## HEMATOGENOUS INFECTIONS OF THE KIDNEY\*

WILLIAM J. MAYO, M.D.  
ROCHESTER, MINN.

The surgical aspects of nephritis have led to extensive discussion, and but little agreement exists with regard to the types that are not clearly surgical. Wide differences of opinion are also manifest among those who have given the most time and attention to the study of nephritis in general. The accumulated literature on the subject is monumental; much of it, unfortunately, is confusing, and often even the fundamentals are the subject of controversy. Recently, however, articles have been published that help to clear up some of the moot questions.

Historically, the chief point of interest with reference to nephritis is the profound knowledge of the various phases of the disease exhibited by Richard Bright,<sup>1</sup> one of a long line of brilliant workers in Guy's Hospital, London. In 1827 and again in 1836 Bright, in epoch marking papers on edema and on albuminuria, pointed out that fundamentally there are two kinds of nephritis: Type 1, the acute or "wet" nephritis; and Type 2, the chronic or "dry" nephritis.

Type 1, which involves the kidney filter, was to be recognized pathologically in cases in which the large white kidney was found. Clinically, the type was characterized by edema, especially in the acute stage, and by urine containing albumin and casts, and at times blood corpuscles, the urinary findings varying in extent with the acuteness of the process and the amount of involvement of the kidneys. Both kidneys are always involved, and exhibit a wide pathologic architecture. The morphology varies as the toxic agents vary in toxicity and affect different structures of the kidney.

### BRIGHT'S TYPE 1 NEPHRITIS

Since the publication of Bright's work, we have learned that Type 1, or the "wet" type of nephritis, is usually the result of toxins developed in the course of infectious diseases. Diphtheria antitoxin affords the best known example of the effect of bacterial toxins on the kidney; it may produce changes in the kidney

analogous to the nephritis which sometimes develops in cases of diphtheria. The frequency with which Bright's Type 1 and infective nephritis follow lesions of the skin and mucous membrane, especially in children, is worthy of note, as shown by the nephritides following scarlet fever, tonsillitis, etc. In the adult, exposure to cold, especially of the cutaneous surfaces of the body, plays a definite rôle. The value of the skin as an aid to elimination in cases of defective kidney function has long been well known. The effect produced by hot packs and similar therapeutic measures is to cause a flow of perspiration which may eliminate large amounts of chlorids and some urea.

It is true that acute nephritis may be produced by other toxic agents, such as cantharides; but to all intents and purposes an infection lies behind it. The edema is to a large extent due to a failure of elimination of chlorids. Chlorids, usually taken in the form of common salt, are a constant requirement of all animal life. The herbivorous and omnivorous animals obtain the necessary amount in the form of salt, while the carnivorous obtain a sufficient amount from the flesh they consume. The chlorids are largely excreted by the kidneys. In acute nephritis, chlorid is not fully eliminated, and edema results. The physical and chemical reactions involved in the production of edema by chlorid retention are still greatly disputed, however, and it is apparent that there are varying factors to be considered.

### BRIGHT'S TYPE 2 NEPHRITIS

Bright's Type 2, called the dry type because edema is not present, involves the connective tissue and blood vessels, especially the arteries; the patient suffers from headache, nausea, vomiting, hypertension and other symptoms of uremia. The symptoms may be latent for long periods. Urea retention is one of the final consequences of this type. While urea will not of itself, when in excess in the blood, produce uremia, it is closely associated with if not one of the agents which produce the uremic manifestations. Both kidneys are involved, and pathologically in the typical case the kidneys are contracted and granular. The urine is of low specific gravity, pale, and large in amount. The urinary findings may consist only of an occasional cast and a trace of albumin, although at times there may be large amounts of albumin. This type of Bright's disease is closely associated with or is a part of a general vascular disease, and perhaps should not be described as a true primary nephritis. Changes in the heart are so characteristic of chronic Bright's disease that the appellation of cardiorenal disease is at times not inappropriate. The pathologic architecture varies with the situation of the chief con-

\* Read before the Section on Urology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1918.

Bright, Richard: Reports of Medical Cases with a View of Illustrating the Symptoms and Cure of Diseases by a Reference to Morbid Anatomy, London, Longmans, Green & Co., 1837-1831, 2 vols., xvi, 421 pp.; xl, 724 pp.; Cases and Observations Illustrative of Renal Disease Accompanied with Secretion of Albuminous Urine, Guy's Hosp. Rep. 1: 138-379, 1836; Tabular Review of the Morbid Appearances in One Hundred Cases Connected with Albuminous Urine, with Observations, Guy's Hosp. Rep. 1: 380-400, 1836.

recessive tissue deposits and the changes in the renal vascular system. Bissell<sup>2</sup> and other pathologists call attention to the fact that many of the changes in the kidney called nephritis are regressive in character. Neither infections nor the products of infection, so far as is known, play an important part in the etiology of Bright's Type 2. The cause of the condition is as yet unknown, but it is probably due to disorders of metabolism.

Edema may develop in chronic Bright's disease (Type 2), but if it does it is almost invariably the result of cardiac failure and not of salt retention. Widal had divided nephritis functionally into two forms; the chloremic or salt retention type, corresponding to Bright's Type 1, and the azotemic, nitrogen or urea retention type, corresponding to Bright's Type 2. It has been asserted by various authorities that chronic Bright's Type 2 is the late result of Type 1. I am convinced, however, that Bright's Types 1 and 2 are entirely independent diseases.

A discussion of the differentiation is unnecessary here, but the confusion seems to arise from mixed types. In certain varieties of Bright's Type 1, chronicity may be a feature. This is especially true of a form of Type 1, caused by chronic focal infections. I have seen what were believed to be cases of Bright's Type 1, caused by chronic infections of the teeth, tonsils, gallbladder, or by duodenal ulcer, etc. These patients recovered from the nephritic disturbance after operative cure of the focus of infection. Subacute infections, with slowly sterilizing abscesses, will often cause symptoms of a nephritis which disappear as the cause is removed. Excessive connective tissue may develop in the kidneys in some cases of Type 1 so that the resemblance is close to the contracted kidneys of Type 2; but the vascular changes are different. Again, chronic Bright's disease, Type 2, acts as a cause for lowered resistance of the kidneys, and a secondary true nephritis of Type 1 may be added to the condition, especially as a terminal infection leading to the frequent postmortem finding of death from acute nephritis superimposed on chronic nephritis. This confusion is further increased in some cases by pathologic changes in the kidney, the late results of unrecognized hematogenous infection which might well be called Type 3.

#### FUNCTION OF THE KIDNEY

Rowntree<sup>3</sup> calls attention to the fact that medicine of the last decade centers around the question of function, so far as the kidney is concerned. The capacity of the kidney to carry on its work, rather than its appearance, has come to be recognized as the important factor. This is well shown by the value clinically of the phenolsulphonphthalein test and the test of the chemistry of the blood. The percentage of urea in the blood or the phenolsulphonphthalein test will frequently give a clue to the state of the kidneys that cannot be obtained from the urinary findings.

That the kidney in health filters bacteria out of the blood, and by so doing receives no injury, is a fact too well known to require comment. It is the retention of the bacteria in the kidney which produces the

trouble. But we know much less about its ability to filter out toxic materials. In the greater number of cases of nephritis, no bacteria are found, and we must believe that it is some material, the result of infection, rather than the bacteria themselves that cause the trouble, although it is possible that an ultramicroscopic organism exists as the causative factor. The kidney normally filters out urea, which is the ash of protein derivatives, the amino-acids. The patient with a granular, contracted kidney (Bright's Type 2) must of necessity pass a large quantity of urine; the specific gravity is low because the kidney filter is damaged and fails to eliminate normal concentrations of urea and similar bodies. As these products are not threshold bodies, they are always to be found in both the blood and the urine.

On the contrary, sugar in the blood is a threshold body. When it rises beyond the normal, the excess flows off through the urine, and diabetes results. The threshold, however, is not an exact point, and many persons with crops of boils or carbuncles may, by testing the blood for sugar percentages, be shown to have an increased amount of blood sugar without having sugar in the urine, just as in others a low threshold permits the escape of sugar from slight temporary causes, so-called dietetic or alimentary glycosuria, which is without pathologic significance.

Embryologically, the kidney has a double origin: First, the ureter, the pelvis, the calices, and the straight collecting tubules all lined with pavement epithelium, which are derived from the wolffian duct and have no function beyond that of collecting urine as it is formed. The chief response of the part of the kidney thus derived, when diseased, consists in the development of infections, calculi, etc., and if the disease is a malignant one, it is a true carcinoma. Obstructions to the urinary outflow at any point are most potential of mischief through failure of drainage. The medullary part of the kidney is composed of the urinary collecting channels just described and of the venous channels which carry back the purified blood to the general circulation. Second, the filtering portion of the kidney, which arises from the mesothelium and forms in large part the cortical substance which is the arterial side of the kidney, bringing blood from the general circulation for purification. The common, solid tumors of the kidney that we have miscalled hypernephroma are, as pointed out by Wilson,<sup>4</sup> true mesotheliomas; that is, malignant neoplasms arising in the kidney filter. I think we may agree with Cushman<sup>5</sup> that the kidney does not secrete urine, but filters it. The kidney may be aptly compared to a separator. The arterial blood enters the kidney cortex, the urine is filtered out, and the venous blood passes back to the general circulation. Weld,<sup>6</sup> by his experimental injections of mediums, demonstrated the physics of the process outlined. The partial failure of the two halves of the kidneys to unite, so that the urine, when filtered, is not freely admitted into the collecting tubules, produces the so-called congenital polycystic kidneys that are eventually associated with chronic nephritis.

## TYPE 3 NEPHRITIS

Nephritis, the result of living organisms, may be called Type 3. True nephritis is concerned with the filter portion of the kidney, and the failure to filter out all the bacteria and their retention is responsible for the occurrence of one form of the disease, which is of great surgical importance. As to just how often such infections may be ascending or lymphogenous rather than hematogenous in origin there is a diversity of opinion. My own opinion is that such infections, other than hematogenous, are extremely rare so far as the kidney filter is concerned, though it is possible they may be more frequent in that part of the kidney devoted to collecting urine.

Accepting the idea that there is a common form of true nephritis which differs from Bright's Types 1 and 2 and is caused by a bacterial infection, we quickly see that the effect on the kidney will depend on the nature of the bacteria, their number and on the condition of the kidney itself, on whether, for example, there is an anomaly present, such as hydronephrosis or calculi, which makes the kidney more vulnerable. The importance of this has been shown by Cabot and Craibtree,<sup>7</sup> who demonstrated that the pus cocci affect the cortex of the kidney and often follow lines of least resistance toward the periphery; and that the coliform bacteria affect the straight collecting tubules of the pyramids, extend from them to the pelvis, and there produce a pyelitis. Pyogenic infections may lead to cortical abscesses and other evidences visible to the eye; but with scanty urinary findings beyond a trace of albumin in the acute stage, and a few microscopic pus and blood cells, the urinary evidences are so slight as to be overlooked unless great care is exercised. In the subacute and chronic forms the kidney may be more or less destroyed, and the common forms of pyonephrosis will follow. The pyogenic cocci are short lived and often are not to be found in the pathologic changes their action initiates. On the contrary, colon bacteria, by the production of copious, purulent sediment in the urine, give abundant evidence of infection without abscess formation in the kidney. Acute nephritis (Bright's Type 1) is the result of toxic products, not of living organisms, as in diphtherial and scarlat nephritis, and the two kidneys are equally involved. When the nephritis is the result of living bacteria (Type 3) the kidneys may be involved unilaterally or bilaterally, the unilateral infection being in the kidney which is more vulnerable because of some physical defect. The pus-producing organisms affect the kidney much as do tubercle bacilli, and those who have studied tuberculosis of the kidney will recognize the resemblance.

Hematogenous nephritis is often caused by cocci found in the skin, especially staphylococci derived from boils, carbuncles, etc., and from focal infections generally. The staphylococcus is short lived and often affects only one kidney. Acute streptococcal infections are most malignant. Subacute and chronic streptococcal infections occur commonly as a result of septic endocarditis, and appear in the kidney as a terminal infection, embolic in character.

In the fulminating type of hematogenous pyogenic infection, unless nephrectomy is performed, death may often result within a few days. The acute condition is often confused with acute intraparenchymal infections:

7. Cabot, Hugh, and Craibtree, E. G.: A Classification of Renal Infection with Particular Reference to Treatment, *Boston M. & S. J.* **17**: 789-785 (June 1) 1916.

on the right side, especially, is the differentiation from cholecystitis and appendicitis necessary. This may also be true of the less acute form. In the subacute and chronic forms, natural processes may localize and sterilize the foci of infection, and the patients may fully recover, or partial recovery may later be followed by chronic infection, and the kidney will be converted into a pyonephrosis. The fact should be recalled that septic infarcts rupturing through the capsule of the kidney are the most common cause of perinephritic abscess.

Bright's disease, both Type 1 and Type 2, is of surgical interest only because of complications. But all the nephritides caused by living bacteria (Type 3) are of great surgical interest and have, until recently, been confused with Bright's disease. Hematogenous kidney infection is the one bright picture in a group of maladies that have been discouraging in the extreme. The surgeon of today is as greatly interested in nephritis as is the internist.

In reviewing the large mass of literature on nephritis, rather superficially, it is true, I have been particularly impressed with the clear and logical presentation made by Brewer<sup>8</sup> in a series of published papers beginning in 1911, in which he demonstrates hematogenous pyogenic infections of the cortex of the kidney clinically, experimentally and pathologically. In this connection, I wish to comment on the value of the contributions of the surgeon to such problems. Nephritis has been studied largely from a clinical and a necropsy standpoint. Clinical observations in these cases are notoriously unreliable, while the necropsy shows the terminal conditions that cause death. This exposition of terminal change, determined at necropsy, is exceedingly difficult to interpret in the living, and the final catastrophe leading to the death of the patient produces pathologic changes obscuring those that existed during life. In no other way can I explain the various theories and controversies which have marked the history of the study of nephritis. The clinician attempts, by study of the urine and the symptoms of the patient, to explain the terminal conditions found after death, which may not have existed at the time the clinical examinations were made. The surgeon, not by reason of greater acumen but by opportunity, now furnishes the missing link in the investigation which carries the truth, and makes possible an exact study of the kidney before the terminal infections, which are encountered at necropsy, obscure the picture.

Payne and MacNider,<sup>9</sup> and Buerger<sup>10</sup> have shown the hematogenous origin of certain of the so-called chronic, essential hematurias, demonstrating that infection in and about the straight tubules, resulting in the development of scar tissue, which interferes with the venous circulation, causes congestion and varicosity of papillae and leads to rupture and renal hemorrhage. This gives a pathologic explanation for several cases in which we explored to find the cause of renal hemorrhage, and in which one or more papillae were found to be the seat of varicosities.

I have been greatly interested in the chronic form of hematogenous nephritis of bacterial origin. In a number of instances, I have explored and found small, cortical, pimple-like collections of fluid in the kidney in various stages of sterilization. I have been able to link up another most interesting sequel to the condition, namely, the occasional deposit of calcium carbonate in such an infected area, usually close to or connected with the capsule, which produces a roentgen-ray shadow resembling that of stone. The diagnosis of stone is often justified by the history of the acute, severe attack which marks the onset of infective nephritis. I have known such deposits of lime to form as soon as two months after the primary symptoms. Why, in some persons, lime is deposited during the process of the cure of the infection, I do not know. The kidneys in such cases are often painful. Our patients were relieved by the excision of the lime masses, and by decapsulation. In several cases, the deposits of lime were deeper in the cortex. There are almost no urinary signs or symptoms in these cases, as the masses are in the cortex with little communication with the collecting parts of the kidney. It is very evident, too, that in some painful kidneys, with dense scars in the capsule, the origin is similar, and the condition may be relieved by decapsulation. I have been slow to admit that capsular compression of the kidney could be the cause of symptoms, but I have seen at least three cases in which hypertrophy of the remaining kidney within its fibrous capsule, after the removal of its fellow for disease, produced pain from the stretching of the capsule. The kidneys were low and movable, and the patients thin, and I was able to follow the compensatory hypertrophic enlargement by palpation, and to satisfy myself that the hypertrophy caused the pain.

In our experience, decapsulation has been valuable in this small group of cases in which there are scars and lime deposits in the capsule of the kidney, and in another group still more rare, that of acute nephritis (Bright's Type 1), in which, as pointed out by Morris,<sup>11</sup> the operation occasionally enables the kidneys to functionate when urinary function has ceased and the patients are apparently in a dying condition. For movable kidney, etc., we have seen no good effect from nephrorrhaphy other than the psychic.

#### ABSTRACT OF DISCUSSION

Dr. HEN H. YOUNG, Baltimore: Dr. Mayo's paper is somewhat parallel to an article I wrote a number of years ago, in which I took up the history of urology. Among other things it was easy to prove that John Hunter was originally a urologist, although the pathologists claimed him as the father of pathology, and the internists claim him as the father of modern medicine. In regard to this society, as one of the original founders of it, I may say that the reason we called it the section on genito-urinary diseases, was just with the idea of grouping here all types of scientific men interested in the urinary tract, not only general surgeons but also internists and physiologists and all others who are interested in the urinary tract. Dr. Mayo's point that the surgeon has played a very important part in clearing up the pathology of many parts of the body is, I think, very well taken. We know how the pathologist and the internist groped for many, many centuries over typhlitis and perityphlitis, and had no conception of the internal pathology of

the real fundamental basis of the condition until the surgeon cleared it up. Real pathology of the kidney made very little progress since the time of Bright, and it is interesting to note that Dr. Mayo goes back to the classification of Bright as the standard classification of renal infections. For a number of years the question as to the possibility of a unilateral nephritis has been a mooted one. Casper claimed that unilateral nephritis was possible. The trouble was that these cases were not seen early, or that the disease was not studied thoroughly. Undoubtedly those cases are apt to be caused by some obstruction below. Undoubtedly the kidneys filter out bacteria constantly, which probably is one of the ways the body has of getting rid of bacteria, and happily the kidneys are able to take care of it, and there is no infection in the large majority of cases. When the bacteria are retained there is probably some condition below which prevents their elimination. I think that obstructive conditions of the urinary tract are present in a far greater number of cases than we realize. Whatever is the cause of these conditions is a question that needs working out in every individual case. Dr. Mayo spoke of focal infections in the kidney, one of the most interesting and puzzling conditions met with in the kidney. His fulminating type is rarely seen. They are not generally seen except by the internist or the general surgeon who is called to operate on a man who is desperately sick, and he may accidentally find the condition present. It has been extremely rare in my experience. The relation of that condition to the more chronic types is not very definite, because those patients very frequently die before the condition becomes chronic.

Dr. WILLIAM LINDER, Brooklyn: The subject of hematogenous infection of the kidney is of great interest to the surgeon as well as to the general practitioner. It has been pointed out that this disease early involves only one kidney. The clinical picture is one of an acute upper abdomen. The history is one of acute onset, ushered in with a chill and frequently preceded by some external lesion, such as a carbuncle or a sore throat. Examination will reveal a distended abdomen, tenderness in the upper abdomen but no rigidity. This alone differentiates it on the right side from a perforated gastric or duodenal ulcer. It, however, must also be differentiated from an acute perforative appendicitis in the retrocecal region. But the history of appendicitis will aid us not to be misled, i. e., general abdominal pain, vomiting then localization to the right side and finally rise of temperature will point to appendicitis. The most important sign or symptom is tenderness and a sense of rigidity in the costovertebral angle. The Murphy fist percussion sign is of great aid. The urinary findings in this condition do not help us; one may find a few white and red blood cells. Therefore, it can easily be differentiated from an acute pyelitis where pus is frequently found in the urine. In my service at the Jewish Hospital I have operated in more than 100 cases of this type of kidney infection. Some of these patients were pregnant women and a diagnosis of unilateral kidney infection was made and confirmed at the operating table. The treatment in these cases of the fulminating type is nephrectomy; fortunately these cases are few in number. In the subacute type, decapsulation, if the patient is seen early, will save both the kidney and the patient. Hence, the importance of early diagnosis. These lesions, as has been pointed out by Dr. Mayo, are cortical and a metastatic infection is carried by the blood stream. They are minute military abscesses and decapsulation allows these abscesses to rupture and drain.

Dr. GUY L. HUNNER, Baltimore: I would like to ask Dr. Mayo if he thinks it is really safe teaching to recommend nephrectomy in many of these cases? I am familiar with Brewer's recommendations in that line, but for some reason they have not appealed to me. In the first place, we cannot differentiate, within the first few days, in the acute cases, between these acute cortical abscess cases and mere pyelitis cases. Even in the acute pyelitis case the urine contains albumen, blood and casts, that we usually consider characteristic of these acute cortical infections. There is the same high temperature, the chills, the prostration and, as

11. Morris, H.: Notes on the Surgical Treatment of Affections of the Kidney. *Ann. Surg.* 5:209-305, 1887; *Surgical Diseases of the Kidney and Ureter, Including Malformations and Mispacements*, New York, Cassell & Co., 1911, 2, 670 pp.

far as I know, it is rather impossible to differentiate which the patient has. If you are going to operate at all it probably ought to be done early, and that is Brewer's teaching. I think Dr. Mayo will agree that some of these patients undoubtedly recover spontaneously if we leave them alone and treat them as we would a pyelitis patient. He has spoken of a series of cases in which he finds evidences of past infection, with the lime deposits, showing that some of those patients have recovered. So altogether it seems to me that if we are going to operate at all in these cases it would be safer teaching for the average surgeon to recommend mere drainage, or, perhaps, decortication. If I operated at all on a case of that sort I should prefer drainage. In such cases a few kidneys will be saved, and a few, of course, will remain infected, and perhaps have to be removed later. But in any of these cases, another point in favor of some form of conservative operation is the fact that we cannot tell whether they are unilateral, or bilateral. The symptoms may all be referred to one side; but I have had cases where later, after the patient had recovered, investigation showed that both kidneys were infected, whereas in the acute attack we considered but one kidney to be infected. I would like to ask Dr. Mayo's opinion about these points.

DR. LEON LOUISA, Brooklyn: I have learned of the type of infection of the kidney to which Dr. Mayo refers only during the last few years. The subject was entirely new to me, and it was only by observing the findings on the operating table that I could clarify in my mind the pathology of this disease. Hematogenous infection of the kidney is distinct from pyelitis, it is due to a general infection, with localization in the kidney. There are fulminating cases, which are not recognized at all—or only too late to save the patient's life. At the Jewish Hospital of Brooklyn, I have seen a number of these cases and referred them to the surgeon. The internist sees them first, and he must make a diagnosis. We deal with a general infection very frequently following a tonsillitis, with metastases in one kidney. Some throat is often followed by chill and fever, but the patient does not localize the pain; still, if you keep in mind this type of kidney infection, and press your finger firmly in the costovertebral angle you easily elicit an acute pain; and if you can exonerate the appendix and gallbladder, the diagnosis is made. After the conclusion has been reached, our attitude in these cases should be identical with that in cases of appendicitis. Nobody can predict the course of an acute appendicitis; so then, in acute hematogenous kidney we cannot be sure, *a priori*, that the infection, left alone, will not destroy the life of the patient, or at least one kidney, while both may be saved by timely surgical intervention. Internists have learned that the appendix belongs to them only until they make the diagnosis, and then it becomes the property of the surgeon. I think the same principle ought to be applied to the acute kidney. A surgeon ought to be consulted; if experience has taught him that this particular kidney can be saved without operation, well and good, we will stand by him; otherwise an operation ought to be performed. No single surgical procedure should be binding, the surgeon ought to proceed without a contract; no promise of saving the kidney can be made to the patient in advance. If on inspection of the kidney the surgeon feels that the organ can be saved, he will not do a nephrectomy, but he will resort to a minor operation, decapsulation, nephrotomy or partial excision. If you are sure that the patient has another kidney, and the partner is functioning properly, the hazard is not great, as we know that man can live with one kidney. A few years ago I said that I felt that nature was provident in giving us two kidneys, in that she assigned one to the surgeon and left one for the patient.

DR. FRANK HINMAN, San Francisco: Two points might be emphasized in this discussion: In the first place, the type of infection. We all know that the colon bacillus does not produce abscesses in the kidney, and it seems to me that this discussion is confused by the fact that many of these acute infections of the kidney, probably the great majority of them, are due to the colon bacillus. And these kidneys can always be left alone. They do not demand operation in

the acute stages. On the other hand, streptococcus or staphylococcus infections of the kidney are the type of acute infections of the kidney that are so frequently hematogenous and surgical and are the kind that sometimes demand immediate operation to save the patient's life. I inferred from Dr. Mayo's paper that this was the type he referred to particularly. The other fact that should be emphasized is that the kidney is not an excretory organ for bacteria by choice; it is only that when the circulation is overwhelmed with bacteria, or when the kidney is injured, or is nonresistant that infections of the kidney occur. This can be shown experimentally in a great many ways. If you inject animals with living cultures of bacteria you will find that the liver and the lungs, the gallbladder, and the other organs of this animal will be loaded with bacteria, and the kidney will show relatively few. The kidney, therefore, is not an excretory organ for bacteria. Marked infection of the kidney occurs much more often with potato cultures than with broth cultures due to the clumping and the resultant capillary emboli in the former instance. The type of infection, whether colon bacillus or coccus, and a knowledge of the particular renal injury present, in view of the fact that the kidney is not, by choice, an excretory organ, can often shed considerable light on questions of surgery, particularly in reference to these acute septic kidneys.

DR. WILLIAM J. MAYO, Rochester, Minn.: I was particularly interested in having Dr. Hugh Young lead this discussion because I believe that in the Brady Institute which is under his charge there is a great opportunity to solve such problems as this by attacking them from every side. Organized effort will clear up moot questions in urology just as has been done in other fields. Dr. Hunner has brought up an important point with regard to nephrectomy. Nephrectomy is only for the exceptional case. In a very high percentage of these acute cases the patients get well or eventually develop a chronic condition of pyonephrosis and come to operation later. Many cases may be in their inception so mild that we do not appreciate the condition as an acute, or even a subacute process presenting so few symptoms. There are cases, however, as pointed out by Brewer, in which nephrectomy is necessary to save life. I have removed a kidney in a few such cases. On two occasions I operated from in front, expecting to find acute suppurative cholecystitis, but on exploration I discovered that the real seat of the trouble was in the kidney. The kidney when removed was found to be riddled with acute abscesses. I could not conceive that such a kidney might be cured by decapsulation or drainage. It should not be assumed for a moment that the kidney should be removed early in all cases; probably nine out of ten such patients in this condition will either enter into a chronic or get well. I wish again to call attention to the fact that these cases may sometimes be seen in the process of sterilization. In some instances little pimple-like masses were shown to be bacteria free, and others contained bacteria, and in the late stages of cure carbonate of lime may be deposited in the sterilized area giving rise to roentgen-ray shadows.

**A Literary Fragment on Syphilis and Tobacco.**—The following quotation from a curious document printed in London in 1604, entitled "A Counterblaste to Tobacco," affords some insight, both into the belief of that day as to the origin of syphilis and as to its treatment: "For Tobacco being a common herbe, which (though under divers names) grows almost every where, was first found out by some of the barbarous Indians, to be a Preservative, or Antidot against the Pockes, a filthy disease, whereunto these barbarous people are (as all men know) very much subject, what through the uncleanly and adust constitution of their bodies, and what through the intemperate heate of their Climat; so that as from them was first brought into Christendome, that most detestable disease, so from them likewise was brought this use of Tobacco, as a stinking and un-avorie Antidot, for so corrupted and execrable a Maladie, the stinking Suffumigation whereof they yet use against that disease, making so one canker or venome to eate out another."

## STUDY IN A FOUNDLING INSTITUTION TO DETERMINE THE INCIDENCE OF CONGENITAL SYPHILIS\*

L. R. DeBUYS, B.S., M.D.

Professor of Pediatrics, Tulane University School of Medicine

AND

MAUD LOEBER, A.B., M.A., M.D.

Instructor in Pediatrics, Tulane University School of Medicine

NEW ORLEANS

This study consisted in examining all the infants and children in a foundling institution in an effort to determine the incidence of congenital syphilis. Their bloods were examined by means of the Wassermann reaction; luetin skin tests were made on them; and they were subjected to complete physical examinations, careful observations being made with regard to the growth and development and the usual symptoms attributable to congenital syphilis.

The bloods were obtained from the infants with open anterior fontanels from the longitudinal sinus and, in those whose fontanels were closed, from the vein at the bend of the elbow, and in a few instances from the vein over the inner malleolus. The bloods were collected in accordance with the usual method and transmitted to the laboratory for examination. The original Wassermann test was made on each blood, and, in addition, a second test was made by modifying the original test in using one unit of hemolysin instead of two as in the original, and in incubating over a longer period of time. The readings in both the tests corresponded in every case.

The luetin skin tests were made according to the technic outlined by Noguchi, and were carried out minutely. Readings were made every twenty-four hours over a period of nearly two weeks. The duration of the reaction was from two days to nine days, and in some instances the induration remained even longer. The earliest pustular reactions occurred in two days. These reactions were not always the ones to remain the longest time.

### REACTIONS TO LUTIN AND WASSERMANN TESTS

There were, in all, 106 infants and children on whom both luetin and Wassermann reactions were made. The luetin reactions were positive in seventy-nine cases, negative in eighteen, and doubtful in nine. In twelve of the negative and four of the doubtful cases the age of the infants was 3 months or under; in the remaining negative and doubtful cases, six and five, respectively, the children were above that age. Of the positive luetin reactions the age of the infants in six cases was 3 months or under, the youngest 1 month and 2 days, the next 2 months and 5 days, and the remainder ranged up to the oldest child investigated. The doubtful reactions were also more frequent the younger the child.

The Wassermann reactions were negative in all the cases. This seemed to be an extremely unusual occurrence and one entirely unlooked for, so that without any desire to discredit the value of the Wassermann reaction in congenital syphilis, but in order to exclude the possibility of an error's having crept in, the following checks were made:

1. A series of eight bloods, four from children showing positive luetin reactions and four from children showing negative luetin reactions, were obtained by the same investigator and by the technic by which the original bloods were obtained, and were submitted to another serologist, without specifying the origin of the cases. This serologist made the original Wassermann test and, in addition, a Tschurnogubow modification of the original, all with negative results.

2. Another series of bloods was then obtained from the children by the second serologist and examined by him, and these also gave the same negative findings. These two series excluded the possibility of error either in the technic of securing the blood for the serologist, or in the technic of performing the Wassermann tests, with the possibility of improper material.

Further evidence as to the reliability of the results of the original tests is manifested when it is shown that while these bloods were being examined and were giving negative Wassermann reactions, an interesting series of ninety-six positive Wassermann reactions was simultaneously being found in the bloods of 160 persons, not at all connected with this investigation, by the original serologist who reported on the bloods of the inmates of this institution. This clearly showed the reliability of the method and of the technic employed by him in his investigation at the foundling institution.

The question naturally arose as to the reliability of the luetin tests and their readings. The technic consisted in cleansing the inner aspect of the forearm of any visible dirt with soap and water. It was then dried and wiped with ether. The skin was allowed to air-dry, and the luetin was injected intradermally by means of a tuberculin syringe with a fine steel needle. The readings were made by each of us separately and the results compared, the findings being identical. So as to check the technic of the luetin tests, physiologic sodium chlorid intradermal injections were made in the same manner as for the luetin tests, in five cases giving positive luetin reactions and in five cases giving negative luetin reactions, and in every instance the reading was negative. To dispel the idea of a defective luetin being used (which was not believed to be the case), a luetin secured from another manufacturing house was obtained, and a series of injections was made which included four previously positive cases and four previously negative cases. In each instance the reading corresponded with the reading in the original test.

In making the readings of the luetin reactions on the first occasion, an interesting development occurred: Instructions had been given to withhold all medication pending the investigation. These instructions were carried out, with this exception: On reading the luetin reactions in the room of a certain group of bottle feeders, attention was immediately called to the violence of the reactions, which was emphatically stated by one of us to be due to the use of iodids. After an immediate investigation it developed that the dietitian, in making the daily food, had continued to add the usual drops from a container to the usual bottles for each baby, as was customary. This container held a solution of syrup of ferrous iodid.

These luetin readings were not considered as positive in this series, but were carefully watched. On the cessation of the iodids, the reactions promptly subsided, and at the end of eight days, when the reac-

\* Read before the Section on Diseases of Children at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

tions had disappeared, with the exception of only a small indurated area, a second luetin test was made. In seventeen instances, the reactions at the end of twenty-four hours were diffuse, and somewhat resembled the iodid reactions; but in another twenty-four hours they had lost their diffuse appearance and resembled the iodid reactions; but in another twenty-four duration. In the seven remaining instances, the reactions were all positive and pursued the course of the normal positive luetin reaction.

Of the 106 infants and children investigated, fifty-seven were males and forty-nine females. Their ages ranged from 1 month to 5<sup>10</sup>/<sub>12</sub> years, with the exception of one child of 7 years. The ages and the numbers of cases are given in the accompanying table.

NUMBER OF CASES AT THE VARIOUS AGES

Years	Months	No. of Cases	Years	Months	No. of Cases
..	1	5	2	9	1
..	2	13	2	10	2
..	3	4	3	1	2
..	4	1	3	3	1
..	5	2	3	4	1
..	6	1	3	5	1
..	7	1	3	6	2
..	8	6	3	8	2
..	10	2	3	9	1
..	11	4	3	10	1
..	12	5	4	1	1
..	15	3	4	3	1
..	17	1	4	3	1
..	18	4	4	4	1
..	19	3	4	7	1
..	21	2	4	9	1
..	2	1	4	11	2
2	1	3	5	1	3
2	2	3	5	1	1
2	3	2	5	2	1
2	4	1	5	7	1
2	5	5	5	10	1
2	7	1	7	1	1
2	8	2	7	..	1

There were twenty-two cases in children under 3 months, and eighteen in those under 2 months. From 3 months to 6 months inclusive, there were four; from 6 months to 1 year, eighteen; from 1 year to 2 years, fourteen; from 2 years to 3 years, twenty-one; from 3 years to 4 years, twelve; from 4 years to 5 years, ten, and from 5 years to 7 years, five. Forty-one and six tenths per cent. were under 1 year; 33 per cent. in children from 1 to 2 years; 11.3 per cent. in children from 2 to 3 years; 9.4 per cent. in children from 3 to 4 years, and the remaining 4.7 per cent. in children from 4 to 7 years.

LEGITIMACY

Fifty-nine of the infants and children were legitimate, forty-three were illegitimate, and in four the legitimacy was not known. Of the fifty-nine legitimate, forty-six, or 77.97 per cent., returned positive reactions; six, or 10.17 per cent., negative; and seven, or 11.8 per cent., doubtful reactions. Of the forty-three illegitimates, thirty, or 69.76 per cent., returned positive reactions; eleven, or 25.58 per cent., negative reactions; and two, or 4.65 per cent., doubtful reactions. Of the four children whose legitimacy was unknown, three, or 75 per cent., returned positive reactions, and one, or 25 per cent., negative reactions.

There were under 3 months of age, six legitimate, and fifteen illegitimate infants, and one whose legitimacy was unknown. Of the six who were legitimate, two returned positive reactions; two, negative, and two, doubtful reactions. Of the fifteen who were illegitimate, four returned positive reactions; nine, negative reactions, and two, doubtful reactions. The infant

whose legitimacy was unknown returned a negative reaction.

One legitimate and nine illegitimate infants in whom negative reactions were obtained had syphilis skin eruptions. All of these infants were under 3 months of age. Forty-seven, or 79.66 per cent., of the fifty-nine legitimate children and thirty-nine, or 90 per cent., of the forty-three illegitimate children were therefore syphilitic. These, together with the three positive cases of doubtful legitimacy, gave a total of eighty-nine positive cases in the 106 inmates, or an incidence of 83.96 per cent. as revealed by all available methods of diagnosis.

PHYSICAL CONDITION

*Weight.*—Weights were studied in ninety-three cases. In eighty-seven they were below the normal average, in four instances they were normal, and in only two instances were they above the normal average, namely, in one child, aged 5, and in another, aged 2 years and 6 months. In seventy-one cases in which children returned positive reactions the weights were below normal in sixty-six, normal in three, and above normal in two. And in sixteen cases in which the reaction was negative, weights were below normal in fifteen, and normal in one. In six doubtful cases the weights were below the normal. The weights of the legitimate children were below normal in forty-six instances, and normal in one; of the illegitimate children, below in thirty-eight instances and normal in three, and of the three children whose legitimacy was doubtful, below in each instance.

*Height.*—The heights were studied in eighty-four instances, in which there were sixty positive, seventeen negative, and seven doubtful reactions. The heights were normal in two cases in which the reaction was positive; above normal in ten cases in which it was positive, in eight in which it was negative and in three in which it was doubtful; and they were below normal in forty-eight positive, nine negative and four doubtful cases. With the legitimate children, the heights of ten were above normal; that of one, normal, and thirty-two below normal; while the heights of the illegitimate children were above normal in ten, normal in one, and below normal in twenty-eight cases. In the two cases in which the legitimacy was unknown, the heights were above and below in one instance each.

*State of Nourishment and General Appearance.*—The nourishment and general appearance coincided almost exactly in 104 cases. They were fair in twenty-two positive cases, three negative cases, and three doubtful cases; poor in forty-four positive, fourteen negative, and five doubtful cases; and very poor in eleven positive cases, one negative case, and one doubtful case. The nourishment and the general appearance of the legitimate children were fair, poor and very poor in twenty-one, thirty and seven instances, respectively; of the illegitimate children, fair, poor and very poor in seven, twenty-nine and six instances, respectively, and poor in four instances in which the legitimacy was not known.

*Nails.*—The nails were found to be claw shaped or ridged in fifty-five instances, including thirty-nine positive, ten negative and six doubtful cases. In this classification were thirty-two legitimate children, twenty-one who were illegitimate, and two regarding whom legitimacy was not known.

*Glands.*—Glandular enlargements were present in eighty instances. The glands found to be enlarged

were the cervical, the inguinal, the axillary and the epitrochlear. The frequency of their enlargements were in the order named. They were enlarged in fifty-nine positive, thirteen negative, and eight doubtful cases; or in forty-two legitimate children, thirty-five illegitimate children, and three whose legitimacy was not known.

**Costal Beading and Flaring Ribs.**—Costal beading and flaring ribs were found in forty-five instances: twenty-four times in positive cases, fifteen times in negative cases and six times in doubtful cases; or in twenty-five legitimate children, nineteen illegitimate children, and one child whose legitimacy was not known.

**Liver.**—The most constant symptom in the entire study was the enlarged liver. This was present in eighty-three instances: in fifty-eight positive, seventeen negative and eight doubtful cases; or in forty-six legitimate children, thirty-three illegitimate children and in all four of the cases in which the legitimacy was not known.

**Spleen.**—Next in frequency to the enlarged livers and glands were the enlarged spleens, which were found in sixty-seven instances: in forty-five positive, fifteen negative and seven doubtful cases; or in thirty-six legitimate children, twenty-eight illegitimate children, and three of the four cases in which the legitimacy was not known.

**Skin.**—Skin eruptions were present in fifty-five cases, or in 51.89 per cent. of the inmates of the institution. In twenty-two, or 20.75 per cent. of the inmates, the eruption was diagnosed as of syphilitic origin, or, 40 per cent. of the cases of skin eruptions were syphilitic. In this study the younger the individual the more frequently were skin eruptions found. This was more particularly so with regard to the syphilitic skin lesions. The positive syphilitic skin eruptions were found in twelve positive luetin cases, eight negative luetin cases and two doubtful luetin cases. Twelve of the positive skin eruptions were found in infants during the first three months of life, or sixteen infants aged 1 year or less, the remaining six being found in infants aged up to 2 years and 5 months. The eight negative and two doubtful luetin cases with positive syphilitic skin eruptions were in infants aged 3 months or less. The syphilitic skin eruptions were found in five legitimate and seventeen illegitimate children.

The ten positive skin eruptions in the negative and doubtful luetin cases were associated with enlarged livers in nine instances, enlarged spleens in seven instances and enlarged glands in eight instances. Costal beading was present in three cases; flaring ribs in two; ridged or clawed nails in four; anal fissures in two, and wig, snuffles, and discharging ears in one instance each.

The skin readings were made after the other tests and consequently a greater time had elapsed after medications had been withheld. It was stated by the attendant that the skin eruptions had increased when medication had been stopped.

Fissures were present in four positive cases, five negative cases, and one doubtful case. The symptoms of snuffles, wig, scaling soles and palms and disturbances of the ears and eyes, nose, and bones and joints were practically absent. Heart murmurs were found in four positive and in two doubtful cases. Bosses were present in twelve positive cases and in one negative case.

The earliest complete eruption of teeth was in an infant aged 1 year and 5 months, a legitimate child who had shown a positive reaction. The oldest infant with no teeth was 1 year and 3 months, and was an illegitimate child who had shown a positive reaction.

One child, an illegitimate child who had given a positive reaction, at 3 years and 8 months had only eighteen teeth and was 6 inches under size and 12 pounds under weight. Another child, who was illegitimate and had given a negative reaction, at 2 years and 6 months had fourteen teeth and was 9 inches under height and 7½ pounds under weight.

The anterior fontanel was closed in a legitimate child who had shown a positive reaction at 11 months and 8 days, and in another child in the same class the fontanel was still open at 2 years and 8 months.

#### NOURISHMENT

The nourishment in the institution consists of the ordinary foods usually given in such institutions, with a fair amount of milk. The infants and children up to 2 years receive the same mixture of milk, which contains, from analysis: total solids, 11.36 per cent.; ash, 0.49 per cent.; fat, 1.45 per cent.; protein, 1.62 per cent.; lactose, 7.8 per cent.; acidity (as lactic acid) 0.69 per cent. This information was secured because of the number of diaper eruptions (intertrigo), in the very young infants. All the infants are given the same mixture, though the quantity varies. The older children, from 2½ years on, are given whole cow's milk as part of their daily rations.

#### ROUTINE MEDICAL CARE

The routine medical care of the newly born in this institution is of interest, especially in view of our laboratory findings. We were informed that twelve powders of 1 grain each of mercury with chalk are given to each infant, three powders daily for four days, and on the fifth day 2 drams of castor oil. Should the skin show any eruption, this treatment is followed by applying mercurial ointment, 33 per cent., in quantities approximately the size of the adult terminal thumb joint, on a linen belly-band. The baby is permitted to wear the same band for two or three days without changing; then the band is changed or the ointment renewed or discarded according to the response from the child. At the same time that the ointment is applied, or in those cases in which the infants have responded completely to the powders of mercury with chalk, syrup of ferrous iodid in doses of 5 drops three times a day is given in bottle feedings, for infants under 6 months of age. Over this period and, approximately until the age of 1 year the infant receives 10 drops three times a day in bottle feedings. At this age the infant is then transferred to a second nursery, in which he receives 5 drops three times a day in bottle feedings. Those not being bottle fed in this nursery do not receive the syrup of ferrous iodid. The older children, that is, those from 2½ on, receive no routine medication.

The symptoms which determine the mercury ointment treatment—for it must be remembered that the twelve powders of mercury with chalk are indiscriminately given to every child who is admitted into the infant nursery—are peeling of the skin and bleeding from these excoriations of the skin, especially of the heel, blisters on any part of the body, and snuffles. The skin manifestation of the heel seems, according to the attendant, to be the most prevalent symptom.

## CONCLUSIONS

1. The Wassermann reactions and luetin tests were shown to have been performed accurately, as was proved by the controls made.

2. The negative Wassermann reactions in every case investigated may be explained by the intensity of the treatment to which each child had been subjected, or it may be that the bloods had not yet become positive.

3. The luetin test in this series proved of greater value as a diagnostic measure than the Wassermann reaction in detecting cases of congenital syphilis, and the clinical findings were of greatest value at that time when the value of the luetin was at its minimum, namely, in the first few weeks.

4. The effect of the iodids on the luetin reaction was again shown in this study. The lesion is characteristic and cannot be confounded with the normal positive luetin reaction.

5. Because of the ages of those examined and the character of the institution, this investigation afforded an excellent opportunity to study the various available means of detecting the existence of congenital syphilis. Seventy-four and six-tenths per cent were infants up to the age of 2 years, of whom 41.6 per cent. were under 1 year of age.

6. Congenital syphilis was found to be relatively more frequent in the illegitimate than in the legitimate children.

7. Of course, this series does not constitute a fair criterion for a comparison of the Wassermann and luetin reactions. It does, however, afford a good idea of their relative values in connection with congenital syphilis at this time of life.

It must be remembered that the mortality from congenital syphilis is very great, and that those cases in which the earliest ravages of the disease are escaped are those of less severe infection, or are those in which the patient has been partially or thoroughly treated. This study, therefore, we believe to be a fair test of the relative merits of the two reactions under these circumstances.

8. The existence of skin eruptions of syphilitic origin in cases in which both Wassermann and luetin reactions were negative is of decided interest, and further emphasizes the necessity of employing all available means, including complete physical examination and laboratory tests, before deciding a case to be syphilitic or nonsyphilitic.

9. The skin eruptions were more frequent the younger the subject. This was especially true of the syphilitic skin eruptions; twelve of the total of twenty-two instances of it were found within the first three months of life. Ten cases of positive syphilitic skin eruptions were detected at this time in which the luetin reaction had been negative. The syphilitic skin eruptions seemed to be of greatest diagnostic value at that time when the negative laboratory tests are most likely.

10. With very few exceptions, all of the inmates of the institution were below the normal averages in weight, height, development and nutrition. This is of interest in view of the constitutional background of the inmates.

11. Enlarged livers, spleens and glands appeared to be the most constant of the clinical evidences of congenital syphilis.

12. The infrequency of the other clinical manifestations of congenital syphilis in this study, such as

snuffles, fissures, wig, and scaling palms and soles, may have been influenced by the system of routine treatment in vogue in the institution as the cases were not followed by us from birth.

13. The incidence of congenital syphilis in this institution, as revealed by the study, was 83.96 per cent. Seventy-nine cases, or 74.53 per cent., were shown by means of the luetin reaction and ten cases, or 9.43 per cent., were shown by the clinical findings, revealing syphilitic skin eruptions. Many of the other cases classified as doubtful or negative had certain of the clinical symptoms of congenital syphilis, but not sufficient to warrant a positive diagnosis.

## ABSTRACT OF DISCUSSION

DR. WALTER R. RAMSAY, St. Paul: Some interesting comments have been made on a series of cases under the Wassermann test in an article published about a year ago. I have looked into this matter and have found that we have been giving mercury in much larger quantities than is necessary.

Dr. J. McKey, Philadelphia: I am reminded of the practice of the late Alexander Buehler, who sent his patients for a Wassermann test to five different laboratories. He found three of the five absolutely unreliable.

Dr. LAURENCE DEBUYS, New Orleans: No dark field examinations were made in this study. There are many cases in which positive luetin reactions are obtained in which the Wassermanns are negative. When the Wassermann reaction was first employed, I made a study in a series of about 250 instances in which the blood of the mother and child were examined. There were nine irregularities in this study, namely, the mother positive and the child negative, or vice versa. When Noguchi introduced his luetin test, I was anxious to determine the relative value of this test as compared with the Wassermann, and made a comparative study. In this study as many of the old cases were secured as was possible, particularly those previously classed as irregular, and it was shown that where the Wassermann had been positive in either the mother or the child in the previous study, both gave positive luetins. In making the luetin test it must be remembered that the luetin must be injected intradermally and not subcutaneously. It was of interest to note the small size of the children investigated in the study presented today. While this work does not offer a fair comparison of the relative reactions of the Wassermann and luetin, it does afford a fair comparison under the existing conditions. It must be remembered that the mortality in syphilitic infants is very high, and it is possible to have a greater number survive if the most prompt and thorough treatment is instituted. It is possible, therefore, that in this institution where inmates are from that part of society which is least moral that many of these infants may have survived because of the most energetic treatment employed in this institution, and that the inmates were in an inactive state of syphilis, which is the probable explanation of the negative Wassermann. It should be borne in mind that the luetin reaction is an ally, while the Wassermann reaction reveals the existence of an active process. I believe the luetin test made properly is of value.

## Local Health Authorities Can Quarantine Infected Persons.

The supreme court of Nebraska in a recent case (Ex parte Brown, 172 N. W., 522) upholds the right of local health authorities to quarantine a person infected with venereal disease. A woman was arrested and on examination was found to be infected with a venereal disease. The health commissioner of Omaha ordered her to be detained in the detention home of the city for treatment until there was no further danger of communicating the disease. In a habeas corpus proceeding to secure her release from quarantine the court upheld the action of the health commissioner and denied the writ.—*Pub. Health Rep.* 31, 623 (July 25) 1919.

## TRANQUIL TRACHEOTOMY, BY INJECTING COCAIN WITHIN THE WINDPIPE\*

SIR ST. CLAIR THOMSON, M.D. (LOND.),  
F.R.C.S. (ENG.)

Professor of Laryngology, Surgeon for Diseases of the Nose and Throat, King's College Hospital  
LONDON, ENGLAND

As a general rule the opening of the trachea is accompanied by so much disturbance that there often ensues a scene which the elder dramatists would have described as one of "wild excursions and alarms." It is thus depicted by Clinton Wagner:<sup>1</sup>

The introduction of the knife, together with the flow of blood, produces violent reflex action. The larynx rises and falls spasmodically and very rapidly, and the use of a knife or scissors is fraught with danger. The operator at this moment has need of all his coolness and presence of mind. Blood will find its way into the trachea and lungs, and death on the table from asphyxia may suddenly take place.

Apart from the risk of such a catastrophe, I remember the days when, before opening the trachea, one had

to advise the audience to "take cover" behind the head of the operating table, as the cough started with the first entry of air into the windpipe frequently resulted in blood being shot out with such force that it bespattered the assistants, the walls and even the ceiling.

All this commotion can easily be avoided by the intratracheal injection of cocain in the way to be described. I acknowledge my indebtedness for the idea to Dr. Crosby Green,<sup>2</sup> who, in an article on "Thyrotomy for Cancer of the Larynx," describes how, before splitting the larynx, he injected a 1 per cent. solution of cocain through the cricothyroid membrane into the cavity of the larynx. He, it appears, is not in the habit of performing a preventive tracheotomy in this operation, and he makes no mention of injecting cocain within the trachea. If not the first to use it in tracheotomy, I think I am the first to employ it in England. This I did in the year 1913.

It is employed in the following way: An ordinary hypodermic syringe is charged with about 20 drops of a 2.5 per cent. solution of cocain. As soon as ever the tracheal rings are laid bare the syringe is grasped, as one does a pen, with the forefinger about 1 inch from the extremity of the needle, and with this the windpipe is sharply stabbed between two rings. The middle, the ring and the little finger of the operator's right hand

are resting on the neck, and they prevent the point from penetrating more than one-fourth to one-half inch within the lumen of the trachea. The cocain solution is injected into the cavity of the windpipe, from 5 to 15 drops, and the needle is sharply withdrawn.

The liquid in the windpipe at once gives rise to a slight, stuffy cough. It causes no spasm or distress; and as it trickles down toward the region which endoscopists know to be the sensitive spot of this area, namely, the carina at the bifurcation of the trachea, this tickling cough soon ceases. If there is no great urgency, ten minutes should be allowed to elapse, the time being occupied by clearing the front of the trachea, checking all bleeding, preparing the tube and so forth. At the end of that time, the incision can be made into the trachea and the cannula introduced, without pain, spasm or even the slightest cough, as quietly and smoothly as the original incision through the skin. The calm with which this proceeding takes place is in striking contrast to the agitated, hurried and often bloody and dangerous operation of former days.

