{9}{8}$, minor seventh $\frac{16}{9}$, and major seventh $\frac{15}{8}$, are discords. There is no difficulty, on the theory above enunciated, in explaining these facts, because it must respond to the prime tones and partials of both the notes forming the interval; but it is not easy to see why the sensation should be disagreeable when two portions of the basilar membrane sufficiently near are thrown into vibration. Still, similar phenomena occurring in the other senses show that, for some unexplained reason, if two nerves sufficiently near in their central terminations are stimulated, or if they are stimulated intermittently, the sensation is disagreeable. Helmholtz compares the sensation of dissonance to that of a flickering light on the eye. "Something similar I have found to be produced by simultaneously stimulating the skin, or margin of the lips, by bristles attached to tuning-forks giving forth beats. If the frequency of the forks is great, the sensation is that of a most disagreeable tickling. It may be that the instinctive effort at analysis of tones close in pitch causes the disagreeable sensation" (Schäfer's *Text-Book*, *op. cit.* p. 1187).

(*e*) *Combination Tones.*—Frequently, when two tones are sounded, not only do we hear the compound sound, from which we can pick out the constituent tones, but we may hear other tones, one of which is lower in pitch than the lowest primary, and the other is higher in pitch than the higher primary. These, known as combination tones, are of two classes: differential tones in which the frequency is the difference of the frequencies of the generating tones, and summational tones having a frequency which is the sum of the frequencies of the tones producing them. Differential tones, first noticed by Sorge about 1740, are easily heard (Sorge, *Vorgemach musikalischer Composition*, 1740). Thus an interval of a fifth, 2 : 3, gives a differential tone 1, that is, an octave below 2; a fourth, 3 : 4, gives 1, a twelfth below 3; a major third, 4 : 5, gives 1, two octaves below 4; a minor third, 5 : 6, gives 1, two octaves and a major third below 5; a major sixth, 3 : 5, gives 2, that is, a fifth below 3; and a minor sixth, 5 : 8, gives 3, that is, a major sixth below 5. Summational tones, first noticed by Helmholtz, are so difficult to hear, that much controversy has taken place as to their very existence. Some have contended that they are produced by beats. It appears to be proved physically that they may exist in the air outside of the ear (Forsyth and Sowter, *Proc. Roy. Soc.* vol. lxiii. p. 396; and Rücker and Edser, *Phil. Mag.*, April 1895). Further, differential tones may be generated in the middle ear (Preyer, *Wiedemann's Annal.* xxxviii. S. 131). Helmholtz also demonstrated their independent existence, and he states that "whenever the vibrations of the air or of other elastic bodies, which are set in motion at the same time by two generating simple tones, are so powerful that they can no longer be considered infinitely small, mathematical theory shows that vibrations of the air must arise which have the same vibrational numbers as the combination tones" (Helmholtz, *Sensations of Tone*, p. 235). The importance of these combinational tones in the theory of hearing is obvious. If the ear can only analyse compound waves into simple pendular vibrations of a certain order (simple multiples of the prime tone), how can it detect combinational tones, which do not belong to that order? Again, if such tones are purely subjective and only exist in the mind of the listener, the fact would be fatal to the resonance theory. There can be no doubt, however, that the ear, in dealing with them, vibrates in some part of its mechanism with each generator, while it also is affected by the combinational tone itself, according to its frequency. (For a discussion of this question, see Sedley Taylor, *op. cit.* p. 181).