I have used cocain of the strength of 2.5 per cent.

for the simple reason that a 5 per cent. solution is usually at hand, and it has been convenient to dilute it one half. In children, a 1 per cent. solution and 5 drops would be sufficient.

The method is employed with either general or local anesthesia. Local anesthesia is sufficient in adults when opening of the trachea is the only operation to be performed at one sitting. With procain used endermically and the cocain used in this way within the windpipe, there is neither pain, spasm nor coughing in performing a tracheotomy. A patient gets up from the table and walks back to his ward, to eat his usual meal.

I have records of twenty-five cases of laryngofissure in which this method has been used in performing the preliminary tracheotomy, and the numerous visitors to my practice have been able to see the calm which it secures. In these five years it has been used in dozens of cases of tracheotomy by myself, my assistants and the house men in King's College Hospital, with uniformly good results and no drawbacks.

It has not come my way to use it in children younger than 4 years, but, with the precaution I have advised, I think it can be safely employed. Nor have I had occasion to use it in sudden asphyxia—the "opération d'urgence." Most cases of extreme stenosis of the larynx ought to be provided against by a timely tracheotomy, and even when there is dyspnea, the few minutes entailed by this useful detail are more than compensated by the calm and security with which the operation can be completed.

64 Wimpole Street, W. I.

Injection of cocain within the lumen of the trachea.

## ABSTRACT OF DISCUSSION

DR. FRANK C. ROSE, London, England: This morning I received a letter informing me that I had been elected to honorary membership in this Association. I should like to thank you all very sincerely for that honor. I recognize, of course, that the honor is intended for the society in London of which I happen to be secretary at the present time. I should also like to thank the Fellows of this Association for the great kindness and generous hospitality that has been extended to the visitors from my own country and others. We have heard much of American hospitality, but the reality surpasses my expectations. For a number of years past we have realized that any young man who wishes to become thoroughly efficient in the practice of laryngology and otology must study what is being done on this side of the Atlantic. We have read the papers published, we have had opportunity to meet certain of the American workers in London, and it only added to my own desire to come over here and see for myself what was being done. And now that I have come and have had opportunity to listen to your discussions and hear the various papers read, and seeing some of your operators at work—in addition to the pleasure I have also a feeling of regret—regret that I did not come before; regret that this is my first visit instead of the second or third visit to this side. In this department the American surgeons have a great past; this meeting alone shows how important the present is, and I am convinced that in the future lies the most splendid era for American work in this and other branches of medicine and surgery. And on my return home I shall endeavor to impress as far as I can on my colleagues of my own age and standing, and particularly on the younger ones, how important it is that they, if they mean to perfect themselves in their own branch of work, make a visit to this side and see for themselves what is being done.

It remains for me to open the discussion of a paper which is not here. To hold a postmortem without a corpse is difficult. Only the title, so far as I am concerned, remains to discuss, and I wish to assure Sir St. Clair Thomson that I like his title. It is a very good title: Tranquil Tracheotomy. My feeling is that if the patient will be tranquil, and the surgeon will be tranquil, two of the most important factors for success are already present. In the matter of detail, my own feeling coincides with that of Sir St. Clair Thomson, that in approaching the trachea it is advisable and convenient to divide the isthmus of the thyroid. That has been my own practice for a number of years.

DR. FERNAND LEMAITRE, Paris, France: For eight or nine years I have been accustomed to inject cocaine in cases of tracheotomy exactly as Sir St. Clair has so well demonstrated. I may say that a tracheotomy done in this way is quite different from the ordinary tracheotomy we are accustomed to seeing. After the injection is made I wait a moment before beginning the tracheotomy, and I utilize this time in making the suture, in putting some catgut in, if necessary, and one or two stitches at the upper and lower part of the wound. Before the operation is quite finished, it seems we have forgotten one stage, and that is the opening of the trachea; but when this is done the operation is immediately finished.

DR. OTTO GLOGAU, New York: I first saw this method that Sir St. Clair described, the tracheotomy and the ligating of the isthmus, in the Bellevue Hospital about two months ago, and it is astonishing how easily the patients stand it and how little discharge comes from the trachea. I would also like to mention that in these cases the use of suction apparatus is advisable. It relieves the bleeding of the wound as well as the discharge.

DR. M. F. ARBuckle, St. Louis: I have had the pleasure of seeing several of these laryngeal fissure tracheotomies done, and it is marvelous to me. There is no cough, no excitement or worry.

SIR ST. CLAIR THOMSON, London, England: I am very pleased that this has been described before. I do not claim to be the Messiah of the subject, nor would I say that I am an apostle to the Gentiles, but I am very glad to spread the good news.

PHYSICAL RECONSTRUCTION APPLIED  
IN THE TREATMENT OF PUL-  
MONARY TUBERCULOSIS

FRANK BILLINGS, M.D.

CHICAGO

Physical reconstruction may be defined as continual treatment, carried to the fullest degree of maximum physical and functional restoration consistent with the nature of the disability of the patient, by the employment of all known measures of modern medical and surgical management, including curative, mental and manual work (in wards, workshops, schools, gardens and fields); physiotherapy (thermotherapy, electrotherapy, hydrotherapy and mechanotherapy, massage, calisthenics, gymnastics and the like), and sports, games and amusements indoors and outdoors.

The application of physical reconstruction in the treatment of soldiers disabled by illness and injury during the great war was a new policy of the Medical Department of the Army. The measure had a few advocates, some tolerant but doubtful friends, and many opponents in the medical department, including officers of the permanent military establishment and others holding temporary commissions.

The failure of many to recognize the therapeutic value of the measures enumerated is due chiefly to the fact that with the exception of the curative factors enumerated under physiotherapy (and of these electrotherapy, mechanotherapy and massotherapy have been too often exploited by unqualified people and by quacks), the medical profession as a whole has had little or no experience in the application of these additional forms of treatment of the sick and injured.

The profession has found no use for these curative measures because, as a rule, physicians and surgeons are satisfied with physical cure. The average physician rejoices when the patient with pneumonia has passed the crisis. Unless some unusual symptom attracts attention, he makes no investigation to ascertain whether the lungs and heart have regained normal function. The average surgeon is happy if his patient with a fracture of a long bone gets through without deformity or shortening of the lower limb, and the possible suit for malpractice is escaped. As a rule, he does not see to it that the function of the joints and muscles of the involved extremity are exercised and trained to restore function definitely.

Modern medicine and surgery must take heed of functional as well as physical restoration. The physician and surgeon must continue to have an interest in the convalescent patient and to prescribe the necessary measures in proper doses to insure restoration of function or to establish it as nearly as the nature of the disability permits.

The application of physical reconstruction in the treatment of the patient with pulmonary tuberculosis has been strenuously opposed by many conscientious and honorable physicians. The objections advanced are sound in the sense of the application of the measure embraced under physical reconstruction during the active and febrile stage of the disease. On the other hand, I maintain that, when indicated, physical and mental rest, even to the most absolute degree practicable, is as much a factor in physical and mental rehabilitation as physiotherapy, curative work or play when these agents are rationally called for.

Tuberculosis is an infection which, as a rule, is focal in character. The primary focus usually located in a lymph gland or glands is acquired, usually in childhood. Later in life the pathogenic agents take on added virulence, or the resistance of the tissues of the host to general or to wider local invasion is diminished or both conditions are present. The causes of increased virulence of the pathogenic invaders and the reasons for the lessened immunity of the host need not concern us in this discussion.

With more general invasion and involvement of the lungs, the course of the disease depends also on the degree of virulence of the invaders, including possible mixed infection, and on the degree of general and local tissue resistance of the host.

#### MEASURES THAT SHOULD BE APPLIED

Experience has shown that during the acute or active stage of pulmonary tuberculosis, rest as absolute as practicable is the best method of passive control of the disease. Unfortunately, with some patients the virulence of the invaders is so great that the most painstaking application of rest treatment does not prevent the involvement of new tissue and a final hopeless extension of the disease. We all recognize the advantages of pure night and day air, rational feeding, correct personal hygiene, including adequate nursing, proper sponge bathing, and the use of simple medication when needed during the active stage of the disease. The contention for and against the use of specific and non-specific antisera or antigens administered hypodermically or intravenously to increase the resistance of the host to the invading micro-organisms or to destroy the infectious agents is not germane to this discussion.

If the patient is fortunate, the active stage abates and in an indefinite time the patient reaches the stage of inactivity of the disease. The reward of improvement of the pulmonic disease by adherence to the rest treatment is associated, in the average tuberculous patient, by lessened tone of the tissues, especially of the muscles, and by relatively poor blood circulation. Inadequate blood and lymph circulation means lessened nutrition of the tissues generally, although the weight of the patient may not indicate it. Long physical rest begets mental unrest and discontent. In other words, the patient's physical disease is much improved, but the function of his mind and the circulatory and locomotor organs is far below the normal.

Until the blood and lymph circulatory organs function properly, cellular nutrition will remain low. Rationally we cannot prolong absolute rest beyond the active or febrile stage.

The second stage of treatment embraces alternating rest and *controlled* mental and physical exercise. Individual management is indicated throughout the whole treatment program. But in this second stage, the dosage of mental or physical exercise prescribed, and the frequency of the repetition, must be under watchful medical supervision. If the progress is favorable the bed rest periods become shorter and less frequent, and conversely the active period in chair and walk become longer and more frequent.

Now, it is during this transition period, between absolute rest and the ambulatory stage, or third period, of treatment that the wise physician will apply such physiotherapy as hydrotherapy and massage, and occupational therapy modified in kind and dosage to meet the needs of the individual patient.

The sponging with warm water and alcohol, admissible in the febrile stage, may become a sponge or spray bath in bed or in a chair, sufficiently cool or cold, to arouse physical reaction for the purpose of improvement of the lymph and blood circulation. Short periods of light friction massage of the extremities and, in permissible cases, of the skin of the trunk will also improve the circulation, the tone of the muscles, and the cellular nutrition.

Mental and manual occupational therapy should be applied as early as mental and physical activity is permissible. The problem is to divert the attention of the patient, by simple recreation, through reading, pictures, games, handicraft and the like, with a view to securing a genuine interest in the attainment of a worthy end. The end most certain to hold the attention of the patient and to claim his best efforts is his future vocation. Hence, the reading, the handicrafts, or the academic study chosen to occupy the patient, for the sake of diversion, should be of a character, if that is possible, which will lead by successive steps to the more purposeful training which he may take during the ambulatory stage of the disease. Chair and porch patients will be able to take increased periods of occupational exercise.

In addition to what may be termed purely diversional occupations, such as woodcarving and whittling, toy making, weaving, bead stringing and block stamping, the patient may take academic courses in English and other languages, including arithmetic, penmanship and the like, read textbooks on and practice stenography, typewriting, Morse telegraphy and radiotelegraphy, bookkeeping, banking, and the like.

If the application of these measures is properly controlled by adequate medical supervision, the recovery of the patient will be enhanced. The lowered morale incidental to homesickness, illness and discontent, with all the retarding influence of these factors on the improvement of the patient, will be overcome by rationally applied curative manual and mental work.

When the patient has reached the ambulatory stage, all of the measures embraced under physical reconstruction may be applied with benefit to the tuberculous patient. But medical supervisory control must continue. Hydrotherapy in the form of the simple overhead shower or the hand spray may be applied safely and with great benefit by alternating from hot to cold for short periods. Few physicians realize the benefit and the ease and safety of the applications of the alternating hot and cold shower or spray baths. It is inexpensive and self applicable. The blood is made to flush the whole body, and in consequence aids in washing out toxic waste material and in the improvement of muscular tone and general nutrition. Pulmonary ventilation is improved.

The end-result is equivalent to considerable active exercise, like gymnastics or walking, without the attendant fatigue of the latter. For those physicians who object to hydrotherapy in the treatment of the hospital tuberculous patient, let me advise them to try it out with patients who have reached the afebrile stage and who show no tendency to hemorrhage.

Likewise rationally applied massotherapy will justify the expense of the necessary qualified personnel to apply this form of therapy too often reserved for the wealthy patient.

In the ambulatory period, occupational therapy may be applied in more diversified forms, either prevocational or vocational. Shop and outdoor pursuits, especially the latter, are applicable to the ambulatory tuberculous patient. The academic and commercial courses may be continued, or shop and trade courses in motor mechanics, motor driving, engineering, electrical wiring and the like, or gardening, including greenhouse cultivation, farming and stock raising.

Controlled recreation in the form of graduated walks, gymnastics, calisthenics and games indoors and out has an important place in the treatment of the convalescent tuberculous patient.

When the tuberculous soldier has reached the stage of arrest or inactivity of the pulmonary disease, he may be discharged from the army. No physician possesses sufficient knowledge to judge the degree of virulence of the infectious micro-organisms that remain in the lung tissue or in the bronchial lymph glands, or the status or degree of immunity of the general or local tissues of the host, to renewed activity and further tissue invasion by the infectious agent.

For the patient with arrested tuberculosis in civilian practice, the conservative physician desires to maintain and to improve the resistance of the host to the unfriendly parasites, by attempts to have the patient follow a rational hygienic life and, if the bank account permits, to spend seasons characterized by inclement weather at resorts where favorable climatic conditions permit one to live comfortably in the open air.

These measures are correct and rational enough; but why not adopt measures of physical reconstruction at this period of convalescence which will so completely rehabilitate the patient that he will be practically immune to further active tuberculous disease?

It will be necessary and an economy to hold the dependent tuberculous patient, whose disease has been arrested, in public sanatoriums for a period sufficiently long to permit the application of the needed physiotherapy, curative work and play until the desired physical and functional rehabilitation has been effected. During this period, real vocational training may be utilized profitably as occupational therapy. Dr. Philip King Brown has demonstrated that efficient training in pottery and tile making insures permanent cure and lucrative jobs in industrial life, and that a sanatorium may become practically self supporting if sensible trade training in productive enterprises is adopted as curative work. Dr. S. Adolphus Knopf<sup>1</sup> has recently written and lectured on the important subject of prevention of relapses in cases of arrested tuberculosis among soldiers. I heartily concur in the principles and practice announced by him.

Physical reconstruction is especially applicable to the patient with arrested or clinically inactive tuberculosis, and should have wider application in the final hardening process before the discontinuation of individual medical supervision.

#### RESULTS OBTAINED

The results of the application of these measures in the treatment of disabled tuberculous soldiers in the military sanatoriums have been so beneficial that it is my belief that curative work, massotherapy, hydrotherapy and regulated play will be applied hereafter

practically, when local conditions permit, by all physiotherapists.

The number of tuberculous patients treated in the military sanatoriums from the beginning of the war to Dec. 31, 1918, was approximately 8,500.

The application of curative work was not applied in the treatment of soldiers suffering from tuberculosis as it was to the other types of disabled soldiers. The reason therefor was that two of the present sanatoriums were under course of construction, and were not ready for the reception of patients and for the application of measures of physical reconstruction until late in 1918.

All of the seven military sanatoriums utilized for the treatment of tuberculous patients have excellent facilities for the application of occupational therapy.

During April, 1919, there were approximately 6,000 tuberculous patients in the seven military sanatoriums. Of those who took curative work, 2,941 were occupied with the handicrafts and arts, 339 took ward academic instruction in languages and the like; 1,932 received training in commercial and professional subjects; in technical courses including carpentry, shoe repairing, motor mechanics, agriculture, gardening, stock raising and the like, and 725 utilized recreational play in and out of doors. The sum of these figures gives the total enrollment for the month. The total number of patients who took curative work was less than the last figure because some patients were enrolled in two or more curative work occupations.

Finally, it must be recorded that the almost universal testimony of the commanding officers of the hospitals, the ward surgeons, the educational personnel, and the patients is to the effect that curative work in wards, schools, shops, gardens and fields is of the greatest psychologic and material value in the treatment of pulmonary tuberculosis.

Tribute must be paid to the fine women who as reconstruction aides in occupational therapy made the ward training in the arts and crafts, in academic and commercial study, a success. The occasional misfit among them does not militate against the great value of their presence and service in the wards for the benefit of these disabled soldiers.

The chief of the educational service and the personnel of instructors have given wholehearted qualified service, splendidly cooperating with the ward surgeons in the work. A few ward surgeons have not subscribed to the principles involved. They are a small minority, who would become advocates probably of physical reconstruction under a favorable environment.

122 South Michigan Avenue.

**Prevention of Ill Health.**—An essential factor in any scheme for the improvement of the public health is the need for enlightenment of the people on health subjects. They must be taught how to live healthy lives; how disease in its early stages can be recognized, and how the spread of the infectious diseases can be avoided. Undoubtedly expenditure on education will be amply repaid by a saving in the cost of treatment of persons who have become ill through ignorance of how to keep well. No sanitary problem was ever solved by caring for its victims. Education may be provided either by a health bulletin, filled with trite sayings and striking pictures, issued periodically, containing in pithy language essential points in the prevention of ill health. Popular lectures should be given; and cinema films, dealing with health subjects, should be shown in the schools.—*Medical Officer* 22:52 (Aug. 16) 1919.

## PROCTOLOGY IN A WAR HOSPITAL \*

LOUIS J. HIRSCHMAN, M.D.

DETROIT

When base hospital units were being organized to accompany the American Expeditionary Forces, I joined Unit No. 17 (Harper Hospital, Detroit) with the hope of being of service to the Army in a general way and, perhaps, having occasional demands made on my special knowledge of enteroproctology.

When our unit arrived in France early in July, 1917, we were stationed in the city of Dijon, the capital of ancient Burgundy. This city was located on the main railroad line over which the bulk of the American troops had to pass from the base ports to the training centers and fighting front. Many thousands of troops were encamped and billeted in the villages surrounding Dijon, and it was a very important center of the American activities.

A great deal of construction work was carried on; immense warehouses and depots for quartermaster, ordnance and the supplies of other departments were being erected by thousands of engineers and labor troops. Heavy work, continual drilling and training, coarse foods and inadequate latrine facilities were some of the factors which very soon indicated that in our hospital at least, the proctologic service would be not an inconsiderable one.

Before the Americans were actually in the trenches, the base hospitals, which had been established early, were fairly well filled with patients suffering from the ordinary diseases encountered in civilian activities.

The work of the medical staff was subdivided so as to render any special skill possessed by its members available for all patients who required it. My service, embracing abdominal surgery and proctology, consisted, during this phase of hospital activity, of the treatment of hernia, appendicitis, rectal and colonic diseases. The work was so classified that individual wards were devoted to each of these classes of disease.

The vast majority of cases of appendicitis were of the acute variety, many of which were suppurative and not a few ruptured. When one stops to recall that our patients were all young men of the age when appendicitis is most commonly found and their living conditions were such as to intensify any predisposition to that disease, the frequency with which appendicitis affected our boys was not unusual. Patients who were tired and hungry and had plainly been sick for some time before the seriousness of their condition was recognized, were taken off troop trains after a two or three days' journey from the sea port, in a box car, with a straw-covered floor.

Other patients, suffering from ruptured appendix and general peritonitis, were brought in by ambulance from camps from 30 to 50 kilometers distance.

The number of hernia cases was exceptionally large.

One could always tell when a new convoy of troops arrived from the United States by the flood of patients suffering from hernia and chronic hemorrhoids, who would arrive at the hospital in groups of from fifteen to fifty at a time. So many of these patients gave histories of long continued existence of hernia, hemorrhoids, or both, that it was perfectly clear to us that

somewhere in the chain of physical examinations in the United States there was a weak link or two.

Our acute proctologic cases consisted of thrombotic hemorrhoids, fissures, abscesses and impactions. It is interesting to note at this point that the rarest proctologic condition, with the exception of carcinoma, was that syndrome known as pruritus ani.

In the operative treatment of all cases of hemorrhoids, acute or chronic, fissure, polypi and most cases of abscess and fistula, the anesthetic of choice was the infiltration of 0.25 per cent. solution of procain. All patients were given an enema the night preceding operation, and this was repeated the following morning. A quarter grain of morphin and 1-150 grain of atropin were administered hypodermically forty-five minutes before operation. Skin sterilization was accomplished by the use of alcohol followed by iodine. The patients were placed in the exaggerated Sims position.

External thrombotic hemorrhoids were removed by infiltration, excision, evacuation of clots, and closure without suture. Prolapsing internal hemorrhoids were removed by the author's technic of high ligation and excision. Fissures were treated by incision or excision, depending on their extent and chronicity.

Abscesses, when very extensive, were sometimes punctured under local anesthesia, allowed to drain and contract for a couple of days, and then opened to their widest dimension.

Fistulas were incised if simple, or their tracts excised, if chronic or multiple. It is interesting to note in this connection that at one time I had under my care seven patients suffering from old chronic sinuses resulting from sacral or coccygeal dermoid cysts. All of these patients claim that the condition existed when they were still in the United States and that medical officers knew of the condition, but allowed them to go to France, nevertheless, and clutter up hospital beds needed for more urgent cases.

Our work was so well organized that we were able to handle our cases of rectal surgery with much expedition. Under local anesthesia, we handled four cases an hour in the operating room, and had the majority of our patients on their feet and in the mess line on the third day. Rectal patients do much better on their feet and outdoors, than lying around the hospital ward.

As the American forces took their places on the fighting fronts, the character of the work in an advanced base hospital, such as ours, took on a different aspect. All patients with hernia and chronic hemorrhoids were evacuated to hospitals nearer the sea ports and farther removed from front line activities.

The proctologic surgeon along with other specialists took over a certain number of general surgical wards, but in addition took special charge of all wounds involving the intestinal tract. All types of ammunition and projectiles were responsible for these wounds. Direct penetrating wounds of the abdomen, when the patient's condition did not contraindicate operation, called for laparotomy, location and closure of intestinal wounds.

In extensive tears of the intestine, it was found better in some cases to perform temporary enterostomy. In penetrating gunshot wounds of the rectum, simple cleansing and drainage of them sufficed. On the other hand, extensive lacerated wounds in which the sphincter was involved would call for temporary colostomy until the lower wound could be repaired, if at all.

\* Read before the Section on Gastro-Enterology and Proctology at the Seventeenth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

In wounds of the buttocks communicating with the rectum, it was occasionally found necessary to convert these into open or gutter-wounds. After irrigating for several days with surgical solution of chlorinated soda (Carrel-Dakin solution), we were able to accomplish secondary suture with marked success.

It might be mentioned in this connection that we were able to follow the same procedure with a number of our fistula cases. The use of the Carrel-Dakin solution, with daily bacterial counts in the surgical treatment of fistula, is a valuable addition to the treatment of this condition. It is surprising how a wound in this locality can be cleaned and kept clean if the Carrel-Dakin technic is carefully carried out. Secondary suture of fistula wounds will, I believe, become more commonly practiced when the employment of this technic becomes more generally known.

During several epidemics of dysentery, the proctologist became of great service to the internist in the differential diagnosis between the various types of dysentery and between these and other colonic diseases. Several cases of true amebic dysentery were recognized by smears taken from rectal and colonic ulcers and examined on the warm stage.

The possession of a sigmoidoscope by a medical officer skilled in its use was of great advantage to the base hospital with which this officer was stationed.

On account of conditions mentioned above, fecal impaction was frequently encountered. The use of 25 per cent. hydrogen peroxid enemas proved to be of the greatest service in their treatment.

As is well known, mustard gas burns were found most frequently in the region of the genitals and buttocks. The treatment of these cases fell to the lot of the proctologist. Alkaline baths, free opening of blebs and blisters, exposure to sunlight, which was one of our rarest therapeutic agents in France, and protecting with zinc oleate or stearate proved very efficacious in our hands.

As has been mentioned above, pruritus ani was one of the rarest diseases encountered among our troops. Pruritus ani is supposed to be caused by practically every disease affecting the anal region; but in spite of our large proctologic service, pruritus was a condition conspicuous by its absence.

Those soldiers who did complain of itching in the region of the rectum and who did not present evidence of parasitic infestation were found to be suffering from proctitis, fistula, fissure or ulcer. The indicated surgical treatment for these conditions very quickly cured the pruritus.

In all of our proctologic work, the employment of local anesthesia was the greatest single factor in lessening the length of a soldier's hospitalization. He was returned to his command in from one-third to one-half the time ordinarily required for convalescence from operations performed under general anesthesia. As every day saved in a soldier's absence from duty was of direct assistance in keeping up the man power of the Army, local anesthesia in proctology did its little bit in winning the war.

When a surgical team was sent from the base hospital to the front, medical officers representing all of the different specialties took their turn on the team. The proctologist was no exception to the rule, and on account of his experience in abdominal surgery, he served a very useful purpose. Whether called on to remove a piece of shell from the brain, to sew a lacerated pleura, to remove a tight tourniquet and save a

limb, or to perform the most delicate of intestinal repair, he always gave the best that was in him.

The attention to detail in after-care, which the surgical specialist is wont to give in his own special field, always stood him in good stead when doing his share of general war surgery in an advanced hospital unit.

After all, the proctologist, in whatever he did in the medical service during the war, represented only one class of specialist. They were all alike; although most of them were beyond the so-called military age, they were all willing and anxious to do anything in the realm of medicine and surgery to help win the war. Whether acting as interns or consultants, they were always medical officers in the Army of the United States, and always tried to be good soldiers.

#### ABSTRACT OF DISCUSSION

DR. ALOIS B. GRAHAM, Indianapolis: There is no essential difference between military and civil practice in the ordinary proctologic cases. The same fundamental principles that govern the one govern the other. It is very true, as Dr. Hirschman has said, that a surprisingly large number of proctologic cases occupied beds in base hospitals that could have been used to much better advantage in caring for soldiers suffering from gunshot wounds. We did most of our proctologic work in Base Hospital No. 32 under local anesthesia. In a few cases we employed nitrous oxid and oxygen. We also used a modification of Depage's anesthesia (ethyl chlorid, ether and chloroform) and it proved most satisfactory.

DR. D. C. MCKENNEY, Buffalo: Dr. Hirschman has covered the subject of war proctology very fully, and I agree with everything he said. There is absolutely no question that many men, who ought not to have gone, slipped into the army and were sent abroad with their rectal conditions not remedied. Each man so disabled took one man from the fighting front, besides requiring the employment of other men needed for other work to take care of him at some hospital. I saw very little constipation in the army and I am not sure that the squatting position during defecation, that was employed so generally all over France, had something to do with it. About the wounds, although many cases involved the rectum, an interesting observation was that with most horrible wounds of the buttocks, the rectum frequently escaped injury. Wounds that involved the rectum very often also involved the bladder, so that it was necessary to do a laparotomy and repair the wounds inside the abdomen as well as do a colostomy to allow the rectal wound to heal. Frequently it was necessary to add a suprapubic bladder drainage.

DR. JOHN L. JELKS, Memphis, Tenn.: A boy with an enormous mass of hemorrhoids, bleeding, oftentimes inflamed, passed the board A-1, went to France and fought and bled—but not from bullet wounds. Another man with a tuberculous fistula also passed the board. He was in the hospitals for months, an expense to his country, a burden to the shipping capacity, and finally, after months of no service, at an expense to his government, with loss of health to himself, he returned to Memphis, and I have been treating him ever since for the tuberculous fistula. These two cases illustrate how little attention is paid rectal conditions. I have known of several men who went into the army with infectious diseases of the rectum and colon. Not only were they an expense to the army but they were a menace to those with whom they came in contact. Therefore, I emphasize the importance of not allowing these men to go unexamined.

DR. DWIGHT H. MURRAY, Syracuse, N. Y.: In my address as retiring chairman of this section I recommended that a committee of five members be appointed, and a committee was appointed consisting of Martin E. Rehtanus, chairman, Dr. Dudley Roberts, Dr. William Gerry Morgan and myself. We went to Washington for the purpose of putting this thing before the army medical officers, and we did it. The final result was that thirty-two gastroenterologists and pro-

tologists were appointed. Dr. Graham was one of them. Some of them were proctologists, but most of them were gastro-enterologists, and one was assigned to each base hospital in this country. There is no doubt that the army could have done much better if it had appointed a proctologist with each gastro-enterologist.

DR. J. COLFS BRICK, Philadelphia: I wish to relate an instance which I think would be a proper basis for a plea that this society make in Washington, as a matter of record, in case of a future war, for the appointment of a reference board for the examination of rectal cases, and I will mention a case which I think will justify it. A man was passed in Class A and he was ready to go to camp when he made the statement to his physician that he had a marked rectal prolapse. The examining surgeon failed to locate any rectal trouble. The man came to me and I gave him an enema in order to demonstrate the degree of prolapse, and found a proctidemia. The rectal wall came out four inches, making eight inches outside of the anal margin. I gave him a certificate stating that this could be produced at will by giving an enema and having him bear down. The examining surgeon declined to accept it, still putting him in Class A, unless I would make an affidavit that he was unfit under military conditions, which I did. In other words, "he passed the buck." Now, it seems to me if this society sees fit to make certain recommendations to the authorities at Washington for the appointment of a reference board to determine the rectal conditions with reference to military service it would be apropos.

DR. A. CITARTIER, Sorel, Quebec, Canada: I cannot let this occasion go by without telling you the way we acted in Canada, especially on rectal cases. The instructions received by the examiners were that men suffering with rectal diseases, such as hemorrhoids and fistulas, should not be placed in class A; and, therefore, they could not go in the fighting line and become, if I may put it that way, a burden to the hospitals at the front. The men were placed in classes B, C and E, depending on the seriousness of the trouble. As for being in the trenches and unfitted for the work by rectal troubles, I believe that very few were there, because the medical boards all through our country had received instructions on the classing of men and the examination of the rectum was never neglected.

DR. J. DAWSON REEDER, Baltimore: In defense of some of the surgical records, I feel that perhaps a little injustice has been done us. I was a member of the Medical Advisory Board, No. 1, of the state of Maryland, and have been limiting my practice to proctology for at least ten years. I had nothing to do with the assignment, but was assigned as a genito-urinary expert on this board, and a gynecologist was assigned to make the general inspection, carry out the orders of the War Department, which included the inspection of the ano-rectal region. Some of the mistakes that have been presented here today were due to the faulty assignments in the various medical advisory boards throughout the country.

DR. LOUIS J. HIRSCHMAN, Detroit: If a criticism of the method of examinations seems to be implied in the paper it was absolutely meant as a criticism—not a criticism of the individual medical officer who did his bit, whether he did it on an examining board or whether he did it on the front line, but a criticism of our military methods. The War Department was warned by a committee sent by this section, as Dr. Murray has told you, and instead of heeding the warning given early they did not profit by it, and "by their fruits you shall know them." Every man who was in a base hospital in France will tell you the same story that I told you, that we had beds littered up with rectal cases that should have been taken care of at home. Class C men should have been made into Class A men by being operated on at home and then sent over, and they would have saved a great loss of man power. So far as our duty in the matter is concerned, it is very clear. It is up to us, in some way, shape or manner, perhaps through our delegate who represents the section in the house of delegates, to bring up some sort of a resolution calling the attention of the War Department to the fact that through our histories received from

patients we discovered that many of them were not examined at all for rectal diseases, and that those that were examined were examined very superficially. I have had officers tell me they were examined by sergeants who were not even medical men, and a note was made on the medical history. We should ask for a recommendation of this kind, that a proctologist should be appointed for each training camp for medical officers, and if he does not do another thing he should teach the medical officers the way to make a proper examination of the rectum and the reason for such an examination. By showing figures which can be compiled very easily from the Surgeon-General's report of the thousands of operations done in France, which should have been done at home, we can make our point. We can instruct men who are assigned to rectal operations how to do them, and in that way we can get some service for our men in the next war. In the British army the examination was very thorough. In the American army, however, we would not put a man with prolapsing hemorrhoids or any rectal disease even in Class B, because our Class B men were sent in the service of supply that had to do with supplies and transportation, and if you can imagine a Class B man with a big prolapse of the rectum carrying a big 100-pound sack of flour on his back, you will see he was working just as hard in the Class B service as in Class A. So I still maintain that the complete treatment and the complete relief of proctologic conditions should take place not anywhere near the zone of war, but at home before the men are sent away.

### CIRCUMSCRIBED PHLEGMONOUS GASTRITIS (SUBMUCOUS ABSCESS OF THE STOMACH)

REPORT OF A CASE WITH RECOVERY AFTER RESECTION OF THE STOMACH

EMIL NOVAK, M.D.

Instructor in Clinical Gynecology, Johns Hopkins University  
Medical Department

BALTIMORE

Phlegmonous gastritis is one of the rarest of diseases encountered by the abdominal surgeon. It is almost always fatal, and in only a very few cases have surgical measures been employed for its relief. Indeed, so far as I have been able to learn from a fairly thorough review of the subject, the case I am about to report is only the second in medical literature in which radical cure of the disease, by resection of the stomach, has been resorted to.

#### REPORT OF CASE

*History.*—C. E., a girl, aged 19, unmarried, who was referred to my service at the South Baltimore General Hospital by Dr. J. A. Miller of Baltimore, and whose family history was uneventful, had enjoyed good health, with the exception of frequent attacks of tonsillitis, up to the time of the onset of the present trouble. In January, 1918, she was operated on at another hospital for chronic appendicitis. At this operation, which was performed through a McBurney incision, the appendix was found to be very much adherent. The upper abdomen was not explored at this time. For about three years previous to her admission to the hospital, the patient had suffered with pain after eating, the distress coming on sometimes even while eating, and lasting from about one half to three quarters of an hour after meals. The pain was confined to the epigastric region, although there was said to be a slight "pulling" pain in the right iliac fossa previous to the operation for appendicitis. Following the operation, this pain in the right side disappeared, but the stomach symptoms above described still persisted.

For the six months previous to admission, pain in the epigastrium had been constant, although, as a rule, it was made

worse by eating. During this period there had been at least five severe exacerbations, with a great deal of pain, lasting usually about one week. Throughout the entire illness there had never been any nausea or vomiting. April 2, the patient was taken with sudden excruciating pain while on the street car coming from her work, so that she had to be taken home in a taxicab. Rest in bed and anodynes did not ameliorate the pain, and when the patient was seen, April 4, in consultation with Dr. Miller, the pain was so sharp that she could not move. There was a slight evening fever at this time, which continued until the patient was admitted to the hospital. April 7, when the evening temperature was 101. Her pulse, however, was normal.

**Examination.**—There was an oblique scar over McBurney's point. No tenderness was present in the lower abdomen. Pressure over the gallbladder region, even when very light, caused much pain. There was marked rigidity over the gallbladder area, and, indeed, over the entire epigastrium. A tentative diagnosis of cholecystitis was made.

**Operation and Result.**—The operation was performed, April 9. An incision was made in the right rectus, about 1 inch to the right of the midline, beginning a short distance below the costal margin and extending almost to the umbilicus. As soon as the peritoneal cavity was entered, the stomach, which was much distended with gas, projected into the wound. It was at once seen that the pyloric end of the stomach was the seat of a large tumor mass. The area of the tumefaction extended from the pyloric ring for a distance of about 2½ inches, being more marked along the lesser curvature than along the greater. The external surface of the stomach over the growth was covered with numerous adhesions, and showed also, along both curvatures, a chain of enlarged glands. The gallbladder was normal except for some adhesions which extended down to the region of the pylorus.

The whole pyloric mass was about the size of a lemon, and firmly adherent to the surrounding structures—transverse colon, pancreas, etc. The exact nature of the growth could not be determined from external examination. The general feel was exactly that of an advanced carcinoma of the pylorus. In view of the patient's age and also of the extensive inflammatory reaction, it was thought quite possible that it might, however, be an enormous gastric ulcer with extreme inflammatory reaction. At any rate, it seemed wise to attempt removal of the lesion by resection of the stomach. This operation was carried out with difficulty, owing to the extensive adhesions and the extreme vascularity of the tissues. The technic employed for the operation was that recommended by Balfour. The duodenum was severed and the distal end inverted. The proximal cut end of the stomach was then anastomosed directly into the side of the jejunum, the loop of bowel being carried up in front of the transverse colon. This part of the operation presented no unusual difficulty.

The patient left the table in good condition, the pulse being 96. Recovery from the operation was uneventful. The patient is now enjoying perfect health and is entirely free from digestive symptoms of any kind.

**Pathologic Report.**—The specimen consisted of the pyloric end of the stomach and about 2 cm. of duodenum, the length of the entire specimen being about 11 cm. The external surface of the stomach was covered with numerous adhesions. Along the lesser curvature was a thick fringe representing the greatly infiltrated lesser omentum. Several enlarged lymph glands were seen on both curvatures. On opening the resected portion of the stomach along the greater curvature, a tumor-like mass was seen to arise from the lesser curvature (Fig. 1). It was sessile, its base measuring about 6 cm. in length. From this, the tumor, which was somewhat pear-shaped, projected for a distance of 3 cm. into the lumen, so that it almost touched the opposite curvature. A small channel, however, measuring about 1 cm. in diameter, was left between the tumor and the greater curvature (Fig. 2). The surface of the tumor was perfectly smooth. The larger end, pointing toward the cardiac end, was rather plum-colored, while the mucosa covering the narrowed portion, extending toward the pyloric orifice, was pale and macerated. There was no evidence of gastric ulceration, the mucosa covering the mass being absolutely intact. The consistency of the tumor was soft, with an indefinite sense of fluctuation.

On making a longitudinal section into the tumor, it was seen at once that it contained a large cavity filled with thick, whitish pus (Fig. 3). The inner dimensions of the abscess cavity were 4 by 3 by 3 cm. The enveloping wall varied in thickness. Internally it was very thin and crustlike, while the floor of the abscess merged into the wall of the stomach, which was enormously infiltrated, measuring as much as 2 cm. in places. The inner lining of the abscess cavity was shaggy and necrotic looking.

**Microscopic Examination.**—Microscopic examination presented a striking picture. Beginning at the extreme cardiac end of the resected portion of the stomach, its wall was practically normal. As the abscess cavity was approached, however, it

was found that the submucosa showed increasing infiltration, with polymorphonuclear leukocytes and small round cells. This infiltration was intense immediately surrounding the cavity. The latter, it was easy to see, was developed in the submucous layer of the stomach wall, which seemed to be bifurcated, the mucosa and muscularis mucosae being raised to form the roof of the abscess, the muscular and serous layers forming the floor of the cavity. The immediate lining of the abscess wall was an irregular zone of inflammatory exudate, made up chiefly of leukocytes and round cells, the former predominating (Fig. 4). Along the floor, however, were broad areas showing beginning cicatrization, indicating the probable chronicity of the condition.

While the phlegmonous process was most marked in the submucosa, the infiltration extended also, to a certain degree, into the other coats. The mucosa overlying the abscess showed little change except a slight infiltration of the deeper layers and considerable hemorrhage in the superficial portions. The gland epithelium was normal in appearance. The muscular coats showed a considerable degree of involvement, especially in the form of clumps and chains of round cells extending along the lymph spaces.

Fig. 1.—Resected portion of stomach opened along greater curvature, exposing the mass, which is seen arising from the lesser curvature. At the left is the removed portion of the duodenum. Note thickening and infiltration of stomach wall.

## TYPES OF THE DISEASE

Types of phlegmonous gastritis are encountered in the literature under various names ("submucous abscess of stomach," "gastritis purulenta," "phlegmon of stomach," etc.). The designation adopted in this paper—phlegmonous gastritis—is the one most commonly employed, in spite of some theoretical objections. The disease occurs in two forms, the diffuse and the circumscribed. In the former, as will be described later, the phlegmonous process involves a greater or less extent of the stomach wall in a diffuse manner,

Fig. 2.—Seat of origin of growth and manner in which it infringed on cavity.

while in the circumscribed variety the disease is localized, with the formation of one or more abscesses. My own case is obviously of the circumscribed type.

**HISTORY**

According to Leith,<sup>1</sup> the first description of phlegmonous gastritis was given by Varandaeus as far back as 1620 ("Tractatus de Morbis Ventriculi"). Other early reports were those of Borel ("Opera," 1656), Sand (1701), and Bonet (1700). It is interesting to note that all of these earlier observations on phlegmonous gastritis had to deal with the circumscribed variety of the disease. Indeed, it was not until 1839 that Andral<sup>2</sup> gave what seems to have been the first description of the diffuse type. From that time, cases of both varieties have been reported at intervals. In 1861, Raynaud<sup>3</sup> was able to collect twenty-one instances of both types, while, in 1907, Bovée<sup>4</sup> estimated that seventy-five cases of both varieties had been observed. More recent figures for the total number of cases, as given by Leith in 1910 and Jensen<sup>5</sup> in 1911, are 100 and 131, respectively. In an earlier paper, published in 1896, Leith<sup>6</sup> stated that references were to be found to thirty cases of the circumscribed abscess group. These figures, however, include quite a number of questionable cases, such as the one of Deininger.<sup>7</sup> To illustrate the variance of statistics on this point, Mayo Robson and Moynihan<sup>8</sup> were able to find only eleven undoubted cases of the circumscribed type up to 1904. It is certainly true, as has been stated, that not over 20 per cent. of all cases of phlegmonous gastritis are of the circumscribed variety, and it is doubtful whether the total number of authentic cases of the latter exceeds twenty, or at most twenty-five.

## PATHOLOGIC ANATOMY

Little need be said concerning the pathologic anatomy except to emphasize the fact that the seat of the purulent disease in all cases seems to be the submucous coat. The mucosa is, of course, hyperemic and mildly

infiltrated with inflammatory products, and may, as in our case, be more or less hemorrhagic. In some of the reported cases, one or more openings, usually very fine, have been found on the mucosa, overlying a circumscribed abscess, suggesting the appellation of "carbuncle of the stomach." The infiltrated submucosa is thickened, edematous, and usually a pale, yellowish white.

Microscopic examination reveals enormous numbers of polymorphonuclear leukocytes and round cells. In cases of circumscribed abscess, the purulent process is localized, with the formation of an abscess cavity of variable size. The mucosa and the muscularis mucosae are lifted away from the muscularis by the pus accumulation, as in the case I have reported. The muscularis is practically always the seat of at least a moderate degree of cellular infiltration, especially along the lymph channels. According to Leith, the serous coat is often unaffected. In my own case, however, as well as in a number of others, there had been an intense peritoneal inflammatory reaction, with widespread adhesions. The lymph glands along both the lesser and greater curvatures of the stomach may be much enlarged.

The pathology of this disease, its tendency to chronicity in certain cases, and the fact that the principal involvement is in the submucous coat suggest a possible relationship with linitis plastica. This disease, like phlegmonous gastritis, may be either diffuse or circumscribed, the latter type involving the pyloric region most frequently. Although these various facts are suggestive, no direct relationship, so far as I am aware, has as yet been traced between these two diseases.

## ETIOLOGY

The immediate cause of the disease is an infection of the stomach wall, the organism concerned being almost always the streptococcus. Mixed infection is not uncommon, the secondary organism being usually the colon bacillus. Just how the organism makes its

entry into the gastric tissue is still a point of discussion. Most cases are of the so-called primary or idiopathic type, only a few being secondary or metastatic, that is, consequent on such diseases as cancer, ulcer of the stomach, or puerperal fever. The streptococcus, according to the work of Lubarsch<sup>9</sup> and Dörnerberger,<sup>10</sup> is a normal inhabitant of the stomach, in spite of the

10. Dörnerberger: Jahrb. f. Kinderh. 35: 395 (quoted by Hermann).

presence of the slightly acid gastric juice. Whether the organism finds a portal of entry in some abraded or otherwise weakly resisting point in the gastric mucosa, or whether the infection is blood borne, according to our modern conception of focal infections cannot be stated in the present state of our knowledge.

The disease may occur at any age, the youngest patient in Leith's series being 10, and the oldest 85. It is far more frequent in men than in women, Oser<sup>11</sup> giving the proportion as eight to one, Leith as between three and four to one. Dietetic errors and alcoholic excess have been considered by some as important etiologic factors, but their influence is very questionable.

#### SYMPTOMS

In the great majority of cases, the onset has been quite sudden. Pain is perhaps the most prominent symptom, being present in at least 75 per cent. of the cases (Leith). It is usually described as pressing in character, but may be violent. It is located chiefly in the epigastrium. Not infrequently, however, it may be more marked on one side or the other, usually the right, as in our own case. Associated with the pain there is often much tenderness and rigidity, so that it is easy to understand why the picture may simulate that of cholecystitis. Vomiting is described as an almost constant symptom. Leube is quoted as saying that "it was absent in only one of the cases recorded, and even then there was a disposition to emesis."

It is interesting to note, therefore, that in my patient vomiting had not occurred throughout the entire course of the illness. The vomiting may persist throughout the malady, or it may cease after a day or two, perhaps reappearing with the onset of peritonitis.

Vomiting of pus is rare, but may occur. In one case, that of Deininger,<sup>7</sup> 0.25 liter (quart) of pus is said to have been vomited, recovery ensuing. The correctness of the diagnosis in such a case is obviously open to question. Fever is a common but not invariable symptom.

The later symptoms merge into those of the peritonitis which almost always supervenes. The pain spreads over the abdomen, the fever rises, the pulse becomes more rapid, the abdomen becomes tympanitic, delirium may occur, and the patient gradually succumbs.

#### DIAGNOSIS

From what has been said, it may be seen that it is perhaps true that, as Leith says, "we cannot hope to do more than guess at the diagnosis" of phlegmonous gastritis. In only a few instances (Chvostek, Dörbeck, McCaskey), not all of established authenticity, is diagnosis said to have been made during life.

#### PROGNOSIS

The prognosis is grave. Recoveries from the diffuse form of the disease are exceedingly few, and even in

these the diagnosis must remain open to doubt. In the circumscribed cases, it is conceivable that recovery may follow spontaneous evacuation of the abscess into the stomach. The occurrence of one or more perforations into the stomach is not, however, a guarantee of recovery, as shown in Koenig's case,<sup>12</sup> in which there were numerous fine openings through the mucosa, although the abscess still remained. I am convinced, however, that Koenig is correct in his belief that in a certain proportion of cases, phlegmonous gastritis, after an initial acute attack, may sub-side into a subacute or chronic stage, characterized by the formation of a definite, localized abscess, often simulating a neoplasm in its gross appearance. This I believe to have been

Fig. 4.—Above is the mucosa, showing slight infiltration and hemorrhage. Below this is the muscularis mucosae, while the abscess itself is within the submucous layer. Note intense infiltration with leukocytes and round cells. (Photomicrograph by Schapiro.)

the history in my own patient, which is indicated not only by the long clinical course but also by the evidences of beginning cicatrization detected on microscopic examination.

#### TREATMENT

In all except a few of the cases reported in the literature, treatment has been purely symptomatic. In one undoubted case of von Mikulicz, reported by Lenge-  
mann,<sup>13</sup> saline irrigation and gauze tamponade resulted in recovery. The patient in Leith's case was subjected to exploratory laparotomy, with irrigation of the peri-

12. Koenig, F.: Deutsche med. Wochenschr. 14: 631 (April 6) 1911.  
13. Lengenmann: Mitt. a. d. Grenzgeb. d. Med. u. Chir. 9: 76, 1902.

tonium, but death ensued. Gastro-enterostomy was also performed in two cases by Robson and Moynihan,<sup>8</sup> once successfully and once unsuccessfully. In Bovée's case,<sup>4</sup> in which the disease was of the diffuse variety and involved the pyloric end of the stomach, recovery followed incision of the diseased stomach wall and drainage by a rubber tube, which was tightly stitched into it.

I myself, however, have been most interested in the case reported in 1911 by Koenig,<sup>12</sup> because of its close similarity to my own. In Koenig's case, as in mine, the pyloric end of the stomach, when it was exposed at operation, appeared to be the seat of a soft tumor, like a medullary carcinoma, while there was an extensive inflammatory reaction in the peritoneum, with adhesions and lymphadenitis. Resection of the pyloric end of the stomach was performed by the Kocher technic, the patient making an uneventful recovery. When the resected portion of the stomach was opened, a raised abscess was disclosed, with numerous sieve-like openings. As far as I can gather from the rather brief description and from the illustrations accompanying the article, there was not the very distinct tumor-like appearance which characterized the abscess in my patient.

It would seem that, in the present stage of advancement of stomach surgery, the outlook in the cases of phlegmonous gastritis which will be observed from time to time will be less devoid of hope than it has hitherto been. This applies especially to the circumscribed form, which should be just as amenable to cure by resection as any other benign pyloric lesion. In my own case, pylorotomy was performed by the Balfour technic,<sup>14</sup> a modification of the Polya method.<sup>15</sup>

It may not be amiss to express the satisfaction I have derived from the Balfour operation in the small series of cases in which I have had the opportunity of using it. I have been impressed with its advantages over both the Polya operation and the Billroth No. 2, which I had used formerly. It is easier and quicker, and, as has been amply demonstrated at the Mayo Clinic, it is safer for the patient.

## HEMANGIO-ENDOTHELIO-SARCOMA OF THE LIVER

A DISEASE OF EARLY LIFE\*

JOHN FOOTE, M.D.

WASHINGTON, D. C.

In a recent communication not as yet published, I reported a case of hemangio-endothelioma of the liver in an infant, and cited four other cases previously reported. A study also of the histories of a number of so-called primary hemangiosarcomas of the liver in infants led me to the conclusion that some of these, at least, were really hemangio-endotheliomas and should be so classified. Because of gross and microscopic anatomic details found in the cases reported as sarcomas by Lendrop<sup>1</sup> and de Haan,<sup>2</sup> and despite meager histologic facts in the cases of Parker<sup>3</sup> and Bondy,<sup>4</sup> it is certain that all of these so-called angiosarcomas were really hemangio-endotheliomas of the liver, and should be added to the number of these rare growths reported up to the present time.

Because of the confusion in terminology, and since, according to Adami,<sup>5</sup> "the actively growing tumors of transitional lepidic character have also from this standpoint to be considered as sarcomatous," I suggested that all malignant hemangiomas of this type be called "hemangio-endotheliomas."

I shall briefly summarize the case which I recently reported.

CASE 1.—A boy, aged about 3 months, was brought to the hospital suffering from obstinate constipation and enlarged abdomen which the family physician thought might be due to an intestinal obstruction. There was nothing notable

in the past history of the infant, except difficulty in feeding and constipation extending over some weeks and accompanied by loss of weight. The abdomen was enlarged and distended, and a large mass occupied the liver region, 7 cm. below the costal margin in the mammary line and extending backward to the left till it reached the pelvic brim. The mass was soft, and no distinct or sharp outline could be felt. The child had not been jaundiced, and the mother had not noticed the enlarged liver till about a month before. An exploratory laparotomy was performed by Dr. Crook to relieve, if possible, any cause for obstruction. Nothing of note was found except a large, purplish, nodular liver, one of the cut nodules

Fig. 1.—Area of compressed tissue, containing lacunae, near edge of nodule;  $\times 106$ .

of which was bleeding freely. The infant died twenty-four hours later. The necropsy revealed a very large purplish liver, studded with nodules varying in size from that of a millet seed to that of a walnut. Some were confluent and all showed lighter under the liver capsule. Cut sections revealed these nodules consisting of a whitish ring with a dark red center throughout the liver. The liver, after hardening, weighed 750 gm. Histologic sections showed the liver cells degenerated and vacuolated, especially near the nodules. The interlobular septums were increased in size. The smaller blood vessels were choked with endothelial cells in multiple layers. The nodules were filled with these cells with large vesicular nuclei; also some nodules showed red blood cells and leukocytes. The larger nodules had areas of dense fibrous material around them made up of compressed liver tissue and in places containing lacunae. Mitotic figures could be seen in many of the endothelial cells.

Section of the other viscera showed no metastatic growths. A diagnosis of hemangio-endothelioma was made.

It is important to differentiate these growths which are recognized in the liver of the infant shortly after birth, from the malignant changes which occur in hemangiomas, especially of the liver, among adults. The condition we are now considering is distinctly a disease of early life since none of the patients reported have lived to be over 6 months old. The disease appears early and undoubtedly exists at birth. That a supposedly benign angioma may develop into the endothelial sarcoma type is proved in the case of the skin tumor cited by Dutton<sup>6</sup> and in Fischer's<sup>7</sup> study of three cases of hemangioma of the liver of an endothelial type found in adults. It is true that these adult growths

these adult cases seems to have reverted to an embryonic type, it is probable that in the rapidly fatal infantile type the endothelium has never wholly lost its

Fig. 3.—Beginning infiltration of blood vessels in interlobular septum;  $\times 450$ .

Fig. 2.—Degenerated liver tissue with septum, showing larger blood vessels without multiple layers of endothelium;  $\times 100$ .

primitive characteristics. This embryonic type of liver endothelium, retaining even an embryonic function of hematopoiesis, has been described by Borst and others, though not especially in this particular connection.

A striking peculiarity of these new growths is that in no case has metastasis been demonstrated. In 1899, Hewlett<sup>8</sup> reported a case which, though called a sarcoma of the liver, unquestionably belonged in the hemangio-endotheliosarcoma group. The history, gross anatomy and histology corresponded to the case histories already cited. Metastases in the lungs were described by Hewlett in the form of nodules of the same general structure as the liver nodules. Unfortunately, he did not offer any histologic detail of these lung nodules except as to fibrosis and thickening of the alveolar walls. It is quite possible that metastases might occur in hemangio-endotheliosarcoma of the liver, but proof is so far lacking, in marked contrast to the frequency of metastases in simple sarcomas. If the case just cited be added to those already reported, the total number of protocols will be ten—a number sufficient to summarize the main characteristics of these interesting growths.

SUMMARY OF TEN CASES<sup>9</sup>

*Family History.*—No history of malignant disease of the liver in parents was given in any case.

8. Hewlett: *Intercolon*, 3, J. Australia 4: 615-619, 1899.  
9. These cases include the five reported in Footnotes 1, 2, 3, 4 and 5, together with:  
Cherevinsky: *Arch. de physiol. norm. et path.* 6: 553, 1885.  
Bruchanow: *Ztschr. f. Heilk.* 20: 431, 1889.  
Vveder and Austin: *Am. J. M. Sc.* 104: 102-107, 1917-1913.  
Stern: *Arch. Diagnostics* 8: 72-73, 1911.  
Foote, John. In *Older Anniversary Volume*.

are similar histologically to the infantile type now under consideration; but while the endothelium in

6. Dutton, J. E.: *Liverpool M. Chir. J.* 184: 369-376, 1898.  
7. Fischer, B.: *Frankfurt Ztschr. f. Path.* 12: 399-421, 1913.

*Character of Labor.*—No peculiarities of note occurred during pregnancy or parturition.

*Precious History.*—Ten were breast fed at the beginning. All were well nourished, but developed digestive troubles and constipation later.

In seven cases, nodules were described as being seen throughout the liver. In only six, reports were made of the appearance of the nodules on section, and in all these the nodules were said to be dark red in the center and surrounded by whiter areas or rings. Three were described as having some confluent nodules.

*Histology.*—Six protocols describe multiple layers of endothelial cells in the smaller blood vessels, nodules packed with large round or oval cells with vesicular nuclei, with or without hemorrhagic areas. Seven also describe the effects of pressure in causing fibrosis around the nodules and degeneration of liver cells. In two the histologic details are incomplete or fragmentary, and a mere statement of the diagnosis is made in one case. Round cell infiltration of liver tissue is observed in every case, and in one a "fine cirrhosis" is noted.

#### SUMMARY

Summing up the information gained from a study of these cases, we may define hemangio-endotheliosarcoma of the liver as a congenital disease manifesting itself by an enlargement of the liver and some digestive disturbances within three months after birth, and caused by rapid and unrestrained proliferation of the endothelium of the liver capillaries causing the formation of nodules on the surface of and within the liver and a rapid and progressive increase in the size of that organ with a fatal termination usually before the sixth month as a result of pressure and obliteration of liver tissue. Jaundice and ascites are not usually observed, and metastases are not found. The liver is purplish, and is studded with nodules varying in size from that of a millet seed to that of an egg, some of which are confluent. These nodules are lighter in color than the surrounding tissue, and are also seen throughout the liver in cut sections to be dark red in the center surrounded by a lighter colored ring. Histologically the liver shows an infil-

Fig. 4.—Center of a nodule;  $\times 450$ .

*Date when Liver Enlargement was Noticed.*—In some cases, abdominal enlargement was not noted till the patient was brought to the hospital. In two cases the growth was noted at 3 weeks, in two at 6 weeks, in two at 10 weeks, in one at 12 weeks, in one at 15 weeks and in two at 16 weeks. In no case was the nodular outline observed by the mother.

*Special Symptoms.*—In addition to enlargement of the abdomen, all patients suffered from constipation, and one from vomiting. Disturbances of digestion occurred shortly before or after the third month.

*Clinical Course.*—Four cases were reported as anemic. In three, mention was made of undigested stools. In no case was any jaundice observed after the initial jaundice of the new-born had subsided. Five patients were submitted for treatment because of a discovered abdominal mass, one because of indigestion, one for constipation and vomiting, and three for constipation alone. One patient had angiomas of the skin. No abnormalities of pulse or respiration were noted. Ascites was not observed except in a case on which a laparotomy had been performed.

*Date of Death.*—One child died at 5 weeks, one at 7, one at 11, one at 12, two at 15, two at 16 and one at 24 weeks. In two cases exploratory laparotomy was performed. Progressive weakness and exhaustion was cited as the cause of death in seven cases.

*Metastases.*—No metastases have been demonstrated.

*Description of Liver.*—The smallest liver weighed 522 gm., the largest, 1,625 gm. The average in the six cases in which the specimen was weighed was 902 gm. All were described as purplish or dark red. Nodules showed lighter under the capsule in every case. In one, the nodules were described as "of all sizes"; in one, of "varying sizes up to a walnut"; in one, "pea to a cherry size"; in two, simply "covered with nodules"; in two, "millet seed to walnut sized"; in one, "millet seed to a marble," and in two, "pea to hen's egg" size.

Fig. 5.—Center of a nodule;  $\times 100$ .

tration of the more normal areas with small round cells. In places the liver cells are distorted, atrophied and vacuolated. The interlobular connective tissue is increased. The smaller blood vessels are choked with large endothelial cells, some showing mitotic figures.

The nodules are surrounded by a fibrous band of compressed liver tissue. In some places this fibrous band shows lacunae containing degenerated liver cells. The larger nodules are packed with large round or irregular cells with large nuclei, some areas resembling

Fig. 6.—Larger vessels show swollen endothelium, smaller ones infiltration;  $\times 100$ .

myxosarcoma. Giant cells and polymorphonuclear leukocytes are also seen in some areas. Hemorrhagic areas are also noticeable in some fields.

1726 M Street N.W.

SOME UROLOGIC ASPECTS OF  
DERMOID CYSTS\*

WILLIAM C. QUINBY, M.D.  
BOSTON

Although in gynecologic and surgical literature and textbooks the varying clinical manifestations caused by dermoids are well known and frequently noted, it is only in rare instances that they are brought to the attention of the urologist. Such growths may at times, however, give rise to marked disturbance and involvement of the urinary tract, and it is to emphasize this fact that the following case histories are reported:

REPORT OF CASES

CASE 1 (7888).—*Dermoid cyst of the vesicovaginal septum, causing ulceration of the bladder with profuse hematuria.*

*History.*—A married woman, aged 25, entered the Peter Bent Brigham Hospital complaining of hematuria. She had had two children without any complications of delivery. Nine years before her entrance into the hospital, there had occurred occasional attacks of urgent urination. About one year previously, these attacks had become more severe, and at this time undue frequency of urination also appeared. There was a feeling at the end of micturition as if she still should pass water, but she was unable to do so. There was never any pain in the bladder. About two months before her admission, hematuria began, and at times the blood was

seen in clots. More recently, the bleeding had increased definitely in amount.

*Examination.*—The general physical examination disclosed nothing abnormal. Vaginal examination revealed a moderate sized cystocele and a slight lateral tear of the cervix uteri. Otherwise, the pelvic organs were normal.

Examination of the bladder by use of the cystoscope showed it to be normal except for an area 2.5 cm. in circumference situated on the left aspect of the trigon, just inside the internal urinary meatus. This area was raised above the level of the bladder, and the mucous membrane was irregular, eroded and ulcerated. In one or two areas there were hemorrhagic spots, evidently the source of the bleeding. In other areas there were extensive phosphatic deposits. The ureters were uninvolved and normal in appearance. Normal urine, free from blood, came from each. It was felt that this area in the floor of the bladder was probably neoplastic in origin because of (1) its long duration without other signs than those of bleeding, and (2) its tendency to necrosis with a deposit of lime salts. It seemed wise to advise excision of the area.

*Operation.*—The abdomen was opened, Dec. 24, 1917, by a vertical incision in the midline extending from the pubes to within 3 cm. of the umbilicus, the patient being in the high Trendelenburg position. Through this incision the intestine was walled off by gauze packs and the uterus drawn backward. The peritoneum was incised transversely at the level of its reflection onto the bladder, and the bladder separated from the anterior surface of the uterus by blunt dissection. There were no evident areas of neoplasm in this region. The bladder was then opened by a vertical incision made from above downward on its posterior wall, and the ulcerated area inspected. This was found to be considerably raised above the general surface as previously described. On ocular

Fig. 1 (Case 1).—Dermoid of vesicovaginal septum causing ulceration of bladder.

inspection, however, it did not look especially malignant. By extending the incision in the bladder wall downward, and by the aid of sutures placed over the edges of the cut to aid in traction, it was possible to surround the ulcerated area by an elliptic incision, cutting through all thicknesses of the

bladder. The area in question was thus excised. The bladder was repaired by interrupted stitches of fine catgut in a double row. It was found impossible to place accurately the stitches nearest the urinary meatus, and therefore this was left to be approximated from the vaginal approach. After closure of the bladder as high as its vertex, the peritoneum was sutured by a running catgut stitch, and a drain was left in the bladder to divert the urine. The abdomen was then closed in the usual manner by a continuous stitch for the peritoneum, interrupted stitches for the fascia, and silk for the skin.

The patient was then placed in the lithotomy position, and preparation was made to separate the anterior vaginal wall from the neck of the bladder. On following the transverse incision below the urethra, it was at once seen that what had previously been considered a cystocele was a dermoid cyst. This was excised and found to be filled with possibly 10 c.c. of material like yellow, thick cream. The wall of the cyst was excised and found to connect superiorly immediately with the area of the bladder which had previously been dissected. The bladder floor was closed over this incision by interrupted stitches, and after being sure that the wall of the cyst was entirely removed, the anterior vaginal mucosa was sutured with interrupted chromic catgut. A vaginal pack was put in place for twenty-four hours.

It is evident that we have here dealt with a chronic bleeding ulcer of the bladder, which was a complication of a dermoid cyst of the anterior vaginal wall, and was caused by it. Although the diagnosis was not made before operation, it seems probable that in this condition in the bladder would have responded readily to no treatment other than excision.

*Postoperative History.*—The patient made an uninterrupted recovery and was discharged on the nineteenth day after the operation. At this time, cystoscopy revealed a perfect healing of the bladder floor.

A recent note from the patient states that she is entirely cured.

*CASE 2 (10055).*—*Dermoid cyst of the ovary filling the true pelvis; communication with vault of bladder; severe cystitis.*

*History.*—An unmarried woman, aged 43, entered the Peter Bent Brigham Hospital, complaining of dysuria. Except for the fact that the patient had had an attack of "peritonitis" when she was 23 years old, the past history was essentially negative. Until four months before entrance, she had been entirely well. She then noticed suddenly that urination was painful, and the condition had persisted ever since. There was moderate frequency of urination, and the urine was turbid. There was never any hematuria, and there were no attacks of fever. During the month before admission, the bowels had become exceedingly constive. The patient also

noticed that she was losing weight. During six weeks preceding her admission to the hospital, the dysuria and frequency became more marked, and she was finally required to urinate at least five or six times at night. There had been a dull, intermittent, suprapubic pain for two weeks, and this was not relieved by emptying the bladder. Pain in the lower abdomen, on walking, had also been a late development.

*Examination.*—The patient was poorly developed and nourished. The only abnormality found was a mass above the pubes, rounded in outline with its base below, extending half way up to the umbilicus. Its greatest width was 11 cm. Palpation revealed a firm, moderately tender tumor which did not disappear on emptying the bladder. There was no tenderness in either costovertebral angle. When this mass was palpated by rectum, it was found to fill the whole pelvis and to cause marked downward dislocation of the uterus. On account of extreme tenderness it was impossible to determine the relations of this mass definitely.

The urine was cloudy, with a specific gravity of 1.017, and in the sediment were many leukocytes and small round cells. No blood or casts were found.

On cystoscopy, the bladder was found to be of slightly diminished capacity, and contained a considerable amount of thick,ropy pus. There was considerable infection in the region of the trigon. In the posterior upper portion of the bladder wall, just below its vertex, was seen an area, about 1 by 2 cm. in size, showing sloughy and irregularly hyperemic elevations and depressions, and surrounded by bullous edema. It was considered to be uncertain whether this area in the vault represented a definite penetration of the bladder or whether it was merely due to circulatory changes in the wall, due to adhesions formed between it and the pelvic mass.

Fig. 2 (Case 2).—Large adherent dermoid of ovary filling the pelvis and communicating with the bladder.

*Operation.*—March 6, 1919, with the patient in the Trendelenburg position, a linear incision was made from above the symphysis to the umbilicus, in the median line. The omentum was found firmly adherent in a large mass low just behind the pubes in the region of the vault of the bladder. Below this adherent omentum was a tumor mass with a roughly nodular surface, semifluctuant. On further exploration, this mass was found to be intimately adherent to all the pelvic structures. It was necessary to resect the omentum in order to lift it upward. This was done, cutting after tying off with sutures passed on needles. It was then found that the mass represented the right ovary, and that it was a dermoid cyst containing pulsatous material and hair. After enucleation from the posterior surface of the right broad ligament, firm adhesions to the sigmoid were encountered. These were cut after ligation and the mass lifted upward. On the extreme left it was not adherent, but above the fundus of the uterus and in front it was densely adherent to the bladder, and in separating these adhesions the bladder was inevitably entered, with the escape of some of its contents into the pelvis. The bladder was sutured, after removal of

the cyst, as well as might be, although it was quite impossible on account of the absence of peritoneum to make a satisfactory separation of the bladder from the peritoneal cavity. Following removal of the cyst, the pelvis was drained with one large ciregret tube, and the bladder drained by a self-retaining catheter in the urethra. The operation was exceedingly difficult on account of the density of the adhesions, and its duration was two hours. The patient's condition, however, at the end of the operation, was quite satisfactory.

**Subsequent Condition.**—Six days after the operation the following note was made:

"Since operation the patient has been showing increasing signs of intestinal obstruction. She has vomited at irregular intervals, which have grown more frequent. She has been quite unable to retain any nourishment and there have been frequent intervals when the pulse has been poor. She has had no fever at any time. The bladder condition has been fairly satisfactory. The catheter has drained well enough for the most part, although two days ago there were signs of leakage around the abdominal drain, and this was therefore replaced by a small sized tube. The output of urine has been only moderate in amount, but seems to have been sufficient. Today the abdomen is tensely distended, but there is no dullness to be found in either flank, although the patient is vomiting green bile. She is very weak and has typical abdominal facies. It is evident that in spite of repeated enemas and stomach washouts she is not making progress. Secondary operation is therefore necessary to relieve probable obstruction."

**Second Operation.**—March 13, 1919, under light anesthesia, the old incision was opened and the abdomen explored. No collapsed bowel could be found, all the bowel, large as well as small, being markedly distended. There was no purulent peritonitis present, although over the coils of the pelvis there were occasional bits of fibrin with adhesion. One coil of ileum was quite markedly kinked deep in the pelvis on the right side, and, after release, its gas was heard to move freely through the intestine. All coils of bowel which had become adherent in the site of the previous operation were freed, and a Mixer tube was quickly sewed into the cecum. This was led out from the abdomen through a small incision in the right lower quadrant. The pelvis was again drained with a deep ciregret wick and the wound closed in the usual manner.

From the second operation the patient did not rally, and death occurred about thirty-six hours later.

**Postmortem Examination.**—Paralytic ileus following fibrinous peritonitis was found at necropsy, together with necrosis of the posterior wall of the bladder, with cystitis, and cellulitis of the perivesical tissues.

This condition was undoubtedly the result of partial rupture of the adherent dermoid during its removal, with some soiling of the pelvis. The content of dermoid cysts is well known to have a toxic proteolytic action on any fresh tissue with which it comes in contact. In the peritoneum this action is marked and results in a nonbacterial adhesive peritonitis. Leakage of urine through the sutured area in the bladder probably played a very minor part in causation of the peritonitis, if leakage occurred at all, for at the second operation the suture seemed to be holding firmly.

**Examination of Dermoid Cyst.**—Gross description: The specimen consisted of a cyst about 7 cm. in diameter. The surface was rather bright red. There were numerous injected blood vessels. It felt boggy. Its contents consisted of a large mass of brownish hair mixed with a grayish yellow material about the consistency and general appearance of thin clay. The wall varied in thickness from 2 to 4 mm. It was quite fibrous, and anteriorly was covered with a very vascular granulation tissue on which was a layer of yellow necrotic tissue about 1 to 2 mm. in thickness. This could be stripped off, exposing a very vascular, roughened surface. From one place over an area about 2 cm. wide the growth of hair seemed to spring, the hair being intimately adherent to the wall by a red, fibrous pedicle. There were two or three areas where the wall was thickened and quite firm, and on section it was pale white and with the consistency of cartilage. A frozen section of this portion of the wall showed

it to consist chiefly of a hyalin framework in which there were numerous leukocytes and necrotic cells. A frozen section in another portion of the wall was seen to consist chiefly of granulation tissue. Smears of the yellow exudate showed necrotic leukocytes, necrotic cells and gram-negative bacilli.

**Microscopic Report:** There were three sections from various parts of the cyst wall. Lining the cyst was a thick layer of granulation tissue containing numerous giant cells and occasional small areas of necrosis. Beneath this layer the wall was composed of dense fibrous tissue which in great part was of a pale, hyalin appearance. There were numerous small abscesses in the wall with intense polymorphonuclear reaction and areas of necrosis. Many of the smaller blood vessels showed the changes of obliterative endarteritis and perivascular mononuclear infiltration.

**Diagnosis:** The diagnosis was: a dermoid cyst, with acute and chronic inflammation of the wall.

A third case illustrating in striking manner the action of dermoid cysts when causing renal colic is found in the recent report of Fagge.<sup>1</sup>

**CASE 3.—History.**—Nurse H., aged 27, complained one evening of dull "stomach-ache," which she had endeavored to treat with castor oil, but without success. The history she gave was that she had had scarlet fever in childhood, but no other illness of importance. The recent pain had been at first a diffuse abdominal pain. She had taken a dose of castor oil, and then, as the first dose had made her sick, she had taken another.

The physician who first saw her regarded the case as one of so-called gastritis, and gave her an anodyne; this alleviated the pain, and she slept fairly well. By the following evening, however, the pain had returned; it originated in the left loin, radiated to the left subcostal region, around the waist, and (a little later) toward the groin. It was of a colic-like nature, and accompanied by nausea, though not by actual vomiting. No tumor could be felt in the renal region, or elsewhere, and the urine was reported by the sister of the nurse's sickroom to be normal on chemical examination.

Renal colic due to calculus was suspected, and a roentgenogram was taken, which cleared up the diagnosis. Two teeth were to be seen very plainly at the level of the pelvic inlet—the root-canals could distinctly be seen in the original plate. Since the patient had not swallowed any teeth, it was evident that she was suffering from an ovarian dermoid cyst. Moreover, roentgenograms of the kidneys gave no evidence of calculi, so that the cyst was probably the cause of the symptoms, and not merely incidental.

The patient was transferred to a surgical ward. While awaiting the visit of the surgeon in charge, a sudden change occurred in her condition. She began to vomit violently and became distended and tympanic; in short, she showed not only signs of pressure on the ureter, but also those of intestinal obstruction. It should be remarked that prior to this attack of obstruction, she had suddenly passed an unusually large quantity of urine, suggesting that the renal symptoms which had predominated at the early stage of her illness were due to hydronephrosis—closed at first and finally opened.

**Operation and Result.**—In view of the sudden change in the patient's condition, a laparotomy was performed with the least possible delay; it was found that there were two ovarian cysts, firmly impacted in the pelvic brim. Both were multilocular, and contained hair and pultaceous material of the usual kind. The teeth were found in the right cyst, while the left cyst had evidently pressed on the pelvic colon and caused the obstructive symptoms. The left ureter showed no external signs of obstruction, but as some hours had elapsed since the discharge of urine, it is not surprising that no such sign was seen, and the absence of any such indication in no way controverts the diagnosis of hydronephrosis. The pelvic colon showed the usual signs of recent moderate

1. Fagge, C. H.: Bilateral Ovarian Dermoid Cysts Simulating Renal Colic, *Brit. J. Surg.* 6:468 (Jan.) 1919.

obstruction. Both cysts were excised. No trace of ovarian substance or of supernumerary ovaries could be seen macroscopically. Recovery was uneventful.

The further history of the case is not at present ascertainable, but it seems probable that complete amenorrhea will soon set in, with all the ordinary train of physical and psychic changes, for the girl's appearance, prior to the operation, was such as to suggest that her supply of ovarian internal secretion had long been deficient.

The main interest of the case centers in the unusually complete simulation of renal trouble at the start, and then the sudden transformation into a case of intestinal obstruction; and also in the rapid and certain aid to diagnosis afforded by the roentgen rays.

The teeth in the right dermoid were about as long and as thick as adult canines; the crowns were slightly flattened, and showed several little cingula near the top. Each tooth had a single root, though the apex of one of them was a little bent to one side. No trace of dental or bony matter was found in either cyst beyond these two teeth, though there were a few partially calcified areas in the debris.

## COMMENT

Such cases as these are illustrations of the fact that a dermoid cyst, frequently quite benign, may later take on characters of growth causing marked adhesion and even penetration into an adjacent viscus. When the bladder is thus involved or the ureters occluded by pressure, a knowledge of such characteristics by the urologist is all important.

## ABSTRACT OF DISCUSSION

DR. HUGH H. YOUNG, Baltimore: A man came to the dispensary of the Johns Hopkins Hospital some time ago bringing with him a small calculus that he had passed in his urine. It was attached to a hair. We cystoscoped him and found another calculus on the anterior wall of the bladder. It, too, was attached to a hair. As the patient was shaking, it would move back and forth like a pendulum, and it was very easy to trace it to a little opening on the anterior wall of the bladder, which very evidently had some pocket. He was not willing to go into the hospital then, therefore we caught this calculus with a cystoscopic rongeur and removed it, thinking that it might possibly cure him. In a few months he returned with another hair calculus. I did a suprapubic cystostomy and removed a pocket in the anterior wall which contained a very small amount of hair. Apparently he has been cured by this simple procedure.

DR. ARTHUR L. CHUTE, Boston: About two years ago I saw a case of dermoid of the ovary that had ruptured into the bladder. The patient, who had been having urinary distress with an infected urine, showed, on cystoscopic examination, a bladder that contained great masses of hair. A mass as big as my fist, filled with hair, was removed abdominally and the opening into the bladder was closed. The patient made a good recovery.

**Influenza in the Philippines.**—In the *Revista Filipina de Medicina y Farmacia*, Dr. Eugenio Hernando, the chief of the provincial division of the sanitary service of the Philippines, reviews the epidemic of influenza that occurred in the Philippines from June to December, 1918. The total number of deaths caused by the epidemic was 70,513. It is estimated that the disease attacked 40 per cent. of the total population of about 7,000,000, the mortality being about 2.5 per cent. of those attacked. The epidemic really began in June although it did not assume severity until October. The groups of ages that suffered most were those between 10 and 29 years. The disease did not seem to be imported, since cases were occurring before any ships arrived from infected countries, although after the importation of cases it assumed a more severe form. The June epidemic seemed to confer a certain degree of immunity during the second outbreak of the disease in October.

THE SIMULATION OF MENINGITIS  
BY INFLUENZA

FRED H. STANGL

Resident Pathologist, Cook County Hospital  
CHICAGO

In reports of the pandemic of influenza and its complications, reference has been made to toxemia and to the symptoms of shock and meningitis. Thus, Keeton and Cushman<sup>1</sup> mention the delirium observed early as well as late in the disease, and liken the shock to that following operations. They noted the engorged conjunctival blood vessels, so constantly seen in the acute exanthems, in a number of the patients suffering from influenza and pointed out the difficulty not infrequently encountered in differentiating influenza from meningitis.

Evidence of this systemic infection is also present in statements regarding toxemia and delirium in the reports made by Friedlander and his co-workers,<sup>2</sup> and by Snyttott and Clark.<sup>3</sup> Strouse and Bloch<sup>4</sup> mention one case, in the 500 studied clinically by them, at first suggestive of meningitis but with the spinal fluid unchanged except for increased tension. Nervous manifestations were observed in the patients suffering from influenzal pneumonia and also from uncomplicated influenza by Lyon and others<sup>5</sup> at Camp Upton. More recently Neal<sup>6</sup> has made this feature of influenza the subject of special consideration. She reports twenty instances in which she observed meningeal symptoms, headache, stiffness of the neck, positive Kernig sign, and extreme apathy, in patients convalescing from attacks which clinically appeared to be influenza. The spinal fluids in her patient's were negative in chemical and cytologic constituents with rare exceptions. Bloomfield and Harrop<sup>7</sup> and Alexander<sup>8</sup> have referred to the evidence of systemic infection in cases of influenza and have likened the onset to that of the acute infections and acute exanthems with constitutional reactions, such as headache, chills, fever, general aching, malaise, prostration, anorexia, nausea and vomiting. Generalized infection in influenza is also referred to by Le Count,<sup>9</sup> who states that it is difficult to ascribe death to the small amount of lung tissue actually pneumonic in many cases of influenzal pneumonia.

With these matters in mind we have reviewed again the records studied by Keeton and Cushman with the addition of those which have accumulated since their report, 3,400 cases in all, and find that nearly 1 per cent. of these patients had symptoms suggestive of meningitis or cerebral involvement. They varied

from slight neck rigidity and unilateral or bilateral Kernig reactions to deep delirium and marked rigidity of the neck, and in one case to opisthotonos. These cases, numbering twenty-nine, are conveniently considered in two groups: first, those in which a diagnosis other than influenza was incorrectly made as shown by postmortem examination; and second, those in which influenza or influenzal pneumonia was clinically diagnosed with meningeal complications which prompted the performance of spinal puncture. In each of the latter group the diagnosis was influenza or influenzal pneumonia complicated by meningitis.

TABLE 1 (GROUP 1).—EIGHT FATAL CASES FOLLOWING INCORRECT DIAGNOSIS

Case	Clinical Diagnosis	Total Days Ill	Total Hours in Hospital
1	Epidemic meningitis.....	24	48
2	Uremia.....	Unknown	17
3	Uremia.....	14	1
4	Uremia.....	Unknown	1
5	Tuberculous meningitis.....	10	23
6	Apoplexy.....	Unknown	2
7	Apoplexy.....	1	16
8	Polyarthritis.....	14	108

The eight cases of the first group were shown by necropsy to be influenzal pneumonia with diagnosis incorrectly recorded as follows: uremic coma, three; apoplexy, two; epidemic meningitis, tuberculous meningitis, and toxemia and septicemia secondary to polyarthritis, each one. In all of these patients active delirium or deep unconsciousness was present associated with rigidity of the neck, and positive Kernig and Brudzinski signs. The spinal fluid was constantly under increased tension, but the demonstration of globulin, albumin and increased cell counts was variable; the spinal fluids were sterile.

Among these eight cases, both early and late, involvement of the lung was found at necropsy. An instance of the early fulminating type is illustrated by the following case:

CASE 1.—An Irishman, aged 32 years, was brought to the hospital in a stupor and active delirium with an admission diagnosis of meningitis. Relatives of the patient stated that he had complained of soreness in his joints, headache and stiffness of the neck for two days. Bubbling râles were heard in the lungs, but nothing else of importance was demonstrated. The neck was markedly rigid, Kernig's sign was distinctly positive, and the spinal fluid was under increased tension but was otherwise unchanged. The clinical diagnosis was recorded as: acute polyarthritis with severe toxemia and delirium all out of proportion to the other manifestations of the disease.

Five days later the patient died, and necropsy was performed the same day. No changes were found in any of the joints of the extremities. The pia-arachnoid vessels were engorged; the spinal fluid was abundant but bacteriologically negative. The mucous membrane lining the larynx, trachea, bronchi and finer bronchioles of the left side was decidedly hyperemic. In the lumen of the trachea and left bronchial tree was a moderate amount of frothy mucopurulent material. The right lung was but little changed. The following description was made of the left: There is a large confluent subpleural, interlobar hemorrhage, 5 by 6 cm. in opposite dimensions, surrounded by many millimeter-sized petechiae on the posterior surface of the lung. There are similar hemorrhages; one, 1 by 1.5 cm. on the posterior surface of the upper lobe; two, 0.5 by 1 cm., and 2 by 2.5 cm., respectively, on the posterior surface of the lower lobe. The pleura is raised up over these. In the lower lobe there are nine irregular, dark brown regions firmer than the surrounding tissue adjacent to bronchi and in the periphery of the lung,

They are from 0.6 by 2.5 cm. to 0.6 by 5 cm. in size. There are four similar places having a maximum diameter of 1 cm. in the upper lobe.

Changes like these have been noted by others in acute fulminating influenza and called "hemorrhagic pneumonitis." They are mentioned by the British Medical Research Committee<sup>9</sup> and by MacCallum.<sup>10</sup>

Evidence of systemic infection, with active delirium and meningeal symptoms occurring in a late stage of influenzal pneumonia is illustrated by the subjoined case:

CASE 2.—A laborer, aged 41, was brought to the hospital in delirium with an admission diagnosis of epidemic meningitis and alcoholism. No areas of consolidation were found in the lungs. There was marked rigidity of the neck, and the Kernig and Brudzinski signs were positive. Spinal fluid was under moderately increased tension, the globulin tests were positive and the lymphocyte count was from 10 to 12. All cultures of the fluid remained sterile. The patient died at the end of forty-eight hours' stay in the hospital, and post-mortem examination was made a few hours after death. The brain was found to be very edematous and the spinal fluid increased in amount and clear. Bacteriologic examination of the fluid was again negative. The trachea and bronchi contained thick, green mucopurulent material which revealed an intense hyperemia of the mucosa of the air passages. There was no consolidation in the left lung. The pleura of the right lung on the posterior surfaces of the adjacent parts of the middle and upper lobes was raised, dark and firm. The lung underlying these areas contained two dark red, consolidated, liverlike regions, each 2 by 3 cm., one in the upper part of the middle lobe, the other adjacent in the lower part of the upper lobe.

In the second group are twenty-one cases (Table 2) diagnosed as influenza or influenzal pneumonia with meningism, the latter being made after negative spinal fluid examination. There are two types of cases in this group; first, thirteen patients with active delirium and unconsciousness and second, eighteen who were able to give a history and respond intelligently to ques-

tions. There were five deaths among the thirteen severe cases and but two deaths among the eight less severe. In all of the twenty-one patients, a rigidity of the neck was noted; in thirteen the Kernig sign was positive; in six the Brudzinski sign was positive and opisthotonos was present in one, a baby of 10 months, which later recovered. The tension of the spinal fluids of all these patients was increased and all

9. Abstracts of Foreign Literature by the British Medical Research Committee, J. A. M. A. 71: 1375 (Nov. 9) 1918.  
10. MacCallum, W. G.: Pathology of Pneumonia Following Influenza, J. A. M. A. 72: 729 (March 8) 1919.

the fluids were clear. The albumin and globulin tests were positive in one instance, but in no instance was there an increase in the lymphocyte count.

Postmortem examination was performed on the bodies of four of the patients in the second group. The changes were similar to those usually found in the later stages of pneumonia following influenza. The mucous lining of the air passages was acutely inflamed, and a thick mucopurulent material was present in the lumens; in the lungs pneumonia, lobular in arrangement, with much blood and a scarcity of fibrin was present. The brain and its membranes presented only edema and engorgement of the blood vessels.

#### SUMMARY

A severe toxemia and active delirium with definite meningeal manifestations such as is encountered in systemic infections and the acute exanthems occur in some patients suffering from influenza and influenzal pneumonia.

The clinical picture in some instances closely simulates that of an actual meningitis or other intracranial causes of delirium and unconsciousness, and post-mortem examination fails to reveal any inflammation of the brain or its membranes.

## HEMOLYTIC STREPTOCOCCI IN THE NOSE AND THROAT

WITH SPECIAL REFERENCE TO THEIR OCCURRENCE AFTER TONSILLECTOMY \*

M. S. TONGS, B.S.  
Intern, St. Louis Hospital  
ST. LOUIS

Since the epidemic of interstitial bronchopneumonia, either primary or secondary to measles, in the army camps of the United States, a new interest has been aroused in the hemolytic streptococci.

First, I wish to review briefly the most recent literature regarding the morphology and cultural characteristics of hemolytic streptococci in the throat of the healthy and sick, and then to present my results from cultures of the nose and throat with special reference to the occurrence of streptococci after tonsillectomy.

#### CULTURAL CHARACTERISTICS AND MORPHOLOGY OF HEMOLYTIC STREPTOCOCCI FROM THE THROAT AS DESCRIBED BY DIFFERENT AUTHORS

Andrews and Horden<sup>1</sup> isolated fifty-five strains of hemolytic streptococci from the throat in tonsillitis and scarlet fever, and according to Gorden's tests they were identified as *Streptococcus pyogenes* and *S. anginosus*.

Savage<sup>2</sup> also obtained from the inflamed and normal throats these two types of streptococci. In broth the organisms from the inflamed throat appeared in long chains and those from the normal throat in short chains. In experiments on goats<sup>3</sup> they failed to produce mastitis; hence he classified them as of the human type.

\* From the John McCormick Institute for Infectious Diseases, Chicago.

<sup>1</sup> This work was aided by a grant from the American Medical Association through its Committee on Scientific Research.

1. Andrews and Horden: *Lancet* 2:775, 1906.

2. Savage: *Rept. of Med. Officer, Local Govt. Board, London, 1907*, p. 359.

3. Savage: *Rept. of Med. Officer, Local Govt. Board, London, 1908-1909*, p. 294.

The organisms of the Chicago epidemic of septic sore throat in 1912 were studied by Davis<sup>4</sup> and Rosenow.<sup>5</sup> These streptococci were capsulated and appeared in pairs or in short chains. On blood agar plates the colonies were large, moist, and surrounded by a narrow, hemolytic zone. On the agar slants the colonies had no mucoid appearance.

The hemolytic streptococci in the septic sore throat studied by Hamburger<sup>6</sup> usually appeared as diplococci surrounded by "halo," but no capsule was demonstrated.

During the epidemic of tonsillitis in Massachusetts in 1912 and 1914, Smith and Brown<sup>7</sup> demonstrated two types of streptococci, namely Alpha and Beta, the former being surrounded by a zone of partial hemolysis and the latter by a zone of complete hemolysis.

During the severe infections with hemolytic streptococci at Camp Zachary Taylor, Alexander<sup>8</sup> isolated nineteen strains from the tonsils and forty-eight from the throat. On blood agar plates the colonies appeared small, round, raised and gray, and were surrounded with a wide, clear, hemolytic zone. They usually produced a sedimental growth in 1 per cent. glucose broth.

Davis<sup>4</sup> isolated several strains of hemolytic streptococci from the actinomycetes-like granules with a marked anaerobic property.

Keegan<sup>9</sup> recently described a type of hemolytic streptococci isolated from the sore throat which seems different from the ordinary *Streptococcus pyogenes* in cultural characteristics. On blood agar the colonies were large and moist, and on drying they tended to flatten out, sometimes showing radial lines or concentric rings. Hemolysis was not marked. Cultures in glucose broth gave at first uniform turbidity and then formed sediment at the side and bottom of the tube, the cocci being diplococci in short chains.

#### OBSERVATIONS ON THE OCCURRENCE OF HEMOLYTIC STREPTOCOCCI IN THE NOSE AND THROAT OF THE HEALTHY AND SICK

Cole and MacCallum<sup>11</sup> studying the prevalence of hemolytic streptococci in the throat found that thirty-nine out of sixty-nine patients in measles wards harbored this organism in their throats, whereas on admission only five out of forty-four gave positive cultures.

Levy and Alexander<sup>12</sup> found that 77.1 per cent. of measles patients admitted to the hospital were carriers of hemolytic streptococci, while the percentage of carriers among new recruits was very low—about 14.8 per cent.

Cunning, Spruit and Lynch<sup>13</sup> reported that 35 per cent. of measles patients and 6 per cent. of average

individuals were found to have hemolytic streptococci in their throats.

Nichols and Bryan<sup>14</sup> obtained hemolytic streptococci from the crypts of tonsils in 75 per cent. of the cases examined, and from the nose in five of nine cases, that is, 55 per cent.

Keegan,<sup>15</sup> studying the bacteriology of influenza, found hemolytic streptococci in the throat in pure culture in 4 per cent. and in mixed culture in 19 per cent. of influenza cases, and in 20 per cent. of convalescent patients.

Blanton and Irons,<sup>16</sup> from the swabbing of the throat and nasopharynx of influenza patients, obtained hemolytic streptococci in 34 per cent. of the throat cultures and in 75 per cent. of the nasopharyngeal cultures.

During the epidemic of influenza at Camp Sherman, Friedlander, McCord, Sladen and Wheeler,<sup>17</sup> studying cultures from the throats and nasopharynx, found hemolytic streptococci in only 4 per cent. of all the influenza cases.

Opie, Freeman, Blake, Small and Rivers<sup>18</sup> recorded that hemolytic streptococci were present in the throat in 22.4 per cent. of normal persons, in 1.3 per cent. of pneumonia patients, and in 3 per cent. of bronchitis patients. The incidence of hemolytic streptococci in the throat of measles patients was very low—about 2.7 per cent.—on admission, but later gradually increased to as high as 24.1 per cent.

Blanton, Burhans, and Hunter<sup>19</sup> obtained hemolytic streptococci from the tonsils of normal persons in 90 per cent. and from the depth of tonsils in 80 per cent. of their cases. Furthermore, they emphasize especially the number of streptococci in the individual throat. For this reason, they investigated the percentage of throats showing over 50 per cent. of hemolytic streptococci as compared with the other organisms on a plate. They found 11.4 per cent. in normal throats in the camp organization; 10.1 per cent. in normal throats among the laboratory workers; 47.6 per cent. from patients with upper respiratory infection; 42.8 per cent. from patients convalescent from pneumonia, and 30.1 per cent. from patients with empyema.

Smillie<sup>20</sup> found that about 50 per cent. of normal throats harbored hemolytic streptococci, but the Beta type of streptococci he found only once in the 100 normal throats studied.

After studying streptococci from scarlatinal and normal throats, Ruediger<sup>21</sup> concluded that hemolytic streptococci were present in 59 per cent. of the normal throats and constantly in abundance on the tonsils of patients with tonsillitis and scarlet fever.

Davis,<sup>22</sup> studying the bacteriology of tonsils from various diseases, presents his results as follows: Twenty-five of twenty-eight cases of arthritis, nine of

ten cases of nephritis, six of ten cases of endocarditis, and fifty of sixty-one cases of tonsillitis hypertrophy gave hemolytic streptococci in the crypts of the tonsils.

HEMOLYTIC STREPTOCOCCI IN THE NOSE AND THROAT OF DISPENSARY PATIENTS

Cultures have been made from the nose and throat of 567 persons on blood agar plates and studied. The presence of hemolytic streptococci of the Beta type is spoken of as a positive culture. Most of the patients were from the services of Dr. E. L. Kenyon and Dr. T. W. Lewis in the Central Free Dispensary, Rush Medical College. To them, I am greatly indebted.

*Technic.*—A sterile cotton swab was rubbed against the tonsils, the anterior pillars of the fauces, and the posterior wall of the pharynx in such a way as to avoid other parts of the mouth as much as possible. The nasal cultures were taken as follows: The nostrils were opened wide with a nasal speculum, and a sterile

cotton swab was then introduced into the nasal cavity as far back as possible and rubbed against the nasal mucosa. The swab was placed in a tube containing 2 c.c. of plain broth, immediately after a surface streak on a blood agar plate was made. With this broth another blood agar plate was made by the shake method in each case; this served to determine whether the hemolytic streptococci would be overgrown by other organisms on the surface streak. The blood agar plate was incubated at 37 C. and studied at the end of twenty-four and forty-eight hours' incubation. The number of hemolytic streptococci colonies, if any, was counted carefully.

The blood agar was made according to Becker's<sup>23</sup> standard blood agar method. From 4 to 5 ounces of plain agar were placed in a flask; this flask was heated until the agar was melted, and then cooled to from 45 to 50 C. Now 1 c.c. of the defibrinated goat blood was added to each 6 c.c. of agar. Approximately 7 c.c. were used for each plate. In the shake method, 1 c.c. of goat blood was added to 6 c.c. of melted agar in a tube at 45 C. This tube was incubated from the culture in broth, and the whole was thoroughly mixed and poured into a Petri dish.

Of 100 cultures made from the throat, sixty-seven showed the presence of hemolytic streptococci; of the nasal cultures, only five in 100 examined gave positive results. Of the 100 individuals, thirty-nine were school-children sent for examination by their schools, and thirty-two, or 80 per cent. of them, harbored hemolytic streptococci in their throats. Of sixty-one average individuals of this series, thirty-five, or 57 per cent., were found as carriers. The higher percentage of carriers among schoolchildren so far examined is probably due to the tonsillar hypertrophy, as almost every schoolchild examined had large tonsils (Table 1).

In my experience, the shake method is more reliable than the surface streak in detecting the hemolytic

streptococci. There were seven throat cultures that seemed negative on the surface streak plate but gave positive results by the shake method.

#### RESULTS OF CULTURES OF THE TONSILLAR SURFACE COMPARED WITH THOSE OF CULTURES OF CRYPTS

One hundred and twenty-five pairs of excised tonsils were examined. Before each tonsillectomy, an ordinary throat culture was made and placed in 2 c.c. of plain broth. The tonsils, after removal, were placed in 25 per cent. silver nitrate for five minutes. The tonsillar capsule, if any, was removed by a sterile knife. One or two loopfuls of crypt contents were taken and placed in a broth tube. Blood agar plates were made at once according to the shake method. The plates were studied after twenty-four hours' incubation and again later. The results are given in Table 2.

TABLE 2.—COMPARISON OF CULTURES FROM TONSILLAR SURFACE WITH THOSE FROM CRYPTS

Number of Cases	Positive Cultures from Tonsillar Surface		Positive Crypt Cultures	
	Number	Per Cent.	Number	Per Cent.
125.....	74	60	98	83

The outcome is quite in accord with the results of Davis<sup>22</sup> and Nichols and Bryan<sup>14</sup> in the United States Army, and Pilot's unpublished observations mentioned by Davis.<sup>21</sup>

#### THE INCIDENCE OF HEMOLYTIC STREPTOCOCCI IN THE NOSE AND THROAT AFTER TONSILLECTOMY

I have examined 342 persons, medical students and dispensary patients, to learn whether hemolytic strep-

tococci are as frequently present in the nose and throat after tonsillectomy as before. Of this large number of tonsillectomized persons only seventeen throat cultures and ten nasal cultures made in the way described showed hemolytic streptococci. In six cases positive cultures were obtained from both nose and throat. In five of the cases giving positive throat cultures, rem-

24. Davis, D. J.: Hemolytic Streptococci, J. A. M. A. 72: 319 (Feb. 1) 1919.

nants of tonsils were found on careful examination; and it is also known that tonsillectomy had been done from three weeks to five years before (Table 3). These results appear to agree with those of Blanton, Burhans and Hunter, Nichols and Bryan, and Davis.

In order to learn whether hemolytic streptococci may be present or absent regularly in throats with the tonsils removed, four tonsillectomized persons previously found to be carriers, and eleven also tonsillectomized persons known to be noncarriers, were selected

tococci in throats studied by different authors are the same strains.

CONCLUSION

The tonsils, especially when hyperplastic, are a breeding place for hemolytic streptococci, and complete tonsillectomy appears to be followed in most cases by the absence of hemolytic streptococci from the throat.

St. Louis City Hospital.

\* In cases 13 and 15, hemolytic streptococci were found in successive examinations, owing probably to tonsillar remnants in throats.

for subsequent examinations. The interval between the examinations varied from six to ten days. The result is given in Table 4.

CULTURAL CHARACTERISTICS AND MORPHOLOGY OF HEMOLYTIC STREPTOCOCCI FROM NOSE AND THROAT

Most of the surface colonies on blood agar plates appeared small, round, raised, moist and gray. They were surrounded at the end of twenty-four hours by a clear hemolytic zone, from 2 to 4 mm. wide. The deep colonies appeared in different shapes under the microscope: some were oval, some round with smooth edges, and others with irregular edges and nucleus in the center. Their hemolytic zone was usually narrower than that of the surface colonies. Three cultures from the throats of patients with acute tonsillitis produced large, flat, moist and gray colonies surrounded by a narrow hemolytic zone, but this characteristic was lost on subsequent cultures.

In smears from plain broth cultures after twenty-four hours' incubation at 37 C., all the strains were proved gram-positive. In some strains the cocci appeared spherical and in others elongated. There

INFECTIONS OF THE GENITO-URINARY TRACT COMPLICATING INFLUENZA \*

HENRY G. BUGBEE, M.D.  
NEW YORK

Medical literature for the past nine months has been flooded with reports and statistics relative to the influenza epidemic which has spread throughout this country and abroad. Complications involving the respiratory, circulatory and nervous systems have been recorded in large numbers, but little has been reported concerning the genito-urinary tract. One brief report<sup>1</sup> of four cases of focal infection of this tract is the sole contribution to date, other than references to the kidneys from a purely medical standpoint.

In a comprehensive review of the literature of the recent pandemic as it occurred in Europe,<sup>2</sup> it is stated that influenza recurs every twenty to thirty years in explosive waves spreading through whole continents, and that although twenty-seven years elapsed since the last pandemic, there has been neither an intelligent anticipation of the event nor certainty as to the true nature of the gigantic outbreak when it appeared.

A disease which causes such inroads on the community should certainly be studied in all its phases if similar outbreaks in the future are to be anticipated and a better knowledge gained of the complications and their management when these occur.

The teaching of the Pfeiffer school, that the Pfeiffer *B. influenzae* is the causative organism, and that the various non-Pfeiffer epidemics were not true influenza, was upset when Stephan, in August, 1917, described a diplococcus mucosus as the agent of a clinically typical epidemic of influenza which broke out in December, 1916, in Strümpell's clinic at Leipzig. It is not necessary here to trace the subsequent bacteriologic history of this protean disease. It is safe to say, however, that the entry of various cocci into the bacteriologic arena will more and more direct attention to complications and sequelae other than those affecting the respiratory system. It is in this connection that attention may be drawn to involvement of the genito-urinary system and clinical observations reported.

Medical reports mention a general hyperemic condition of the kidneys.

Blanton, Burhans and Hunter<sup>3</sup> hold that it is impossible to divorce a discussion of streptococic infection from such antecedent diseases as influenza, measles,

were nine strains of diplococci in short chains; the rest were arranged in long chains. All the strains were bile insoluble. In litmus milk all produced acid, and six produced a firm coagulation on the third day. Forty-five strains were tested for carbohydrate fermentation. The result is found in Table 5.

According to Holman's classification,<sup>25</sup> *Streptococcus pyogenes* ferments lactose and salicin but not mannite; *Streptococcus anginosus*, lactose but not salicin and mannite; *Streptococcus infrequens*, all three sugars. These forty-five strains, therefore, can be divided into these three groups according to their fermentation. Owing to lack of details of information it is not possible to say whether all these strains of hemolytic strep-

3. Blanton, J. B.; Burhans, C. W., and Hunter, O. W.: Studies in Streptococic Infections at Camp Custer, Michigan, with Special Reference to Influenza and Other Antecedent Infections, *J. A. M. A.* 72: 1520 (May 24) 1919.

and upper respiratory inflammations. Among other localizations of streptococci, these writers mention abscesses of the kidney.

Bradbury and Krumbhaar, in twenty-eight necropsies at No. 16 (Philadelphia U. S. A. Army) General Hospital, out of 533 cases of influenza, representing the height of the epidemic in that locality, found abscesses in the kidneys in two, among other lesions representing a general pyemia. The kidneys in other cases at necropsy showed dark congestion.

Sofré,<sup>4</sup> of Naples, in summing up the principal features of the epidemic, gives severe acute nephritis as a constant finding in fatal cases.

Dalmier<sup>5</sup> found, in a systematic daily examination of the urine, the presence of a large quantity of albumin in a high percentage of cases quite distinct from febrile albuminuria. He has seen numerous instances of acute and even hyperacute uremia in such cases, and is inclined to believe that the cases of acute edema of the lung recorded by Ravaut<sup>6</sup> were really examples of this kind.

A large number of cases of acute nephritis with well marked edema and dropsy among soldiers from the front, and also among civilians, have recently been studied by Dünner and Pupko.<sup>7</sup> As the cases were observed during an outbreak of influenza, this disease suggested itself to the writers as the cause of nephritis. In all the cases the patient's serum agglutinated *B. influenzae* in from 1:200 to 1:400. The influenzal etiology of the nephritis was rather supported by (1) its occurrence during an epidemic; (2) the exclusion of other well-known causes of nephritis; (3) the fact that the nephritis was recent, and not a recrudescence of an old process.

Lichtenstern<sup>8</sup> observed fifteen cases of vesical hemorrhage which occurred on the third or fourth day of the disease, lasted on the average three or four days, and slowly subsided. Examination of the bladder showed considerable swelling and injection of the vesical mucous membrane, apparently due to subepithelial ecchymoses. The amount of the hemorrhage was usually very great. In one case severe hemorrhage occurred on the second day, and it was necessary to plug the bladder. In three cases well-marked diminution in the urinary secretion took place, and was accompanied by severe pain in both loins. These symptoms lasted for twenty-four hours, and then the amount of urine gradually increased. In two cases unilateral pyelitis developed.

Stengel<sup>9</sup> states that renal complications were apparently infrequent in the epidemic of 1889 to 1890. No figures could be given as to the frequency of albuminuria and cylindruria, but it is quite certain that very few cases of actual nephritis developed. In the pandemic of 1918 albumin and casts were very commonly found in the urine, and seemed to Stengel to be

of little significance except when they were accompanied by other evidence indicative of nephritis. A few cases of acute hemorrhagic nephritis with pronounced uremic symptoms were observed in the series.

Of sixty-two urinary examinations made fairly early, Ely, Lloyd, Hitchcock and Nickson<sup>10</sup> found that twenty-six showed albuminuria and hyaline and granular casts; seven showed albumin only, and twenty-nine were normal. The kidneys, at necropsy, were found enlarged and congested, an edematous condition frequently being found about the suprarenals.