(*f*) *Other Theories.*—In 1865 Rennie objected to the analysis theory, and urged that the cochlea acted as a whole (*Ztschr. f. rat. Med. Dritte Reihe*, Bd. xxiv. Heft 1, S. 12–64). This view was revived by Voltolini (Virchow's *Archiv*, Bd. c. S. 27) some years later, and in 1886 it was strongly urged by Rutherford (*Rep. Brit. Assoc. Ad. Sc.*, 1886), who compared the action of the cochlea to that of a telephone plate. According to this theory, all the hairs of the auditory cells vibrate to every note, and the hair cells transform sound vibrations into nerve vibrations or impulses, similar in frequency, amplitude, and character to the sound vibrations. There is no analysis in the peripheral organ. Waller, in 1891 (*Proc. Physiol. Soc.*, Jan. 20, 1891) suggested that the basilar membrane as a whole vibrates to every note, thus repeating the vibrations of the membrana tympani; and since the hair cells move with the basilar membrane, they produce what may be called pressure patterns against the tectorial membranes, and filaments of the auditory nerve are stimulated by these pressures. Waller admits a certain degree of peripheral analysis, but he relegates ultimate analysis to the brain. These theories, dispensing with peripheral analysis, leave out of account the highly complex structure of the cochlea, or, in other words, they assign to that structure a comparatively simple function, which could be performed by a simple membrane capable of vibrating. We find that the cochlea becomes more elaborate as we ascend the scale of animals, until in man, who possesses greater powers of analysis than any other being, the number of hair cells, fibres of the basilar membrane, and arches of Corti, are all much increased in number (see Retzius's table, *supra*). The principle of sympathetic resonance appears, therefore, to offer the most likely solution of the problem. Theories dispensing with this principle have also been advanced. Hurst's view is that with each movement of the stapes a wave is generated which travels up the scala vestibuli, through the helicotrema into the scala tympani, and down the latter to the fenestra rotunda. The wave, however, is not merely a movement of the basilar membrane, but an actual movement of fluid or a transmission of pressure. As the one wave ascends while the other descends, a pressure of the basilar membrane occurs at the point where they meet; this causes the basilar membrane to move towards the tectorial membrane, forcing this membrane suddenly against the apices of the hair cells, thus irritating the nerves. The point at which the waves meet will depend on the time interval between the waves (Hurst, "A New Theory of Hearing," *Trans. Biol. Soc. Liverpool*, 1895, vol. ix. p. 321). More recently Max Mayer has advanced a theory somewhat similar. He supposes that with each movement of the stapes corresponding to a vibration, a wave travels up the scala vestibuli, pressing the basilar membrane downwards. As it meets with resistance in passing upwards, its amplitude therefore diminishes, and in this way the distance up the scala through which the wave progresses will be determined by its amplitude. The wave in its progress irritates a certain number of nerve terminations, consequently feeble tones will irritate only those nerve fibres that are near the fenestra ovalis, while stronger tones will pass farther up and irritate a larger number of nerve fibres the same number of times per unit of time. Pitch, according to this view, depends on the number of stimuli per second, while loudness depends on the number of nerve fibres irritated. Mayer also applies the theory to the explanation of the powers of the cochlea as an analyser, by supposing that with a compound tone these are at maxima and minima of stimulation. As the compound wave travels up the scala, portions of the wave corresponding to maxima and minima die away in consecutive series, until only a maximum and minimum are left; and, finally, as the wave travels farther, these also disappear. With each maximum and minimum different parts of the basilar membrane are affected, and affected a different number of times per second, according to the frequencies of the partials existing in the compound tone. Thus with a fifth, 2 : 3, there are three maxima and three minima; but the compound tone is resolved into three tones having vibration frequencies in the ratio of 3 : 2 : 1. According to Mayer, we actually hear when a fifth is sounded tones of the relationship of 3 : 2 : 1, the last (1) being the differential tone (*vide supra*). He holds, also, that combinational tones are entirely subjective (Max Mayer, *Ztschr. f. Psycho. und Phys. d. Sinnesorgane*, Leipzig, Bd. xvi. and xvii.; also *Verhandl. d. physiolog. Gesellsch zu.*, Berlin, Feb. 18, 1898, S. 49). Two fatal objections can be urged to these theories, namely, first, it is impossible to conceive of minute waves following each other in rapid succession in the minute tubes forming the scalæ—the length of the scala being only a very small part of the wave-length of the sound; and, secondly, neither theory takes into account the differentiation of structure found in the epithelium of the organ of Corti. Each push in and out of the base of the stapes must cause a movement of the fluid, or a pressure, in the scalæ as a whole.