In a clinical study of influenzal pneumonia, Adolphus D. Rood<sup>11</sup> found that the kidneys presented nothing worthy of special note on microscopic examination. Most cases showed the urine of atoxic parenchymatous nephritis. The specific gravity was raised from 1.020 to 1.025 or 1.035, varying with its concentration. Albumin was found in nearly every case, and varied from a slight trace to 30 per cent. by volume, or even more. Rood considered its presence of prognostic value, although many patients recovered even with large amounts of albumin. Hyaline casts and cylinders were present in varying amounts, but usually disappeared toward the end of lysis, or shortly after the temperature had reached normal. The presence of granular casts indicated that the patient was very seriously ill, and with few exceptions, when showers of granular casts were reported, the patient seldom recovered. It was striking to note how quickly the urinary picture cleared after toxic symptoms began to abate.

Riesman<sup>12</sup> considered it a striking feature of the majority of cases, both good and bad, in the recent epidemic in Philadelphia, that there was free diuresis, probably connected with the abundant water intake and fairly efficient kidney function. Albuminuria was commonly present; no more, however, than is seen in other acute infections. In a few cases a true hemorrhagic nephritis, with marked albuminuria, dark and light granular and cellular casts, and abundance of free blood, was noted. Even in some of these the quantity of urine kept up very well. A not infrequent symptom, sometimes overlooked, was retention of urine with great distention of the bladder.

While the foregoing gives evidence that the kidneys in the severe cases are overwhelmed by the intense toxemia which is shown in other organs of the body, it is surprising that more local complications in the genito-urinary organs have not been recorded. It is possible that in the extremely severe cases the patient is so ill that the local signs or symptoms are masked or overlooked.

The changes, varying from acute congestion to renal hemorrhages and severe nephritis, certainly predispose to acute infection of the kidneys, and the fact that we have seen thirty-nine cases of definite infectious foci in the genito-urinary tract makes us feel that these complications have been unrecognized and that careful histories taken in the future will disclose the starting point in many lesions in the influenza attack.

In twenty-two of these thirty-nine cases, kidney infections were shown in one or both kidneys; in five, perinephritic abscess was shown; in four, prostatic abscess; in one, perinephritis and prostatic abscess; in six, epididymitis, and in one, seminal vesiculitis.

#### KIDNEY INFECTIONS

The kidney infections were as follows: right pyelonephritis in fourteen, left pyelonephritis in two, double pyelonephritis in five, right pyonephrosis in one. Nineteen of these patients were females, three were males. The ages were as follows: under 20, 2; 20-29, 2; 30-39, 8; 40-49, 2; 50-59, 6; 60-69, 2; total, 22.

Of these twenty-two patients, fourteen gave a history of no previous urinary symptoms.

Four of these fourteen presented prolapsed kidneys which drained poorly, and two were pregnant. In two, the right kidney was prolapsed and involved, in two others, both kidneys were prolapsed and the infection was bilateral. All of the remaining eight gave a history of pneumonia complicating the influenza, and were profoundly toxic.

The histories of the eight patients with previous urinary symptoms were interesting. In three patients, a nephrectomy had been done twelve, ten and five years previously. In each case there was a well-marked pyelonephritis in the same kidney, the opposite kidney not being involved, and in each case the kidney was low and in two cases it was freely movable, yet these patients state that they had had no local discomfort since the operation until the attack of influenza. The fourth patient had a ureteral calculus, but had had no symptom of kidney infection until seized with the influenza. The fifth gave a history of two attacks of hematuria, four and two years previously, and examination revealed polycystic kidneys. The sixth gave a history of two attacks, seven and three years previous to this one, which were similar in every way and which were apparently attacks of pyelonephritis. The seventh had noticed frequency for eighteen years, but had no local kidney symptoms. The eighth gave a history of painless hematuria for eighteen months. A papilloma of the bladder was found. Four of these eight cases gave a history of pneumonia.

These twenty-two patients with kidney infections were seen during the height of the influenza attack; or as late as six months afterward. From observation and the histories of these cases, the symptoms indicating a kidney involvement came on from four days to two weeks after the onset of the influenza, the average being nine days.

The symptoms were pain and tenderness in the kidney region; frequent, burning, painful urination, except in two cases in which the ureter on the affected side was occluded; high temperature, chills, malaise. In thirteen cases one or both kidneys could be palpated at the time of the examination.

Cystoscopic examination and ureteral catheterization revealed a very much injected bladder; distinct ecchymoses in six cases, moderate congestion in the others; poor drainage on the affected side in eight of the unilateral cases; pus and blood cells from the affected kidney, in each case, from both kidneys in the

bilateral infections; profuse hematuria in two cases, and deficient function on the affected side in each case. Nineteen cases showed casts in the urine.

Bacteriologic examination of the catheterized specimen revealed colon bacilli in twelve cases; staphylococci in three; diplococci in three; bacilli, reported as possible influenza, in three.

The cases of pyelonephritis were treated by catheter drainage, pelvic lavage, diet, colonic irrigation, and urinary antiseptics. The acute symptoms subsided rapidly. The uncomplicated cases have been cured; the others are improved.

The case of pyonephrosis necessitated a nephrectomy, and the case of ureteral calculus had a primary carcinoma of the kidney which had previously given no symptoms. This kidney was removed.

#### PERINEPHRITIC ABSCESS

There were five cases of perinephritic abscess, one a female, four males. The ages of the patients were 14, 21, 24, 31 and 46 years.

The patients presenting perinephritic abscess were all distinctly septic, having had severe attacks of influenza. Of the five patients, three had had pneumonia, two had other septic foci.

These patients were seen from seven days to four weeks after the acute onset, and the local symptoms, pain in the side and back, tenderness in the lumbar region of the affected side, had persisted from five days to two weeks when first observed. Each patient had a persistent temperature, three had chills, and in four there was distinct bulging in the flank.

One patient had frequent and painful urination. Cystoscopic examination and ureteral catheterization revealed no definite renal lesion in any case other than the urinary changes in acute renal congestion.

Incision and drainage was made in each case. In one case no pus was found, but the symptoms subsided at once.

Cultures showed streptococci in one, staphylococci in one, colon bacilli in one, and possible influenza bacilli in one.

All patients made a complete recovery. This was slow in two cases owing to the septic condition of the patient.

#### PERINEPHRITIC AND PROSTATIC ABSCESS

F. E., a man, aged 48, presented a perinephritic and a prostatic abscess. These foci were both well marked on his entrance into the hospital, four weeks after the onset of the influenza. His chief complaint, retention of urine, had been present for twenty-four hours. A large, boggy, tender mass was present in the prostate. Pressure on this bulging mass per rectum caused pus to exude from the meatus. Influenza bacilli and staphylococci were reported in the pus. A second bulging mass was palpable in the left costovertebral angle. Both foci were drained. The convalescence was slow, owing to the poor condition of the patient.

#### PROSTATIC ABSCESS

Four patients presented prostatic abscesses. The ages of the patients were 32, 44, 47 and 52. Two of these presented abscesses of large size, distinctly palpa-

ble by rectum, necessitating perineal incision and drainage; the other three presented one or more small foci distinctly palpable by rectum (a suppurative prostatitis), which drained by the urethra. These patients gave a history of the onset of the local symptoms ten, thirteen, seventeen and twenty-one days after the onset of the influenza. Two had pneumonia. Influenza bacilli were reported in one, staphylococci in two, and there was no bacteriologic report on the other two. Two of these patients gave a history of gonorrhéal infections eleven and fifteen years previously, but no urinary symptoms subsequent to that time until the onset of the present trouble. One developed a urethro-rectal fistula. All made good recoveries.

#### EPIDIDYMITIS

Acute epididymitis developed in six cases, from four to fourteen days after the onset of the acute influenza. The ages of the patients were 31, 36, 38, 44, 47 and 48. None of these patients had pneumonia or other complications. The epididymitis developed rapidly; the swelling became of large size, although not so large as gonorrhéal epididymitis; it was painful, and subsided slowly; the urine became cloudy, in four cases showing pus, in two cases, colon bacilli, in one, staphylococci, and in one, streptococci.

There was no venereal history of recent date, nor were there previous urinary symptoms in any of these patients.

#### SEMINAL VESICULITIS

A man, aged 51, developed violent frequency, tenesmus and painful urination, three days after the onset of a severe attack of influenza. These symptoms persisted, and when I saw him, two weeks later, the physical and urologic examinations were negative other than for the presence of large, boggy seminal vesicles. The urine was clear until pressure was applied over the vesicles, after which it became cloudy with pus. Colon bacilli were found in the expression. The condition was entirely relieved by local treatment.

#### SUMMARY

These cases bear out the present understanding of the disease, namely, that the system of the infected individual is overwhelmed by a toxemia so severe that the resistance of the several organs is reduced, allowing various organisms to become active. The genitourinary tract is not an exception.

These cases demonstrate that kidneys once the seat of a lesion, or subject to interference with drainage, are more vulnerable when the individual is attacked by a severe infection. This should lead one to study the kidneys more carefully, favoring elimination, especially when they are known to be pathologic.

Perinephritic abscess, prostatic abscess, and epididymitis may be a part of any hematogenous infection.

**Organic Heart Disease in Children.**—The importance of safeguarding the growing heart is shown by the large number of cases of organic heart disease among children. In New York it is estimated that 2 per cent. of all schoolchildren are suffering from organic heart disease. That all cases of organic heart disease in children are not due to rheumatic infection is brought out by a report made by Dr. Goodman in a series of cases studied in the Jacobi Ward in the Lenox Hill Hospital, in New York, where 80 per cent. of the cases were due to rheumatic infection, 16 per cent. to contagious diseases of childhood and 4 per cent. to developmental defects.—Dr. Julius Levy.

## ETIOLOGY OF EPIDEMIC (LETHARGIC) ENCEPHALITIS

### PRELIMINARY NOTE\*

LEO LOEWE, M.D.

AND

ISRAEL STRAUSS, M.D.

NEW YORK

In previous articles<sup>1</sup> it has been demonstrated that there is present in the nasopharyngeal mucous membrane of patients suffering from epidemic encephalitis a filtrable virus capable of producing in monkeys and rabbits lesions typical of those found in the brain in human cases. By the use of Berkefeld (V and N) filtrates of nasal washings and nasopharyngeal mucous membrane from fatal cases, we were able to develop in monkeys and rabbits the clinical and pathologic pictures of the disease.

In the second article it was stated that cultivation of all material on ordinary laboratory mediums was negative both aerobically and anaerobically. We further stated that the studies by the Noguchi method had been undertaken and were then in progress. We now wish to describe the results of the latter studies on the nasal washings, nasopharyngeal mucous membrane, and brain in both human cases and inoculated animals.

The methods used were identical with those employed by Noguchi<sup>2</sup> for the cultivation of spirochetes. A successful growth was manifested on the fifth to the seventh day by clouding of the mediums, commencing about the region of the kidney tissue and extending rapidly upward to within about 1 cm. of the top of the ascitic fluid column. At times extensive disintegration and autolysis of the tissue caused deceptive clouding. By means of dark-field illumination and examination of control tubes and stained specimens, the positive cultures were disclosed. The clouded tubes were all recultivated on ordinary laboratory mediums to exclude contamination. The growth in solid mediums appears as minute colonies, more numerous about the region of the kidney tissue. The optimal solid medium is of a gelatinous consistency, made so by the addition of 1 part of 2 per cent. nutrient agar to 4 or 5 parts of ascitic fluid, the kidney tissue being added as usual. All control studies were negative with both fluid and solid mediums.

Smears were stained with Giemsa solution or with methylene blue after preliminary fixation in methyl alcohol. The organisms appear as small, globular, purplish or bluish bodies. They assume different arrangements, occurring singly, in diplo forms, chains or clumps. Larger degenerated forms are seen in older cultures. On dark-field illumination they appear mostly as diplo forms and as masses. They are not motile. The reaction to the Gram stain depends a great deal on the medium used and the age of the individual culture. Young cultures and those grown on solid mediums are mostly gram positive. Older cultures and those grown on fluid mediums tend at times to be gram negative.

\* From the Pathological Laboratory of Mount Sinai Hospital, Aided by a grant from the Altman Fund of the Neurological Division.

1. Strauss, Hirschfeld and Loewe: *New York M. J.* **100**: 772 (May 3) 1919. Loewe, Hirschfeld and Strauss: *J. Infect. Dis.*, to be published.

2. Noguchi, Hideo: *J. Exper. M.* **14**: 99, 1911; **15**: 90, 1912; **16**: 199, 211, 1912. Flexner, Simm, and Noguchi, Hideo: *Experiments on the Cultivation of the Virus of Poliomyelitis*, *J. A. M. A.* **60**: 362 (Feb. 1) 1913; *J. Exper. Med.* **18**: 461, 1913.

As a whole, in morphology, appearance of colonies and growth, the organism resembles that described by Flexner and Noguchi<sup>2</sup> in poliomyelitis. It differs in results obtained with animals and particularly in the susceptibility of rabbits to this organism.

Up to the present time, the filtrable organism has been carried to the twelfth generation. It has been recovered from the brains of rabbits and monkeys injected with filtrates of human nasopharyngeal mucous membrane and of brains of inoculated animals. Monkeys and rabbits injected with the later generations (seventh to eleventh) of the organism, originally obtained from human mucous membrane and not previously passed through animals, have succumbed with typical symptoms. Necropsy findings and microscopic pictures are characteristic of those found in the human being. The organism was recovered from the brains, and, in a few instances, from the mucous membranes of the nasopharynx of these animals. Use of the later generations excludes the possibility of the transmission of sufficient original virus to produce any such results.

The organism was recovered from 50 per cent. glycerinated filtrate of human nasopharyngeal mucous membrane kept on ice for four months. The organism remains viable and virulent in cultures for a period of at least six weeks.

## OPEN AIR CLASSES \*

LEOPOLD MARCUS, M.D.

Supervising Inspector of Open Air Classes, Bureau of Child Hygiene,  
Department of Health  
NEW YORK

The Bureau of Child Hygiene of the department of health of New York City conducts only activities of preventive medicine. These activities cover a period of the child's life from the prenatal state until the completion of the elementary school. The activities are controlled by definite divisions of the bureau to cover various periods of life, as well as special activities. The division of baby welfare supervises the prenatal work and care of the infant from birth until the second year is reached. The division of midwives and foundlings issues permits to midwives and supervises their methods in carrying on their practice. It also issues permits for the privilege of keeping foundlings, and supervises the care they receive. The division of school medical inspection conducts a progressive campaign of preventive medicine throughout the year, both in the schools and in the homes of the pupils. The division of employment certificates issues certificates only to schoolchildren of correct age who are in physical condition to work. There is a division of eye clinics and a division of dental clinics which conduct their special branches of medicine exclusively for the benefit of schoolchildren.

The preschool age of the child, that is, from the second year until the child's entrance into school, is not systematically supervised. Some pioneer work has been done by our bureau, and the necessity and value of it have been conclusively proved. This period of the child's life can no longer be neglected, and one of the next steps in public health and preventive medicine will be the giving of more attention to it.

One of the activities of the division of school medical inspection is the medical supervision of the open air classes of the public schools. The pedagogic work of these classes is conducted entirely by the board of education.

The classes were organized to provide special opportunities for the physically subnormal pupils, after an experiment had been conducted in one class to ascertain the value of such organization. The results have been so gratifying that there are now 110 open air classes. The classes are at present located on the roofs of the school buildings, roofs of auditoriums, in public parks and in the school buildings.

Our experience has proved that in a large city these classes are best placed in the school building, in a classroom properly located and with the required structural changes. Besides, it is difficult to protect them from the rain, snow, direct sunlight and dust. Roofs require the climbing of too many stairs. Locations in the parks would be ideal were it not for the expense of the structures required. Besides, in our city, the parks available are so inadequate that only a small number of classes can be located in them. When the original school building is being constructed, very little additional cost is added by providing one or more open air classrooms. The board of education now provides at least one open air classroom in every new school building.

At present the following types of children are admitted to the open air classes:

1. Children exposed to tuberculosis at home, or in whose family there has been a recent death from this disease.
2. Children who have had tuberculosis which is now arrested or cured.
3. Children suffering from malnutrition.
4. Children who become tired easily or show languor or fatigue before the end of the day, and on this account are unable to carry on their class work.
5. Children suffering from nervous diseases except chorea.
6. Children who frequently are absent because of colds, bronchitis, etc.
7. Children suffering from cardiac disease, who are recommended by the private physician as pupils who ought to be put in these classes.

The classification provides for the tuberculous, pre-tuberculous and physically subnormal children who may be benefited by becoming pupils in one of these classes.

The regular equipment for open air classes consists of individual school study chairs, cots and sleeping bags. The study chairs are easily movable, and groups of any of the children can be formed for the convenience of the teacher. The children use their sleeping bags when sitting in their study chairs or lying on their cots.

The important factors in the success of this work are fresh cool air, light, food, correction of physical defects that retard growth and development, and proper hygienic living conditions. These are all provided for during the school session. But it must be borne in mind that the children are in school only five hours a day on school days and that we have about 190 school days a year.

During the school hours, the children are completely under control and receive the care they require. The classrooms have ample light and air, as they are always located where these can be provided. Our choice is always a southern and eastern exposure when these are procurable. We have found that the cold air

\* Read before the Section on Preventive Medicine and Public Health at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

is a decided advantage and that no temperature is too low, provided the children are properly protected by their clothing and their sleeping bags. The greatest increase in weight is always made during the colder weather. With the first return of warm weather, the increase of weight is retarded. This is, to a great extent, because of the influence of the temperature on the appetites of these children. Their appetites are always better in colder weather.

Food is one of the essentials for children of these types, and we have found that three meals a day are not sufficient to assist them to a normal average weight. Extra feeding is always provided between breakfast and lunch and, as far as possible, between lunch and supper. This extra food is absolutely required by the children during the colder weather, and they all anxiously await it. Milk and bread and butter are the best foods for them; but our funds, which all come from private sources, have been limited, and for the past year and a half we have had to rely on cereals and milk. All classrooms located in new buildings, as well as many in the old ones, have a separate kitchen in which to prepare the food.

The children whose growth and development has been retarded because of physical defects, such as adenoids, hypertrophied tonsils and carious teeth, respond very quickly after their defects are properly remedied. Though they would in most cases improve in regular classes after correction of their defects, the improvement is more rapid when they have the advantages provided in the open air classes. Nearly all of these children having physical defects improve while in these classes, but return to their previous condition rapidly if sent back to a regular class.

TABLE 1.—DAILY ROUTINE OF AN OPEN AIR CLASS

9:00 to 10:00 a. m.	School work
10:00 to 10:15 a. m.	Extra feeding
10:15 to 11:00 a. m.	School work
11:00 to 12:00 noon	Rest period
12:00 to 1:00 p. m.	Lunch period
1:00 to 2:45 p. m.	School work
2:45 to 3:00 p. m.	Second extra feeding

In school, the children have frequent short recesses for recreation. They have a rest period of one hour before lunch, during which time all children lie on their cots. Some learn to sleep during this period, but many merely rest. The daily routine followed in an open air class (Table 1) divides the day into three periods: two hours for school work, two hours for rest and lunch and, again, two hours for school work. We have the long rest period before lunch, as we have found that if we stop the school work after two hours to give the children a long rest, they do not become overfatigued. They recuperate rapidly, and by lunch time are fully back to their normal condition; and, furthermore, not being fatigued, they have good appetites, and derive the benefits which accrue from eating large meals.

Classes that are located on the upper floors have a rest period from 1 to 1:10 p. m. also. The time is deducted from the morning period of rest, and is given to afford the children a short rest after climbing so many stairs.

Parents are instructed to have their children rest at home before supper, and they are also urged to continue the morning extra feeding and to see that the children rest during the usual time on those days when the school is not in session.

The most difficult problem we have to contend with in a large city is that of the hygienic conditions at home. They entail a great deal of social service work, which, however, our teachers and nurses willingly do. This work may appear foreign to the subject, but it cannot be neglected, for all the results gained in school will avail nothing unless the home conditions are properly corrected.

From our present experience, I believe that the factors already enumerated are the important ones, and none of them can be slighted if success is to be our goal.

#### MEDICAL ATTENTION AND TEACHERS

The classes are visited daily by the school nurses of the health department. Their duties are definitely defined, and they work in cooperation with the medical inspectors and the teachers. The medical inspectors of the health department have full medical charge of these classes. They admit and discharge pupils, make regular systematic physical examinations of all pupils, and repeat the examination in any individual case as often as the child may require it. All the work of the nurses and inspectors in the classes and in the homes of the pupils is recorded on individual record cards for each pupil.

The medical inspectors decide the extent of physical exercise in which each pupil is permitted to participate. The department of physical training of the board of education supervises the exercises and play, and regulates them for each pupil according to the limitations ordered by the medical inspectors.

The scholastic work is entirely under the supervision of the board of education. The classes are limited to a registration of twenty-five pupils. As these pupils are usually in various grades, the group method of teaching is used. Only essential subjects can be taught.

Teachers of open air classes are specialists, and only those filling the required qualifications are selected. The qualifications considered essential are: good health; even temperament; capacity for doing a large amount of school work well, as a number of grades must be taught; physical ability to make home visits; tact in handling both children and parents; willingness to do social service, and a desire to study the problems of this work in the class by reading and taking an appropriate study course.

A poor teacher, or one not physically strong, is a great handicap to an open air class, as the success of the work rests to a great extent on her.

#### RECORD OF PUPILS

Children who are transferred from the open air class to a regular class are seen at least once a month by the

TABLE 2.—CASES DISCHARGED FROM OPEN AIR CLASSES

Gained Weight	Remained Same	Lost	Scholarship Improved	Same	Worse
319	43	5	70	292	5

nurse, who keeps a record of their condition, weight and scholastic standing. Of 506 children transferred, 367 were followed up, with the results observed in Table 2.

The effects on all pupils in the open air classes are shown in Table 3.

Those children who failed to gain in weight were suffering from physical defects of such marked char-

acter that it is most reasonable to attribute their failure to gain to this known cause. The children who failed at least to maintain their regular scholastic standings are mental defectives, as their previous records show. These children ought not be placed in open air classes, as it is impossible to give them there the attention they demand.

TABLE 3.—PROGRESS OF ALL PUPILS IN OPEN AIR CLASSES

Gained More Than Average	Average Gain	Less Than Average	Scholarship Improved	Same	Worse
2,131	796	79	718	2,198	90

We have one open air class with pupils of the usual average physical condition. This class has been conducted by the same teacher for five years, and the pupils, all boys, are in one of the grades of the last two years of the elementary school. It is a regular class placed in an open air classroom. All the work of their grade is covered. They have no coats, and only short recesses without a rest period. They do receive the morning extra feeding. They do their drawing and shop work in a regular classroom during the cold weather. All the rest of their school work is done in their own room, which is always at the temperature of the outside air. This class has a registration of forty-five pupils.

The observations made during the past five years, of ten separate classes, fully demonstrate many facts which are all proved by the records of the various classes. These results can be best summed up by drawing a comparison between the scholastic and physical records maintained in the open air classrooms and those in the regular classrooms of the same grades, as shown in Table 4.

TABLE 4.—STANDARDS IN OPEN AIR CLASS ROOM AS COMPARED WITH THOSE IN REGULAR CLASS ROOMS

	Pupils	Teacher
Scholastic Record	Work: Full work or more. Penmanship: Satisfactory. Application: Better . . . . .	Easier to get results. Less mental tax. Can cover more than prescribed course in assigned time.
	Progress: More rapid. . . . . Effort: Increased . . . . . Written work: Not handicapped. Absences: Decreased . . . . . Sickness: Lessened . . . . . Promotions: Higher Average. Less home work required.	
Physical Record	More active and responsive to work. Display ability and willingness to do more. Show an increase in weight more than the average gain. Show no fatigue from scholastic work.	Physical condition easily maintained. No loss of weight. Absences less. Daily fatigue not appreciable.

The improvement in the physically subnormal children in open air classes over those in regular classes is now a well established fact, and the only handicap is the number of such classes necessary. A great many more are required than are now provided for; but we are unable to use many more classrooms for only twenty-five pupils while there are so many part time classes in existence in our city. The open air classroom is still an experiment and must remain so until

we have ample school buildings to permit the organization of as many open air classes as are required.

OPEN AIR CLASS WORK FOR ALL PUPILS

Our experiment with a regular class in an open air classroom opens up another field, however; now that there is such an active campaign to improve the physical condition of the nation, there appears to us no better way to effect the improvement than by extending the use of the open air classroom to every schoolchild. If the routine can do so much for the subnormal, is it not natural to expect at least as much for the average child? To change to open air class work would naturally entail a marked reform in our school buildings and could not be immediately put into operation. But we do look forward to the time when we will strive to raise a hardy race and not hothouse plants. A building properly constructed would require no heat in any other classrooms than those used for manual work, such as shop work, designing, cooking, etc., provided the children were properly equipped to be protected from low temperatures. Such a step would be a great progress in preventive medicine. Any one who has the opportunity of visiting a regular and an open air classroom during the winter can readily decide for himself which one is conducive to growth, development and health. We look forward to the time, not far off, when we shall be able to conduct an entire school of normal children as an open air class school.

RESULTS

From the observations made so far, these results of open air class work can be enumerated:

1. Physically subnormal children improve in their mental and physical condition.
2. Their nutrition and weight improve.
3. The gain, in most instances, will be permanent.
4. In arrested cases of tuberculosis there are no relapses.
5. The nervous system is restored to a normal condition.
6. In cardiac cases pupils kept under proper medical supervision improve markedly.
7. The capacity for doing work is increased and brought to at least a normal average.
8. Absence from school on account of illness is greatly reduced.
9. A proper diet is followed, and the food is properly prepared.
10. Good habits are established.
11. Hygienic rules are lived up to.
12. Children learn how to do the right things at the right time.

It is our firm belief that average children will give even better results if afforded the same opportunities.<sup>1</sup>

ABSTRACT OF DISCUSSION

MISS ANNIE MORRISON, Grand Rapids, Mich.: I find that the dangers with the ungraded rooms are often greater than the dangers with the normal children in the realm of education. As to the personal guidance, when the abnormal children reach the age at which they go to work, between 14 and 16, is there any vocational guidance in New York for these children? We find that when the child in the ungraded room of the open air school leaves the school and goes to work, it ought to be guided, because it is not fitted bodily for the average work which is required of a physically fit laboring man or woman. Then, again, is any study given to the kind of work that the child afflicted with tuberculosis should be engaged in after the school age

<sup>1</sup> A detailed account of the method of conducting open air classes of New York City appeared in the Monthly Bulletin of the Department of Health, City of New York, October, 1918.

half hour is seated in a previously warmed bath tub the outlet of which is open. From a small tub or large basin water at a temperature of 90 F. is dipped with a broad mouthed vessel and poured with some force over the shoulders, back and chest of the patient successively. Begin with two affusions over each part, reduce the water temperature daily or twice daily when needed, until 65 F. is reached, then increase the quantity of water used. Dry the patient and send him out of doors. Good reaction is required, or at least an absence of chilliness after dressing. The water temperature is not increased if the patient feels chilly after dressing, but the procedure is made brief and is gradually restored in duration as reaction improves. In the beginning reaction may be promoted by friction, but the aim of all procedures for this neurovascular training is to evoke spontaneous reaction.

**Knee Joint Injuries.**—Thirty-two patients of the eighty-two whose clinical history was analyzed by McWilliams and Hetzel did not have a fracture. Eight had simple fractures, while the remaining forty had combinations of comminuted fractures, the patella being fractured in eighteen, the femur in twenty-nine, the tibia in twelve cases and the fibula in one case. Of seventy-three patients operated on for knee joint injuries, of whom final reports were obtainable as to infection, fifty-seven remained clean; in seventy of seventy-six known cases the synovial membrane was completely closed while six were drained into the joint. In general, Wilkess' treatment was not well carried out. Generally a splint was not used, except in cases where a fracture made it imperative but the lack of night nurses made active motion at night impossible and in the daytime the patient was left to make the motions by himself. There was no general system, even in the daytime, for forcing the patients to make active motions regularly. Even with this abortive plan, all the operators say that early motion gave excellent results, function having returned well in a short time. The too early evaluations sometimes stiffened the joints irremediably.

**Treatment of Recent Wounds of Knee Joint.**—Pool and Jones emphasize that in all cases of wounds of joints by projectiles, except certain perforating (through and through) wounds by bullets, operation should be done. The principles of conservative treatment are thus summarized: complete debridement of the tract of the projectile through the joint; absolute closure of the joint by suture; primary or delayed closure of the superficial parts according to the rules laid down for primary suture of the soft parts alone; finally, early active motion. Thirty-four cases are analyzed.

**Open Operation Through the Knee Joint.**—Open amputation through the knee joint, as opposed to open amputation through the lower end of the femur, Smith claims, offers the full range of advantages: Fresh bone and marrow cavity are not exposed to infection; there is opportunity for a longer, and in some instances an osteoplastic stump; operative shock is minimal.

**Correction of Deformity in Fractures.**—In Thomas' opinion the roentgen ray is not being used with sufficient frequency to determine the results of efforts at reduction of fracture deformity. He is convinced that sufficient use of it for this purpose would probably demonstrate that reduction of overlapping of fragments in fractures of the shafts of long

bones, without operation, is rarely accomplished. The contraction of the surrounding muscles caused by the irritation of fragments never relaxes until the muscle is permanently shortened by organization of the traumatic exudate which always infiltrates these muscles about the fracture. Probably no known method of extension can effectively overcome this contraction. Thomas claims that most fractures and dislocations of the upper extremity are probably due to falls on the hand. A dislocation is merely a fracture of the skeleton at a joint with displacement of the fragments. In a fall the upper extremity is interposed, palm down and elbow rigidly extended, to break the force of the fall, so that the mechanism by which the force is applied to it is essentially the same in all falls. The common and typical displacements in fractures and dislocations of the upper extremity can be explained more effectively by such a fracturing force than by the theory of the pull of certain special muscles.

**Pneumoperitoneum.**—From personal observation Dandy is convinced that perforation of the intestines or the stomach can be diagnosed by the roentgen-ray findings. The escaping intestinal gases accumulate under the diaphragm if the head is elevated. The roentgenogram shows the diaphragm and liver sharply outlined and a collection of air separating these structures. Localized collections of gas in the abdominal walls, the buttocks, etc., may betray a colon infection and therefore an abscess resulting from a perforated bowel. No intraperitoneal injections of air have been made in patients, although Dandy feels that the procedure is safe and should offer valuable information which may lead to correct diagnoses in obscure cases. By determining the exact shape, size and position of various abdominal structures, a big lead will be obtained not only as to the exact organ which is diseased but also as to the pathology of the organ involved. Many patients may thereby be spared a useless exploratory laparotomy by the disclosure of inoperable conditions, whereas others may be offered specific rather than exploratory operations, or a rational rather than an empiric form of treatment.

**Treatment of Infected Bone Wounds.**—Cotton reviews the work done in these cases at U. S. Army General Hospital No. 10, Boston. The good results obtained are credited to Carrel's technic and the use of surgical solution of chlorinated soda. Three hundred and forty-six patients were admitted. One hundred and eighty-two operations were performed. There was one death; a patient with empyema, who came in moribund, died before he could be operated on. There were two amputations, one for a hopelessly crushed and crippled leg with a septic knee, one deliberately after the wounds had been healed for a limb so badly damaged and paralyzed as to be worthless. There have been no reamputations, no resections and no cases of secondary osteomyelitis after the cleaning operation.

**Method for More Accurate Study of Injuries to Atlas and Axis.**—The principal object of George's method is to leave with students some fundamental facts: first, the study of the anatomy; second the variations from the normal.

\*Crusial Case of Granuloma Annulare. A. W. Stillians, Chicago.  
—p. 580.

\*Neurodermatoses and Pseudolichens. F. Wise, New York.—p. 590.

**Alkali Reserve in Skin Diseases.**—The authors confined their attention almost entirely to the inflammatory dermatoses. They examined 139 patients of whom eighty, or 59.7 per cent., gave normal values; fifty, or 35.9 per cent., gave values indicating a moderate acidosis, and one, or 0.7 per cent., showed a severe acidosis. This last patient had diabetes complicated with carbuncles. Included in this group were cases of sycosis, acne, psoriasis, eczema, pruritus, erythema nodosum, dermatitis herpetiformis, erythema multiforme and lupus erythematosus.

**Granuloma Annulare: Cure by Means of Radium.**—The odd features in Stillians' case were the entire absence of ringed lesions, the failure to localize on the hands, its occurrence in a patient who has a persistently positive Wassermann reaction, and its superficial resemblance to xanthoma. The administration of potassium iodid, 10 grains, three times a day, and mercurial inunctions, had no effect whatever on the lesions. Salicylic plaster, worn for forty-eight hours, made no impression on the lesions. Roentgen rays administered short of the erythema dose gave no result. The Kromayer lamp pressed on (without blue filter) long enough to cause a sharp reaction, had no effect on the lesions. Radium, filtered through 4 mm. of aluminum, cleared up the ankle and knee lesions promptly, but those on the elbows were stubborn, requiring a larger dose, which was sufficient to leave a scar in one spot, without clearing up the lesion entirely.

**Neurodermatoses.**—Wise discusses a certain peculiar morbid change in the skin, to which a variety of names has been allotted, the most familiar being lichen simplex chronicus, lichen chronicus circumscriptus, neurodermatitis, prurigo circumscriptum and pruritus with lichenification. He also makes a brief report of his own observations, based on clinical and microscopic studies.

**Investigation of Pediculicide Substances.**—A number of derivatives of cresol, preserving the general cresol structure, but diminishing the volatility, were experimented with by Moore and Hirschfelder to test their power to kill lice. The calculated amount of bromin was dropped from a separating funnel directly into glacial acetic acid containing the cresol and a small piece of bright iron wire as a catalyzer. Bromination, as shown by titrating a sample with potassium iodid and thiosulphate, was complete in less than one hour. The mixture was then neutralized, separated and filtered off, washed first with sodium thiosulphate to remove any excess of bromin or bromin that had entered the hydroxyl group, then with sodium bicarbonate and water and finally filtered or separated off. Chlorin was introduced by bubbling into the glacial acetic acid solution of cresol in the presence of iron wire until the calculated weight of chlorin had been taken up. The substances were otherwise treated in the same way as the bromin derivatives. Iodin was introduced in saturated sodium bicarbonate solution in the presence of potassium iodid. A series of monobrominated and dibrominated chlorinated and iodo cresols, orthocresol, metacresol and paracresol was thus prepared in which the halogen had entered the ring. By this mode of treatment the trihalogen compounds of the metacresol only are formed and not trihalogenated ortho and para compounds were obtained. Chlorin was also introduced into monobrominated metacresol and in this way a monobrom, monochlor and monobrom-dichlorometacresol was formed and in the same way a dibrom, monochlormetacresol. The substances which were found to be best suited to the purpose were the dibrommetacresol which lasted ten days and the dichloromonobrommetacresol which lasted thirteen days. These compounds seemed to fulfil the requisites of the problem so far as a laboratory trial could demonstrate.

**Relation of Pancreas to Diabetic State.**—The experiments reported on by Ervin show that a depancreatized animal as long as six hours after depancrectation develops a hyperglycemia and glycosuria just as in the true state of pancreatic diabetes, yet consumes glucose at the same rate as the normal animal. The hyperglycemia and glycosuria are dependent on the rate of synthesis of glucose into glycogen and not on interference with the normal rate of oxidation. Ervin believes that the internal secretion of the pancreas is an enzyme, similar to the external secretion but diverted into the portal blood for the rapid synthesis of glucose into glycogen. The failure of its action is the cause of the state of pancreatic diabetes; a diabetic is one who fails to synthesize the absorbed glucose into glycogen at a sufficiently rapid rate to prevent a hyperglycemia.

**Cholesterol Determinations in Cancer Research.**—Luden's observations suggest that the test for cholesterol is capable of giving valuable clinical information, although it should not be looked on as a specific, diagnostic test, such, for example, as the Wassermann test. It might fully be compared to the test for albumin in the urine. The test furnishes information concerning cholesterol metabolism; it will, therefore, furnish information about the disturbances of cholesterol metabolism connected with cholelithiasis and carcinoma, for instance. A detailed account of the technic used by Luden is given. This technic is based on the determination of more than 1,500 individual blood samples. The cholesterol content of the blood is influenced by the nature of the diet, the rate of basal metabolism, radium treatment, bacterial infection (ulceration, infectious disease) and hemorrhage. Luden insists that determinations of blood cholesterol should have a place in cancer research. Details of observations made in sarcoma and carcinoma cases are given.

**Isaacson Method for Estimating Glucose.**—The rapid colorimetric for determining glucose in urine, which was published by Isaacson, was tried out by Pennell with unsatisfactory results.

**Floccule Formation Reactions and Wassermann Test.**—McCann investigated the methods of Forges and Meier, Elias, Neubauer, Forges and Salomon, Klausner and Herman and Lertz. From the results obtained the author is convinced that, possibly with the exception of the Herman and Lertz

tionately large enough, no matter what the origin, to admit of a routine exploration either in front of or behind the sinus. Despite the fact that 62 per cent. of all cerebellar abscesses originate from the petrous pyramid, and notwithstanding the importance of the surgical localizing value of a dead labyrinth (namely, with a dead labyrinth, the cerebellar abscess is likely to be on or near the anterior surface of the cerebellum, frequently admitting of operative localization by exploration in front of the sinus), the number of cerebellar abscesses of labyrinthine or perilyabyrinthine origin that are not accessible by this route is large enough to preclude its routine employment.

Similarly, cerebellar abscesses, originating from a thrombosis of the lateral sinus, while generally located on or in the posterior two thirds of the cerebellum, are frequently so situated, either on the upper or under surface of the cerebellum, as not to be accessible by puncture from behind the sinus.

In the treatment of cerebellar abscess, to meet the surgical requirement that the operative procedure may be attended by a systematic exploration which will admit of a uniform operative localization of the supuration and its complete evacuation, it is necessary in all cases:

1. To obliterate and doubly ligate the descending portion of the lateral sinus. The sinus, no matter how large, may be quickly obliterated and ligated by invulsing the external wall into its cavity.<sup>1</sup>

2. To expose the dura of the whole cerebellar fossa of the affected side; and, as the affected hemisphere occupies a position beyond the median line, the bone over the unaffected hemisphere should be freely removed.

3. To perform a ventricular puncture in order to relieve the internal hydrocephalus.

4. Then to incise the dura as far forward as possible, the incision extending outward through the obliterated sinus and continued in whichever direction necessary.

Because of the variety of situations of cerebellar abscess as found at postmortem, no other surgical manipulation promises uniformly to locate the abscess or allow of its complete evacuation, and the introduction of drainage material within the abscess itself.

#### ABSTRACT OF DISCUSSION

DR. GEORGE F. COTT, Buffalo: As to the mortality, some claim 20 per cent. and some from 40 to 50 per cent., but mine has been 100 per cent. I have not had more than six or seven cases of brain abscess in the last twenty-five years, and two of these were cerebellar abscesses. The doctor spoke of the radical mastoid operation being done when there is a cerebellar abscess. He must remember that when we are called to the country to operate we have neither hospital, nor nurse, nor time to study the case; we have nothing, except a patient in bed with a chronic suppurative middle ear and we are supposed to give relief. I have seen a number of these patients die who no doubt had brain abscess of which we knew nothing. Every case of chronic middle ear suppuration should be studied carefully before we decide what to do; in that way a cerebellar abscess may be discovered which would otherwise escape detection.

PROF. FERNAND LEMAITRE, France: Before discussing the paper of Dr. Eagleton I wish to express my appreciation of the great honor you have done me by electing me to honorary membership in your society. With your permission I shall

relate some of my observations in cases of cerebellar abscess. In cases of cerebellar abscess of static origin the route of surgical approach is of prime importance. Three routes are before us: in front of, behind and through the lateral sinus. Which is the best? Considered from the purely anatomic standpoint, the posterior route is preferable, the anterior being too narrow (this is particularly true when the sinus is of the procedent type), and the middle route requiring opening the sinus. However, pathologic conditions greatly modify our choice of routes. The best route is the shortest. For this reason it is not possible to choose a route until the location of the pus is known. I have usually found the abscess located in the interior portion of the cerebellum, and for this reason I have usually used the anterior route. The great question, after all, is the location of the pus.

But how solve this problem? There are three ways: (1) The clinical symptomatology: I realize that localization in the cerebellum is far from being precisely worked out. However, the spontaneous deviation of the index finger seems to me to be in favor of localization anteriorly. On the contrary, a decided retropulsion is in favor of a localization posteriorly. The adiadokocinesis and hypermetria are observed in both localizations. (2) The lesions as observed during the operation: The general principle of otology, "The specialist must follow the course of morbid process," finds here a most useful application. This procedure usually allows one to find the pus in the most direct way, and, what is more important, it makes it possible to penetrate the meninges and subarachnoid space at the point where spontaneous walling off is already under way. (3) The needle puncture: When dura and sinus are exposed, the exploring needle introduced where the abscess is supposed to be, shows pus, its localization and its depth. Following these guides, I have rarely found the abscess behind the sinus, but most frequently in front of it. In one case, finding the sinus full of pus, I was led to the cerebellar abscess on the farther side of the sinus wall. Consequently, I believe we are frequently forced by the circumstances to choose the narrow space existing between the anterior part of the sinus and the posterior part of the petrous portion of the temporal bone, removing a portion of the latter, if necessary.

I should also like to say a few words concerning my method of walling off the subarachnoid spaces. This method is as follows: When the meninges are exposed and the pus location has been indicated by means of the needle, instead of cutting the membranes by a sharp instrument, I introduce at the site of the needle a grooved director, allowing the pus to partially evacuate by this means. In abscess of cerebrum this is important, but it is of even more importance in cerebellar abscess, because it is known that the pus under tension is not as well borne by the cerebellum as by the cerebrum. Then a small rubber drainage tube is introduced through the small meningeal opening. I have observed that the presence of this tube provokes the formation of fibrous adhesions, which wall off the subarachnoid space. Every day a larger tube is substituted until a diameter of from 9 to 11 mm. is reached. By this time a strong, firm ring of fibrous tissue surrounds the tube, which now functions as a drain. In cerebellar abscess, at this stage I replace the soft tube by a vulcanized one, which is specially prepared in my laboratory. The particular features of these tubes are that they are fenestrated and the anterior ends are cut obliquely. This obliquity prevents contact between the tube and anterior portion of the sinus, thus avoiding traumatism and grave hemorrhage. In subsequent dressings these tubes are diminished in length but not in caliber, as granulation tissue appears and pushes the tube outward. It is better to await spontaneous expulsion than to withdraw the tube. I have the detailed record of a case of cerebellar abscess following a concussion injury to the ear, in which there was complete recovery after having been treated in the manner just outlined. This case forms part of a paper dealing with the general subject "The Exclusion of the Subarachnoidal Space."

DR. EWING W. DAY, Pittsburgh: I wish to make a plea for compulsory postmortems. Dr. Eagleton and the others who have studied his subject are hindered by the lack of

1. Eagleton, W. P.: Original Device for the Control of Hemorrhage from the Large Sinuses of the Brain by Invulsion of the Outer Wall into the Lumen, M. Rec. 95:274 (Feb. 15) 1919.

good postmortems and the published reports. I would like to urge every member of this society to go before the board of governors of your hospitals and have them enact a rule requiring postmortems in all cases in which death was due to trouble within the cranium. We have been diverted from this for some time on account of objections we thought might arise. In 1908 we had it introduced in the Pittsburgh Eye and Ear Hospital; it has therefore been in force for eleven years. We have had only three objections, and they did not amount to anything. They have patients sign an agreement before they go into the hospital, drawn up by competent legal authority, making it a contract, that in consideration of the treatment received in the ward, in case of death there shall be a postmortem. When we do that our knowledge of intracranial conditions will be greatly enlarged.

DR. EDWARD J. BERNSTEIN, Detroit: I would like to ask what relation Dr. Eagleton has found between the various diagnostic aids we have and the location of cerebellar abscess.

DR. JOSEPH C. BECK, Chicago: Of the fifteen cases of sinus thrombosis that I have had in twenty-five years only two patients have lived. In only one case have I made use of a point that Dr. Eagleton mentioned, the ventricular puncture, and that was after I saw the late Dr. Beckman of Rochester, Minn., in operating on a gasserian ganglion, use this method. I only bring this up because this is the one thing that is bothering us in the operation on the brain, the tremendous intracranial pressure.

DR. WELLS P. EAGLETON, Newark, N. J.: I think we should recognize that there is no one method of treatment that is adapted to all brain abscesses. I want to emphasize the importance of diagnosing between two separate and distinct conditions, both of which are classed as cerebellar abscess, viz., intrapia-arachnoid abscess situated within the pia-arachnoid; and intracerebellar abscess, situated within the cerebellar tissue. To obtain the best results, they must be treated differently. In intrapia-arachnoid abscess puncture and the insertion of a drain will not stop the suppurative process. The pressure of the brain against the dura prevents evacuation by drainage; the suppurative process continues to extend beyond the dural opening and the patient ultimately dies. All books on abscess of the brain speak of these cases as giving a high mortality, because, I think, of reliance entirely on drainage. Professor Lemaitre spoke of puncture; unquestionably it is the best treatment of acute intracerebellar abscess. We should differentiate between acute and chronic abscess. If we operate without complete preparation we will have a high mortality. A brain abscess requires the undivided attention of the surgeon from the time he makes a provisional diagnosis. I have seen four deaths, all possibly avoidable, because the surgeons had other engagements. The operations were put off for a day and during the delay the patients died. We should examine a case of suspected cerebellar abscess most carefully. If the patient is conscious he can be put in a chair and rotated over and over again. He may object, but if the family are told the importance of making the diagnosis, they will submit, and with the aid of assistants and a great deal of patience, all the tests may be applied. I have had more than one case in which the diagnosis between cerebellar and cerebral involvement was made by rotating in a Bärány chair. Dr. Beck spoke of ventricular puncture. Why it has not been more generally applied I do not know. It is of the greatest importance. If a large dural incision is followed by herniation, a ventricular puncture will reduce the herniation. I want to call attention to the fact that the direction of maximum pressure should be considered in selecting the site of the dural incision. Attention has never been called to it before; but theoretically there are points of maximum increased intracranial pressure, incision over which will be followed by herniation, and other points of minimum pressure where herniation is absent or slight. The obliteration of the lateral sinus and incision through it, although it is recorded but twice in literature, should be resorted to in every case of suspected cerebellar abscess, because of the advantages of anterior approach, the incision being in the line of minimum pressure.

## Clinical Notes, Suggestions, and New Instruments

### FORMULAS FOR USE IN STANDARDIZING AUTOGENOUS VACCINES

LEO R. TEHON, A.B., URBANA, ILL.  
Sergeant, Medical Department, U. S. Army

In the preparation of autogenous vaccines, we used, as a routine, Wright's method of counting. In so doing I have experienced some little discomfort in handling the array of figures usually employed in making the necessary computations.

As a short cut, the formulas here given have proved useful and satisfactory, it being entirely unnecessary to compute the number of organisms per cubic centimeter in the suspension. The result obtained in working out the formulas gives the number of cubic centimeters of the suspension of organisms needed to make up a desired quantity of vaccine which will contain the desired number of organisms.

#### FORMULAS

Quantity of Vaccine	Millions of Organisms per C.c.		
	1,000	500	200
10 c.c.	$1.82 \times a$	$0.909 \times a$	$0.5656 \times a$
	$b$	$b$	$b$
15 c.c.	$2.72 \times a$	$1.36 \times a$	$0.5454 \times a$
	$b$	$b$	$b$
25 c.c.	$4.54 \times a$	$2.27 \times a$	$0.909 \times a$
	$b$	$b$	$b$
50 c.c.	$9.09 \times a$	$4.54 \times a$	$1.818 \times a$
	$b$	$b$	$b$
100 c.c.	$18.18 \times a$	$9.09 \times a$	$3.64 \times a$
	$b$	$b$	$b$

In computing these formulas the number of red blood cells is arbitrarily taken to be 5.5 million per cubic millimeter; "a" is the average number of red blood cells obtained from the count, and "b" is the average number of organisms.

Suppose we wish to make up 15 c.c. of vaccine which shall contain 500 million organisms per cubic centimeter. The red blood cell count we will suppose to have been 50, and the bacterial count 75. We now substitute these numbers in the proper formula as given, and have:

$$\frac{1.36 \times 50}{75}$$

which is equal to 0.9.

This is the number of cubic centimeters of the suspension of organisms which, when made up to 15 c.c., will give a vaccine containing 500 million organisms per cubic centimeter.

When the exact content per cubic centimeter of red blood cells is known for the blood used in the comparison, the following formula may be used in any case.

Total number of organisms needed

$$\frac{b}{a} \times \text{number of r. b. c. per c.c.}$$

This gives the number of cubic centimeters of the suspension of organisms in making up a desired quantity of vaccine with a desired content of organisms.

NOTE.—Hosp. Sgt. B. H. Brown, professionally an instructor in mathematics, made, at the request of the author, the first formula used by the author in standardizing vaccines. The author extends thanks and credit.

**Treatment of Mental Disorders.**—It is decreditable to the intelligence and humanity of any community when no better provision for a delirious or frenzied sick person is made than the police station or lockup, and when no more skilled nor tender attention can be supplied than those of the constable and the poormaster. ## TSUSUGAMUSHI DISEASE IN JAPAN

For many years, some of the river valleys of Japan have been known to harbor in endemic form a peculiar malady designated as tsusugamushi disease. The old Chinese literature makes it probable that something of a similar nature was prevalent long ago in parts of China; and recently the same disease has been observed in Formosa. The descriptions indicate its close resemblance to typhus fever and allied infections. The origin of tsusugamushi disease is attributed to the bites of certain insects found in the affected regions. As long ago as 1893, Kitasato ascribed the causation to a plasmodium-like organism which he believed he had discovered in the red corpuscles of afflicted persons. The theory of plasmodial causation has been opposed by various other Japanese investigators who were unable to find protozoa in the blood of their patients.

Of late, the study of the disease, which formed the subject of a report by the American investigators Ashburn and Craig<sup>1</sup> in the Philippine Islands in 1908, has been renewed by the experts of the Kitasato Institute for Infectious Diseases in Tokyo.<sup>2</sup> They have verified the peculiar periodicity of tsusugamushi, which occurs most frequently in the summer months, beginning with June and ending with October. This corresponds with the development of the insect "akamushi," the now assumed carrier of the Nippon "river fever."<sup>3</sup> This insect appears to be the larva of a form resembling the European *Leptus autumnalis*. The summer likewise is the season when the peasants who suffer from it enter the infected zones. The insects, which begin to attack human beings in June, are extremely prevalent until the fall months. The mortality is a variable one, but has on several occasions exceeded 50 per cent.

The close resemblance of tsusugamushi disease to typhus fever and Rocky Mountain spotted fever has

been recognized for some time. There is a similarity in the type of febrile reaction elicited; the peculiar eruptions coincident with the height of the attack are also reminiscent of those seen in the better studied typhus-like infections. Indeed, one might be inclined to suspect a complete identity of the diseases except for the recent Japanese investigations, which assert a distinction between the "river fever" and the conventional typhus fever quite as marked as that still postulated between "spotted fever" and its nearest analogues. The nonidentity is asserted primarily on the basis of immunologic investigations and the failure of infection with one type to protect against the subsequent occurrence of the other.

The rôle of the field mouse (*Microtus montabelli*), as bearer of the parasitic insects that transmit the etiologic agent to man and as host of the infectious microorganism, seems to be established. With respect to prophylaxis, it is difficult to prevent the bites of the insects under existing conditions. Excision of the area of the sting does not prevent the distribution of the virus. The best prospect of relief seems to lie at present in the eradication of the mice so far as this is practicable. Precisely what the nature of the etiologic factor is, whether it belongs to the so-called ultramicroscopic agents or some comparable group, is still to be determined. It appears to be independent of the spirochetes that have lately been reported so often in Japanese rodents. Thus far, attempts at chemotherapy with preparations of iodine, mercury, arsenic, quinin or dyes have proved unavailing.

## INFLUENZA

The suffering and loss of life that characterized the influenza epidemic of last year are still vivid in the minds of physicians and the public, and there is much speculation as to the extent to which influenza will appear during this fall and the coming winter, and what measures are of value in its prevention. In the anxiety to do everything possible to lessen the anticipated danger, it is important to maintain a judicial attitude in evaluating any proposed method of prophylaxis, and to inquire carefully into its merits before recommending it for general public use. If we may judge by the experience of the past in other epidemics of influenza, or, indeed, in epidemics in general, a considerable incidence of influenza may be anticipated during the coming fall and winter. During the past spring and summer there have been scattering cases, for the most part mild, or at least not usually complicated by the fatal bronchopneumonia of last winter. While opinion as to the degree of immunity conferred by one attack of influenza is not unanimous, there are many facts that appear to support the view that one attack does confer immunity to the disease. If this view be accepted, it may be assumed that the epidemic

1. Ashburn, P. M., and Craig, C. F.: A Comparative Study of Tsusugamushi Disease and Spotted Fever of Montana, Philippine J. Sc. 3: (B), No. 1, 1908.

2. Kitashima, T., and Miyajima, M.: Studien über die Tsusugamushikrankheit, Kitasato Arch. Exper. Med. 2: 91 (July) 1918.

3. The life cycle of this insect has been studied especially by Miyajima, M., and Okumura, T.: Kitasato Arch. Exper. Med. 1: No. 1, 1917.

of last year, which affected perhaps 30 per cent. of the population, presumably conferred an immunity on a large proportion of the susceptible persons, and that therefore a recurrence of the epidemic of the same magnitude is very unlikely. On the other hand, no doubt there are a number of persons who escaped infection last year, but who through changes in resistance, or by accident of exposure, will suffer from the disease this year. It must not be forgotten that infections resembling and possibly identical with influenza, or la grippe, are with us practically always, especially in the winter, and there is a great temptation at such times to call any sickness that has not a definite entity "influenza." Conditions that are ordinarily called "colds" are now being given the more popular name "influenza."

The practical value of vaccines in the prevention of influenza has been much debated. In one group are those who are enthusiastic over the alleged success of vaccines in the prevention of influenza, citing numbers of instances in which persons did not become ill from influenza following prophylactic injections, and in which those who did become ill suffered less severely than others not injected. In another group are those more conservative, who present carefully studied series of persons who had been vaccinated, with like numbers of unvaccinated controls, and point out that the incidence of the disease was practically the same in the vaccinated as with the unvaccinated persons. The conclusion seems unavoidable that the efficacy of vaccines in the prevention of influenza is still unproved. The virus of influenza is not as yet discovered, and thus further doubt is thrown on the probable value of vaccines whose action, if any, would be nonspecific so far as influenza itself is concerned.

How, then, shall we answer the many queries of patients as to whether they shall be injected with vaccines or what they shall do to avoid falling victims to the disease? Certainly they should not at present be led to believe that by submitting to vaccination they can hope to acquire immunity in any degree comparable to that resulting from antityphoid inoculation. Until the value of prophylactic vaccines is clearly proved, they should not be recommended to patients as a sure method for the prevention of influenza. The question as to the value of vaccines in the prevention of infectious diseases of the respiratory tract other than influenza is still under investigation. Other procedures, such as good ventilation, cleanliness and hygienic measures in general, are of value in that they contribute to good personal and home hygiene. But no one of them is all important to the exclusion of the others. There is no scientific evidence that gargles and sprays, no matter what drug may be used, are of value, except as temporary cleansers. There is one point in regard to influenza, however, on which there is general agreement: The pulmonary complica-

tions of influenza, which make it so serious a disease, may be avoided to a large extent by rest in bed at the onset of the illness. Influenza itself is not usually fatal, and general insistence on the importance of rest and warmth at the onset of illness will accomplish more than all else in preventing complications and reducing fatalities from this disease.

#### THE LEGAL FOUNDATIONS OF PUBLIC HEALTH FUNCTIONS

Students of the history of American legal problems realize that, in harmony with the economic changes that have taken place during the past century, the interpretation of the constitutional limitations of the federal government is becoming correspondingly and progressively more liberal. Few persons interested in national welfare from the standpoint of public health are accustomed to ask themselves whence the necessary legal authority for the enforcement of hygienic measures is derived. Yet, as we are living under a constitution that permits the federal government to exercise only those powers clearly granted to it by that instrument, it is important to know the legal basis for permissible sanitary measures.

The constitution makes no direct mention of any power over the public health. In an address before a recent conference of state and provincial boards of health held at Atlantic City, President Goodnow<sup>1</sup> of Johns Hopkins University interpreted the sources whence the authority of the federal health organization may be assumed to be derived. The first great source upheld by numerous court decisions lies in the power of Congress to regulate commerce. The earlier limitations that kept this function strictly within the narrow construction of commerce with foreign nations and among the several states have been enormously extended with our national growth. The power of the national government, says Dr. Goodnow, to regulate commerce may be exercised not merely with the idea of promoting commerce from an economic point of view but also with the idea of limiting commerce in order to protect the public health or safety. It includes, therefore, the power to establish quarantines and to deny the right of entry into the country or of transportation from one state to another of objects or persons when that entry or that transportation may, in the opinion of the competent authorities of the national government, endanger the public safety.

The federal health authority is also held by Goodnow to be a function of the power to lay taxes and duties and thus provide for the common defense and general welfare of the United States. Congress may thus prevent the production and distribution of harmful substances by imposing prohibitive taxes. This is

1. Goodnow, F. J.: *Constitutional Foundations of Public Health*. *Am. J. Pub. Health*, 9: 561 (Aug.) 1919.

an instance of a repressive application of the power of taxation. The same privilege may be employed to promote directly the public welfare by appropriating funds designed for the establishment and activity of public health agencies.

Fortunately the federal government has rarely come into clash with the individual states in the conduct of their sanitary routine and the prosecution of their hygienic projects. The Pure Food and Drugs Act of 1906, the Child Labor Act, and the Harrison Act relating to the sale of narcotic drugs have all passed the scrutiny of the courts and found justification and legal sanction in our vaguely specific federal constitution. It is well, however, to remember the limitations of the latter and to realize that any great extension of the national health movements can be based on fundamental legal sanction only so long as the interpretation of our constitution is sufficiently liberal to meet present day needs. "Epidemics," says President Goodnow, "are not respecters of state or even national lines. A keener realization of this fact will unquestionably have the effect of causing a broader interpretation of existing powers, and may well result in constitutional amendment where such broad interpretation is not possible."

#### SOME PROPERTIES OF THE FAT-SOLUBLE VITAMIN (FAT-SOLUBLE A)

The day has passed when even the most skeptical critic of novel hypotheses can deny that certain natural fats, notably milk fat, egg-yolk fat and various tissue oils, exhibit a peculiar potency in nutrition that is not shared by many other wholesome fats which enter into the dietary. Whether the property referred to be designated as a vitamin, a food accessory substance, a food hormone or auximone is of secondary interest so long as its chemical nature and mode of action are still so obscure. The fundamental fact has been firmly established: When a suitable source of the fat-soluble vitamin as it exists either in animal fats or in green plants is lacking in the diet, nutritive disaster is certain to follow sooner or later, even when all other components of the ration are ideally adequate. We are here dealing with some as yet unidentified food factor indispensable for nutritive well-being, even though the quantity that is required may be measured with small units.

The earlier studies of the fat-soluble vitamin were largely directed to the search for its sources, so that it is now possible to catalogue a considerable list of foods of known potency with respect to the factor under discussion. The practical significance of this will be clearer to the medical practitioner when the bearing of a deficiency of the fat-soluble vitamin on the genesis of certain symptoms of malnutrition is further elucidated. A shortage of the vitamin in the human dietary has already been convincingly related to the

appearance of eye disease (xerophthalmia) in children; and English investigators are inclined to ascribe rickets to a similar deficiency factor. During the enforced food shortage of war-time days, the lack of butter, eggs and meats caused considerable concern to the food authorities. We have already pointed out that butter substitutes which are made from beef fats or oleo oils may be physiologically comparable to some extent with butter in their growth-promoting power, whereas those prepared from vegetable oils are inadequate in this respect.<sup>1</sup>

As might be expected, these pioneer studies of distribution are being followed by investigations of the properties of the unique something known as fat-soluble vitamin. It has not been identified with any of the recognized components of fats, such as glycerol, fatty acids, cholesterol, phosphatids or lipochromes. Several investigators, of whom the latest is Drummond<sup>2</sup> of the Cancer Hospital in London, have called attention to the ready destruction of the fat-soluble accessory food factor ( $\Lambda$ ) after relatively short exposure to a temperature of 100 C. (212 F.). Longer exposure at lower temperatures, for example, 37 C. (98.6 F.) may be equally detrimental. This destruction is apparently not a result of oxidation or hydrolysis. The facts just cited render it impossible at the present state of knowledge to "harden" liquid oils, as is now so commonly done in the industries, without effecting a loss of the fat-soluble vitamin which the original fats may contain. This explains, further, why it is that the popular commercial hardened oils are devoid of the vitamin, whatever their origin may have been.

The specific rôle of the fat-soluble vitamin within the organism still remains unknown. The fact that it is found in certain fat depots of the body has suggested that it may play a part in the utilization of fats. Recent observations by Drummond<sup>3</sup> indicate that this is not the case, however. A deficiency of fat-soluble  $\Lambda$  in the diet does not exert any direct influence on the absorption of fat; and animals are able to absorb large amounts of fatty acids and presumably synthesize these into fats, in the absence of the fat-soluble vitamin.<sup>4</sup> Drummond<sup>2</sup> ventures to suggest that the latter is not a clearly defined chemical substance but rather a "labile substance perhaps possessing characteristics resembling those of an enzyme." We shall await further investigations without the bias of a fixed hypothesis.

## Current Comment

### ALABAMA ADOPTS THE MODEL LAW FOR VITAL STATISTICS

Alabama has adopted the model law for the registration of births and deaths, making forty-one states that have adopted this measure. Of the remaining seven states, New Mexico, in its recently adopted law, authorized the state board of health to enact regulations on this subject. Arizona, Nevada and Iowa still adhere to the obsolete method of collecting vital statistics through county clerks. In South Dakota, the secretary of the state historical society is the registrar of vital statistics. In West Virginia, the model bill has been twice introduced but has so far failed of passage. Delaware, although one of the oldest of the states, is still outside the registration area. However, the progress made in the country as a whole, since 1906, when only nine states had any adequate birth and death registration, is both remarkable and gratifying. The passage of the model law in Alabama completes the reformation in the South on this subject. Of the six states still without satisfactory laws, two (Arizona and Nevada) are Western, two (Iowa and South Dakota) are Central and two (West Virginia and Delaware) are Eastern. The passage of the model law by these states should be effected at the earliest possible moment in order that the registration area for births and deaths may be made coterminous with our national boundaries and that the energy that has been devoted to securing the passage of this law in the last fifteen years may be expended in other and greatly needed directions.

### THE CAMPAIGN TO PREVENT INFANT MORTALITY

During the first, second and third quarters of 1918, that year bade fair to prove a record one in the attempt to reduce infant mortality. Local agencies everywhere, under the inspiration of the movement initiated by the Children's Bureau, made every effort to save infant life. Large gains were being made but, unfortunately, the epidemic of influenza made its appearance in the last quarter of the year and upset the good record. The figures for Chicago and New York City well illustrate what happened. In the latter city the infant mortality rate of 1917 was 91.4 per thousand births. In 1918, the rate increased to 93.1. This is still a good rate; but what it might have been will be evident from the following comparison: In the first nine months of 1918, the infant mortality rate was only 86.6 per thousand births; the corresponding rate for 1917 was 94.6. Then came the epidemic and, in the remaining three months, the infant mortality rate went up to 115.2 per thousand births, as against 81.7 in the previous year. It was the respiratory diseases and influenza, chiefly, that were responsible; for the rate from these diseases was nearly twice that for the previous year (more than one third of all infant deaths in October, November and December, 1918, were from bronchitis, pneumonia or influenza). The rate for the congenital causes also increased, being 43 per cent. higher in the

last quarter of 1918 than in 1917. It is possible that this increase was connected with the sinister effects of influenza on pregnant women. Many physicians have noted an increase in the number of premature births during the period of the influenza epidemic, and it is very likely that this was an important factor in the larger number of deaths from congenital causes. The figures for Chicago show a similar situation. The total infant mortality rate decreased somewhat (from 105.9 in 1917 to 104.1 in 1918). But this decrease was entirely due to the record made in the first nine months of 1918. The rate for this period was 95.5 per thousand births, as against 112.6 in the previous year. In the last three months, the infant mortality rate went up to 133.2. Again, we find that the respiratory diseases and influenza were chiefly responsible. The rate was about three and one half times as high as in the last quarter of the previous year. The congenital causes were higher by 21.5 per cent. than in the last three months of the previous year. In Chicago, as in New York, the rate from diarrheal diseases was higher in the last quarter of 1918, although the rate had decreased somewhat in Chicago, and considerably in New York during the first nine months of the year. It is suggested that health officers of other populous centers analyze their infant mortality rate for 1918 along lines similar to the foregoing to determine what effect the influenza epidemic had on their campaign for the reduction of infant mortality.

### THE APPLICATION OF HEAT TO THE ABDOMEN

An old standby among our therapeutic measures is the application of heat to the abdomen. No matter what the pain or discomfort, we are likely to turn to the poultice, the compress, the hot water bottle or the electric pad. The general belief seems to be that the heat will relax spasm, aid digestion, and exert a beneficial influence generally. Can we prove experimentally the correctness of this belief, and if so, can we show how the effects are brought about? Unfortunately, the literature on the subject, though extensive, fails to afford much enlightenment. One thing seems certain, and that is that the effects are not due to an actual penetration of heat to the abdominal organs. Lüdin,<sup>1</sup> using an electropile on the stomach, found that the hottest poultice that the patient could bear, changed frequently during the course of three hours, raised the intragastric temperature at most 1 C. He fails to state whether the person experimented on was fat or thin. Stengel and Hopkins,<sup>2</sup> using a similar method, found practically no rise in temperature with hot water bottles left on for forty-five minutes. They were able to lower the temperature about 1 C. with ice-bags. Carlson,<sup>3</sup> Boring and others have reversed the process, putting ice-water into the stomach and watching the temperature of the overlying skin. They found practically no change. Others have made similar studies with fistulas, with enemas, etc., and have found, as might be expected, that local differences in temperature

1. Lüdin: *Ztschr. f. d. ges. exper. Med.*, 8: 68, 1919.  
2. Stengel and Hopkins: *Am. J. M. Sc.* 1: 52: 101, 1917.  
3. Carlson: *The Control of Hunger in Health and Disease*, University of Chicago Press, 1916, p. 110.

are promptly evened up by the circulating blood. But even if the heat should penetrate to the intestine, it is far from clear how it would act there. Those who have studied the effects of heat and cold applied more directly to the bowel are not in agreement as to the results. We often apply ice to the abdominal wall in the hope of stopping gastro-intestinal movements, quieting inflammation, restraining hemorrhage, etc., yet there is little in the extensive reports of laboratory workers to encourage us in this usage, or to help us in deciding when to use cold and when to use heat. Most of the laboratory experiments indicate that cold stimulates peristalsis. Kelling,<sup>4</sup> however, found that even when he put ice-water into the stomach he could not increase the tone of that organ enough to influence any bleeding that might be present. Apparently we must continue to be disappointed occasionally in our efforts to affect peristalsis by these measures. When we do seem to get results it may be that they are brought about by way of the nervous mechanism connecting the skin and the internal organs. We must, however, be careful how we take refuge in realms in which theory is easy and exact demonstration is difficult.

#### THE CHEMICAL EXPOSITION

During the last week in September occurred in Chicago what was probably the largest exhibition of technical chemistry ever assembled. To the physician intent on medical chemistry and *materia medica* the exhibit was a revelation. In some exhibits were long rows of by-products of oil, coal and metal trades—with strange chemical names—whose actions and uses one could hardly guess. Instead of delicate glass and porcelain apparatus, by far the largest part of the space was occupied by monster steel evaporating tanks, huge crucibles, room high suction devices, and two ton vats. And finally one came to the dye section—row on row of colors—fascinating shades exhausting all the combinations of the spectrum—dyes for cloth, for wood, for leather, for food, for every purpose imaginable. Hundreds of pamphlets told how the infant American dye industry—and the interdependent pharmaceutical trade—stimulated by the war, had already leaped to fill the gap left by the cutting off of German products. And here as a delicate reminder that the dye industry was not Germany's in the first place, one could see in a glass case a silver receptacle containing a piece of pretty mauve colored silk—a part of the goods dyed by William Perkin, of England, in 1857 with the first coal tar dye ever prepared for commercial purposes.

4. Kelling: *Ztschr. f. Biol.* 44: 245, 1903.

**Cancer Research.**—At the recent meeting of the general committee of the Imperial Cancer Research Fund, Sir William Church stated that the effect of war conditions on the cancer mortality figures for the whole country was first apparent in the national statistics for the year 1915. In that year there was apparently a great and sudden increase in the cancer death rate in males. The rate for females was unaffected, and when the necessary correction was made to allow for the withdrawal of large numbers of young males for military service the apparent rise in the death rate disappeared.—*The Medical Officer*, Aug. 30, 1919.

## Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

### ALABAMA

**Personal.**—Dr. Nathaniel A. Barrett, president of the city commission of Birmingham, is convalescent after a long illness.

**Typhoid in Alabama.**—During the week ended August 30, forty-four cases of typhoid fever were reported to the state health department.

**New Hospital.**—The Elizabeth Coffee Memorial Hospital, Florence, was formally opened, August 13. The institution can care for thirty-two patients and Dr. Luther T. Young, Atlanta, will be in charge of the clinic of the institution.

**Alabama to Care for Feeble-minded.**—The house of representatives passed by a unanimous vote, Sept. 19, 1919, the Alabama Mental Deficiency Bill. This bill passed the senate, September 13. The provision is made by an appropriation of \$200,000, for the establishment of the Alabama Home for Mental Inferiors at Tuscaloosa in connection with the Bryce Hospital. A potent factor in securing this appropriation at this time in Alabama was the mental survey of the industrial schools of the state which was made in May, 1919, by Dr. William D. Partlow, Tuscaloosa, superintendent of the Alabama insane hospitals, and Dr. Thomas H. Haines, field agent of the National Committee for Mental Hygiene. This survey was a joint undertaking of the Alabama State Board of Health and the National Committee for Mental Hygiene. The survey was undertaken at the request of the Alabama Board of Economy and Control. It resulted in showing that 129 of the 654 juvenile delinquents in the four schools in Alabama are of such low mentality that they must have institution management in order to be managed for their safety and to the comfort of the community.

### GEORGIA

**Typhoid Fever.**—During the first week in September, ninety-two cases of typhoid fever were reported in the state.

**Citizens to Build Hospital.**—The citizens of Athens propose to build a new hospital, to be known as the Athens General Hospital, to cost from \$250,000 to \$300,000, and to occupy a choice 10-acre site.

**Funds for Grady Hospital.**—An extensive campaign was carried on in Atlanta, from September 10 to 30, in an endeavor to secure \$150,000 for Grady Hospital, to be used for the completion of the nurses' home and installation of the sanitary diet kitchen.

**Increased Appropriation for Medical School.**—A report states that the Georgia legislature, at its recent session, increased the appropriation for the medical department of the University of Georgia from \$30,000 to \$55,000. This includes \$20,000 for courses in public health and hygiene.

**Pass Bill for Training of Public Health Specialists.**—The senate has incorporated in the general appropriations bill an item of \$20,000 to provide for the training of public health experts. This training will be carried on at the Medical College of Georgia, Augusta, as a new department of the institution.

**Memorial Wing for County Hospital.**—The campaign to raise \$25,000 for the erection of a soldiers' memorial wing to the Thomas County Hospital, Thomasville, was opened, September 19, and continued until September 30. At present the institution can accommodate only twelve white and eight colored persons at any one time.

### ILLINOIS

**Progress of Hospital Campaign.**—The campaign to aid St. Joseph's Hospital, Bloomington, has thus far resulted in the subscription of more than \$20,000 to the hospital fund.

**State Conference of Charities.**—The Illinois State Conference of Charities and Corrections will be held in Decatur, October 24 to 26, with headquarters at the Orlando Hotel.

**Increase in Influenza.**—The official health record for Chicago, for the week ended September 27, shows a slight

increase in the number of cases of influenza. During the week fifty-seven cases were reported with two deaths.

**Service Men Welcomed.**—Will County Medical Society gave a banquet at the Woodruff Inn, Joliet, to Drs. William R. Fletcher and John W. Krohn, who have recently returned from service. Of the members of the society, eleven were in service during the war; one, Dr. William E. Harwood, Joliet, died in service, and two members are still in France.

**Illegal Practitioners Fined.**—Eva Karasck of North Chicago was arrested by the Department of Registration and Education of the State of Illinois for practicing medicine without a license and was fined \$100 and costs.—Dr. William A. Lucas of Chicago is reported to have been arrested, on complaint of the Department of Registration and Education of the State of Illinois, and fined \$25 for practicing medicine without a license.

**Personal.**—Dr. Harry A. Sullivan, Rockford, is reported to be critically ill with pneumonia.—Dr. Alice Barlow Brown, Winnetka, who has just returned after three years' service in the devastated regions in France, was given a reception by the Winnetka Women's Club, October 2.—Dr. George W. Prince, Chicago, was shot in a struggle with a burglar in a house to which the doctor had been lured in response to a professional call, September 18.

**Sanatorium Notes.**—The protest of people interested in property on the southern outskirts of Champaign over the plan of Champaign County to erect a tuberculosis sanatorium on that locality at a cost of \$75,000 resulted, September 17, in the securing of an option at \$666 an acre on a tract of 16 acres north of Urbana.—Since August, 1918, thirty-six persons have reported to the tuberculosis dispensary of Champaign for examination, and thirty-two of these have returned repeatedly for treatment.—Christian County has ordered a levy of \$60,000 for a tuberculosis fund for the county.

**New Hospital Group.**—Work is expected to commence within sixty days on the new group of hospital buildings to be erected by the state for the University of Illinois, on the site of the old Cubs ball park, Chicago. This group will cost about \$5,000,000 and shall be completed in about three years. The group includes the Illinois Charitable Eye and Ear Infirmary, the State Psychopathic Hospital, the State Surgical Institute for Children and a clinical hospital. By a joint arrangement the state department of public welfare will operate the group as to the administrative features, and the University of Illinois, College of Medicine, will undertake the medical work.

**Training School to Be Continued.**—The Chicago Training School for Home and Public Health Nursing closed its first eight weeks' term, September 30, with nearly 800 students in attendance. The interest in the school has been so great that it has been decided to conduct another eight weeks' term, beginning October 6. The course of instruction includes: bed making—medical, surgical, maternity, and fracture bed; cleansing baths; baths for reduction of temperature; hot and cold packs; maternity nursing—the care of the mother and infant; first aid, medical and surgical; poultices and stupes, and the care of the contagious disease patients. The courses are given at 1358 West Fulton Street, Chicago.

#### INDIANA

**Illegal Practitioner Fined.**—It is reported that Kate A. Braun, alias Mary A. Rose, of Peru, was indicted by the grand jury recently and fined \$150 for practicing medicine without a license. This action was taken through the Indiana State Board of Medical Registration and Examination.

**Personal.** Dr. Maurice C. McKain, Brownstown, has been appointed physician of Union County to fill the unexpired term of Dr. Fred Heller, deceased.—Dr. John N. Hurty, Indianapolis, secretary of the state board of health, who has been convalescent following a surgical operation, was so far recovered as to be able to visit his office at the State House, September 5.

**Cars Burned.**—The following is a list of physicians who lost their cars when the Horace Wood Garage, Indianapolis, burned, September 25: Carl H. McCaskey, William F. Clevenger, William S. Tomlin, Thomas B. Nolle, Albert C. Kimberlin, Joseph W. Wright, Thomas B. V. Keene, and John H. Eberwein. As a city ordinance makes it unlawful to park automobiles in down town streets for over an hour and a half at a time, this garage, being down town, was used by physicians for day storage only.

**Emergency Corps of Physicians.**—Dr. William F. King, Indianapolis, acting secretary of the board of health, announces that an emergency force of 100 physicians is to be organized in Indiana to be used in fighting the recurrence of the influenza epidemic under the direction of the United States Public Health Service and the state board of health. The members of this force will receive a salary of \$200 a month and a per diem of \$4, and the necessary transportation.

**State Association Meeting.**—The Indiana State Medical Association met at the Claypool Hotel, Indianapolis, September 24 to 26. There were more than 700 in attendance and the following officers were elected: president, Dr. Charles H. McCully, Logansport; vice presidents, Drs. Budd Van Sweringen, Fort Wayne; Samuel Hollis, Hartford City, and Charles Stoltz, South Bend; secretary-treasurer, Dr. Charles M. Combs, Terre Haute (reelected); delegates to the American Medical Association, Drs. George W. Spohn, Elkhart, and Albert E. Bulson, Fort Wayne, and alternates, Drs. Charles D. Humes, Indianapolis, and Burton D. Myers, Bloomington. The next place of meeting will be South Bend, September 23 to 25, 1920.

#### MARYLAND

**Memorial Hospital Given.**—Mrs. Caroline Pitt McCready, widow of Edward W. McCready, who was killed in a grade crossing accident near Crisfield, will give a hospital to Crisfield in memory of her husband.

**Typhoid.**—Hagerstown is facing an epidemic of typhoid fever. More than a dozen new cases have been discovered in the northern suburbs of the city and a survey by the county health officer has led to the conclusion that the outbreak is due to an infected milk supply.

**City Hospital Planned.**—A recommendation from Health Commissioner John D. Blake that Baltimore purchase the Northwestern General Hospital, for use in case of epidemics of influenza or minor infectious diseases, has been taken under consideration by the board of estimates. The buildings and grounds together with equipment can be bought for \$50,000, and the hospital can be opened for any emergency on a day's notice. The two buildings contain provision for seventy-five beds and there is, in addition, a nurses' home, with twenty beds; a surgical ward, and two dispensaries.

**Discuss Recurrence of Influenza.**—Plans for providing adequate assistance for the people of Baltimore in the event of a recurrence of an influenza epidemic were discussed at a meeting, held September 23, at the Medical and Surgical Faculty Building, Baltimore, by a number of physicians called together by Dr. John M. T. Finney and Dr. Arthur M. Shipley, the newly elected medical advisers to the emergency committee of the Baltimore Chapter, American Red Cross. A tentative program was outlined preliminary to the work to be done by physicians and Red Cross workers in mapping out complete arrangements which would enable them, should the emergency arise, to provide medical assistance, nurses, bed linen, nourishment and clothing for the sick. Home nursing courses have already been organized by the emergency committee of the local Red Cross and more than 200 students are in training for a period of seven and a half weeks, in which time fifteen home nursing lessons are given by competent teachers.

**Personal.**—Dr. John M. T. Finney has accepted the post of campaign chairman in the \$750,000 drive by the Union Protestant Infirmary, for the erection of its new hospital at Guilford, Baltimore. The campaign will commence, October 20, and close, October 27.—George Walker, Col., M. C., U. S. Army, who went overseas with the Johns Hopkins Base Hospital Unit, but was detached and placed in general charge of the principal ports of debarkation to fight social diseases, has returned to his home in Baltimore on leave.—William Michel, Capt., M. C., U. S. Army, Frostburg, has returned from France after two years' service overseas, and has resumed practice in Baltimore.—Dr. Edward N. Brush, for nearly thirty years superintendent of the Shepard and Enoch Pratt Hospital, Towson, has offered his resignation to the board of trustees, and hopes to be relieved of his responsibility as superintendent, about January 1. Dr. Brush will remain in close touch with the hospital, but will devote most of his time to his duties as managing editor of the *American Journal of Insanity* and to his many other medical interests.—Dr. Harry Friedenwald, Baltimore, has been elected vice president of the Zionists of America.—Drs. William S. Thayer and Hugh H. Young, Baltimore, have returned after a two months' trip abroad.

## NEW YORK

**Personal.**—Dr. Homer F. Smith, Norwich, has been appointed assistant surgeon to the Knapp Memorial Hospital, New York City, and has moved to New York City.—Dr. Clinton P. McCord, health director of the Albany School for seven years, has been appointed head of the newly created bureau of health of Pennsylvania.—Dr. William Hale, Jr., who has been on duty with the Canadian Battalion of the Black Watch, has returned to Utica, after more than two years' service abroad.

## New York City

**Children's Home for Bronx County.**—The Bronx County Society for the Prevention of Cruelty to Children has tentative plans for the erection of a building to be used as a children's home, which will cost \$100,000. Already many large subscriptions have been pledged.

**Maternity Centers Opened.**—The Maternity Center Association has, during the past year, opened three new maternity centers in Harlem and Yorkville. An educational campaign is being carried on in these neighborhoods to show the advantages of advice and help to mothers.

**College of Physicians and Surgeons Opens.**—The opening exercises of the College of Physicians and Surgeons were held at Columbia University, September 24. Dr. William Darrach, the newly appointed dean of the college, delivered the opening address, his subject being "Productive Medicine."

**Academy of Medicine Opens Season.**—The opening meeting of the New York Academy of Medicine for the season 1919-1920, held on October 2, was the occasion of the Carpenter Lecture. This was delivered by Sir Arthur Newsholme, late principal medical officer of the Local Government Board of England; lecturer on public health, Johns Hopkins School of Hygiene. His subject was "The Increasing Socialization of Medicine."

**Personal.**—Dr. John William Perilli has been appointed a member of the board of trustees of Bellevue and Allied Hospitals, for a full term of seven years. The board consists of six laymen and a president who is a medical man, and Dr. Perilli is the first medical man to be appointed on the board in addition to the president.—The king of Denmark has conferred the Order of Danneberg on Dr. Ejnar Hansen, who served through the world war as a captain and major in the Medical Corps of the United States Army.

**Visiting Women Physicians Entertained.**—The foreign delegates to the International Conference of Women Physicians, now in session in this city, have been invited by Mrs. Raymond Robins, president of the National Women's Trade Union League, to meet the member of the Trade Union League at a tea, on the afternoon of October 3. The conference took a recess from September 26 to October 1, during which the foreign delegates took a trip to Boston, where they visited Harvard, Radcliffe and Wellesley colleges and were entertained at a tea by Dr. Sarah Sweet Windsor, Boston, at her country home.

## NORTH CAROLINA

**Personal.**—Dr. Cyrus Thompson, Jacksonville, has been nominated as a member of the North Carolina Reconstruction Commission whose intention it is to examine the economic and military needs of the state and report with recommendations at the next session of the legislature.—Dr. Louis J. Picot, Littleton, was elected president of the Seaboard Railway Surgeons' Association at its recent annual meeting in Jacksonville.—Dr. Sidney E. Buchanan, Concord, has been elected full-time health officer for Cabarrus County.

## OHIO

**Seek Fund for Training School.**—A committee of the board of trustees of the University of Cincinnati has been appointed to confer with the citizens of Cincinnati relative to the raising of a fund of \$100,000 to be utilized in carrying on the work of the school to train physicians in the study of industrial relations between employer and employee and in sanitation and fundamentals of safety and the care for the general welfare of the worker.

**Personal.**—Dr. Louis F. Bucher, who has served for several years as medical inspector in the city schools of Dayton, has been appointed supervisor and teacher of hygiene under the board of education and will be assisted by Drs. Warren C. Breidenbach, Dayton, and Frederick J. Driscoll, Ashtabula.—Dr. Frank G. Boudreau, Columbus, after service of nearly two years with the British Forces in France and

Belgium, has resumed his duties as head of the department of communicable diseases of the state board of health.—Dr. Edward J. Schwartz, Salem, has been made supervisor of the Northeastern Ohio District of the state department of health.—Dr. Ralph W. Holmes, Chillicothe, has been elected president of the Tenth District Medical Association.—Dr. Georges Rasetti, Cincinnati, who returned to France five years ago on the occasion of the first call to arms, and served throughout the war, has decided to remain in France.

## PENNSYLVANIA

**State Medical Meeting.**—The sixty-ninth annual session of the Medical Society of the State of Pennsylvania was held at Harrisburg, September 22 to 25. At the annual business meeting the following members were elected: Dr. Henry D. Jump, Philadelphia, president-elect; vice presidents, Drs. J. Wesley Ellenberger, Harrisburg, Spencer M. Free, DuBois, Charles B. Wood, Monongahela, and Anthony F. Myers, Blooming Glen; secretary, Dr. Walter F. Donaldson, Pittsburgh; assistant secretary, Dr. Christian B. Longenecker, Philadelphia; treasurer, Dr. John L. Lowman, Johnstown; trustees, Drs. Frank C. Hammond, Philadelphia; Howard C. Frontz, Huntingdon; Theodore B. Appel, Lancaster; Donald Guthrie, Sayre; Irwin J. Moyer, Pittsburgh; G. Frank Bell, Williamsport; Harry W. Mitchell, Warren; R. G. Shumaker, Reading; Harry W. Albers, Scranton, and Jay B. F. Wyant, Kittanning; delegates to the American Medical Association, Drs. William F. Bacon, York; George R. S. Corson, Pottsville; Herbert B. Gibby, Wilkes-Barre; Wilmer Krusen, Philadelphia, and George G. Harman, Huntingdon. Pittsburgh was chosen as the next place of meeting.

## Philadelphia

**Occupational Therapy Needs Women Aides.**—A call for fifty women to train immediately as aides in occupational therapy was issued, September 22, by the state supervisor of occupational therapy.

**Maternity Section for Bryn Mawr Hospital.**—A drive to raise funds to build, equip and maintain a maternity section in the Bryn Mawr Hospital will begin, October 8, and last until October 18. The receipts from the Bryn Mawr horse show will go to this fund.

**University Hospital Needs Funds.**—The board of managers of the Hospital of the University of Pennsylvania has decided to ask the public for \$1,000,000, and a drive for this amount will be made during the week of October 6. Headquarters have been established at the Bellevue-Stratford and there will be 360 workers, divided into sixty teams, thirty of women and thirty of men.

**Personal.**—Dr. J. Harold Austin of the medical department of the University of Pennsylvania goes to the Rockefeller Institute, New York.—Dr. William H. F. Addison has been made a full professor of histology and embryology; Dr. Oscar H. Plant has been promoted to a full professorship in pharmacology; Dr. Byron M. Hendricks and Raymond Stehle have been promoted to assistant professorships of physiologic chemistry, medical department, the University of Pennsylvania.

**University Graduate School.**—Graduate classes in medicine, the first ever organized at the University of Pennsylvania, will open, October 6, with headquarters at the Polyclinic Hospital. This is the direct outgrowth of the merger of the University Medical School with the Medico-Chirurgical College in 1916 and with the Polyclinic in 1918. Dr. G. H. Mecker is dean of the new school. The faculty of 150, many of whom formerly were on the teaching staff of the Medico-Chirurgical College, will conduct the classes. The admission requirements prescribe graduates in medicine who have practiced.

## CANADA

**Medical Inspection of Schools in Montreal.**—The school commissioners of Montreal desire that the medical inspectors should be under the direction of the commission, but at the same time officers of the department of health.

**Personal.**—Col. Robert A. Bowie, Brockville, Ont., is still overseas. Recently he has been appointed consultant in surgery to the Canadian Headquarters in London, England. He was for a time second in command of the Ontario Military Hospital, Orpington, Kent, England.—Brig.-Gen. Arthur E. Ross, Kingston, Ont., has been sworn in as a member portfolio of the Ontario government. It is understood that when

a department of health is created in that province he will be the minister in charge.

**University News.**—The Western University, London, Ont., has been given the library of Dr. J. Davis Barnett, Stratford, Ont., a library which is especially rich in Shakespeare.—Dalhousie University, Halifax, N. S., has decided on a campaign for an increased endowment.—President Klinok of the University of British Columbia has just returned to Victoria after an extended trip East. He states that the universities are stripped of men in science and economics and he experienced extreme difficulty in getting instructors in these branches. The university this session will be greatly crowded, the total attendance running about 800, of whom 400 are freshmen.—Prof. W. S. Lindsay, from No. 13 Mobile Laboratory in France and Greenwich Hospital, has been appointed to the chair of bacteriology and pathology in the University of Saskatchewan.—Dr. John G. Fitzgerald, an associate professor in the department of hygiene in the University of Toronto, has been advanced to full professorship, taking the place vacated by Dr. John A. Amyot. Dr. Fitzgerald is also head of the Connaught Laboratories and the two offices will now be combined.—Dr. Horst Oertel has been appointed professor of pathology in McGill University, Montreal, succeeding Prof. J. George Adams.

### GENERAL

**Bids for Naval Hospital.**—Secretary of the Navy Daniels, while in Honolulu, in August, cabled the Bureau Yards and Docks to entertain bids for the construction of a large naval hospital at Pearl Harbor, Hawaii, at a cost of about \$300,000.

**Southwestern Medical Association to Meet.**—The annual meeting of the Medical Association of the Southwest will be held in Oklahoma City, October 6 to 8. The association includes the physicians of Oklahoma, Mississippi, Kansas, Arkansas and Texas.

**Child Hygiene Association Meeting.**—The annual meeting of the American Child Hygiene Association, formerly known as the American Association for the Study and Prevention of Infant Mortality, will be held at Asheville, N. C., November 11 to 13, under the presidency of Dr. S. Josephine Baker, New York.

**Millions for Medical Education.**—The newspapers report that John D. Rockefeller has given to the General Education Board, founded by him in 1902, \$20,000,000 to be used in improving medical education in the United States. The announcement states that the income and the entire principal is to be distributed within fifty years and that a preliminary survey of the medical schools will be made to determine which are worthy of being improved.

**Interallied Conference on War Disablement.**—The third interallied conference for the study of problems relating to war cripples will be held in Rome, Italy, October 12 to 17. An effort will be made at this conference to arrange for a cooperation between the various allied countries in caring for disabled soldiers so that if a wounded soldier of one nation be located in another of these countries, he would find available medical care and facilities for reeducation, etc., of which he may be in need. The Medical Department of the United States Army will be represented at this conference by Col. Nathaniel Allison and Col. Harry E. Mook. The Medical Department of the United States Navy has not announced an official representative. The United States Public Health Service will be represented by Surg. Carl Ramtus.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

Woman's Hospital, Children's Hospital, Christ Home for Children, each \$20,000, and the Pennsylvania Institute for the Deaf and Dumb, Mount Airy, \$140,000, in the event of the death of his daughter without further issue, by the will of George Gilpin, Philadelphia.

Deaconess and Hospital Society of the Atlantic Conference of the Evangelical Association, \$700, by the will of Hannah Litzinger.

Kingston, Ont., General Hospital, \$100,000 for the treatment of tuberculous patients, by the will of the late Senator H. W. Richardson.

American Red Cross \$2,241.65, by the will of Oscar Hanschik, Clay County, Neb.

The library of the Georgia Medical Society, Savannah, \$1,000 for the endowment fund, by the will of Dr. J. Lewis Meers, who several years ago gave the society the William Mears Medical Library Foundation, collection of works on surgery.

For increasing public bathing facilities in Indianapolis, \$5,000; Indianapolis Orphan Asylum and Home for Aged and Friendless Women, Indianapolis, each \$3,000; The Deaconess Home of the Indiana Conference of the Methodist Episcopal Church, \$2,500, by the will of Dr. John T. Burford.

### FOREIGN

**Foundation of Institute for Biochemistry at Milan.**—A legacy of \$60,000 was bequeathed by the late Dr. Rizzi, physician in chief of the Ospedale Maggiore at Milan, to found an institute for the research and practice of biochemistry.

**Fiftieth Professional Anniversary of Professor Romiti.**—The University of Pisa recently organized a festal meeting to honor the fiftieth professional anniversary of Prof. G. Romiti of the chair of anatomy. A marble portrait bust was unveiled, and Romiti presented the university with his magnificent library on anatomy.

**Americans Equip Greek Orphanage.**—The Red Cross Bulletin (3:3 [Sept. 22], 1919) announces that a national orphanage home for hundreds of little Greek children has been dedicated by King Alexander and General Adossides of Macedonia. In the vestibule of the building has been erected a tablet commemorating the American Red Cross workers who equipped the institution and organized the work.

**Deaths in the Profession Abroad.**—Dr. Filiberto Mariani, professor of clinical medicine at the University of Genoa and author of important works on various phases of internal medicine and therapeutics, many of them passing through many editions, up to his latest, "Tecnica Medica." In the last few years he has devoted himself to cardiopathology, and founded in 1916 the monthly *Le Malattie del cuore e dei vasi*, which has appeared regularly ever since.—Dr. R. Raimondi, a well known pediatricist of Paris, and writer on subjects connected with his specialty.

**The Medical Journals and the Strikes.**—We mentioned recently that the Swedish Medical Association had announced that until the prevailing strike of printers was over no attempt would be made to get out the monthly, the archives and the transactions published by the Association. Our Buenos Aires and Cuban exchanges were also delayed for weeks on account of the general strike, but—judging from the appearance of the journals—the printing did not seem to have been interfered with. The *Revista Médica del Uruguay* comes delayed with an apology that the recent conflicts between the publishers and the printers had prevented the regular issues. The latest *Correspondenz-Blatt* of Basel, Switzerland, is a delayed double number with a similar notice, and the *Polichinico* of Rome has not been seen for some weeks but a notice has been received apologizing for the delay on account of the printers' strike. The *Nederlandsch Tijdschrift* of Amsterdam also arrives after some delay, merely a very thin number with few of the usual departments, and a notice to the effect that on account of the printers' strike this issue had been made up only of matter already in type. Of course no medical journals have been received from Russia since the end of 1917. France, Brazil and western South America do not seem to have suffered so far in this respect, but the *Journal de Médecine de Bordeaux* announces that after September its price will be raised by 50 per cent. except for students. The expense of publication, it states, has increased by 300 per cent. since 1914. The morning's mail (October 1) has brought the missing Stockholm and Amsterdam exchanges.

### LATIN AMERICA

**Malaria in Cuba.**—According to the director of sanitation of Cuba, the death rate from malaria in that country has dropped since 1898 from 25 per 10,000 to 1.8 in recent years. When the Americans took charge of Cuba malaria occupied the first place in the list of causes of deaths while now it occupies the sixteenth place. In the last two years, however, the mortality has been 2.7 and 2.4 per 10,000, respectively.

**Public Health in Recife.**—In a report on public health in the municipality of Recife in 1918, just presented by the director of public health of Brazil, he states that during that year there were 9,163 deaths with a mortality rate of 37.4 per thousand which was largely due to the epidemic of influenza. There were only four deaths caused by yellow fever, one by plague, twenty by leprosy and none by smallpox.

**Safeguarding Santo Domingo's Health.**—It is announced that an appropriation has been made by the American Red Cross to cover the expenses of sending a medical director to Santo Domingo to take charge of the hospital and to make a study of the general health conditions of the island. Disease is prevalent throughout the island and hospital facilities are wholly inadequate. There are only three graduate nurses in the republic, although a training school has just been opened. The military government plans to open a chain of free dispensaries.

## Government Services

### Personnel of the Medical Department

For the week ending September 26, there were 5,296 officers in the Medical Corps, a decrease of 940 from the previous week. The Medical Reserve Corps contained 3,472. The total number of physicians discharged since the beginning of the war is 26,917.

### Army Decorates Navy Officers

Secretary of War Baker, September 5, conferred the decoration of the Distinguished Service Medal on Com. John J. Snyder, M. C., U. S. Navy, a member of the staff of the C. T. and F.

### Public Health Service Changes

Sr. Surg. Joseph H. White, Memphis, Tenn., has been directed to proceed to Chicago to investigate hospital facilities in that city. Sr. Surg. Julius O. Cobb, Chicago, has been directed to act as supervisor of District No. 8, with headquarters at Chicago, succeeding Colonel Caldwell.

### Foreign Decorations for Navy Officers

The decoration of Commander of the Order of the British Empire Military Division has been awarded to Capt. Charles M. Devalin, M. C., U. S. Navy, in command of Base Hospital No. 3, Leith, Scotland, and Dr. Edwin S. Bogert, M. C., U. S. Navy, in command of Base Hospital No. 2, Strathpeffer, Scotland.

### Motor Equipment for Public Health Service

Legislation to provide automobiles for the use of the United States Public Health Service throughout the country has been introduced in both the Senate and House of Representatives. It is proposed to transfer a part of the surplus motor equipment of the War Department to the Public Health Service. The legislation has the approval of the chairmen of the military committees of both the Senate and House and favorable action is anticipated.

### School for Naval Medical Officers

A class has been organized at the Naval Medical School, composed of naval medical officers who have completed a course at sea. The school sessions began, September 9, and the course pursued is to be along the lines of the usual instruction, but with a special view of determining the capabilities of the officers in special lines of their profession. It is expected that after ten weeks it will be possible to arrange clinical courses in large medical centers where those student officers who have displayed a marked aptitude in special work may be given advanced postgraduate study.

### Army Medical Department Assignments

Brig.-Gen. Walter D. McCaw, assistant Surgeon-General of the Army, returned, July 28, from France, where he had been chief surgeon of the American Expeditionary Forces, and has resumed his duties as head of the Army Medical School, Washington, D. C.—Brig.-Gen. Robert E. Noble, assistant Surgeon-General of the Army, has been relieved from duty in Atlanta, and has reported for duty in the Surgeon-General's Office as chief of the library division, relieving Col. Francis A. Winter, formerly head of the Army Medical School, who has been made chief surgeon of the Southern Department, with station at San Antonio, Texas.

### Government Uses New York Hospitals for Injured Soldiers

The United States Public Health Service has taken over the New York Polyclinic Hospital to use exclusively for the

treatment of war risk insurance cases. Former soldiers who were injured, if ailments develop directly or indirectly from their war experience, will be treated at this hospital, which until recently was known as Debarcation Hospital No. 4. The Public Health Service took over the Hudson Street Hospital last June. There are accommodations for 450 patients at the Polyclinic and for 120 in the Hudson Street Hospital. Major James L. Robinson, M. C., U. S. Army, is in charge of the former, and Dr. Richard A. Kearney, Washington, D. C., of the latter.

### Vacancies in Army Medical Corps

A large number of vacancies occur in the lower grades in the Medical Corps of the regular army. The demand for physicians in the service is still very marked, but only a few physicians apparently now look on the army medical work as a desirable career. One difficulty is that physicians must serve as first lieutenants for five years before they can be promoted to captaincies, and the increased cost of living is cited as a most serious obstacle, the pay of these grades being insufficient. It is understood that there are about 700 vacancies in the medical corps. About seventy-five young physicians recently took the examinations for admission to the Army Medical School, October 1.

### Discussion on Establishment of Department of Tuberculosis

The United States Public Health Service has sent the following memorandum to the United States Senate in connection with a measure introduced by Senator Joseph E. Ransdell to establish a department of tuberculosis:

TREASURY DEPARTMENT,

BUREAU OF THE PUBLIC HEALTH SERVICE,

Washington, Aug. 20, 1919.

Memorandum for Senator JOSEPH E. RANSDELL.

It appears from the discussion on Aug. 18, 1919, by the Senate of the bill (S. 1660) to provide a division of tuberculosis in the Public Health Service that there was no difference of opinion as to the necessity of the Public Health Service having appropriations for the study and control of tuberculosis, but there does seem to be a difference of opinion as to the administration of such a fund.

The necessity for the Federal Government bearing its just proportion of the work of the control of tuberculosis is set forth in the report of the Surgeon General of the Public Health Service, under date of January 18, 1919. I do not feel that it is necessary to make any supplemental statement in this regard.

There seems to be no opposition to the Federal Government undertaking its share of the work, but there does seem to be some opposition to the creation of an administrative division to carry on this work. Whether such administrative division is created or not, it is obvious that additional appropriations would require some additional administrative personnel, but the amount expended for administrative personnel would be a negligible part in the expenditure of funds appropriated for the investigation of tuberculosis. Administrative personnel would not be in the nature of large increases as has been forecasted, but would be somewhat along the lines that you have indicated, i. e., the detail of an additional medical officer to the bureau to take charge of the division, and the employment of some additional office personnel which probably would not exceed six or eight assistants and clerks. It has always been the policy of this bureau to decentralize so far as possible its work, and I believe that investigation will show that it conducts its activities with a smaller overhead charge for administration than any other bureau in the Federal Government.

As to the statement that the creation of such a division would require a great building rented in the District of Columbia, I beg to assure you that there is no such intention on the part of this bureau, but a very large proportion of the sums appropriated for tuberculosis work would be expended in field investigations and demonstrations. All that would probably be necessary to house such a division in the District of Columbia would be the provision of four or five office rooms for administrative purposes and for the storing of records and correspondence. It is believed that the Treasury Department would be able to provide this space in buildings already under the control of that department.

I am glad to note in the RECORD that the Senator from Utah [Mr. Smoot] has made the following statement:

"I have no objection to the Government making appropriations for the purpose of assisting in the investigation of tuberculosis. The Senator from Louisiana is no more interested in the subject than I am. The Senator from Louisiana does not know of its ravages and what it has done to the people of the United States more than I know it."

With the above explanation that only a relatively small office force will be involved in the creation of a new division in the bureau, taken in connection with the attitude, as indicated in the above quotation

of the Senator, it is hoped that the Senator will withdraw his opposition and consent to the consideration of this bill, the enactment of which is urgently needed in order that the Federal Government may properly discharge its responsibilities to the Nation and the people.

J. C. PERRY,  
Acting Surgeon General.

A determined opposition has arisen in the Senate to the establishment of a separate division of the Public Health Service for this work. It is explained that there is no objection to a federal appropriation to fight tuberculosis, the opposition being to the additional administrative expenses which would come with the creation of the new department. A number of senators want assurance that the money will be used for preventive and combative work in the field and that it will not be used for administrative purposes in the Washington offices of Public Health Service.

Athens—McNichols, L. T.

officer of Evacuation Hospital No. 7, at Chateau Montomglaust, he performed his exacting duties with unflagging energy and marked executive ability. Overcoming grave difficulties due to inadequate personnel and equipment he succeeded in receiving, treating, and evacuating a large number of wounded from the Marne offensive with notable success, thereby rendering service of the utmost value to the American Expeditionary Forces."

Major SAMUEL J. TURNBULL, Medical Corps, U. S. Army. "For exceptionally meritorious and distinguished services. As commanding officer of Evacuation Hospital No. 9, he performed his exacting duties with notable success. Overcoming numerous obstacles, by his keen foresight and administrative ability, he was instrumental in securing the prompt evacuation and effective treatment of a large number of sick and wounded."

**Foreign Correspondence**

**PARIS LETTER**

PARIS, Sept. 11, 1919.

**Postbellum Organization of the Medical Department of the French Army**

The cessation of hostilities does not relieve the Army Medical Corps of the obligations imposed by the war. July 10, 1919, the number of sick and wounded still amounted to 78,000, three times the number of equipped beds existing in time of peace. The task that remains to be accomplished would be impossible of performance if the special provisions adopted for the duration of the war with reference to the personnel of the Army Medical Corps and its material means of support were now to be suddenly canceled. While the normal enrolment of the Army Medical Corps during peace times consisted of 1,710, the losses of war have reduced this to 1,400, 116 of whom are in Morocco and 215 on special missions or with the Army of the Orient. It is, therefore, indispensable to keep in the ranks of the Army Medical Corps a sufficient number of active members to permit the assumption of the obligations incumbent on it until such time as medical study and the reorganization of the Ecole du Service de Santé militaire shall be definitely resumed. In view of these facts the minister of war has recently filed the following bill:

During the six months following the date fixed for the cessation of hostilities, and longer, if need be, until the ministerial order shall be issued providing for the readmission of civilian physicians to the Ecole d'application du Service de Santé militaire du Val-de-Grace, doctors of medicine, members of the reserve medical corps or of the territorial army, may be admitted to active service under the conditions established for the duration of the war by the law of Dec. 21, 1916.

The physicians, pharmacists, dentists and administration officers of the Army Medical Corps belonging to the reserve of the army in active service and to the territorial army may, during the two years following the cessation of hostilities, at their request be admitted to intensive courses of instruction with pay, the duration of which shall be definitely fixed for each applicant in accordance with the needs of the service and within the limits of the credits appropriated for such purpose.

**Transportation for Physicians in the Liberated Regions of France**

M. Doizy, member of the chamber of deputies, recently inquired of the commissioner of the liberated regions as to what measures had been taken to provide transportation for the members of the Army Medical Corps who were devoting their time to the care of the civilian population in the liberated regions, and he is now in receipt of the following reply:

Both civilian and army physicians of the liberated regions have been furnished with credentials in present to the prefects of the departments and to the heads of the transportation service in order that they may secure the needed transportation. On the other hand, the commissioner of the liberated regions has been endeavoring for some time to find a means of replacing automobiles commandeered among the civilian population of the liberated regions by the general in command and placed at the disposal of army physicians. Since March 29, negotiations with the United States Army have been pending in regard to securing for the service of the transportation department 1,500 Ford trucks provided with special sanitary equipment. The attention of the administration is likewise directed to the question of the means of transportation to be furnished civilian physicians who have become reestablished in the liberated departments. Within a short time, it will be settled what new or used automobiles shall be appropriated to this service. Automobiles so assigned may be used only by persons performing service that inures to the general welfare.

**United States Aid for France**

Being desirous of coordinating the activities of the various organizations founded especially to bring aid and succor to

**Awards of Distinguished Service Medal**  
The Distinguished Service Medal has been awarded by the commanding general, American Expeditionary Forces, by direction of the President, to the following named officers:

Col. WEBB E. COOPER, Medical Corps, U. S. Army. "For exceptionally meritorious and distinguished services. He commanded with notable success Base Hospital No. 8, at Savenay, which under his efficient administration became the nucleus of a large hospital center, which developed into the largest classification and evacuation hospital in France for patients returning to the United States. By his marked ability in directing the numerous activities under his control he rendered services of conspicuous worth to the American Expeditionary Forces."

Col. PAUL S. HALLORAN, Medical Corps, U. S. Army. "For exceptionally meritorious and distinguished services. He served with great credit as division surgeon of the 90th Division from the date of its organization throughout its service in the field, displaying sound judgment, marked professional skill, and untiring energy. By enforcing effective sanitary measures he maintained the combat strength of his division, and by his able direction of the medical services he was largely responsible for the proper care of the sick and wounded."

Col. CLARENCE J. MANLY, Medical Corps, U. S. Army. "For exceptionally meritorious and distinguished services. He organized and commanded with signal ability the Hospital Center at Beanne, taking charge of it when it was in an unfinished state and at a time when increased facilities were urgently needed. Overcoming numerous adverse conditions, he expedited its completion and rendered invaluable services in furnishing effective medical treatment for large numbers of sick and wounded of the American Expeditionary Forces."

Lieut. Col. WILLIAM H. TRFPT, Medical Corps, U. S. Army. "For exceptionally meritorious and distinguished services. As commanding

France, the Americans have organized a federation entitled the Federation of American Agencies for the Relief of France. The federation, which has as its American president Myron T. Herrick, former American ambassador at Paris, and as its French president M. Casenave, director of the French services in New York, has sent to France several representatives charged with making an inquiry on the ground, at first hand. Mr. Lawshe, one of these representatives, has arrived in Paris and has conferred with the representatives of the press in order to set before them the program of the federation.

Mr. Lawshe announced the arrival in France of two other representatives of the federation: John Moffat, vice president of the organization, and Mrs. William Astor Chanler, who have brought with them a preliminary fund amounting to several million francs, to be used in the alleviation of the most pressing needs. During their stay in France, they will proceed to make a thorough investigation and then will return to America, where a nation-wide subscription will be opened to raise the sum of \$100,000,000, which will be used not only in aid of the population of the devastated regions of France, but also to replenish the funds of various French welfare organizations.

It may also be announced in this connection that the Fonds des orphelins de guerre, which is associated with the American Red Cross, takes care of thousands of war orphans. This orphan fund has just received a check from General Pershing for 94,625 francs. This sum represents a collection taken among the officers of the general staff to which General Pershing had also contributed.

#### A French Federation of the Societies of Natural Science

The Fédération française des sociétés de sciences naturelles has been formed consisting of thirteen distinct society units: les Sociétés Zoologique, Entomologique, d'Acclimatation, de Pisciculture, l'Association des Anatomistes; les Sociétés de Botanique, de Mycologie, de Pathologie végétale; la Société de Biologie; la Société philomatique; la Société géologique; la Société des Naturalistes parisiens; la Société de Chimie biologique.

This federation has already commenced work. The chief task that it has set for itself is the creation of five categories for the purpose of bibliographic documentation: (1) botany; (2) anatomy and embryology; (3) zoology; (4) general biology; and (5) physiology. Whether this system of documentation shall be founded on an entirely new basis, or whether an adaptation of the systems as they exist at present shall result, it would seem that so vast a program could not well be realized by one nation alone. The creation by an interallied agreement of a bibliographic office would therefore be desirable.

#### Dental Attention and Gratuitous Medical Attention

Senator Henry Cheron has just introduced a bill in the senate which provides that dental attention shall be included in the law pertaining to gratuitous medical assistance.

#### MADRID LETTER

MADRID, Aug. 19, 1919.

#### Ferrán's Antituberculous Vaccination

Physicians may recall the so-called Ferrán campaign, when in 1885 at the acme of a cholera epidemic, Jaime Ferrán, a physician from Catalonia, began to make in Alcira, Valencia, injections of vaccines or dead cultures of cholera germs. On that occasion, Alcira remained free from the epidemic that played havoc with the neighboring towns, and it has always been grateful to Ferrán. In that campaign Spanish physicians were divided into two partisan groups. As soon as the epidemic was over, Ferrán isolated himself in his laboratory and began to concern himself with the prevention of tuberculosis. To this he has devoted himself since. He has now decided to submit his laboratory results to the fullest clinical investigation. To show the harmlessness of his new vaccine, he has repeatedly injected himself, his wife, his 30-month-old child, his relatives and his pupils. He has obtained a promise of the government, in which the minister of the interior, Dr. Jimeno, was his former assistant, that the authorities would not oppose his carrying out experiments on a larger scale. He decided to do this in Alcira in remembrance of his campaign there in 1885. August 7, accompanied by his wife and a number of prominent physicians from Madrid, Barcelona and Valencia, among whom were Dr. Martínez Vargas, former president of the University of Barcelona, Dr. Pastor, the president of the University of Valencia and also the president of the Medical Association of Valencia, he went to Alcira to begin

his investigation there. Dr. Pulido, the president of the board of health of Spain, acted as secretary. In this capacity Dr. Pulido stated that as this was an experimental study which presented no dangers, as shown again and again by the investigator, the sanitary authorities were interested and did not want to hamper with delays due to red tape. More than half of the total population of the town were vaccinated, the vaccinations amounting to 14,000 and the revaccinations to 500. The work yet to be done is the collection of statistics and the compilation of observations.

#### SCIENTIFIC FOUNDATION FOR FERRÁN'S ANTITUBERCULOSIS VACCINE

What is the scientific basis of Ferrán's new vaccine? I have interviewed him in order to get this information for THE JOURNAL. There are bacteria which change on growth in various nutrient mediums. Among these are the types of *B. coli*, the typhoid fever bacillus and the misnamed Pasteurella. The virulence of the different bacteria seems to depend on the medium in which they develop. When the organisms do not cause death, they become adapted to antigen immunizes against the inflammatory effects produces the syndrome of the pretuberculous state. These strains are agglutinated by antituberculous serum. In its turn, the serum obtained through the utilization of such bacteria as antigen immunizes against the inflammatory effects, produced by the albuminoid toxins of the tubercle bacillus. On the contrary, it does not exercise any apparent action against the sclerotic and caseous changes produced by the lipid toxins of the same bacillus. There are some varieties of these germs which become so naturalized in the intestine that they finally form part of our intestinal flora. When they induce acute processes they are easily isolated, but it happens otherwise in chronic cases. Ferrán insists that these germs are deeply modified by the medium in which they live for several generations. *The nontoxic strains immunize the body against the action of virulent ones.* The multiple infectious processes which they cause can be healed if they are used as a vaccine, either in the form of killed nontoxic cultures or with antitoxic serum obtained from them. The infectious produced by them are very frequent in young animals and men, because these germs, the habitat of which is the intestine, are widely disseminated in nature and because we are born without specific immunity against them. Many of these bacteria, Ferrán believes, can transform themselves into tubercle bacilli in the organism which they are infecting, thus causing the phenomenon of a change of species through sudden mutation. The effort required to accomplish this is so great that very few bacilli can perform it; for this reason, and because the bacilli thus originated are not virulent at the start, instead of causing tuberculosis they are digested and assimilated by the organism as fast as they are produced. This assimilation, he says, makes the body sensitive to tuberculin without being actually tuberculous. We become tuberculous when these mutations are frequent or the resulting tubercle bacilli are virulent. As the albuminoid toxins which are produced by the nonacid-fast bacteria confer a certain immunity against the toxins of the tubercle bacillus, when this germ appears it will find the organism more or less well immunized, and the disease will be more or less acute according to the degree of immunity thus acquired. The tubercle bacillus, grown in series in broth, retains during many generations its most typical characteristics; but after a large number of transformations it ends by losing them and becoming a nonacid-fast bacillus, i. e., what it was before it became an acid-fast bacillus. This property, therefore, constitutes an assumed character which certain nonacid-fast bacteria can use to disguise themselves.

Since tuberculosis must necessarily be preceded by an infection with nonacid-fast bacteria which are endowed with great immunizing power, it will be enough to immunize against these in order to become protected against tuberculosis and in addition against all the processes which such nonacid-fast bacteria can produce.

#### College for Physicians' Orphans

This month there has been inaugurated in Madrid a college for the needy orphans of physicians. This is an official foundation named after the Principe de Asturias, which was created by a royal decree suggested by Dr. Cortezo. Into this orphan institution, there are admitted the children of physicians who die without leaving any resources to educate their children, something which unhappily happens very often. The funds to support this asylum are furnished by the Colegios de Médicos (medical guilds) which in turn

obtain them, chiefly through the fees for the use of the so-called seal of the Colegios de Médicos, which it is necessary to attach to all official certificates signed by physicians in regard to public health matters, diseases and deaths. Thirty children have already been admitted to the college, all of whom are receiving the best of care. The board of trustees is presided over by Dr. Cortezo, and the treasurer is Dr. Isla Boromburo, dean of the provincial board of charities of Madrid.

### LONDON LETTER

LONDON, Sept. 10, 1919.

#### Women in Industry

Last September the prime minister appointed a war cabinet committee on women in industry. To the committee Dr. Janet Campbell, medical officer to the board of education, presented an able memorandum. Her conclusions are as follows: The average woman is physically weaker than the average man. She cannot compete with him satisfactorily in operations requiring considerable physical strength, while competition in operations of a less arduous but still exacting character may be detrimental to her health in that her power of endurance and her reserve energy are usually less than a man's; and she is often compelled to spend time and strength on domestic tasks which do not fall to his lot. The second fundamental physiologic difference is potential or actual motherhood. This governs to a large extent her industrial power, efficiency and value, and prevents equal competition with men in industry. The conditions under which men and women were employed before the war were not such as to enable them to develop full health and vigor. Low wages, long hours, an inadequate dietary, and lack of exercise in the open air resulted in physical and industrial inefficiency and caused too low a value to be placed on woman's strength and capability. Employment under the conditions existing in the past has probably had an injurious effect on women, though it is difficult to dissociate this from social conditions generally. The insurance act disclosed a large and unsuspected amount of sickness among employed women which compares unfavorably with men. The rise during the war of the tuberculosis death rate among urban women suggests that any considerable increase in the number of women employed and in the period of their employment may cause the female death rate to approximate that of the male. The effects of employment on motherhood are not easy to determine with exactitude. The direct result on the reproductive system is probably largely negligible, except in the case of the multipara engaged in heavy or fatiguing work. The indirect effect is considerable impairment of the general health and vitality. The increasing employment of women has probably accelerated the steady decline of the birth rate observed since 1876. The influence of employment on infant mortality is not clear. Employment of the expectant and nursing mother may react on her personal health by imposing a double burden. But employment under suitable conditions is not in itself injurious to the pregnant woman, while the money earned may enable her to be properly fed. Employment under war conditions has emphasized the importance to health of good food, clothing and domestic comfort, which can be obtained when the wages represent a reasonable recompense for labor. It has been proved that properly nourished women have a much greater reserve of energy than they have been credited with, and that they can be advantageously employed on more arduous occupations than considered desirable in the past. Direct supervision of the health of industrial workers was almost nonexistent before the war. War conditions have emphasized the need for more effective supervision and for research into the cause of industrial fatigue and the methods of preventing occupational diseases. Factory hygiene must become a part of the general system of preventive medicine, which is likely to be the most important branch of medicine of the future.

#### Demonstration of Artificial Limbs

A large audience of men disabled by the loss of limbs in the war attended a meeting convened by the British Red Cross and the London War Pensions Committee to witness a demonstration of the use of artificial limbs. Illustrations were shown by the cinematograph of the use of and proficiency in artificial limbs, and demonstrations were given by two Americans who had overcome what might have seemed insurmountable difficulties. One was Judge Corley of Texas, who had lost the right arm and shoulder and left arm below the elbow in a railway accident. Without financial resources he reeducated himself and learned a new way of earning a

living. He studied law and politics and was elected county judge. He demonstrated the mechanism of the hook attachment to the left elbow, which he had invented and perfected himself, by which he could do all the things that ordinary people could do. He could garden, play croquet, swim, and drive an automobile. He was independent of help. His trouble was that people would insist on helping. Mr. Michael Dowling, president of the Olivia State Bank, Minnesota, said that at the age of 15 he was frozen in a blizzard, resulting in the loss of both legs below the knee, the left arm below the elbow, and the fingers of the right hand, leaving only a third of the thumb—a bit of thumb which he explained was worth a million dollars. A son of Irish emigrants, he was without means and without relatives. He was boarded out at public expense for two years, but got his chance by getting two terms in a college, on which he founded his self-education and subsequent career. He is an expert motorist and can do everything that an ordinary person can do except tie a bow-tie.

#### Tuberculin Still a Doubtful Remedy

It is disappointing to find that after the immense amount of research devoted to vaccine therapy in general and tuberculin in particular the value of the latter should still remain doubtful. A report on the sanatorium and tuberculin treatments for consumption has been issued by the Medical Research Committee. It is found that sanatorium treatment does not restore the patients to the average health of the general population. As to tuberculin, many who received the treatment made good recoveries, but there are no grounds for supposing that they would not have progressed as satisfactorily had the injections been withheld. This conclusion is described as "distinctly disappointing."

Charles Arthur Mercier, M.D., F.R.C.P. (Lond.),  
F.R.C.S. (Eng.)

Dr. Mercier, the alienist and criminologist, has died in his sixty-seventh year. Like many distinguished Englishmen, he was of Huguenot stock. The son of a clergyman who died leaving the family in poor circumstances, he began life as a cabin boy and later became clerk in a London warehouse. He reached a position which enabled him to follow his bent to study medicine. He joined the London Hospital and came under the influence of Hughlings Jackson and specialized in psychology. He was appointed medical officer in two large public asylums and then resident physician in a private asylum. A logical and incisive writer and a keen controversialist, he was the foremost authority on the legal aspect of insanity. In 1909 he was awarded the quinquennial Swiney Prize by the College of Physicians for the best work on jurisprudence. This was his book on "Criminal Responsibility in the Insane." In the present year he received the same distinction for his work on "Crime and Criminals." Other works from his pen, which have all achieved fame, are "Sanity and Insanity," "The Nervous System and the Mind," "Lunacy and Law for Medical Men," "Psychology, Normal and Morbid," and "Textbook of Insanity." In 1910 he entered into another field and published his "New Logic," in which he attacked the Aristotelian logic with great vigor, though not with great success. His definition of crime as "due to temptation or opportunity, the environmental factor of stress, acting on the predisposition of the offender, the inherent or constitutional factor," may be taken as a typical example of his capacity for analysis and clear and logical thinking.

## Marriages

LEO BRISON NORRIS, Lieut. M. C. U. S. Navy, Washington, D. C., to Miss Marion Hlungertorf of Marshall, Md., September 16.

EUGENE HENRY McCAFFREY, Des Moines, Iowa, to Miss Margaret Alice Carroll of Davenport, Iowa, September 24.

ROSS RYNSOLDS MAY, Whitewright, Texas, to Miss Pauline Lenox of Pendleton, Ark., at Pine Bluff, Ark., August 27.

NATHANIEL W. WINKELMAN, Philadelphia, to Miss Lillie C. Gabel of Savannah, Ga., at Philadelphia, September 16.

SIDNEY YANKAUER, New York City, to Miss Margaret Irene Kerriss, in New York City, September 22.

ROBERT CULLEN GOOLSHY, Forsyth, Ga., to Miss Margaret Laney of Columbus, Ga., September 2.

## Deaths

**August Hoch**, Montecito, Calif., well known as a psychiatrist, died in the University Hospital, San Francisco, from nephritis, September 25. Dr. Hoch was born in Basle, Switzerland, April 20, 1868, and came to America in 1887, having had the training of the Gymnasium at Basle. He received his medical degree at the University of Maryland in 1890. Subsequent to his graduation he worked in the Johns Hopkins University from 1890 to 1893 and at the Universities of Strassburg, Leipzig and Heidelberg in 1893 and 1894. Returning to the United States he became assistant physician in the MacLean Hospital, Waverly, Mass., from 1893 to 1905, acting as instructor in neuropathology at the Tufts Medical School, Boston, during the last three years in this service. He was assistant physician to the Bloomingdale Hospital at White Plains, N. Y., for four years acting at the same time as instructor in psychiatry in the Cornell University Medical School. In 1909 he became professor in the same school, which position he held until 1917, serving also as director of the Psychiatric Institute of the New York State Hospital for the Insane at Ward's Island, N. Y. He was a member of the American Neurological Society, the American Psychological Association and the American Medical-Psychologic Association. In 1917 because of ill health he went to California, continuing however, to carry on considerable literary work in his specialty. He was for a time on the editorial staffs of the *Journal of Abnormal Psychology*, *Mental Hygiene* and the *Psychiatric Bulletin*. On the foundation of the *Archives of Neurology and Psychiatry*, he became a member of the editorial board, and up to the time of his death, devoted much time and effort to work in connection with this publication. Dr. Hoch was regarded as one of our leading psychiatrists, as a man with well balanced conservatism which prevented him from being swept off his feet by the radical movements which have occurred in modern psychiatry during the last decade.

**Joseph Henry Reuss** \* Cuero, Texas; College of Physicians and Surgeons in the City of New York, 1889; aged 52; a specialist in surgery and gynecology; for many years head of the Marsalis Hospital, Dallas, Texas, and later proprietor of the Reuss Memorial Hospital, Cuero; chief surgeon of the San Antonio and Aransas Pass Railroad; formerly president of the South Texas Medical Association; a member of the Board of Medical Examiners of the State of Texas from 1901 to 1905; for several years president of the Cuero Commercial Club; died in the Rice Hotel, Houston, Texas, September 17, from acute gastritis.

**Charles Martin Troppmann**, San Francisco; California Eclectic Medical College, Los Angeles, 1897; College of Physicians and Surgeons, San Francisco, 1900; aged 56; adjunct professor of materia medica, pharmacology and prescription writing, and later professor of pediatrics in the College of Physicians and Surgeons, San Francisco; died at his home, September 20.

**Howard F. Pyfer** \* Norristown, Pa.; Jefferson Medical College, 1897; aged 47; a specialist on diseases of the eye, ear, nose and throat; otologist to the Charity Hospital, Norristown; and laryngologist and ophthalmologist to the Norristown State Hospital; also a pharmacist; died at his home, September 5, from bronchopneumonia.

**Theodore F. Brown**, Sandford, Ind.; Indiana Eclectic Medical College, Indianapolis, 1886; aged 75; a practitioner since 1865; a veteran of the Civil War during which he served in the Seventy-First Indiana Infantry, and Sixth Indiana Cavalry, and was a prisoner in Andersonville, Ga.; died at his home, September 1.

**Alexander Agnew Thomson**, Carlyle, Pa.; Jefferson Medical College, 1864; aged 78; treasurer of Cumberland County in 1875; later sheriff, deputy clerk of the courts; in 1890 appointed postmaster, and once county sealer of weights and measures; died at his home, September 15.

**William H. H. Schrock**, Stoyestown, Pa.; Eclectic Medical Institute, Cincinnati, 1908; aged 39; a member of the Medical Society of the State of Pennsylvania; died in the Johnstown Memorial Hospital, August 11, from embolism following an operation for appendicitis.

**Alexander A. McNeil**, Brooklyn; Ensworth Medical College, St. Joseph, Mo., 1898; aged 45; superintendent of the Brooklyn Gas Company; died at the home of his mother in St. Louis, September 8, from meningitis following influenza.

**Patrick James Byrne**, Cleveland; Western Reserve University, Cleveland, 1893; aged 53; coroner of Cuyahoga County, Ohio, for seven years, and a pioneer in the "safety first" movement; died at his home, September 14, from ptomaine poisoning.

**Benjamin Almerin Green**, Longmeadow, Springfield, Mass.; College of Physicians and Surgeons, Boston, 1910; aged 39; an associate Fellow of the American Medical Association; also a dentist; died at his home, September 3.

**Peter S. Clark**, Darien, Ga. (license, Georgia, 1881); aged 62; city physician of Darien, and physician of McIntosh County, Ga.; died in a hospital in Savannah, Ga., September 12, after an operation for appendicitis.

**Hartley Ames Reed**, Fort Ritner, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1904; aged 47; while returning from Albuquerque, N. M.; died on a Santa Fe train, near Chicago, September 11.

**Charles W. Laciari**, South Bethlehem, Pa.; College of Physicians and Surgeons, Baltimore, 1894; aged 48; proprietor of the Bethlehem Bill Posting Company; died at his home, September 9, from heart disease.

**George Davis Swett**, Albany, Ohio; Eclectic Medical Institute, Cincinnati, 1897; aged 48; a member of the Ohio State Medical Association; died at his home, September 14, from heart disease.

**Hamilton Price Duffield** \* Marshalltown, Iowa; Rush Medical College, 1870; aged 74; for many years chief surgeon of the Iowa Soldiers' Home, Marshalltown; died in Omaha, September 7.

**James A. Dickey**, Bristol, Tenn.; American Medical College, St. Louis, 1889; aged 69; a practitioner for nearly half a century; died at his home, September 4, from cerebral hemorrhage.

**Felix B. Hunter**, Falkville, Ala.; Vanderbilt University, Nashville, Tenn., 1881; aged 59; a member of the Medical Association of the State of Alabama; died at his home, August 31.

**Alonzo Maywood Forsythe** \* Maynard, Ohio; Ohio Medical University, Columbus, 1903; aged 51; a specialist in obstetrics; died in Corry, Pa., August 29, from cerebral hemorrhage.

**Charles William Noble**, Dallas, Iowa; St. Louis College of Physicians and Surgeons, 1893; aged 57; also a druggist; was found dead in his office, September 10, from cerebral hemorrhage.

**James Townsend Wolfe**, New Orleans; Tulane University, New Orleans, 1901; a member of the Louisiana State Medical Association; was shot and killed by his wife, September 5.

**Francis M. Smiley** \* Kewanee, Ill.; Rush Medical College, 1879; aged 60; a specialist in diseases of the eye and ear; died in his office, September 15, from cerebral hemorrhage.

**Brinsley Collins Graves**, Cisco, Ill.; Missouri Medical College, St. Louis, 1885; aged 67; died at the home of his brother in Sturgeon, Mo., September 8, from cerebral hemorrhage.

**Francis Marion Smith** \* Refugio, Texas; Memphis (Tenn.) Hospital Medical College, 1902; aged 44; died in the Victoria (Texas) Hospital, September 6, from cerebral abscess.

**William H. H. Roberts**, Grovania, Ga.; Jefferson Medical College, 1860; aged 80; captain in the Confederate service during the Civil War; died at his home, August 28.

**James Hays**, Dayton, Ohio (license, Ohio, 1896); aged 82; a surgeon of U. S. Volunteers during the Civil War; died at the home of his son in Evanston, Ill., September 15.

**Abraham L. Hoover**, Denver; College of Physicians and Surgeons, Keokuk, Iowa 1873; aged 77; died at his home, September 11, from carcinoma of the rectum.

**James W. Good** \* Paden City, W. Va.; University of Louisville, Ky., 1894; aged 61; was killed in a runaway accident near Sistersville, W. Va., September 7.

**Stanley L. Baird**, Phoenix, Ala.; Homeopathic Medical College of Missouri, St. Louis, 1903; aged 43; died at his home, August 26, from pneumonia.

**Charles O. Arnold**, Osage City, Kan.; Chicago Physio-Medical Institute, 1887; aged 62; died at his home, August 31, from cerebral hemorrhage.

**John P. Burford**, Indianapolis; Medical College of Indiana, Indianapolis, 1879; aged 71; died at the home of his brother in Indianapolis, September 13.

**Joseph Vincent Antill**, Philadelphia; Jefferson Medical College, 1889; aged 66; died at his home, September 9, from angina pectoris.

\* Indicates "Fellow" of the American Medical Association.

## The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE JOURNAL'S BUREAU OF INVESTIGATION, OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE FRAUD ON THE PUBLIC AND ON THE PROFESSION

### FORMALDEHYDE LOZENGES

#### Report of the Council on Pharmacy and Chemistry

The Council has voted Hex-Iodin (Daggett and Miller Co., Inc., Providence, R. I.), Formitol Tablets (E. L. Patch Co., Boston), and Cin-U-Form Lozenges (McKesson and Robbins, New York City) inadmissible to New and Nonofficial Remedies, and authorized publication of the report which appears below.

W. A. PUCKNER, Secretary.

Some years ago, the Council published (THE JOURNAL A. M. A., Aug. 28, 1915, p. 816) a report on Formamint, a proprietary medicine widely exploited as a peculiar chemical compound of sugar of milk and formaldehyde. The formaldehyde was said to be liberated slowly by the action of the saliva, and because of this liberation of formaldehyde, Formamint was claimed to be a powerful germicide. Extravagant claims were made for its curative and prophylactic effects. The Council found that the therapeutic claims were grossly unwarranted and that its exploitation to the public was a public danger.

During the recent epidemic of influenza, a variety of tablets or lozenges were advertised, and are still being advertised, having formaldehyde, in some form or other, as the nucleus around which revolve the therapeutic claims. In some cases, the advertising clearly indicates the character of the formaldehyde compound that is claimed to be present; in others the statements are vague and indefinite or misleading.

It is hardly necessary to remind physicians that the use of tablets containing hexamethylenamin or other formaldehyde compounds can neither cure respiratory infections, nor even confer protection against such infections. To be effective, formaldehyde would need to be supplied to the entire respiratory tract continuously for some time or else in concentrations that would be distinctly irritant and damaging to the tissues. Saliva-dissolved tablets, obviously cannot reach the nasal or tracheal mucosae directly; and the application of quickly acting concentrations of formaldehyde is out of the question. This altogether aside from the fact that hexamethylenamin, the basis of some of these tablets, does not liberate formaldehyde in the mouth, and for this reason alone would be quite useless for this purpose! (See Handlik and Collins, *Archives of Internal Medicine*, November, 1913.)

An inefficient antiseptic is more than merely useless; it is a menace to public safety, in that it tends to lead to the neglect of rational and effective protective measures. It therefore seems advisable for the Council again to call the attention of physicians to the subject. Accordingly, three specimens of these products were purchased and examined in the Association's Chemical Laboratory.

#### Hex-Iodin

Hex-Iodin (Hexamethylenetetramine and Iodum) Lozenges are manufactured by Daggett and Miller Company, Inc., Providence, R. I. They weigh 1½ grs. each, are sweetened and are flavored with mint or menthol. The package and circulars do not contain a definite statement of composition. The rather indefinite synonyms "Hexameth. and Iodine Comp." and "Hexamethylenetetramine and Iodum" suggest that the lozenges contain hexamethylenamin and free iodine. The further statement that they "contain the combined medicinal antiseptic and prophylactic properties of Hexamethylenetetramine and Iodum" is also rather indefinite. The therapeutic action claimed for the lozenges, however, could

only be produced by free iodine and by liberated formaldehyde.

It is unnecessary to discuss in detail the extravagant claims made for these lozenges. The inefficiency of hexamethylenamin has already been referred to; the limitations of iodine, free or combined, in lozenge form, need not be discussed because the examination made in the A. M. A. Chemical Laboratory showed that Hex-Iodin lozenges contained no free iodine, and only traces of combined iodine. Neither formaldehyde nor paraformaldehyde was present; hexamethylenamin was present but, the lozenges being neutral no formaldehyde is generated in contact with water or with the alkaline saliva.

Thus Hex-Iodin is shown to be worthless for the purpose for which it is advertised. Of the two important ingredients said to be present, iodine and hexamethylenamin, only traces could be found of the former while the latter, as has been shown, is incapable of exerting any effect when used as the manufacturers direct.

#### Formitol Tablets

These tablets are prepared by the E. L. Patch Co., Boston. Each tablet weighs 13¼ grs. They have the odor of thymol or menthol and an acid taste and reaction. They are, according to the label:

"For the throat and mouth. Soothing, Astringent, Antiseptic. Rapidly destroys germs of infection, preventing and relieving sore throat and mouth."

In a circular, it is stated, that one of the qualities of Formitol:

"... is the generation of formaldehyde when in contact with water or the saliva."

"Besides generating formaldehyde, Formitol, Patch contains astringent, demulcent and soothing ingredients which render the combination unusually effective."

A bacteriologic report is given in this circular in which it is stated that, in 2½ minutes one Formitol Tablet rendered sterile a plate culture of a "characteristic throat micrococcus." The instructions are to dissolve a tablet in the mouth, slowly, once an hour or a half-tablet every half hour.

The A. M. A. Chemical Laboratory reported that Formitol Tablets contained formaldehyde (or paraformaldehyde), an ammonium compound, and some hexamethylenamin. It is probable that the formaldehyde (or paraformaldehyde) was produced by the decomposition of hexamethylenamin originally present in the tablets but decomposed by long contact with the acid.

These tablets differ from Hex-Iodin in that they really contain active formaldehyde and, therefore, possibly produce antiseptic effect in test-tube cultures. The conditions in the mouth, however, are very different from those in the test-tube, since in the mouth the formaldehyde would be immediately "bound" or absorbed. The claimed absence of irritation indicates sufficiently the absence of efficient quantities of formaldehyde under clinical conditions.

#### Cin-U-Form Lozenges

Cin-U-Form Lozenges, manufactured by McKesson and Robbins, New York City, are marketed in bottles of 24 or 25 cents. They have a strong odor of cinnamon, weigh 1½ grs. each, and are acid in taste and reaction. The label states that they contain:

"Cinnamon, Eucalyptus, Formaldehyde and Menthol—all powerful germicides against influenza bacilli, but not injurious to the system in this palatable form."

A circular contains the same statement as to composition and claims further that they:

"... help to prevent the infection of Spanish Influenza, Pneumonia, Grip Colds and to guard against Sore Throat, Tonsillitis, Pharyngitis, etc."

The A. M. A. Chemical Laboratory reported that Cin-U-Form Lozenges contained some formaldehyde (or paraformaldehyde) and no hexamethylenamin. It is obvious that the mouth and throat cannot be "disinfected" by these lozenges. They would be totally ineffective against bacteria that enter through the nose; they cannot prevent influenza, pneumonia, etc.

## Correspondence

### SPOILED CANNED FOODS AND BOTULISM

To the Editor:—In the *Journal of Medical Research* for January, 1919, there appeared an article, "The Bacteriology of Canned Foods," by Dr. John Weinzirl; and an abstract was printed in *THE JOURNAL*, April 5. This paper is a report on the bacteriologic findings in 1,018 samples of factory canned foods. The salient features in the summary to the paper are as follows:

1. About 17 per cent. of the cans examined were spoiled and 6 per cent. underprocessed, the balance being normal edible cans of food.

2. Viable bacteria, bacterial spores, yeasts and molds, representing thirty-eight species, were found in the spoiled and underprocessed cans and in 23 per cent. of the normal cans.

3. The organisms recovered from the cans were obligate anaerobes, obligate aerobes and facultative anaerobes.

4. The organisms found in the unspoiled cans were practically all spore-bearing obligate aerobes.

5. The organisms found in the spoiled and underprocessed cans included both spore bearers and nonspore bearers. The spoilage of cans of fruits and vegetables is attributed to yeasts and anaerobes. Spoilage of the sardines is considered as due to facultative anaerobes of the colon group which enter the cans in the intestine of the fish.

6. It is stated by the author that cans containing anaerobes are likely to spoil before leaving the packer, owing to the favorable anaerobic conditions present in a perfectly sealed can, and that, therefore, such cans would rarely reach the market. Anaerobes are also "apt to decompose food and cause putrid odors."

7. Aerobic organisms are not considered a source of spoilage except in the case of sardines, because they consist mainly of spore-bearing obligate aerobes and, while the spores are not killed by the processing, growth is prevented by the anaerobic conditions prevailing in the cans.

8. The presence of living organisms in the cans is due to insufficient sterilization rather than to leakage.

9. Members of the paratyphoid-enteritidis group and *B. botulinus* were not found in the cans examined.

Dr. Weinzirl draws the following conclusions as the result of his work:

"1. Commercial canned goods as found in the markets are not always sterile, but may contain viable spores of bacteria.

"2. The living spores found in commercial canned goods are unable to grow in the food due to the absence of oxygen.

"3. The vacuum is essential to the preservation of canned food under present methods of processing.

"4. Food poisoning organisms, such as *B. botulinus*, *B. enteritidis*, etc., are not found in commercial canned foods."

From the standpoint of the consumer, the paper is open to a number of criticisms. Perhaps the most fundamental one is in regard to the restricted and therefore misleading use of the term "commercial." To the lay mind the term commercial canned is synonymous with factory canned foods as opposed to home canned foods. But Dr. Weinzirl restricts the term to refer to those factory canned goods in which no spoilage has been detected and which are still being offered for sale. As soon as spoilage is detected and the can removed from the stock or returned by the purchaser, it automatically ceases to be a "commercial" can and becomes a spoiled sample. He admits, however, that spoilage is not always detected and that some spoiled cans remain on the market as commercial cans. Three such spoiled cans are included among the "commercial" or unspoiled cans which he examined. But for some unexplained reason he made bacteriologic examinations of only two of these cans, while the third can, which was the only one suggesting botulinus spoilage was not examined. This is unfortunate in view of the conclusions he derives from his work.

The point that I wish to make clear is that when Dr. Weinzirl says that "*B. botulinus* is not found in commercial

canned food," he means that it is not found in unspoiled factory canned foods. The consumer is likely to draw the conclusion that *B. botulinus* is never found in factory canned foods. A miner or engineer buying a large stock of canned foods to be used months hence would be lured into a false sense of security as regards factory canned foods.

We might just as readily and with as much safety to the consumer divide home canned foods into two groups similar to the "commercial" and "spoiled" samples of Dr. Weinzirl's, and draw the same conclusions concerning them. This would, however, be most misleading and dangerous to the public. There is no sharp line of demarcation between the spoiled and the unspoiled. There is a period during the spoiling process when food is only slightly suspicious, and whether it is eaten or not depends entirely on the alertness of the consumer. A number of women have died of botulism because they tasted canned food to see if it was spoiled, and others have died because the cook failed to detect the spoilage.

Unless the canners can show that no spoilage from *B. botulinus* occurs in factory canned foods, the consumer of such products is no more safe from botulism than the person who eats home canned foods. For it can be said of home canned foods, quite as truly as of commercial canned foods, that *B. botulinus* has never been found in normal cans showing no signs of spoilage. The occurrence of botulism from the eating of slightly spoiled home canned foods was established by examination of necropsy material and of cans showing signs of botulinus spoilage, and not from an examination of normal cans selected at random.

A second criticism of the paper concerns Dr. Weinzirl's justification for the statement that *B. botulinus* is not found in unspoiled factory canned goods.

The total number of "commercial samples" examined was 782 out of a total pack estimated by Dr. Weinzirl as 250,000,000 cases, or more than a billion cans. This is too small a percentage on which to base a conclusion in regard to so vital a subject as food poisoning.

The technic used is open to criticism. The result would be more convincing if the author had made tests for the specific botulinus toxin to substantiate his bacteriologic findings. The most reliable method of demonstrating the presence of *B. botulinus* is to test both the contents of the can and the cultures made from the contents of the can for the specific toxin, rather than to depend entirely on the isolation of the organism. In our own experience we have been able to demonstrate the presence of *B. botulinus* toxin in jars of home canned food from which we failed to isolate the organism. Also the author does not state how long he incubated his cultures before reporting negative findings. In examining recently processed cans it would be necessary to take into account the inhibiting effect of heat on the development of the spores of *B. botulinus*.

No data are given by Dr. Weinzirl as to the length of the periods that had elapsed between the processing of the cans and the making of the bacteriologic examinations. This point is important since it might be assumed that anaerobes if present would develop quickly, owing to the excellent anaerobic conditions present in sealed cans. In tests made to determine the resistance to heat of the spores of *B. botulinus* (*THE JOURNAL*, Jan. 11, 1919, p. 88), it has been shown that development of the spores is inhibited in direct proportion to the length of exposure and intensity of the heat. After exposure to steam at a pressure of 10 pounds for twenty minutes and 15 pounds for ten minutes, the spores of the most resistant strains of *B. botulinus* in my collection remain dormant for fifty and fifty-three days, respectively, at 28 C., and then develop quickly and normally and produce toxin. Strains which are killed by lower temperatures do not lie dormant for so long a period when injured by heat. Fifty days, therefore, represents approximately the limit of heat inhibition. Allowing a month for signs of spoilage to become apparent in the cans, it is evident that at ordinary summer temperatures the bulk of cans containing *B. botulinus* will show signs of spoilage within three months after being processed. If a canner's pack is kept three months and then a few of the unspoiled cans are examined, there will be small chance of isolating *B. botulinus*. On the other hand, if

unspoiled cans are examined before the end of two months and, in incubating, allowance is not made for the inhibitory action of heat, there will be small chance of isolating the organism. Such examinations cannot serve as an adequate basis for drawing conclusions as to the presence or absence of *B. botulinus* in factory canned foods. Dr. Weinzirl gives no data as to the age of his "commercial" samples. He lists three spoiled "commercial" samples, but does not give a bacteriologic examination of the most suspicious one of them.

From a consideration of the foregoing, I am of the opinion that Dr. Weinzirl furnishes very unsatisfactory evidence on which to base his conclusion that food poisoning organisms, such as *B. botulinus*, *B. enteritidis*, etc., are not found in commercial canned goods.

I believe we are justified in assuming, until it has been proved otherwise, that *B. botulinus* will occasionally be present in factory canned foods for the following reasons:

1. It frequently occurs in the garden, and there is no reason for assuming that it is not carried into the cans along with the other bacteria (Burke, G. S.: Occurrence of *B. Botulinus* in Nature, *J. Bacteriol.*, September, 1919).

2. The spores of *B. botulinus* are highly resistant to heat, and the canning processes are not sufficient to destroy them. There is nothing inherent in the factory methods of canning to make these products less subject to contamination with *B. botulinus* than home canned foods.

3. The spores of *B. botulinus* are inhibited by heat, and cans that are put on the market in less than two months may contain such spores. While the bulk of spoilage is probably apparent within three months after processing if the cans are kept at a temperature of 22 C. or above, there may be other inhibiting factors not yet determined which would still further delay development. If the cans are kept at a low temperature, as in cold climates, development will be delayed indefinitely.

4. Cans containing organisms which later cause their spoilage do get on the market, as is evident by frequent lawsuits over the spoilage of goods. Also such spoiled "commercial" cans are responsible for cases of food poisoning, although Dr. Weinzirl states that "although the public press in America has reported cases of food poisoning attributed to canned goods, it may be stated at the outset that this is mere assumption which has never been established by scientific research." This is not altogether true. The syndrome in cases of botulism in human beings and in chickens is well established, and the connection of the disease with spoiled canned fruit and vegetables has been demonstrated beyond all question in outbreaks caused by home canned goods. In regard to outbreaks of food poisoning from factory canned foods to which, of course, Dr. Weinzirl refers although he uses the general term "canned foods," I should like to describe a case of which I have personal knowledge:

In San Rafael, Calif., in April, 1918, a woman and several chickens developed typical symptoms of botulism three days after eating factory canned corn. This corn had been slightly warmed and did not taste foul. The woman recovered slowly, but two of the chickens died on the fourth day. One of these was sent to me for examination. An examination of the crop and gizzard contents was negative for *B. botulinus*. In view of the typical clinical picture in both the woman and the chickens and the record of spoiled canned food being eaten three days before the onset of the disease, this negative finding, although very disappointing, cannot be looked on as casting doubt on the physician's diagnosis.

In many cases of food poisoning similar in every respect to the San Rafael case except that the poisonous food was home canned instead of factory canned, *B. botulinus* has been isolated from the crops and gizzards of the dead chickens and from spoiled cans of the same pack. I have not always been successful in isolating the organism from all the dead chickens. In one case the organism was isolated from seven out of ten chickens, but in another case from only one out of twelve chickens. Obviously, the negative finding in the San Rafael chicken means little. In the case of factory canned goods it is impossible to trace other cans of the same pack.

The San Rafael case was reported as botulism by the physician in charge to the state board of health and to the

U. S. Bureau of Chemistry, and the stocks of the local grocer were searched for other suspicious cans. It seems unfortunate that an expert working for the National Canners Association should not have heard of this case or, having heard of it, should ignore it.

With our present knowledge we must assume that there is a decided possibility of *B. botulinus* being present in factory canned products, and that some of these cans will reach the consumer.

The time is ripe for a thorough investigation of spoilage in factory canned foods to determine if *B. botulinus* is ever present. This will determine the advisability of requiring canners to keep their products at a favorable temperature for three months before placing them on the market.

It is also essential that all cases of food poisoning attributed to factory canned products be investigated with the object of proving conclusively that the poisoning is due to the toxin of *B. botulinus*, or if not to the toxin of *B. botulinus*, to some other definite substance. Physicians, health officers and veterinarians throughout the country can make this possible by familiarizing themselves with the clinical features of botulism (Monograph 8, Rockefeller Institute) and reporting all such cases to the U. S. Department of Agriculture, Bureau of Chemistry, at Washington, D. C., or to Stanford University, Calif., or to other investigators working on the problem. Samples of the spoiled food, dead chickens or necropsy material should be sent to these laboratories together with a full report of the clinical history of the case, brand and condition of the food eaten. It is only by cooperation between the physicians and health officers and the laboratories that the question can be quickly and satisfactorily cleared up. I consider it only a question of time until the connection of botulism with factory canned products is fully and satisfactorily established.

Dr. Weinzirl's paper is important in that it indicates very clearly that factory canning processes are not sufficient to sterilize the contents of the cans, and that therefore spores which are highly resistant to heat, such as the spores of *B. botulinus*, may survive the processing.

I do not wish to minimize the efforts which first class canners are making to put out a good and safe product, nor do I wish to exaggerate the danger of spoiled foods reaching the consumer. Botulism is of comparatively rare occurrence, even from home canned foods, because most people are critical of their food.

The canners and their bacteriologists, however, are not justified in denying the occurrence of botulism from commercially canned foods until they have proved that spoilage from *B. botulinus* never occurs in factory canned foods, and until they have given some other adequate explanation of the cases of food poisoning attributed to factory canned products which are to all clinical appearances botulism.

GEORGINA S. BURKE, Stanford University, Calif.

#### AN AMPLIFICATION OF YOUNG'S RULE

*To the Editor*—The inadequacy of Young's rule when it is desirable to determine the dosage of medicines for infants not exactly 1 year or 2 years of age is felt by most physicians. The difficulty is met by each in his own way, usually entailing the memorizing of doses given by some authority for the different ages.

I wish to submit a modification or amplification of this rule by which the dosage can be calculated for any age in months with the same degree of accuracy as with years.

Take the age of the infant in months and add 144 instead of 12, proceeding as with the old rule. For example, the dosage at five months is thus obtained:

$$5+144=149 \div 5=30 \text{ approximately, or } \frac{1}{10} \text{ of the adult dose.}$$

For a baby of 16 months:

$$16+144=160; 160 \div 10 = 16 \text{ of adult dose.}$$

This operates exactly as Young's rule and is, of course, subject to the same limitations. The possibilities for much more extensive application, however, are obvious.

R. E. CLONN, M.D., Ensley, Birmingham, Ala.

## Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

### TEMPERATURE OF AN ENEMA

To the Editor:—In Osler's Practice of Medicine, Ed. 6, 1906, page 702, under the treatment of uremia, in the seventh line, I find: "Grandin states that irrigation of the bowel with water at a temperature from 120 degrees to 150 degrees is most useful." Is that a safe temperature to recommend? I believe it was a Fahrenheit thermometer that was used to test the heat of the scalding bath at a slaughter shop where I saw hogs scalded at a temperature of 140 degrees. Since that time I have scalded a chicken in half a minute in water at 144 F. With this knowledge I have consulted two other editions of this work, the editions of 1903 and 1917, to see if it might be a misprint; but both have the same statement. I believe that such a treatment could not help but scald the membranous coat of the bowels into blisters. What explanation could you give for Dr. Osler to include such a recommendation to be followed by some man who is at his wits' end as to what next to try and who may not have any idea what a temperature of 140 F. will do? J. E. HOSSETTER, M.D., Gap, Pa.

ANSWER.—The subject of enterocolitis, in all its phases, is discussed at length by Robert Coleman Kemp in the Reference Handbook of the Medical Sciences, 4:40, 1914. The highest temperature of an enema mentioned by him is 120 F.; in fact, water at that temperature is favored in the prevention and treatment of shock from any cause, but especially shock due to hemorrhage. It is possible, however, that the statement by Grandin, quoted by Osler, has reference to the temperature of the water in the container, before it reaches the bowel. Kemp publishes a table, in connection with his discussion of proctocolitis, showing that when the temperature of the water in the container is 190 F., the final temperature of the water in the rectum is only 115 F., the difference in temperature being dependent on the number of drops entering the bowel per minute and the length of the rubber tubing. Water at a temperature of 115 F. in the container will enter the rectum at the same temperature when flowing at the rate of 200 drops a minute.

### REGULATIONS FOR PRESCRIBING ALCOHOL

To the Editor:—Kindly advise me whether special blanks are necessary in prescribing absolute alcohol. F. E. D., Chicago.

ANSWER.—No. Instructions to collectors of internal revenue, issued by commissioner of internal revenue, June 30, 1919, regarding the enforcement of the war prohibition law, direct, under the head of medical uses of wines and spirits, that physicians may prescribe wines and liquors for internal use or alcohol for external uses, but such prescriptions shall be in duplicate, both copies to be signed in the physician's handwriting, the quantity prescribed for a single patient at a given time not to exceed 1 quart, and no alcoholic liquors to be prescribed unless the patient is under the constant personal supervision of the physician. Prescriptions must indicate clearly the name and address of the patient, including street and apartment number if any, date when written, condition or illness for which prescribed, and the name of the pharmacist to whom the prescription is to be presented for filling. The physician must keep a record in which a separate page shall be allotted to each patient. The record must show under the patient's name and address the date of each prescription, the amount and kind of liquors dispensed, and the name of the pharmacist filling the prescription.

### ABBREVIATION IN PRESCRIPTION FOR PAREGORIC

To the Editor:—I write for information. I wrote a prescription and in it I wrote "Tinct. Camp. Co." I was corrected and was asked to write "Tinct. Opii Camphorata." Please tell me whether I was correct in writing it as I did.

ESTHER GUNSON, M.D., Wisconsin Veterans' Home, Waupaca, Wis.

ANSWER.—It depends on what you meant by "Tinct. Camp. Co." "Compound Tincture of Camphor" is official in the British Pharmacopoeia with "Paregoric" as a synonym. "Tinct. Camp. Co." might be interpreted as an abbreviation for this preparation. However, the British "paregoric" differs from the U. S. P. "paregoric" (camphorated tincture of opium) in containing 25 per cent. more opium, 25 per cent. more benzoic acid and about 13 per cent. more alcohol. Further, it contains only 75 per cent. as much camphor and oil of anise as the U. S. P. paregoric. Unless you wished to prescribe the B. P. preparation, you should have written the prescription according to the correction suggested.

### REGULATION OF HOSPITALS IN OHIO

Hospitals in Ohio are now subject to regulation by the commissioner of health in accordance with the following law which was passed by the last general assembly of Ohio. The new act amends, supplements and repeals sections of the General Code relative to classification and inspection of hospitals. It states:

Sec. 1.—That sections 1352, 6259 and 6262 be amended and supplementary section 1236-6 of the General Code be added to read as follows:

Sec. 1236-6. The Commissioner of Health shall have power to define and classify hospitals and dispensaries. Within thirty days after the taking effect of this act, and annually thereafter, every hospital and dispensary, public or private, shall register with, and report to, the State Department of Health, on forms furnished by the Commissioner of Health, such information as he may prescribe.

Sec. 1352. The Board of State Charities shall investigate by report, responsibility and inspection the system, condition and management of the public and private benevolent and correctional institutions of the state and county, and municipal jails, workhouses, infirmaries and children's homes as well as all institutions whether incorporated, private, or otherwise, which receive and care for children. Officers in charge of such institutions or responsible for the administration of public funds used for the relief and maintenance of the poor shall furnish the board or its secretary such information as it requires. The board may prescribe such forms of report and registration as it deems necessary. For the purpose of such investigation and to carry out the provisions of this chapter it shall employ such visitors as may be necessary, who shall, in addition to other duties, investigate the care and disposition of children made by institutions for receiving children, and by all institutions including within their objects the placing of children in private homes, and, when they deem it desirable, they shall visit such children in such homes, and report the result of such inspection to the board. The members of the board and such of its executive force as it shall designate may attend state and national conferences for the discussion of questions pertaining to their duties, and to carry out the provisions so incurred by the members and such of its executive force it shall designate shall be paid as provided by Section 1351 of the General Code.

Sec. 6259. The Commissioner of Health may grant licenses to maintain maternity hospitals or homes, lying-in hospitals, or places where women are received and cared for during parturition. An application therefor shall first be approved by the Board of Health of the city, village or township in which such maternity hospital or home, lying-in hospital, or place where women are received and cared for during par-

turition is to be maintained. A record of the license so issued shall be kept by the State Department of Health, which shall forthwith give notice to the Board of Health of the city, village or township in which the licensee resides, of the granting of such license and of the terms thereof.

Sec. 6262. The Commissioner of Health and the Boards of Health of cities, villages or townships shall annually, and may, at any time, visit and inspect, or designate a person to visit and inspect, the system, condition and management of the institutions and premises so licensed.

Sec. 2. That original sections 1352, 6259 and 6262, and sections 6257 and 6258 of the General Code be, and the same are hereby repealed.

Passed March 11, 1919. Approved March 27, 1919.

### Iowa June Examination

Dr. Guilford H. Sumner, secretary of the Iowa State Board of Medical Examiners, reports the written examination held at Iowa City, June 12-14, 1919. The examination covered 8 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 9 candidates examined, 7 passed and 2 failed. Sixteen candidates were licensed through reciprocity. The following colleges were represented:

College	PASSED		Per Cent.
	Year Grad.		
Loyola University	(1917)		83.7
University of Illinois	(1918)		87.2
State University of Iowa Coll. of H. Med.	(1919)		82.8
University of Kansas School of Medicine	(1919)		80
St. Louis University	(1919)		87.2
Washington University Medical School	(1919)		87.8
University of Pennsylvania	(1918)		86.6
FAILED			
Hospital College of Medicine, Louisville	(1907)		67.2
Eclectic Medical College of the City of X. Y.	(1878)		

College	LICENSED THROUGH RECIPROCIY		Year Grad.	Reciprocity with
	Year			
Hahnemann M. Col., Chicago (1886) Mich.	(1916),	(1911)		Illinois
Blennett Medical College	(1914)			Illinois
Northwestern University	(1910)			Illinois

### June Missouri Examination

Dr. George H. Jones, secretary of Missouri State Board of Health, reports the oral and written examination held at St. Louis, June 17-19, 1919. The examination covered 14 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 93 candidates examined, 92 passed and 1 failed. The following colleges were represented:

College	PASSED		Year Grad.	Per Cent.
	Year			
University of Arkansas	(1901)			79.9
Howard University	(1916)			82.8
Loyola University (1918) 75.7, 77.1, 81.7,				
Rush Medical College	(1919)			82
University of Kansas School of Medicine (1919) 82.5, 84.5, 87.1,				88.2
Tulane University	(1911)			85.9
Johns Hopkins University	(1917)	87.1, (1919)		84.2
Barnes Medical College	(1904)			76.4
Bennett Hospital Medical College	(1893)			81.5
St. Louis College of Physicians and Surgeons	(1918) 77.2, 84.6,			
St. Louis University School of Medicine (1905) 75, (1919) 80.1, 80.1,				
80.2, 80.3, 81.1, 81.1, 81.8, 82.3, 82.4, 82.4, 82.7, 83.1, 83.1, 83.1,				
83.1, 84.1, 84.2, 84.7, 84.8T, 84.9, 85.1, 85.1, 85.1, 85.4, 85.3, 85.4,				
85.6, 85.7, 86.1, 86.4, 86.5, 86.8, 86.8, 87.1, 87.1, 87.4, 88.5, 91.4,

### Book Notices

**THE PERITONEUM.** By Arthur E. Hertzler, M.D., F.A.C.S., Surgeon to the Halstead Hospital, Halstead, Kansas. Two Volumes. Cloth. Price, \$10. Pp. 870, with 230 illustrations. St. Louis: C. V. Mosby Company, 1919.

This is a study of the peritoneum in health and in disease, from the standpoint of the clinician as distinguished from that of the pathologist, the physiologist or the anatomist, so that although the anatomy, physiology and pathology of the peritoneum are given careful attention, we are never allowed to forget that the chief value of the known facts concerning each lies in their clinical application. The first volume deals largely with the abstract problems of the peritoneum; perhaps the most interesting chapters are those from V to IX on wound healing (the formation of fibrous tissue), the nature and genesis of peritoneal adhesions, the prevention of adhesions, changes in the circulation, and inflammatory reaction of the peritoneum—interesting, perhaps, because in them is presented, in clinical language, a summary of what might be termed general pathology of the peritoneum, a subject with which most men are not particularly familiar and which, unfortunately, is not so widely discussed as are the subjects of peritoneal anatomy and, to a lesser extent, physiology. The second volume deals with the diseases of the peritoneum. The subjects are well arranged, the treatment is thorough, and the opinions expressed are, for the most part, orthodox. Interspersed here and there are interesting bits of advice gleaned from experience in the art of the practice rather than the science of medicine—hints which, properly digested and applied, may carry the physician around more than one sharp corner which otherwise might be extremely hard to negotiate. There is one sentence in this volume which every surgeon, particularly he who is inclined to operate with one eye on the clock, should read and ponder: "Quickness is not measured by the clock, but by the degree of traumatism inflicted." Appreciation of the thought expressed here might lengthen a surgeon's operating time, but it might also decrease postoperative morbidity among his patients.

**COLLOID CHEMISTRY: AN INTRODUCTION, WITH SOME PRACTICAL APPLICATIONS.** By Jerome Alexander, M.Sc., Chairman, Special Committee on Colloids, Division of Chemistry and Chemical Technology, National Research Council. Cloth. Price, \$1.50. Pp. 99, with illustrations. New York: D. Van Nostrand Company, 1919.

In this little book—it contains only eighty-three pages of text—the author presents in a simple and terse manner the fundamental facts about colloids. It is delightful to read because it leads one through the rather complicated phases of colloidal chemistry, giving such a scientist as the physician an adequate view of the subject and yet obviating the more involved academic considerations. The important practical applications of this fascinating "twilight zone between physics and chemistry" increases one's interest in this study. The chapter on medicine happily contains no such unscientific statements or proprietary boasts as that of the English "Report on Colloid Chemistry" by the British Association for the Advancement of Science.

## Social Medicine, Medical Economics and Miscellany

### THE COST OF FOOD OF DIABETICS IN HOSPITAL\*

ALICE N. DIKE

Assistant Professor of Cookery, Simmons College  
BOSTON

This investigation was undertaken to find out whether diabetic patients cost the hospital more for their food than other patients, or whether the diabetics were right when on "fasting" days they remarked, "The hospital is making money on us."

Three hospitals, treating relatively large numbers of diabetics, were visited to find where a study could best be made. The New England Deaconess Hospital was selected because there a group of twelve or fourteen patients were in a separate cottage, though, unfortunately for the purposes of the study, about half as many more other patients were in the same house.

The cost of food for one week was estimated roughly, and the result was so startling that it was decided to figure the cost of another week more carefully. This was a matter of a good deal of difficulty because some of the food of the diabetics and most of the food of the other patients was sent over cooked from the main hospital, often in one container for both sets of patients. Some left over food was

#### ESTIMATED COST OF EACH FOOD GROUP PER PATIENT PER DAY

Food Groups	Estimated Cost
Dairy products .....	\$0.118
Groceries (except canned vegetables) .....	.063
Canned vegetables, 0.150; fresh vegetables, 0.158 (all vegetables) .....	.308
Fruits .....	.059
Fish, 0.084; Meat, 0.398 (all meat and fish) .....	.482
Miscellaneous (agar, whisky, liquid petrolatum, bran, saccharin) .....	.055
Total .....	\$1.085

returned to the hospital and therefore had to be accounted for. The following results, while carefully determined by weighing whenever possible, are not strictly accurate in all cases, though with the possible exception of the meats they are, at least, as accurate as ordinary hospital estimates of food costs. All foods used were of the first quality, some even of fancy grade.

During the week June 23 to 30, 1919, for which the food was carefully estimated, there were nineteen different diabetic patients in the hospital, making an average of 13½ patients a day. Of these ten were severe cases, six moderately severe, and three, mild. Several patients fasted one or more days each; but as they were given broth, tea, coffee, and cocoa shells they were certainly costing the hospital as much as postoperative surgical or some medical cases.

At the same time that the study in diabetic food costs was being made, the hospital dietitian, Miss Ruth M. Wallace, estimated the cost of food of all nondiabetic patients. Results showed that the diabetics were costing 29 per cent. more than other patients. This should not be considered surprising when it is remembered that the diet requirements for diabetics in severe cases eliminate practically all the cheap carbohydrate foods, such as bread, breakfast cereals, and potatoes.

Since this study, although not claiming to be strictly accurate, was carried on at the same time that the estimate of the cost of nondiabetic patients was being made, and the two were done by two trained persons working together, it seems fair to conclude that the hospital diabetic is costing at least one fourth more for raw food materials than other patients. It is also clear to any one who has watched the preparation and serving of the food with its "thrice-washed"

vegetables and weighed portions, that the labor cost is also high. For a complete comparison of the cost of the two groups it would be necessary to know the laboratory cost and the nursing cost of each.

The investigation brought out a few other points of interest: Of dairy products, eggs are by far the most expensive item, and it seems unwise to limit their use; milk, butter and cream (20 per cent.) are used in such small quantities that their cost is unimportant. For the strictest economy, butter substitutes may be used in place of other fats. Of groceries, aside from canned goods, coffee and gelatin are the most expensive; cocoa shells when purchased wholesale make a cheap drink. Almost no vegetables outside the 5 per cent. group were used during the week; of these, tomatoes and spinach were the cheapest of the canned vegetables, and cabbage, lettuce, and cucumbers of the fresh vegetables. Fruits are used in small quantities, and even at present prices are an inconsiderable item. Some kinds of fish were cheaper than meat with us in Boston. Cod, haddock, and flounder may be used in place of chicken in cases in which the proportion of fat must be kept low. Of meats, bacon and fowl, both of which were freely used and were of excellent quality, were expensive. During the week of the study, only carefully trimmed expensive kinds of meat were served, as had been the practice of the hospital. If carefully cooked cheap cuts of meat were served, and possibly some cheese, the cost of this large item would be reduced substantially. Broth is a very expensive item, especially if much chicken broth is used, as has been the custom. Only one squab was served, our preliminary study having shown this to be extravagant for all except patients in higher-priced private rooms.

In the group of miscellaneous items, some might possibly be classified as medicines, though all were served with the food. Agar-agar, which is used in the highly prized bran muffins, is expensive; but as it makes possible the one article which in any way resembles bread, and helps to give bulk to the diet, the outlay seems legitimate. The use of saccharin is unlimited but not encouraged; an average of only five one-fourth grain tablets per patient per day was used. The liquid petrolatum included here was used in cooking, and makes possible fried eggs and some other foods.

In spite of the fact that the diabetic diet must be relatively expensive, its cost may be substantially reduced by economy in the use of meats and vegetables. For the strictest economy, tea and cocoa shells should be used in place of coffee; gelatin and agar-agar used sparingly or omitted; butter substitutes used in place of cream and bacon; the cheapest vegetables, canned and fresh, selected; broth omitted, and the cheapest fish and meat used.

### REPORT OF CONNECTICUT SOCIAL INSURANCE COMMISSION

The Connecticut Commission on Public Welfare, appointed by the legislature in 1917, has submitted a report covering health insurance, hours of labor, minimum wage, old age and mothers' pensions, and occupational diseases. Its principal recommendation is the postponement of any further consideration of social insurance until the changes resulting from the war have been fully readjusted. The commission was impressed with the lack of interest in this subject in Connecticut. The state federation of labor in 1918 adopted resolutions favoring health insurance, old age pensions and a minimum wage, but the commission was unable to determine whether the vague expression of opinion implied support of compulsory insurance or not. All of the employers of labor who appeared before the commission agreed that compulsory health insurance at the present time would be unwise. The physicians of the state showed little interest in the subject. A questionnaire sent out by the commission to physicians elicited only about 30 per cent. of replies. To

1. The vegetables in the 5 per cent. group are: lettuce, cucumbers, spinach, rhubarb, endive, marrow, sorrel, sauerkraut, tomatoes, Brussels sprouts, watercress, sea kale, okra, cauliflower, egg plant, cabbage, ananas, beet greens, dandelion greens, Swiss chard, celery, radishes, leeks, string beans, broccoli and peppers.
2. Nearly one-half the weight of the bacon was returned to the hospital and allowed for in figuring the cost.

\* From the Diabetic Clinic of the New England Deaconess Hospital.

the question, "What suggestions have you to make as to how the problem of adequate medical service can best be handled to serve the interest of the state, the physician and the sick of limited means?" only half of those who replied, or about 15 per cent. of the profession of the state, expressed any opinion. "The replies of not a few," says the report, "indicate that they did not look beyond their own immediate practice; a small number favored a better medical organization and suggested an extension of hospital service. Not more than a dozen took sides for or against compulsory health insurance." Physicians who appeared before the commission strongly deprecated any action on health insurance at the present time, declaring that it was a matter to which a great deal more thought and study should be given and that those of their number who were best informed were either in the military service or so much absorbed in duties incident to the war that they could not give the commission the benefit of their knowledge. The opponents of compulsory health insurance in Connecticut prepared for legislative consideration a substitute providing for an elaborate organization and administration of a department of health, on the ground that the enlargement of state health activities was less expensive, less socialistic and paternalistic and would be more effective than compulsory health insurance. The commission is of the opinion that either of these plans would prove more of a burden than the state would care to assume at present. The commission was impressed with some of the arguments in favor of compulsory health insurance for humane reasons, and is convinced that the state should do more to improve living conditions and prevent disease, but is not convinced that any of the measures thus far presented should be enacted. It feels that Connecticut should not be the first state to experiment with such a plan, but should gradually improve and extend its department of public health.

Regarding old age pensions, the commission after considering the arguments and objections pro and con did not regard the situation in Connecticut as sufficiently acute to justify the experiment. Regarding mothers' pensions, it is recommended that Connecticut might well follow the other thirty-six states which have enacted mothers' pension laws and either make provisions directly for such allowances at the cost of the state or confer on the towns the necessary power and authority to make them. The commission also believes that any disease arising out of or in the course of employment should be included within the provisions of the workmen's compensation law and should receive benefits the same as occupational injuries.

### MARRIAGE AND THE UNFIT

Adolf Meyer, director of the Henry Phipps Psychiatric Clinic, Johns Hopkins Hospital, in the July number of the *Canadian Journal of Mental Hygiene*, asks: "Why should we not, in the [marriage] ceremony itself, put the proper emphasis on the real issue of marriage? Why not replace the much discussed question of obedience by the question, put to both parties to the life contract: Do you want this man (or this woman) and no other to be the father (or mother) of your children?" He says, "not until some question as pointed as this is in all cases expected and squarely asked and squarely answered as a matter of general and frank concern as soon as marriage is considered, will the rank and file of people realize the needed obligation to deal fairly with the problem of health and parental responsibility before the knot is tied." Discussing the influence of heredity, Meyer reports the study of a community in which there were four interrelated family groups, represented by thirty-five children at the public school, fourteen of whom were defective, and says in his analysis that the defects were clearly traceable to the influence of parental taint and heredity. He is skeptical of the value of legal restriction on marrying of the unfit, such as was attempted in Wisconsin, and thinks the restraining force should come from education and social pressure. Persons with taint, as distinguished from those with true defects, should not be denied wedlock, but should be permitted to marry only on condition of mating themselves with individuals of better stock than their own.

## Medicolegal

### Privilege Is That of Patient and Not of Physician

(*Markham v. Hipke (Wis.)*, 171 N. W. R. 300)

The Supreme Court of Wisconsin, in affirming an order adjudging the defendant, a physician, guilty of contempt, in refusing to answer in an adverse party examination, says that the action was for malpractice. The defendant was being examined adversely before trial, under Section 4096 of the Wisconsin statutes, and refused to disclose information received by him while treating the plaintiff as a patient, and which was necessary to enable him to prescribe, although the plaintiff expressly waived the statutory privilege of secrecy and he was ordered by the court to answer. For this refusal he was adjudged guilty of contempt, and appealed.

The sole question presented was whether the privilege granted by Section 4075 of the statutes is the privilege of the patient or of the physician. The supreme court thinks it is unquestionably the privilege of the patient. This was so held in *Boyle v. Association*, 95 Wis. 312, 70 N. W. 351, when the statute provided that no physician should be "compelled" to disclose such information. By Chapter 322 of the Session Laws of 1911, the section was amended by the substitution of the word "permitted" for the word "compelled," and by the addition of a provision allowing the information to be disclosed by the physician as a witness in his own behalf in a civil action for malpractice and in a criminal action therefor, when the patient or his legal representatives shall have first given evidence relating thereto. It was not entirely easy to construe the word "compelled" as giving the privilege to the patient, as may be seen by examination of the opinion in the Boyle case; but it is very easy so to construe the word "permitted." The latter word means practically the same as "allowed," which is the word used in Sections 4074 and 4076, protecting communications made to clergymen and attorneys, respectively, and the latter word has generally, if not uniformly, been construed as granting the privilege to the penitent or the client. Cases decided in this court since the last-named change was made inferentially, if not directly, sustain this view.

### Privilege—Compensation for Sufferings

(*Fisleigh v. Detroit United Ry. (Mich.)*, 171 N. W. R. 549)

The Supreme Court of Michigan, in affirming a judgment for \$23,000 in favor of the plaintiff for damages for personal injuries, says that a physician who was called as a witness by the defendant was asked the question whether, without mentioning any names, he ever treated any immediate member of the plaintiff's family for diabetes. During the discussion that followed an objection, it was stated by the defendant's counsel that the question referred to a brother or a sister. The trial court sustained the objection on the ground that the evidence could not be received on the question of heredity, it not being the father or the mother that was referred to. But the supreme court need not consider the reason assigned by the lower court for its ruling, as the supreme court is satisfied that the physician was prohibited by Section 12550, Compiled Laws of Michigan of 1915, from testifying to what he learned in his professional capacity, while treating, and for the purpose of treating, the brother or sister. The privilege was the privilege of the patient, who was not a party to this suit; and there was no claim that the privilege had been waived by the patient.

It was insisted by the defendant that the verdict was excessive. But the supreme court does not think that it should treat it as excessive. When the cars collided the plaintiff was thrown forward, her knee or knees striking the seat in front; on the recoil she struck the back of the seat, which broke, either as the result of her body's striking against it or from others falling on it, and she was struck by the broken seat or a piece of it, an iron rod along with the wood, across the lower part of the back. Some months

afterward she was operated on, and a portion of the coccyx was removed, and later her right ovary was removed. From a robust, cheerful, vigorous woman, a wage-earner, weighing about 150 pounds, she had in twenty-two months' time wasted to a helpless cripple, weighing 98½ pounds, while her sufferings had been great and would so continue. In personal injury cases the amount of damages is not subject to exact mathematical calculation. Primarily the question is for the jury; and the supreme court cannot arbitrarily substitute its judgment for that of the triers of the facts. By the use of the mortality tables the plaintiff's loss of past and prospective earnings could be computed with reasonable accuracy. But there is no market place where pain is bought and sold. Compensation for sufferings must primarily be fixed by the jury with an honest judgment, based on the evidence as their guide. If grossly excessive, if the result of prejudice, or passion, or influence other than the evidence in the case, their determination cannot stand in the reviewing court. But that court must find something more tangible than a difference of opinion as to amount before it should vacate a verdict which has the approval of the trial court.

### The Kind of Insanity That Is a Defense to Crime

(*People v. Morisawa (Calif.)*, 179 Pac. R. 888)

The Supreme Court of California, in affirming a conviction of murder in the first degree, says that the killing was admitted, and the defense was insanity. Complaint was made of the instructions given to the jury as to the test of insanity; but on this matter they were in accord with the well-settled law of California, being substantially to the effect that insanity interposed as a defense in a criminal prosecution means such a diseased and deranged condition of the mental faculties as to render the person incapable of distinguishing between right and wrong, in relation to the act with which he is charged; that in order to establish the defense, it must be proved by a preponderance of evidence that, at the time of committing the act, the party accused was laboring under such a defect of reason, from disease of the mind, temporary or otherwise, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong; that if the defendant at the time he fired the shot at the deceased, if he did so fire, understood the nature of his act, and knew it was wrong and deserved punishment, he was legally responsible for his act, if committed as charged in the information; that the true test of insanity was whether at the time of committing the crime he was conscious that he was doing what he ought not to do; and that if the defendant was in that mental situation in which he did not appreciate the act he was committing, and he did not know it wrong to do it, that, of course, would be a legal defense. Counsel for the defendant contended that the instructions were erroneous in not including, in addition to the elements stated, the element of "power" on the part of the defendant "to adhere to the right and avoid the wrong," "the power to govern his body." But it is now so firmly settled in California as not to require discussion that an irresistible impulse on the part of a person to commit an act which he knows is wrong or unlawful does not constitute the insanity which is a legal defense.

### Privilege Not Waived

(*Arizona Eastern R. Co. v. Mathews (Ariz.)*, 180 Pac. R. 159)

The Supreme Court of Arizona says that in this personal injury case the defendant offered as witnesses two physicians who rendered professional services to the plaintiff, and wanted to prove by them what they discovered or learned of his condition, insisting that he had raised the ban of secrecy because in a previous trial he had examined one of the witnesses in regard to the same subject-matter and had permitted the other to testify without objection. This offered testimony, on objection that it was confidential, was rejected; and the court does not consider that this ruling was erroneous. In *Arizona & New Mexico Ry. Co. v. Clark*, 235 U. S. 669, 35 Sup. Ct. 210, it is said that the statute con-

templates that the patient may testify with reference to what was communicated by him to the physician, and in that event only it permits the physician to testify without the patient's consent. The act gives him the option of excluding the physician's evidence entirely by himself refraining from testifying voluntarily as to that respecting which alone their knowledge is equal, namely, what the patient told the physician with reference to the ailment. It did not appear that the plaintiff, in the former trial or in the present one, testified voluntarily as to what he "told the physician with reference to his ailment." It seems, under the Arizona statute and the construction given it in the Clark case, that the patient can object to the physician's testifying as to what he may have learned in his professional capacity unless the patient has himself "testified to the communications he made to the physician." It not appearing that the plaintiff testified to any communication made by him to the physicians, he did not waive his right to object to their testifying at the second trial, even though they did at some previous trial testify as to knowledge obtained by personal examination.

**Effect of Epinephrin on "Irritable Hearts."**—The reaction to the intramuscular injection of a small dose (0.5 c.c. of a 1:1,000 solution) of epinephrin was studied by Wearn and Sturgis in normal soldiers, and in a group of soldiers showing symptoms of so-called "irritable heart." Of twenty-six normal soldiers, who had gone through the grill of army training in its severest form for fourteen months, not one gave a positive reaction as judged by observation of pulse rate, blood pressure, objective signs or subjective symptoms. Seventy-three patients with symptoms of "irritable heart" were studied. Their symptoms were of long duration and for the most part antedated their entrance into military life. Of this group about 60 per cent. gave a reaction which definitely indicated a hypersensitiveness to epinephrin. Epinephrin has a selective action on the sympathetic autonomic nervous system, therefore, it may be assumed that the symptoms and signs induced in the positive cases are the result of a hypersensitive sympathetic autonomic nervous system. A careful clinical analysis, however, of the patients showing positive and negative reactions has revealed no essential clinical differences between the two groups. Although all efforts were made to improve the physical condition of these men, not one of those who gave a positive reaction, and only three who gave negative reactions were able to go to full duty.

**Effect of Epinephrin on Basal Metabolism.**—Tompkins and his associates found that intramuscular injection of epinephrin causes an increase in total gaseous metabolism in normal men, patients with "irritable heart" and in hyperthyroidism. The increase in metabolism is greater in cases showing a "positive" reaction to the epinephrin than in those showing no characteristic reaction, and it is parallel to the pulse, blood pressure and symptomatic changes. There is an increase in the minute volume of air breathed under the effects of epinephrin, and of either respiratory rate or depth, or both. After intramuscular injection of epinephrin, there is very frequently an elevation of respiratory quotient. The maximum of this elevation ordinarily precedes that of the metabolic increase. The increase in metabolism is due to some factor other than the excitement attendant on injection or the stimulation to heart and respiratory muscles resulting from injection. The increase in metabolism may be due to increased muscular tonus or to hyperglycemia. It may be that these factors are only partial expressions of a general indirect stimulus to the metabolism from the epinephrin by its action on some system capable of direct metabolic activation. As epinephrin is a stimulant to the sympathetic autonomic nervous system, the differences in reaction and metabolic response in the negative and positive cases are probably due to differences in that system.

**Effect of Epinephrin on Electrocardiogram of "Irritable Heart."**—The effect of epinephrin was observed by Clough in normal individuals and in a number of patients with the symptoms of "irritable heart." All of the latter were hypersensitive to epinephrin in the sense that they gave a much more pronounced reaction to a small dose of the drug than do normal individuals. In some cases gross abnormalities of the electrocardiographic record were observed. The most important deviations from the normal were changes in conduction (delayed conduction, partial heart block) and the production of ventricular extrasystoles. Special studies were made of the effect of epinephrin on the conduction time, length of systole and height of the T wave in twelve epinephrin hypersensitive patients with "irritable heart" and in twelve normal men. No changes were found in the conduction time or the length of systole in either type. In both at the height of the reaction there was a decrease in the height of the T wave. An attempt was made to correlate the symptoms complained of by the patients with "irritable heart" at the height of the reaction with abnormalities of the electrocardiogram, but no definite association could be made.

**Experimental Leukocytosis.**—Although there are few endothelial leukocytes normally present in the peripheral blood as compared with the neutrophils or lymphocytes, the percentage may be increased regularly by experimental procedures as was shown by the authors. It appears after an

examination of the usual textbooks and a cursory examination of the literature that a characteristic increase in number in human blood of this variety of leukocyte has not been noted in generalized military or other forms of tuberculosis. Such a leukocytosis was noted by McJunkin and Charlton in the later stages of the usual experimental tuberculosis of guinea-pigs.

**Thyroid Enlargement in Recruits.**—A survey of 21,182 troops coming to Camp Lewis, Washington, from eleven states, comprising an area of approximately one third of the United States, showed a high incidence of simple goiter, in Washington, Oregon, California and Nevada. Twenty-one per cent. of all troops examined showed a definite enlargement of the thyroid. Of these 27 per cent. showed a large or moderately enlarged thyroid, and 73 per cent. were classified as "small." The enlargement of the thyroid was noted as diffuse in 38 per cent. of the cases; isthmus, in 52 per cent., right lobe, in 5 per cent., and left lobe in 4 per cent. Such physical signs as tremor, tachycardia, vasomotor instability of the hands and curved nails were noted, and were found in a larger percentage of men with thyroid enlargement than in those without demonstrable changes in the thyroid.

\*Gaseous Exchange with Unpracticed Subjects and Two Respiratory Apparatuses Employing Three Breathing Appliances. M. F. Hendby, T. M. Carpenter and L. E. Emmes, Boston.—p. 368. Conc'n.

**Associated Pains in Knee and Penis.**—Marshall cites the case of a man who suffered from pain along the course and distribution of the internal pudic and obturator nerves. A diagnosis was made of reducible obturator hernia which pulled or pressed at times on the obturator and internal pudic nerves of the left side. Relief is obtained when it does not descend into the hernial sac.

**Gaseous Exchange with Unpracticed Subjects.**—The respiratory exchange of seventeen untrained medical students was measured by Hendby, Carpenter and Emmes with each of three breathing appliances, namely, mouthpiece, nosepieces and mask, on two different respiration apparatus, the Benedict portable apparatus and a respiratory valve apparatus. The results show that there are no marked differences in the respiratory exchange when the breathing appliance alone is considered. The breathing is slightly more normal with the mask. The oxygen consumption is practically the same regardless of the breathing appliance or respiration apparatus used. The general trend of the oxygen consumption for twelve periods, considered from the standpoint of time, indicates that there is practically no difference from period to period between 8:30 a. m. and 12:30 p. m. The general tendency for the metabolism to remain stationary is confirmed by the course of the pulse rate. There is a slight tendency for the carbon dioxide elimination to be higher with the portable respiration apparatus than with the respiratory valve apparatus. This is due primarily to a tendency to a slightly greater ventilation of the lungs. The average respiratory quotient with the portable apparatus is slightly higher than that with the respiratory valve apparatus, and the lowest with the mask as compared with the mouthpiece and nosepieces. The general level of the respiratory quotient throughout twelve periods of measurement from 8:30 a. m. to 12:30 p. m. remains practically constant. When the measurement of the oxygen consumption alone is desired, the authors found the Benedict portable respiration apparatus the best apparatus for short-period measurement. When more data are desired, such as total ventilation, respiratory quotient, and mechanics of breathing, the respiratory valve apparatus is better. For continued experimenting from period to period without interruption, the mask is preferable to the other two breathing appliances. The detailed data on these experiments are given in full.

- \*Insusceptibility of Man to Inoculation with Blood from Measles Patients. A. W. Sellards, U. S. Army.—p. 257.  
 Role of Roentgen Ray in Diagnosis of Unostanding Renal Tuberculosis. J. A. C. Colton and C. A. Waters, Baltimore.—p. 268.  
 Reminiscences of Two Epochs: Esthesia and Asepsis. S. Smith, New York.—p. 273.  
 Effort Syndrome. E. W. Bridgman, Baltimore.—p. 279.

**Insusceptibility of Man to Inoculation with Blood from Measles Patients.**—Sellards reports the results of the study in human volunteers of the question of prophylactic inoculation against measles. For these inoculations, blood was taken from a moderately severe case of measles twelve hours after the first appearance of the rash. At this time the Koplik spots had already disappeared, the eruption was profuse over the face, back and chest, less intense over the abdomen and only a few scattered spots had appeared on the thighs. Immediately after collection, one portion of the blood was defibrinated and centrifuged for the collection of serum. Part of this serum was mixed with an equal volume of fresh serum obtained from a typical case of measles ten days after the temperature had returned to normal. Another portion of the original serum was diluted with nine parts of physiologic sodium chlorid solution; one portion of the diluted serum was kept at room temperature for a control and the remainder was heavily inoculated with *B. prodigiosus* and passed through a Berkefeld filter (so-called N). Three susceptibles and one immune who had had measles twenty-eight years previously were injected with diluted serum, filtered serum, a mixture of equal parts of patient's and convalescent's serums and defibrinated patient's blood, respectively. None of these four individuals developed any symptoms of measles. Sellards says that while the delay of one hour before injecting this serum and also the absence of red cells might be regarded as factors contributing toward the negative result, it would appear from previous work that the blood retains its infectivity *in vitro* for at least a day. After an interval of one month, a second intravenous injection was given the immune consisting of serum collected from a patient fifteen hours after the appearance of the rash. No symptoms of any kind resulted.

The remainder of the work with susceptible individuals was restricted to an attempt to transmit measles by the injection of patient's blood. Defibrinated blood was injected subcutaneously into two men. Cultures of patient's blood in ascitic broth were inoculated in two other men. None of these four subjects developed measles; neither did any symptoms appear that could definitely be attributed to the injections. After an interval of thirty-five days one of the men injected with defibrinated blood and another injected with blood incubated in broth were reinoculated by smearing the mucous membranes of the eyes, nose and throat with freshly excised morbillous skin lesions. No definite symptoms developed. Two susceptibles were inoculated on two successive days with blood taken before and after the appearance of the eruption. Control inoculations were made simultaneously into two immunes. Blood for these injections was secured from two patients; specimens were obtained from one patient thirty hours and again six hours before the appearance of the rash and from the other six hours before and eighteen hours after the rash appeared. None of these four subjects developed any symptoms of measles. Of the two susceptibles selected for these injections, one gave unusually good evidence that he had never contracted measles. Two susceptibles and two immunes, one of whom had not previously received any injections were inoculated on the mucous membranes of the eyes and nose with the lacrimal secretions and also on the nose and throat with the nasal secretions of a patient, on the day of the preeruptive rise in temperature, i. e., twelve days after exposure and four days before the eruption. A similar inoculation was made on the day before the eruption, i. e., on the fifteenth day after exposure. On this occasion, in addition to duplicating the previous inoculations, the buccal secretions were thoroughly rubbed over the mucous membranes of the throat and mouth of the four subjects. On both occasions the four subjects were in the same room with the patient. One more susceptible was inoculated intravenously

with measles blood taken within from six to ten hours after the appearance of the rash. The blood was injected immediately after withdrawal before it had time to clot. Neither the intravenous injection of blood nor the inoculations of the secretion produced, in these five subjects, any respiratory symptoms or any rash. Only insignificant fluctuations occurred in the temperature and in the leukocyte count.

Sellards points out that in drawing conclusions concerning these inoculations of blood and mucous secretions in these susceptible men, two unknown factors are to be determined, namely, (1) whether the individuals in question at the conclusion of the inoculations were immune and if so (2) whether the immunity was conferred by the injection of blood or acquired possibly through a previous attack of measles. The results of the susceptibility tests leave little doubt that these men were immune. Sellards emphasizes further that conclusive demonstration of the noninfectivity of measles blood on injection into a susceptible individual would still fail to prove the absence of the virus of the disease in the circulating blood. It is very doubtful, for example, whether a susceptible human being would be infected by the injection of a moderate amount of blood of a typhoid patient taken during the stage of bacteremia. It is a theoretical possibility that the blood of a measles patient might reproduce the disease when inoculated on the mucous membranes though not on injection into the body tissues. Sellards points out, further, that there is a striking discrepancy between the negative results following these inoculations of measles blood and the successful experiments previously reported under essentially similar conditions. A careful examination of the data recorded by Sellards has failed to suggest any correlation of these diametrically opposite results.

**War Wounds of Abdomen.**—Bruggeman says that taken as a whole the treatment of gunshot wounds of the abdomen was about the most unsatisfactory work of any phase of war surgery. The responsibility was great and the mortality high. It had none of the red fire features of chest surgery, and it lacked the many novel experiences that accompanied the operative treatment of battle injuries of the brain.

**Appendiceal Abscess.**—Porter's patient was only 9 years of age, she had had influenza followed by pain all over the abdomen, finally localizing in the left side of the pelvis. About a week later there was a copious discharge of pus from the vagina, with relief of symptoms. She remained well for about five months when she began to complain of gastric pain, pain in the right lower quadrant and vomiting. A diagnosis of appendicitis was made, operation being performed thirty-six hours after the onset of this attack. Adhesions were found involving the cecum, ileum and broad ligament, and extending down into the pelvis. During the separation of the adhesions, several abscess cavities were opened. The appendix was found perforated near the cecal end. The patient's progress was satisfactory for about eight days, when she began to complain of back pain and frequent desire to empty the rectum and bladder. The drainage from

the wound had been quite copious until within a few hours of the onset of these symptoms. Rectal examination disclosed a very tender but nonfluctuating mass in the pelvis. The lower end of the original wound was opened and the finger introduced into the pelvis without opening the general peritoneal cavity and without discovering any pus. A drain was placed and a dressing applied. There was a copious serous discharge for two or three days, which finally subsided and the drain was removed. Following this last operation, there was considerable mucopurulent discharge from both the vagina and rectum. The rectal discharge continued for a few days and then stopped. The vaginal discharge diminished but is still present and amounts to a mild leukorrhoea. Immediate relief followed the operation, and it has continued.

Hemato-Respiratory Functions. II. W. Haggard and Y. Henderson, New Haven, Conn.—p. 163.

**Biochemistry of *Bacillus Acetoethylicum*.**—Several microorganisms have been described as forming more or less acetone, and at least two have been used on a commercial scale. Of these organisms, *Bacillus maccranns* was used by Northrup and his associates in this work, inasmuch as it forms ethyl alcohol as a by-product. Since it was not possible to obtain a culture of the organism in this country, the bacillus was isolated from potatoes. The optimum conditions of temperature, reaction of the medium, physiologic state of the culture, size of inoculation, air supply and nitrogen supply have been determined by the authors and are described.

**Studies of Gastric Residuum.**—The average amino-acid nitrogen found by Cessna and Fowler in twenty-six normal cases of gastric residuum was 36.4 mg. per hundred cubic centimeters. The amount of amino-acid nitrogen apparently bears no relationship to acidity or pepsin or trypsin content. In view of these data the authors believe that the high amino nitrogen value of the contents of the fasting stomach appears not to be significant in gastric carcinoma.

**Preparation of Protein Free from Water Soluble Vitamin.**—From the experiments described in this paper it is evident that the commercial cornstarch, which the authors used, contained no appreciable quantity of the water soluble vitamin; for even though this starch constituted about 50 per cent. of the diets the rats died after a short period. That starch furnishes carbohydrate in a form adequate for the normal nutrition of rats has been demonstrated by many experiments made by the authors, which fact, in connection with the ease with which the commercial starch, practically free from water soluble vitamin, can be obtained, makes this an excellent source of carbohydrate for vitamin free diets.

**Nonprotein Nitrogenous Constituents of Human Milk.**—The authors report the results of a series of observations made on the milk of normal women in which they made determinations of total nonprotein nitrogen, urea, uric acid, creatin and creatinin, in an effort to obtain data regarding the relative quantities of these substances present under normal conditions. It is apparent that while there are slight variations in the amount of the various extractive substances present in samples of milk drawn at different periods throughout the day, these variations are relatively small, and could not be considered of importance in the interpretation of results. There is also no apparent uniformity in the slight variations noted, in some cases for instance the highest value for urea was found in the samples drawn during the forenoon, in others a maximum was attained in the late afternoon or evening. The results of the examination of seventy-one samples of milk may be summarized as follows:

	Minimum.	Maximum.
	mg.	mg.
Total nonprotein nitrogen	20.0	37.0
Urea nitrogen	8.3	16.0
Amino nitrogen	3.0	8.9
Preformed creatinin	1.0	1.6
Creatin	1.9	3.9
Uric acid	1.7	4.4

**Oat Protein in Human Nutrition.**—Sherman's experiments indicate that for the purposes of practical dietics equal weights of oat and maize proteins may be regarded as essentially equal in value, and that even the minimum amount of milk which can possibly be regarded as permissible in the light of our present knowledge of nutrition, will apparently so supplement the proteins of either the maize or oat kernel as to make them function with an efficiency comparable with that of the average protein of mixed diet in the maintenance metabolism of man.

**Vitamin Studies.**—The substances used by Dutcher, i. e., thyroxin, desiccated thyroid, pilocarpin and tethelin, apparently produced definite relief in certain acute cases of avian polyneuritis. However, in none of the cases described did he obtain the almost immediate response that is usually observed when vitamin preparations are fed. Pigeons have been relieved of the paralytic symptoms, in avian polyneuritis, by means of thyroxin, desiccated thyroid gland, pilocarpin hydrochlorid and tethelin. The work is being continued along the lines indicated by the above observations.

**Blood Sugar Determination.**—Reviewing all their data Morgulis and Jahr are convinced that the presence of creatinin increases the blood sugar value as determined by the Lewis-Benedict method. It is true that concentrations less than 2 mg. of creatinin per hundred cubic centimeter have no effect on the accuracy of the reaction, but with greater concentrations the error in the sugar analysis increases progressively. It is probable, therefore, that the Lewis-Benedict method is applicable to normal bloods where the creatinin concentration is from 1 to 3 mg. per hundred cubic centimeter, but under pathologic conditions when the creatinin level may rise to 10 to 40 mg. per hundred cubic centimeters the sugar analysis by the Lewis-Benedict method loses its value as a quantitative procedure.

**Iodin Compound in Thyroid.**—Kendall's paper consists mainly of detailed descriptions of methods used to isolate this iodine compound—thyroxin—from the compound.

**Action of Ptyalin.**—Evidence is presented by McGuigan in favor of the view that ptyalin unites with the starch during digestion, and exerts a force which causes hydrolysis.

**Nitrogen and Solids in Blood.**—A method is described by Peters for the determination of total and nonprotein nitrogen and of total solids in from fifteen to thirty drop quantities of human blood so that frequent or serial determinations at short intervals can be made conveniently on the same individual. The use of a single fixed color standard has been developed for the measurements of the Nesslerized nitrogen solutions. The conditions of accuracy have been tested and the quantitative evaluation of the colorimetric results has been adjusted to variations of analytical conditions so that the variability and certainty of the results lie within a few thousandths of a milligram of nitrogen. A procedure for determining the dry weight of a few drops of blood is also described which obviates incomplete or unequal drying.

\*Etiology of Molluscum Contagiosum. Preliminary Report of Experimental Study. U. J. Wile and L. B. Kingery, Ann Arbor.—p. 431.

\*Serologic Reactions in Case of Rhinoscleroma. C. H. Bailey, New York.—p. 447.

Skin Diseases at Army Camp. M. B. Hutchins, Atlanta.—p. 456.

**Etiology of Molluscum Contagiosum.**—Wile and Kingery believe that molluscum contagiosum can be produced experimentally in the human being from the sterile filtrate of typical lesions. The incubation period of experimental lesions probably depends on a number of conditions, among which surely individual predisposition or susceptibility must play a rôle. In the authors' first case an incubation of fourteen days occurred; in the second case, in which injection was made at the same time and under like conditions, lesions clinically diagnosable appeared in about twenty-five days, but were microscopically established only fifty-five days after infection. The authors believe that the so-called molluscum bodies require a longer time for their development than is required for the development of macroscopic lesions; that is to say, that the molluscum body represents a degeneration stage in the evolution of the molluscum tumor, not coincident in time with its early development. It is submitted that molluscum contagiosum is caused by a filtrable virus.

**Serologic Reactions of Rhinoscleroma.**—The blood serum from a case of rhinoscleroma studied by Bailey contained complement-fixing antibodies for its own and one other strain of rhinoscleroma bacillus in very large and similar amounts. Power to fix complement with other species of gram-negative encapsulated bacilli from the respiratory tract, including two strains of *Bacillus lactis-aerogenes* was high, but less high than with the rhinoscleroma bacillus. Complement fixation with two strains of *B. lactis-aerogenes* from the intestinal tract was practically absent. Coincident with clinical improvement under roentgen-ray and radium treatment, there was a diminution in the complement fixing power. The rhinoscleroma bacillus, because of its cultural characteristics and immunologic reaction, recorded here and by other authors, would seem to be as much entitled to recognition as a species distinct from, but closely related to, other members of the group as are others now generally so recognized; and the results of the complement fixation tests favor the view that the rhinoscleroma bacillus is the etiologic factor in this disease.

\*Essential Myoclonia. L. P. Clark, New York.—p. 17.

Uniform Statistical Reports of Insanity now Assured. Official Classification of Psychoses. J. V. May, Boston.—p. 42.

**Phenomena of Neurobiotaxis.**—A study of the displacements of the nerve cells in the direction of the place of stimulation and a comparison with the other phylogenetic changes in the oblongata and midbrain, have given Kappers the conviction that these shifting are caused by the difference in stimulation, i. e., the difference of development to their corresponding posterior roots and the difference in the sensory, optic, vestibular, acoustic, and other reflexes that influence other functions. At the same time changes in the muscular system complicate these factors. The nuclei appear to shift in the direction of the place whence the majority of the stimuli come to them.

**Essential Myoclonia.**—Aside from myoclonia being the symptomatic accompaniment of various organic diseases more or less pronounced, Clark says it appears to exist solely in an ultramicroscopic lesion in the brain per se. An atrophy of the neostriatum or lenticular region between the corpus striatum and the globus pallidus is the most probable seat of the lesion in which the tonic function of the neostriatum is affected.

**Lengthening of Quadriceps Tendon.**—Loss of flexion as the result of fractures of the lower third of the thigh, which require plating or long immobilization because of slow union, Bennett feels is due to shortening and adhesions between the deep central fibers of the quadriceps (particularly the crureus vastus internus and vastus externus). He describes an operation which overcomes this shortening. It consists in severing the central section of the tendon at the point of adhesions, splitting the vastus internus and vastus externus free, and separating the attachment of these muscles from the patella, leaving the central section with a broad attachment to the patella, forcibly flexing the knee, and pulling down the section dissected. The next step is the sewing up of the structures in such a way as to give the greatest amount of strength. The vastus internus and vastus externus are firmly united to the patellar tendon, the sections immediately above are sewed together with either strong silk, kangaroo tendon or chromized catgut, the leg is then fixed in a flexion position of about 80 degrees for a period of three weeks. At the end of this time the plaster is removed, and the leg allowed to be extended fully, giving passive motion each second day.

\*Effects of Chlorin on Body Temperature. H. G. Barbour, New Haven, Conn.—p. 65.

**Stability and Destruction of Salicyl Group.**—According to Hanzlik and Wetzel, solutions of sodium salicylate gradually deteriorate on standing, the loss being greater with weaker solutions. The destruction is due to some form of living matter such as fungi, since solutions containing a preservative (chloroform), and free from fungi, do not deteriorate. Yeast solutions salicylate, but not nearly as much as the fungus which naturally grows in salicylate solutions. Treatment of salicylate with hashed animal organs results in considerable loss of the drug, which in part, at least, is due to destruction of salicyl. There is no difference between the action of liver and other organs. About 20 per cent. of salicylate administered to normal human individuals is destroyed, since the loss cannot be accounted for in sweat and feces or by retention. The destruction in animals (dog and cat) is even greater, amounting to about one half of the salicyl administered. The destruction of salicylate is markedly increased (about 40 per cent.) in febrile conditions of man, drug habits (alcohol and morphine), nephritis of both man and dog, and in exophthalmic goiter. The destruction does not appear to be the special function of a given organ such as the liver, since the excretion in certain diseases of the liver in man in hepatic degeneration in animals was within the normal range. The increased capacity for destruction, therefore, may be ascribed to the general increase in metabolism (catabolism) of febrile conditions and exophthalmic goiter;

to retention with prolonged exposure to the destructive action of the tissues in nephritis.

**Excretion of Salicyl.**—The excretion of salicyl by animals (dog and cat) after the administration of methyl salicylate Hanzlik and Wetzel claim is much less (25 per cent.) than after sodium salicylate. After gastric administration the free ester was found in urine in concentrations of from 0.2 per cent. to 0.52 per cent., and 14.4 per cent. after intramuscular injection. This may be of importance in explaining the greater analgesic properties and toxicity possessed by methyl salicylate, and in urinary and systemic antiseptics.

**Effects of Chlorin on Bronchi.**—The presence of even small concentrations of chlorin Barbour and Williams state leads to a slight relaxation of pulmonary vessels. When a concentration approximating 250 mg. of chlorin to 1 liter of Locke's solution is attained the same response occurs but is soon succeeded by a slow and prolonged contraction of the muscle. High concentrations, 620 mg. per liter, produce no relaxation but a rapid and extensive contraction. These vascular rings will, however, relax again if the solution be replaced by one which is chlorin free. The bronchial musculature yields similar responses to chlorin but the relaxation occurs with less constancy. It was marked however in one case where the concentration was as high as 680 mg. being succeeded by the usual constriction produced by such amounts. Another difference between vessels and bronchi lies in the fact that for the latter the minimal constricting concentration is much lower than for the former, less than 200 mg. per liter sufficing to contract the bronchial rings.

**Morphin After Chlorin Gassing.** Barbour and his associates claim that subcutaneous doses of morphin as large as 10 mg. per kilogram (given twice daily) exert, if anything, an unfavorable effect on chlorin gassed dogs. Smaller doses (3 to 5 mg. per kilogram) do not appear to influence significantly the fatality percentage. It would appear that morphin may safely be used in gassed individuals, for its analgesic effect, if the size and frequency of the doses are limited.

**Epinephrin After Chlorin Gassing.**—Barbour says that it is improbable that either epinephrin or ouabain can be made to exert a favorable influence on chlorin poisoned dogs.

**Effects of Chlorin on Body Temperature.**—In the treatment of gassed patients it is suggested by Barbour that an excessively warm environment may be as dangerous as one which is too cold.

**Causes of Indigestion.**—Vanderhoof has tabulated the clinical diagnoses in 2,000 consecutive cases of chronic or recur-

ring indigestion. The series embraced only those patients whose chief complaint was attributed to some disturbance of digestion, such as "stomach trouble," dyspepsia, abdominal pain, flatulence, vomiting, etc., and entirely excluded patients complaining of other symptoms who were found on examination to have some lesion of the gastro-intestinal tract. Each patient received thorough study embracing a careful history, complete physical examination, and the necessary laboratory analyses, including as a routine one or more gastric analyses, uric examination, and differential blood count, with hemoglobin determination. In the second 1000 cases the fractional method of gastric analysis was employed and routine Wassermann tests of the blood serum have been done. Advantage has been taken of roentgen-ray studies, and much helpful advice has been secured by Vanderhoof in consultations with surgical colleagues. The result was as follows: chronic appendicitis, 436 cases, 21.8 per cent.; chronic cholecystitis, 224 cases, 11.2 per cent.; neuroses, 218 cases, 10.9 per cent.; peptic ulcer, 206 cases, 10.3 per cent.; affections of kidneys, 137 cases, 6.8 per cent.; achylia gastrica (uncomplicated), 81 cases, 4.0 per cent.; visceroperitonitis, 69 cases, 3.4 per cent.; affections of lungs, 60 cases, 3.0 per cent.; affections of heart, 50 cases, 2.5 per cent.; cancer of stomach, 46 cases, 2.3 per cent.; affections of blood and ductless glands, 44 cases, 2.2 per cent.; enterospasm (mucoous colitis), 40 cases, 2.0 per cent.; peritoneal adhesions, 38 cases, 1.9 per cent.; affections of female pelvic organs, 35 cases, 1.7 per cent.; affections of eyes, 32 cases, 1.6 per cent.; migraine, 26 cases, 1.3 per cent.; organic disease of central nervous system, 22 cases, 1.1 per cent.; cancer of intestine, 21 cases, 1.0 per cent.; infectious diseases, 19 cases, 0.9 per cent.; affections of liver, 18 cases, 0.9 per cent.; affections of ears, 16 cases, 0.8 per cent.; enterogenous toxemia, 11 cases, 0.5 per cent.; miscellaneous conditions, 114 cases, 5.7 per cent.; diagnosis not made, 37 cases, 1.8 per cent.

**Mental Changes in Children Due to Malnutrition.**—Blanton reports the results of a study of the changes occurring in the schoolchildren of Trier, Germany, due to malnutrition caused by war conditions. It was found that at least 40 per cent. of the children, were suffering from malnutrition to such a degree as to cause a loss of nervous energy. There was no increase in the percentage of cases normally found of neuroses, psychoses, abnormal "nervousness," organic nervous diseases, tics or conduct disorders. There was, however, an increase of the number of borderline defectives totaling not more than 1 per cent. of the total school population. There was no increase in the percentage of speech defects, especially stuttering, normally found; but there was a marked increase in poor, lisping, slurring speech due to the retardation or interference of the fine coordinations, necessary for good speech, caused chiefly by malnutrition. The percentage of children failing to pass grades increased from an average of 8 per cent. in prewar years to 15 per cent. in 1917 and 1918. It is estimated that about half of this 7 per cent. increase in retardation is due to malnutrition, the other half to war conditions. The specific changes noted in the children caused by malnutrition were a lack of nervous and physical energy; inattention during school hours; poor and slow comprehension for school tasks; poor memory for school work; general nervous restlessness while in school.

**Caring for Delinquents.**—Healy and Bronner point out that a rational method of meeting the needs of the youthful offender, which indirectly affords, of course, the greatest protection to society by thwarting his prospective career, is

only to be developed by utilizing the facts acquired through a good technic of mediopsychology. This procedure, carried out with sympathy and thoroughness, will contribute greatly to the effectiveness of courts and of other human agencies which attempt some solution of the problems of delinquency. Many of the huge number of failures which occur under the ordinary system it will be possible to avoid. Moreover, evaluating any method or régime as conducted under court or institutional auspices is rationally possible only when the essential facts of causation and potentialities of the human material handled form the basis of judgment.

- \*Case of Parenchymatous Nephritis. D. McCay.—p. 297.
- \*Treatment of Cholera. M. P. Chacko.—p. 299.

**Increased Protein Diet in Parenchymatous Nephritis.**—McCay reports a case of nephritis with edema all over the body, in which a cure was finally obtained by increasing the protein in the diet. McCay calls attention to the fact shown by Epstein that when the protein of the blood is very much reduced the osmotic tension falls and fluid passes out into the tissue spaces, and will be retained there unless and until the blood recovers its protein element. Hence, the rational treatment of these cases is to increase the protein of the blood, which is safely done by increasing the protein of the diet. The carbohydrate protein of the diet should be reduced, because one of the main products of its metabolism is water. The protein in the case cited was increased up to 165 gm. per day and this raised the total nitrogen of the patient's blood to 2.03 per cent., which was quite enough to maintain the

equilibrium between the blood fluid and the fluid in the spaces. The patient now takes from 40 to 50 ounces of water every day, and passes the whole quantity out with his urine, whereas before almost every drop of fluid he took used to pass out into the tissue spaces and collect there; and no measures—medicinal or otherwise—could make that water pass out of his body.

**Treatment of Cholera.**—Chacko records cases of cholera treated successfully by the intravenous injection of hypertonic sodium chlorid solution as suggested by Sir Leonard Rogers.

**Autogenous Serum Therapy of Smallpox.**—Hata carried out some clinical observations. In nonhemorrhagic smallpox no death occurred among those who had been treated with autogenous serum. In hemorrhagic cases, it produced 16 per cent. less mortality than the symptomatic treatment. In all the cases of smallpox combined the mortality was 8.6 per cent. less than with the ordinary treatment. The entire course of the illness was made strikingly short. Reconvalescent serum seems to have some therapeutic efficacy. Normal serum (human) seems to have no therapeutic efficacy against smallpox.

- Gunshot Wounds of Nasal Accessory Sinuses. J. F. O'Malley.—p. 333.
- Aqueduct of Fallopius and Facial Paralysis. D. McKenzie.—p. 336.

**Method of Treating Atrophic Rhinitis.**—The treatment discussed by Benians and Hayton is described as a glycoliphic method of bacterial selection, and is directed primarily against the fetor of the disease. The substances used thus far in this method of treatment are glycerin and liquid glucose. These substances are applied copiously to the mucous membrane of the nose in a mixture consisting of pure glycerin with the addition of 25 per cent. liquid glucose. Several applications a day are made with a cotton-wool applicator, the whole of the nasal cavity being gone over and the crusts rubbed off as far as possible. From time to time the flora of the nose is examined to note the cultural properties of the bacteria present and to determine whether or not they are of the strain to ferment the culture medium supplied. Glycerin, though less satisfactory from a theoretical point of view, since it is less easily broken up by bacteria, has some advantages over glucose on account of its physical properties. In some cases where a spray or irrigation is required a mixture of the two substances has been used in a 10 per cent. aqueous solution. The authors emphasize that the whole secret of the success in this method of treatment lies in the fact that the solution must be applied thoroughly to every part of the mucous membrane infected at least four or five times daily at first. As improvement is noted, it will not be necessary to paint so often.

- \*Iodids and The Thyroid. F. Ransom.—p. 433.

**Operation for Carcinoma of Rectum.**—Buck claims that only 30 per cent. of cases of carcinoma of the rectum admit of radical operation when first seen. He insists that when radical operation is impossible, a hypogastric colostomy should be done at once. Radical operations which aim at retaining the anal canal, he says, are pathologically unsound. The only sound radical operations in his opinion are: (1) the two stage operation (colostomy and intraperitoneal excision by the perineal route later); and (2) the combined abdomino-perineal operation. Of these, the former is the better, except in the case of a growth situated at the junction of the sigmoid and the rectum.

**Sedimentation of Tubercle Bacilli in Sputum.**—In the method described by Greenfield and Anderson 5 c.c. of sputum are mixed with twice their volume of sodium carbonate (crystals) 1, phenol 1 and water 100, in a centrifuge tube; the tube is then covered with a rubber cap, shaken for a few minutes and put in the incubator for from twelve to twenty-four hours. At the end of this time the tube is centrifuged for about fifteen minutes, the supernatant fluid poured off, and films made from two to four loopfuls of the deposit are stained in the usual way.

**Relation of Exophthalmic Goiter to Diabetes and Glycosuria.**—Cases are reported by Williamson to illustrate that a relationship exists between exophthalmic goiter to diabetes mellitus and glycosuria.

**Iodids and Thyroid.**—The action of iodids in relieving a condition in which the thyroid secretion is deficient, Ransom says, is due to two facts: (1) Iodin is specifically absorbed by the gland; (2) the iodine in the gland in saturating the unsaturated fatty acids of the blood supply favors the autolysis by which the active principle of the gland is produced. Ransom states further that the efficacy of iodids in tertiary syphilis may be explained on these lines, and it is anticipated that tertiary syphilis may be treated successfully with thyroid.

**Etiology of Scurvy.**—Lind records twelve cases of scurvy from the Idiot Cottages at Kew, Victoria, which showed some interesting features concerning the etiology of this disease. The disease affected the inmates of three cottages only. One of the buildings is situated several hundred yards from the other two buildings, which are about 50 yards from each other, but patients are frequently transferred from one to the other of these buildings. Investigations showed that all the patients affected were crippled and confined to bed or chair. The disease attacked both sexes with the same intensity and frequency. There has been no alteration in the dietary of the patients for years. Other patients suffering from the same crippled conditions and with the same food were unaffected. All the milk used in the institution is boiled before the patients consume it. The food given to these hand fed patients contains excess of carbohydrates over the proteins and it is all cooked. The timing of the onset in each ward suggested a contagious disease. The scurvy cleared up in

the majority of the cases shortly after the patients received a special dietary, consisting of raw eggs, lime water, lemon juice and raw milk. A more liberal supply of vegetables, porridge and beef tea was given to all patients receiving invalid diet. Those patients who died were examined post-mortem and showed extensive hemorrhage under the perosteum of the long bones and separation of the epiphyses. It is suggested that in addition to the lack of certain vitamins, there may be a contagious infection present. The evening temperature of the patients was usually about 38 C.

- Slow Endocarditis in Man of Fifty-Two. A. Cain and J. Paraf.—p. 234.

**Congenital Disease of the Heart.**—Lenoble analyzes the necropsy findings in two additional cases of congenital disease of the heart which had caused no serious symptoms during the thirty-five years of life. He describes further the clinical findings in three other similar cases, this report supplementing three previous articles in the *Annales*. In less than three years he has encountered (in Bretagne) thirteen cases of these congenital heart lesions. The diversity of the clinical types was extreme.

**Relations Between Luetin and Tuberculin Skin Reactions.**—Blechmann has been comparing the responses to the luetin skin and the Pirquet tuberculin skin tests in eighty children. He obtained a positive luetin reaction in from 30 to 35 per cent. of the children with inherited syphilis, but he also obtained a positive reaction in 40 per cent. of the children free from inherited syphilis. This suggests that the luetin reaction is not specific. His study of the subject seems to indicate that the luetin reaction is quite independent of that to tuberculin, and is rarely so well defined as the Pirquet reaction.

**Pancreatic Diabetes.**—Labbé comments on the invariably grave nature of pancreatic diabetes, as digestive disturbances from the lack of pancreas functioning are superposed on the symptoms from the diabetes. The pancreas should be suspected and investigated in every case of diabetes; if found at fault, pancreatic opotherapy should be instituted in addition to the treatment of the hyperglycemia and acidosis of the diabetes. The pancreas opotherapy should aim to substitute the lacking pancreatic digestive juice, and also to stimulate the internal secretion. Improvement by this means has been realized in some cases but not in all. In his experience, the symptoms from the diabetes were not modified by it in any way but, on the contrary, there was always an important though transient increase in the glycosuria at first, as if the pancreatic opotherapy had suddenly mobilized an increased amount of sugar substances. He analyzes six cases to show the necessity for distinguishing the symptoms for which the pancreas is responsible from those due to the diabetes. He also traces the evolution of the conception of pancreatic diabetes, the "thin type," the digestive disturbances from the insufficiency of the pancreas causing more or less loss of weight. He has examined the pancreas in 19 diabetic cadavers and in 37 nondiabetics. No connection

between the lesions in the pancreas and the intensity of the diabetes was apparent, and sometimes the pancreas seemed absolutely sound in the graver cases of diabetes. But as a general thing many of the islands of Langerhans were pathologic, and transitional states from islands to acini were frequent, while the reverse was rare. In 30 of the 37 non-diabetic cadavers the pancreas was as pathologic as in many of the diabetics, and the lesions were of the same type in both, but in none was there such extreme sclerosis as was found in some of the diabetic cases. Thus neither histology nor pathologic anatomy reveals the secret of the diabetic process. There is no specific diabetic lesion in the pancreas, and we may well be guarded in our interpretation of the physiology of pancreatic lesions. In some of the six cases described, the previously obese patients grew more and more emaciated in spite of their enormous appetite which they were never able to satisfy. In one case the pancreatitis was probably of syphilitic origin.

**Landry's Paralysis After Vaccination Against Typhoid.**—Guillain and Barré are convinced of the causal connection between the antityphoid vaccination of the brigadier of 31, formerly a farmer, and the fatal acute ascending paralysis. He had been given three injections of the vaccine in 1915 and was in good health a year later, when 1.5 c.c. of the current vaccine from the laboratory of the military school at Val-de-Grâce was injected in the shoulder. That evening and the next day he complained of stiffness and numbness in the legs and hands, and by the third day he found he was unable to whistle. The symptoms progressed to paralysis, fatal the tenth day. There had been no preceding infectious disease, and the man had not been bitten by any animal. There was no history of syphilis or alcoholism, and he had three children.

**Some Statistics of Tuberculosis.**—Ménard deduces from his prolonged study of 225 tuberculous soldiers that the onset of tuberculosis may present a wide variety of types. The first sign that anything is wrong may be an *embarras gastrique*, neuralgic or rheumatic pains, functional heart disturbance, "colds," bronchitis, febrile painful lassitude, etc. The remarkable fact is that having begun insidiously with symptoms of a certain order, it persists in exhibiting this same set of symptoms all through the other symptoms which may develop *en route*. There is then a long latent interval—six months, twenty months, thirty-eight months—after the appearance of the first symptoms before the disease manifests itself. Then it throws off its mask and develops openly. What are the reasons for this sudden transformation from the insidious form to this open manifestation? He suggests that this may represent the true problem of pulmonary tuberculosis.

March, 1919, 8, No. 3

\*Nonpuerperal Abscess of the Ovary. E. Chomé.—p. 113.

**Nonpuerperal Abscesses of the Ovary.**—Chomé found that the abscesses were in the corpora lutea in all of his seventeen cases of this kind. The secreting elements of the ovary are on the outside, and when it opens to expel the ovule, this opening may give entrance to germs, and an abscess may develop at the entering point. No inflammatory phenomena have ever been detected in the rest of the ovary, while the abscesses in the corpora lutea always corresponded to an adjacent septic focus in or near the intestines, etc., in the small pelvis. The micro-organisms corresponded likewise, and the functional disturbances were those to be anticipated with disease in the corpora lutea. Menstruation was always profoundly modified, as also the cycle of cholesterolemia.

Bacillary Dysentery and Malaria. E. Job and L. Hirtzmann.—p. 714.

**Amelie Liver Abscess.**—Chauffard and Françon report the case of a young man with an acute abscess in the liver, as large as a mandarin orange, following symptoms of amebic dysentery. They administered emetin and neo-arsphenamin, and recovery was soon complete with merely these medical measures. The Bordet-Wassermann reaction was positive at first, but veered to negative under the first injection of emetin. They know of ten similar cases in which an acute amebic abscess in the liver retrogressed completely under the emetin and neo-arsphenamin without the knife. In any event, the medicinal treatment should precede the operation.

**Hemophilia with Myxedema.**—Renard found marked improvement in both the tendency to hemorrhages and the myxedema under thyroid treatment of the young man in the case described.

**War Nephritis.**—Mallié states that during his stay at the prison camp of Altengrabow in Prussia, where there were 12,000 Russian and 12,000 French and Belgian war prisoners stationed, he took notes of 404 cases of kidney disturbance among the men. The actual number was much larger than this. The only explanation possible for the facts observed, he says, is to assume a toxic action from spoiled meat and spoiled canned goods. The cooking killed the germs, but did not destroy their toxic products.

Aug. 14, 1919, 27, No. 45

\*The Lessons of the War. Sir A. E. Wright.—p. 445.

**The Lessons of the War and the New Views on Therapeutic Immunization.**—Sir Almroth Wright asserts that the war has added two new facts to our knowledge of immunization. We have learned that when the necessary conditions have been provided in an infected wound, that is, when all the devitalized tissues have been excised, the wound can be sutured and the protective forces of the body will suppress the infection except when there is no capacity for reaction, and there are streptococci present. The second fact is that the natural resistance to typhoid fever can be powerfully reinforced by inoculation with typhoid vaccine. If we merely apply these facts in practice this will be some gain, but nothing in comparison to what we can obtain by mastering the principles involved, and by applying them to solve other problems in the treatment of bacterial infections. He apologizes for coining new terms to express the elements involved, saying that the reserves of short and simple words have long been exhausted, and that almost all Latin words have already been incorporated in our language, as well as all the simple Greek words. There is nothing left to draw on but long and compound Greek words. To define a man or an idea, some name has to be used, and a new technical term is the missionary of the idea. Among the new terms he advocates are "phyllactic power," for the defense against infection; "kataphylaxis," the mobilization and transportation of the phyllactic forces to the seat of the infection; "ec-phyllaxis," a region in which the defensive elements of the blood have been rendered powerless or are unable to gain access to the region. Each colony of living bacteria is thus the center of an ec-phyllactic focus. His other term, "epiphyllaxis" represents the reserves of defensive forces that can be brought up; "apophylaxis" is his new term for what he formerly called the "negative phase" following antityphoid vaccination, for instance.

He reiterates that we must cast aside our old belief that every immunization has to be specific. We must call to our aid collateral immunization, especially in old tuberculous or streptococcus infections in which the power to react to the

specific germs has become exhausted. The best vaccine to use is the one that gives the best immunizing reaction to the micro-organism which we are combating. He shows how this can be determined *in vitro*, and how transfusion of blood can be done with blood which has been rendered more bactericidal in the interval after it is drawn, before it is injected into the patient. A case is described in which this "immuno-transfusion" was done, with an immediate change for the better and recovery. The streptococcus infection of the extensive wound in the sacrum and ilium had previously been growing progressively worse even with repeated radical operative measures.

- \*Nitrous Oxid Anesthesia. Desmarest and Amiot.—p. 457.
- \*Gangrene from Malaria. II. Alamartine.—p. 459.
- \*Acute Adenoiditis. R. Ramondi.—p. 461.
- \*The Oculocardiac Reflex. L. Binet.—p. 462.

**Malarial Gangrene.**—Alamartine reports three cases of obliterating endarteritis, with gangrene, all evidently of malarial origin. The patients were soldiers in the *armée d'Orient* and two recovered after amputation of the leg involved. The amputation came too late to save the third. In this latter case alone the malaria was the primary invasion. These cases teach the necessity for suspecting malaria in cases of extensive gangrene which otherwise might be classed as the work of syphilis or old aec. He knows of a total of fifteen cases of the kind at the Macedonian front. The gangrene may be dry and slowly progressive or it may develop rapidly, with grave toxic infectious phenomena, or it may resemble Raynaud's disease and be mistaken for trench foot. In this latter form quinin may cure, but in the other forms quinin seems powerless, and no time should be wasted on it. Armed expectancy is justified in the slow, dry gangrene cases, but immediate amputation is demanded with grave toxic-infectious manifestations. All in this group died when amputation was deferred, while one patient with an extremely grave clinical picture recovered after the prompt, high amputation, pushing quinin at the same time.

**Acute Adenoiditis.**—Raimondi describes the various affections for which acute inflammation of adenoids is liable to be mistaken. If the adenoiditis recurs, he endorses their removal, even in infants.

**The Oculocardiac Reflex.**—Binet asserts that compression of the eyeball modifies not only the heart but also respiratory and motor functioning so that besides the oculocardiac there are oculorespiratory and oculomotor reactions. Among the practical applications of this method of research, he suggests having it used during auscultation of the heart in dubious cases. With an extracardiac murmur there is generally tachycardia. On compression of the eye the heart beat drops from 100 to 60 or 40, and the murmurs disappear, while an organic murmur becomes stronger and more distinct on compression of the eye. Compression of the eyeball may arrest a spasm of paroxysmal tachycardia. Its action on the vasoconstrictors is evident even in the brain; the headache after trephining becomes transiently reduced as the eyeballs are compressed. This may likewise arrest for half a minute respiration in inspiration, or it may slow the respiration, reducing the rhythm but increasing the amplitude. This explains the favorable action on asthma and on hiccup. The inhibiting effect on hiccup is particularly distinct, and Binet commends it for current practice. The oculomotor reflex is particularly pronounced in the shaking with a chill, as compression of the eyeball arrests the muscular contractions. Dulac's recent Paris thesis was devoted to the biologic effects and therapeutic action of compression of the eyeballs. Binet gives the tracings from a case of exophthalmic goiter showing the marked effect on the tremor of compression of the eyeballs. The tremor nearly stopped completely, and it did not resume its original amplitude for some time. In a case of atetosis, likewise, the inhibiting influence of compression of the eyes was marked, and Voisin has recently called attention anew to the arrest by it of neuropathic epileptiform seizures. Baillaert has applied the method further to determine the arterial pressure in the branches of the central artery of the retina, as Binet describes.

## Revue Médicale de la Suisse Romande, Geneva

June, 1919, 39, No. 6

- Morphology of Influenza Bacillus Cultivated on Levinthal's Agar Medium. B. Galli Valerio.—p. 265.
- \*Technic for Blocking Intercostal Nerves. A. Jentzer.—p. 271.
- \*Sclerosis of Coronary Arteries in Switzerland. A. Orliansky.—p. 276.
- \*Congenital Occlusion of Nasal Fossae. Barraud.—p. 286.

**Paravertebral Anesthesia.**—Jentzer has been making a special study of the exact points most favorable for blocking the nerves as they emerge from the spine. This paravertebral anesthesia materially reduces operative shock, even with extensive operations such as resection of the stomach. Much debilitated patients may be able to stand a major operation with this technic. The patient recuperates readily, and in Jentzer's thirty-two cases there was no vomiting although in a very few there was some nausea. In seventeen the anesthesia was quite satisfactory; in the others a few whiffs of ether were required. He gives a table showing that the lower part of the first dorsal apophysis or spinous process corresponds to the second intercostal nerve and the second space between the transverse processes; of the second, to the third nerve and third interspace; of the fourth spinous process, to the fifth nerve and the sixth costovertebral articulation; of the fifth, to the sixth nerve and seventh articulation; of the sixth, to the seventh nerve and eighth articulation; seventh, to the eighth nerve and ninth articulation; of the eighth, to the ninth nerve and ninth interspace; the ninth, to the tenth nerve and tenth interspace; the tenth, to the eleventh nerve and eleventh interspace. There is no nerve at the eleventh apophysis, corresponding to the twelfth articulation, but the twelfth apophysis is the *point de repère* for the twelfth intercostal nerve corresponding to the twelfth interspace.

The subject seated and bending far forward, to throw the spinous processes into relief, the skin is touched with iodine at the lower margin of the first dorsal and the first lumbar spinous process. A horizontal line is then drawn through each of the iodine dots. A point is then marked on the upper line, 4.5 cm. from the spine of the dorsal apophysis, and a second, similar point is marked on the lower line, 2.5 cm. from the spine of the lumbar apophysis. A straight line is drawn between these two points, and the injections are made along this line to block the nerves beneath. The needle is pointed a little toward the median line, and the tip is moved to and fro a trifle to be sure the anesthetic laves the sympathetic nerve and the posterior and anterior roots of the spinal nerve. As far down as the eighth dorsal spinous process, he makes the injection at a depth of 3 cm. From the eighth to the eleventh, at 3.5 cm., and at the twelfth, 4.5 cm. To reach the abdomino-genital nerves at the first lumbar spinous process, the depth must be 5 cm.; at the second lumbar, to act on the femoral and genitocrural, 6 cm., and at the third and fourth lumbar apophyses, 7 cm.

**Sclerosis of Coronary Arteries in Switzerland.**—Orliansky remarks that the numerous deaths from influenza last year enabled remarkably comprehensive postmortem study of the arterial system in robust young people. He sought especially for sclerosis of the coronary arteries, but found evidence of it or of fatty degeneration only in 23 per cent. between 18 and 20; from 21 to 30 the proportion was about the same as that reported from Germany, namely, about 46 per cent. in men and 17 per cent. in women. It has been said that in Germany no coronaries are ever found intact after 40, but at Geneva he found 12.8 per cent. intact in the fifties and 20 per cent. in the sixties.

**Imperforate Nasal Fossae.**—Barraud urges physicians to test the permeability of the nasal fossae as a routine measure in infants, as partial or complete occlusion is not so rare as generally assumed. He reports two cases of bilateral imperforate fossae in a newly born child and a girl of 13, both requiring an artificial opening, which was a simple matter.

## Correspondenz-Blatt für Schweizer Aerzte, Basel

July 17, 1919, 49, No. 29

- \*Rachitis and Osteomalacia. E. Looser.—p. 1065.
- \*Bill to Legalize Abortion in Switzerland. A. Labhardt.—p. 1078.
- \*Influence of Local Heat on Stomach. M. Ludin.—p. 1085.
- Transfusion of Detoxicated Autoblood. O. Vogelgi.—p. 1088.

**Rachitis and Osteomalacia.**—Looser argues that tardy rachitis is the link between rachitis and osteomalacia. This assertion is based on 15 cases of severe tardy rachitis and 10 typical cases of osteomalacia, with 2 of a transitional form. All were examined repeatedly with the roentgen rays. The rachitis in some of the youths had dragged along from childhood. In others it was true tardy rachitis; the ages were from 12 to 20, the majority between 17 and 20; and all were infantile in their aspect, with pronounced backward development of the secondary sexual characters in both sexes. The thyroid was enlarged in some. The arrest in the growth and development is scarcely noticed until the attention is attracted to the early fatigue in walking and standing, and pains in the knees and ankles. They are generally ascribed to rheumatism, but the typical rachitic deformities soon appear, with thickening of the ends of the ribs and cartilage and of the epiphyses, and a tendency to scoliosis, genu valgum or varum and, generally, flatfoot. In florid cases the bones are apt to be tender but this tendency disappears when recuperation begins, and it is thus a good index of the stage of the disease process, and the only clinical symptom of it. The roentgen findings are always less pronounced than the reality.

Under phosphorus, 2 or 3 mg. daily, kept up for months, the pains subsided and the gain improved rapidly and permanently and the roentgen findings promptly changed to approximate the normal in all but one case. This was a girl of 20 with such a tendency to diarrhea that the treatment could not be kept up regularly. He gave the phosphorus in oil emulsion in the proportion of 0.02 or 0.03 c.c. to the 100 c.c. of oil emulsion, with one drop cinnamon oil and 0.01 c.c. saccharin. Cod liver oil was so hard to procure that he gave oil emulsion instead, and could not distinguish any difference in the outcome, while the patients were more inclined to keep up the treatment than with the unpalatable cod liver oil. His experience shows that tardy rachitis is more common than generally assumed. The so-called growing pains, rheumatic pains in young adults, are manifestations of tardy rachitis, and this is the same thing, he affirms, as osteomalacia. The differences between them are merely the different physiologic behavior of the bones in these different periods of life. In some of his cases he followed the development of the process from the fifteenth to the twenty-ninth year, and it was always a continuance, never any definite limit between the tardy rachitis and the osteomalacia. In his ten cases of osteomalacia only one of the patients was a man; in 4 of the women there was no connection between the osteomalacia and a pregnancy, but in the others there was an unmistakable aggravating influence from pregnancies. Benefit invariably followed administration of phosphorus in the oil emulsion, in the maximal daily dose of 3 mg. without other change in the mode of life. The earning capacity was restored in three months in the male case of osteomalacia, after four years of inability to do more than the lightest work.

**Bill to Legalize Abortion in Basel.**—Lahhardt relates that the supreme council of the canton of Basel is now considering a law which removes the legal ban against induced abortion provided it is done by a registered physician and with the consent of both husband and wife or of the pregnant unmarried woman, and provided the pregnancy is of not more than three months' duration. No other restrictions or discriminations are made. Lahhardt protests most emphatically against the proposed measure, presenting a number of obvious reasons why it would be physically dangerous for the woman, socially dangerous for society, and locally dangerous for the reputation of the canton. A copy of his six-page article has been sent to each member of the supreme council.

**Influencing of Stomach Functioning by External Heat.**—Ludin is chief of the local Institute for Physiotherapy, and he here reports clinical and experimental research on the physiologic and therapeutic action on the stomach of heat applied externally. In 151 tests on 23 patients, no modification of the composition of the gastric juice could be detected from the influence of the external heat. The secretory function is not modified by the heat, but roentgen examination of 50 patients showed that the motor function of the stomach was materially promoted by the local heat. With organic

stenosis of the pylorus (10 cases) the evacuation of the stomach was not accelerated, but in 9 patients with pylorospasm from ulcer, the period of expulsion of the stomach contents was materially shortened by external application of heat. This fact may prove important in roentgen differentiation of pylorospasm from organic stenosis of the pylorus. It explains also the relief of pain in the stomach by local heat. In addition to the relief of pain, the relaxation of the spasm of the pylorus is a decided advantage in treatment of gastric ulcer, preventing stagnation of the stomach contents with its train of irritation, hypersecretion and hyperacidity.

July 31, 1919, 40, No. 61

Technic for Lumbar Puncture. Enzo Romanelli.—p. 626.

Aug. 3, 1919, 40, No. 62

\*Sand-Fly Fever. Romano Tonjin.—p. 635.

\*Hunger Edema. Id.—p. 636.

**Sand-Fly Fever.**—In this report from an Italian hospital in Palestine, Tonin mentions the extreme prevalence of three-day fever or sand-fly fever among the Italian soldiers. It was noted moreover that those who had had this brief fever seemed to be immune to influenza during the pandemic that swept over the land about a year later. The virus of both sand-fly fever and of influenza seem to be filterable, and many physicians confuse the two.

**Hunger Edema.**—Tonin comments on the odd fact that polyuria constantly accompanied the hunger edema which was pronounced in all the prisoners of war seen at the hospital. The edema resembled actual dropsy in some cases, but the heart, liver and kidney seemed to be intact.

\*Improved Technic for Tests for Acid. E. Pittarelli.—p. 651.

**Technic for Test for Acidity.**—Pittarelli warns that methyl orange is a derivative of dimethylamino-azobenzol, and that the latter cannot be substituted for it (as is frequently done), without modifying the reaction in testing for acidity.

### Pediatria, Naples

August, 1919, 27, No. 8

\*Acute Poliomyelitis. S. Cannata.—p. 465.

\*Initial Phase of Infantile Scurbutus. O. Cozzolino.—p. 477. Con'n

\*Pycocyaneus General Infection in Infants. A. F. Canelli.—p. 503.

\*Case of Congenital Megacolon. A. Dalla Valle.—p. 515.

**Acute Poliomyelitis.**—Cannata remarks that Luciani reported 5 cases of acute poliomyelitis in 1883, and others reported later small epidemics of only from 3 to 26 cases at seven different points in Italy, until 1909 when Giuseppe reported 62 cases in the Trieste region, and Frisco 105 cases at Palermo in 1910 to 1912. In Cannata's own experience at Naples and vicinity, he has encountered 275 cases since January, 1914. In 68.7 per cent. of these cases there was paralysis of the legs, and in 13.4 per cent. of the arms. The acute poliomyelitis cases formed 2 per cent. of the total children brought to the pediatric clinic. He urges compulsory notification of the disease.

**Scurvy in Infants.**—Cozzolino describes the earliest phase of scurvy in infants, and expatiates on the absolute identity between scurvy in adults and in infants. The gums show the first manifestations of the scurvy, and permit the diagnosis in the incipient stage.

**General Pycocyaneus Infection in Infants.**—Both of the infants died in the two cases of pycocyaneus septicemia described by Canelli. The infants were 14 and nearly 3 months old, brother and sister, and the clinical picture was impressive, with hemorrhagic enteritis and furunculosis, and death in less than two weeks after the symptoms had first attracted attention. The first child's furunculosis had probably provided the portal of entry for the pycocyaneus.

**Congenital Megacolon.**—Dalla Valle reports the case of a boy of 5 who died from the toxins generated in the megacolon with intact mucosa. He knows of only two other cases of megacolon of which this can be said. In all other cases on record the fatality was due to mechanical, physical or other cause.

- \* Stenosis of the Pylorus. S. Martínez Gómez.—p. 385.
- Gallstones. Antonio Lara.—p. 398.
- \* Plastic Linitis. Santiago Carro.—p. 408.

**Stenosis of the Pylorus.**—Martínez reiterates that the only characteristic and pathognomonic symptom and sign of pyloric stenosis is the discovery of residual fluid, and relies of food in the fasting stomach in the morning after a test meal. He adds that we should never class a case as atony of the stomach, chronic dilatation or motor insufficiency until we can definitely exclude stenosis of the pylorus, as this alone is able to induce any or all of these conditions. He has repeatedly noticed that Reichmann's disease is usually followed by actual stenosis of the pylorus—a further argument in favor of the assumption that the former is due generally to an ulcer on or near the pylorus. The value of the stomach tube in solving diagnostic questions in this line is far beyond that of the roentgen rays, especially in cases of what he calls latent stenosis of the pylorus with toxemia. In two cases described, the stomach tube alone gave the clue which first permitted effectual treatment of the puzzling toxemia. In another case of supposed stenosis, the pylorus and stomach were found sound although the latter was dilated. Further investigation revealed cicatricial stenosis

of the duodenum which had caused the symptoms for which the pylorus had been incriminated.

**Plastic Linitis.**—Carro's patient was a previously healthy woman of 30 who had never recovered complete health after an attack of influenza last year. Menstruation was suppressed, and she has been losing weight and strength and complains of pain in the stomach more intense after meals. The pain is strongest in the pylorus region, and keeps up until she has vomited, an hour or half an hour after the meal. The pain increases during exercising, even turning over in bed, but there are no signs of a peritoneal reaction, no ascites, no diarrhea. The most plausible explanation of the symptoms is the assumption of a fibroplastic process in the stomach, secondary to a manifest tuberculous process in both lungs.

**Surgical Treatment of Gastric Ulcer and Its Complications.**—Peláez has been investigating the chemistry of the stomach during the months and years after gastro-enterostomy in 64 cases. He found normal conditions in regard to gastric secretion only in 6 per cent, while hypochlorhydria prevailed in 25.75 per cent, and anachlorhydria in 45.45 per cent. Two of the patients, apparently smoothly convalescing after the gastro-enterostomy for duodenal ulcer, suddenly developed tetany the twentieth and the eleventh days, with incessant vomiting until death the third or fourth day. The duodenum and stomach were enormously dilated in one but only the duodenum in the other. The passages were all permeable; the second patient had had an attack of tetany two months before the operation. In a little over two years, Peláez has operated in 140 cases for peptic ulcer; it was located in the duodenum in 26.42 per cent. of the cases. In the 103 gastric cases there were two ulcers in over 5 per cent., and in over 6 per cent. there was malignant degeneration. The operative mortality was 11.42 per cent. The gastro-enterostomy was directly responsible for the death in 2.14 per cent. and indirectly in the others.

**Acute Poliomyelitis.**—Blasco Reta states that there have been 68 cases of this disease at Granada since 1905, but the number of cases ran up to 12, 22 and 18 only during 1910, 1916 and 1917. The highest figure in the intervening years was 3.

\*Malaria in Cuba. J. Le-Roy y Cassá.—p. 422.

**Maxillary Sinusitis.**—Alemán reiterates that nothing but extensive opening up of the sinus will permit a radical cure. This can be counted on in three or four weeks unless other sinuses are involved. In one case of seven years' standing, long rebellious gastro-intestinal derangement subsided almost at once as the sinus healed.

**Malaria in Cuba.**—Le-Roy states that practically every one in Cuba had malaria at the close of the war. There were 4,107 deaths from malaria in 1900. But when the Americans took hold, their efforts to eradicate yellow fever reduced the numbers of malaria mosquitoes as well as of the stegomyia. In 1913 there were only 447 deaths ascribed to malaria. In ten years the malaria death rate had been reduced from 2.52 to 0.33 per thousand inhabitants of the island, and in Havana from 1.30 to 0.02. He gives eleven large tables showing the number of cases by provinces, ages, months, etc., and the corresponding weather charts.

Severe Poisoning with Both Arsenic and Mercury with Recovery. J. W. T. Lichtenbelt and E. H. Jannink.—p. 29.

**The Arthritic Diathesis.**—Van Breemen has found in the course of his ten years of service as consulting physician for the Institute voor Fysische Therapie at Amsterdam that a number of the cases of chronic rheumatism did not fit into the usual classification. Study of this group over months and years confirmed that they were in a class apart from ordinary chronic articular rheumatism. This was particularly evident in the benign course of the joint affection, and in the favorable influence of appropriate treatment. Also in the way in which the disturbances shifted about, from joints to muscles, to tendons, then to neuralgias, the patients finally becoming classed as neurasthenics. The manifest influence of depressing worry and grief on the course of these disturbances was often evident, as also the chronic tendency, and the difficulty of differentiating them from gouty phenomena. Another feature of this group was the unmistakable familial and hereditary stamp, and the frequency of asthma, diabetes, and kidney stones in the men of these families and of gallstones in the women, early arteriosclerosis, and functional nervous affections and psychoses.

All the above is included in the French term of arthritism or the arthritic diathesis. Renault defines it as a loss of the normal balance between the manifestations of nerve force and the muscle force, and van Breemen has been making a study of the behavior of the muscles in persons of this category, and the behavior of the circulation in the skin. He found that the muscles became fatigued much more readily and recuperated much more slowly than in other persons; also that lactic acid, which seldom occurs in normal urine, appears in the urine of this group after physical exertion, and may reach a total of 4 or 6 gm. per liter. On the other hand, experience has shown that rheumatic disturbances occur in them after immobilization as, for instance, after a fracture, much sooner than in other persons. The muscles are thus seen to be substandard both as regards exercise and rest. The muscles are not capable of executing normally the will that seeks to control them.

He found further that the skin changes to the temperature of the environment during cold and wet much more rapidly than normal skin, while it responds less actively than in normal persons to heat-supplying procedures. Both of these anomalies seem to indicate defective functioning of the circulation in the skin. The classification of these cases in a group apart permits proper treatment as they require other procedures than those needed with ordinary chronic rheumatism, a different diet and different mineral waters and baths treatment. It will surely be a great progress when we can class together and treat from a general standpoint, eczema and nutritional disturbances in infants, bronchitis, joint affections, etc., striving to modify the causal factors, rather than to attack merely the symptoms by local treatment. There can be no question that the treatment of a large number of functional neuroses depends on the acceptance or non-acceptance of the idea of the arthritic diathesis. Long continued and systematic exercise of muscles, and massage, have often proved an actually causal treatment.

**Correction of Paralysis of the Muscles of the Hip.**—Van Assen reports very encouraging results from utilizing the external oblique muscle as the abductor for the hip. He followed Samter's technic in the main, but obtained better functioning than Samter realized himself, according to the latter's report in 1917, eight months after the operation. The incision runs from the greater trochanter to and above the crest of the ilium, and then curves forward and inward, ending thus

somewhat inside the superior anterior iliac spine. A piece of cartilage and bone, 5 cm. long, is then pried loose from the external margin of the exposed crest, beginning 1 cm. back of the spine. This piece is cut off from below upward, thus obtaining access from below to the space between the external oblique and the internal. The fascia is then separated downward, the skin incision extended a little for this purpose. Then on the posterior surface of the femur and trochanter a strip of perosteum, 1.25 cm. wide, is outlined front and rear and below, and with a chisel it is pried off along with a small layer of the corticalis. The flap thus lifted up, but still attached to the top of the trochanter, is turned upward and sutured firmly to the external oblique muscle which is drawn down over the crest of the ilium for the purpose. The suture is reinforced with the flap of cartilage and bone from the crest of the ilium. By this means the upper end of the femur is powerfully abducted and extended and twisted a little inward. A plaster cast is applied which holds the upper bone in 45 degrees of abduction, 10 degrees overextension, and 10 degrees twisting inward, the knee in extension. In the case described the cast was taken off the twenty-second day and a splint applied, maintaining the abduction. Twice a day the splint was taken off and active abduction exercises done. The thirty-first day the splint was discarded, but a plaster bandage was put on each knee to hold them stiff and enable the boy to run about until he had suitable braces. The braces were applied in about three months, and the boy now runs about without holding on to any support. The illustration shows how perfectly he can actively abduct the leg. As he does this, the band running from the trochanter over the crest of the ilium can be felt drawn taut. No illustrations are given of the technic, and no details beyond those given above.

\*Reconstruction of Bone and Primary Suture with Compound Fracture. J. Nordentoft.—p. 945.

**Reconstruction of Bone and Primary Suture with Compound Fracture.**—Nordentoft reviews his experiences with osteosynthesis and with primary suture with compound fractures in a number of cases in which he applied to industrial and other injuries the lessons learned from the war surgeons in regard to reconstruction of bone and primary suture. Brilliant results were obtained, healing by primary intention in 70 and in 90 per cent. of the cases—even with the most serious lesions. At first it seems wrong to treat such lesions in this way, but the benefits from it are enormous, he reiterates, shortening the stay in bed, rendering the after-treatment far simpler and easier, and giving incomparably better functional results.

Aug. 20, 1919, 62, No. 34

\*Diet in Treatment of Heart Disease. V. Rubow.—p. 969.

**Diet in Treatment of Heart Disease.**—Rubow refers to chronic insufficiency of the heart, and expatiates on the importance of the calory content and the salt and water content of the food as affecting the course of the heart disease. Even a little restriction in these three lines, with bed rest, may cure dropsy. If not, more vigorous restriction may accomplish it, supplemented by heart stimulants. This is

exemplified in the Karell course of treatment in which the patient is kept absolutely still in bed and is allowed nothing but 800 gm. of milk in the twenty-four hours. The benefit from this Karell course confirms the great importance of dietetic measures in heart disease. The metabolism is low on this diet, and the heart is taxed less to correspond. The specific action on the edema from the Karell course is evidently due to the small intake of water. Sometimes it is accompanied by a slightly increased diuresis. The dry substances in the blood may increase by 10 per cent. under a Karell course as the mass of the blood shows less and less water. This increases the osmotic interchanges, and the edema fluid streams from the tissues into the blood, carrying with it large amounts of salt, and the salt is rapidly eliminated through the kidneys provided they are permeable for salt. The elimination of water through the skin can be promoted by sweating procedures, but it must not be forgotten that every kilogram of edema fluid thus evaporated through the skin throws from 5 to 8 gm. of salt on the kidneys for elimination. If the kidneys are unable to secrete urine with much salt content, the salt may be retained in the blood. The resorption of the edema fluid thus acts like an intravenous injection of a hypertonic saline solution, and the diuresis may be increased as early as the second or third day. This rapid increase in the diuresis cannot be regarded as always a favorable sign, as it may occur in consequence of kidney disease.

In other cases, however, the edema disappears in the first day or so without material increase of the diuresis but later, the third to the fifth day, there may be more or less increase. The explanation of this is probably that, as the metabolism declines and the edema is reduced, the work of the heart is lightened, and conditions in the circulation improve. It is possible also that the lesser volume of the blood cooperates in relieving the insufficiency of the heart functioning.

Another advantage of the Karell course is that the lesser intake of salt reduces the thirst. Free ingestion of water with a salt-poor diet in some cases of cardiac insufficiency reduces the diuresis, and there is less thirst. With a moderate, constant supply of water, considerable reduction in the salt intake does not lead to increase of the diuresis with cardiac edema, but the edema may be kept stationary with it. In management of the case after the Karell course, the dietary must be water-poor and salt-poor and the calories kept down to the actual needs of the metabolism. A combined after-treatment, giving digitalis and ordering absolute repose or the Karell course or other dry diet for a few days every week or month—according to the severity of the case—is often the most effectual and the easiest to realize of all measures with cardiac insufficiency. Treatment of this kind can be kept up successfully for years.

\*Treatment of Spastic Hemiplegia. H. Abrahamsen.—p. 1273.

\*The Blood in the Elderly. K. M. Hansen.—p. 1281.

**Treatment of Spastic Hemiplegia.**—Abrahamsen reviews spastic hemiplegia in general, and describes a clinical case following a stab wound of the neck. The spasm was localized and extremely severe, but there was no actual contracture. After complete failure of persevering medical measures, he decided to weaken the reflex impulses and follow with systematic exercises of the muscles. For this it was necessary to resect half of each branch innervating the various muscles involved, reaching the nerves through the popliteal space and the inguinal region, and, in the arm, resecting half of the median nerve. The different nerves were easily reached and resected, and all the spastic phenomena subsided completely except for a slight lifting of the foot as the young man steps.

**The Erythrocyte Count and the Hemoglobin Percentage in the Aged.**—Hansen has been examining forty persons who seemed to be normal for their advanced age. The tabulated findings correspond closely to similar findings earlier in life, age in itself, apparently, not modifying the red corpuscle count or the hemoglobin percentage. The range of the latter in the men was from 87 to 102, and in women from 84 to 97.

## PRACTICAL POINTS AND COMMON ERRORS IN THE TREATMENT OF STERILITY

EDWARD REYNOLDS, M.D.  
BOSTON

A now considerable experience in the management of reference cases of sterility has made the history of certain failures in diagnosis and treatment so familiar that it is easy to classify under a number of distinct headings those which occur most frequently. The fact that certain particular points turn up with such unvarying frequency makes it seem that a brief description of them might be of interest.

The classes so formed comprise sterilities due to mistakes in the marital relation; to neglect or failure to appreciate sterility in the male; the subjection of innocent abnormalities to unnecessary and nonproductive operations, and failures to detect evident causes of sterility from lack of special training in microscopic examinations.

Each one of these subjects would be sufficient to occupy an entire paper if fully discussed, and the attempt to treat them all within a single article necessarily implies a restriction of each of them to but a brief outline, with, in a few instances, a skeletal report of an illustrative case.

### STERILITY DUE TO MISTAKES IN THE MARITAL RELATION

Mistakes in the management of the marital relation are not infrequently by themselves a sufficient cause of sterility, usually by the production of congestion and its results. Such mistakes in marital life are not usually perversions. They may even appear trivial and yet, if long persisted in, produce important results or even changes in the organs which may demand operative treatment before pregnancy can be obtained. It is very disappointing for patients to travel, perhaps long distances, to see a specialist only to receive directions to try a change of habit and if this is unsuccessful to report again, and this is a very frequent cause of sterility which the general practitioner ought really to be capable of detecting, and of correcting, so far as change of habit is concerned, before sending his patients away.

Many practitioners find it difficult to question patients on this subject, partly from consideration for the feelings of the patient and partly from failure to know themselves exactly what questions should be asked. The subject is, to be sure, a difficult one; but such patients are usually conscious of an imperfection

or defect in their sensations. When sterile they are often very anxious about it, and if the subject is opened frankly and without preface it is often surprising to see with what readiness and, indeed, eagerness they respond to questions which they themselves instinctively believe are essential to a proper understanding of their case. Especially women often express the greatest gratitude for a frank discussion of this subject and for the instruction which follows it. It is quite essential that each partner should be questioned separately, and the keynote to the subject is that any continued error of habit which produces excitement without subsequent relief by the orgasm tends toward chronic congestion and its unfortunate results.

The point which the patient has noticed is usually decrease or lack of satisfaction during coitus. Frequent amorous caressing without cohabitation appears to be a not uncommon mistake in married life, and if habitual and frequent it is always unfortunate in its results on the organs of one or both partners.

Want of simultaneous chronicity in the orgasm, i. e., ejaculation by the male before the female has reached the possibility of the orgasm, is an extremely frequent cause of chronic congestion in the female and of its consequences in the uterus, tubes and ovaries. If it is a mere personal idiosyncrasy of the male it can in most instances be altered by psychologic restraint on his part after the necessity for it has been explained to him. It is sometimes, however, the result of a local irritation somewhere in the male organs which produces premature ejaculation, and it then demands the appropriate local treatment.

The very common practice of prevention of pregnancy by withdrawal usually deprives the female of the orgasm, and many cases are seen in which prudential prevention of pregnancy in early married life has set up consequences of congestion which persist after pregnancy is desired.

Marked congestion of the feminine organs sometimes produces a mental condition in which desire is frequently present in advance of cohabitation, and even at times when it is impossible, but in which the orgasm fails to appear during coitus, with consequent increase of the congestion. In these cases, decrease of congestion by glycerin depletion of the vagina will frequently break the vicious circle and restore normality.

Habitual excess in even normal coitus tends to congestion and, if long continued, to sterility.

Merely psychologic causes of failure to obtain the orgasm are also quite common among women and may sometimes be dispelled by ascertaining the origin of a psychic impression of distaste for coitus and giving appropriate advice.

This subject is evidently too complicated for brief discussion; but adherence to the principle that excitation without orgasm is a frequent cause of local disturbance and consequent sterility furnishes a safe guide for questions. When any one of these or other mistakes in coitus is remedied before it has been of long continuance the mere correction of habit, or such correction in connection with minor local treatment, frequently yields a prompt pregnancy. When, on the other hand, the congestion which results from such habits has been long persistent it has not infrequently produced changes in the prostate, deep urethra or vesicles, or in the cervical or uterine mucous membrane and even in the ovaries, which may require long continued treatment or even an operative correction before pregnancy can be secured.

#### MALE STERILITY

Impregnation is the result of the cohabitation of a fertile male with a fertile female, and the fertility of both sexes is essential to it. It would seem ridiculous to insist on so elementary a point were it not that almost daily experience in practice shows that the public, and a large portion of the profession, has the habit of taking the fertility of the male for granted. This is far from being the fact either in the human race or among domestic animals. In my experience with human sterility the male has been involved in about 50 per cent. of all cases, and, moreover, the majority of male sterilities have been of nonspecific cause. I am afraid that the profession in general believes that in the absence of a history of venereal disease, and more especially of gonorrhoeal epididymitis, the healthy young male is always fertile. This is far from being the fact. On the contrary, young males of healthy appearance may be, and not infrequently are, infertile from either congenital or local causes without any noticeable disturbance of general health. It may be said here too that at the outset of any intelligent consideration of sterility we must drop the too general conception that a given individual is necessarily either flatly sterile or fully fertile. We must realize that fertility is a relative term, and that we shall deal with every degree and gradation between high fertility and complete sterility. This statement is capable of definite microscopic proof in the male and is probably equally true of the female, although its definite establishment in the human race is in her more difficult. In the case of every male, as also in the female, we must hold ourselves ready to investigate congenital, constitutional and local causes for infertility.

Congenital or, more properly, pubertal sterility is the result of an arrested development of the genital organs, and is not very uncommon even in otherwise fine specimens. It may vary all the way from undeveloped, infantile testicles (usually associated with a rather small penis) and complete aspermia to a mere low normal in both respects. Its susceptibility to improvement varies with its degree. With infantile testicles and complete aspermia there is usually nothing to be done, while, on the other hand, the underdeveloped person who is nevertheless not far from the normal standard may usually be stimulated into a fair degree of fertility.

The profession apparently believes, too, almost universally, that if the inspection of a drop of semen under the microscope shows motile spermatozoa, the male is fertile. Nothing is more common than to see

correspondence, often from physicians excellently well trained in other respects, which states that the husband is all right, whereas subsequent examination reveals that his fertility is so low as to render him a very doubtful element in the case. Experimental studies of animals in the breeding laboratories conducted by examination of their spermatozoa and checked by subsequent breeding of the animals have shown that if specimens of semen are divided into four classes according to the number of spermatozoa occurring in them, and again into four classes according to the percentage of motility in the spermatozoa, the animal may with safety be regarded as sterile unless both numerical frequency and motility are at least of the second class; namely, unless the animal belongs in one of the first four of the sixteen classes so produced. My own experience in the human race has perhaps gone further than this, tending to show that in estimating the fertility of a given male we must not only judge of the numerical frequency of the spermatozoa and of the percentage of motility present, but must, furthermore, study carefully their vitality both as it is determined by duration observations and, what is still more important, by the quality of the motility present. Nothing is more certain than that spermatozoa of merely moderate vitality seldom impregnate a female.

Oligospermia with deficient vitality of the spermatozoa is not infrequently found from constitutional causes. It can be easily demonstrated in animals that both low diet and conditions of life that produce a nervous and excitable state are attended by oligospermia. The same condition is not infrequent in men who have been overworked to the point of neurasthenia or even to a state of great nervous tire. Animal breeders consider it an established principle that a high protein diet in both sexes is essential to full fertility, and somewhat extensive experimental observations of my own support this conclusion so far as domestic fowl are concerned. General clinical impression leads me to the belief that it is probably true for the human race; but this subject has not been studied with sufficient accuracy to warrant a definite expression of opinion.

Moderately oligospermic men with semen that shows somewhat deficient vitality may probably be capable of impregnating highly fertile women (especially women whose genital passages are in a condition highly favorable to the existence of the spermatozoa), while, at the same time, they would be infertile to women whose genitals are moderately hostile to the spermatozoa but who would yet perhaps be not infertile to a male whose spermatozoa were abundant and of high vitality. Men who are oligospermic from constitutional cause, as well as those who are somewhat below the normal from poor development, may often be rendered fairly fertile or sometimes fully fertile by change of habit and stimulative treatment; and though relative infertility of both partners is always rather unfavorable, success may sometimes be attained even in these cases, especially if the sterility is not of long duration.

CASE 1 (Clinical Records No. 4270).—Man, aged 30; woman, aged 24; married ten months. Male: The frequency of spermatozoa was at the upper limit of the fourth class. The percentage of motility and the degree of vitality were of the second class. There were no infections nor local abnormalities. Female: The vaginal secretion was favorable; the cervix was antelexed with pinhole os; the cervical mucus was highly tenacious, entangling all sperma-

tozoa as disclosed by postcoital examination; uterine drainage was poor, both ovaries being somewhat enlarged (at the operation they proved to be distended by retained follicles). Under change of habits of the male and moderate general stimulation by tonics, the semen improved to a low normal. It was believed that there was prospect of further improvement. An operative correction of the abnormalities of the female was then performed. Successful pregnancy followed within two months, an unusually prompt result.

Double gonorrhoeal epididymitis frequently produces absolute aspermia; or, when limited to the upper portion of the globus major, may produce oligospermia by cutting off the greater part, though not all, of the efferent ducts. Oligospermia, with normal motility and vitality, is not absolute sterility, but is of high importance because the percentage of destruction of spermatozoa during their passage through the genital canal of the female is so enormous that the possibility of impregnation by a semen which starts with a deficient number is always poor. When the genitals of the female partner are in a condition which is even moderately hostile to the spermatozoa, impregnation by such a semen becomes so unlikely as to be not even a probability. The only treatment of either oligospermia or aspermia due to the results of epididymitis is by resection and anastomosis of the vas deferens, an operation which is sometimes, though not invariably, successful.

Local conditions in the male genital tract that are quite insufficient to affect the general health in any noticeable degree may nevertheless be sufficient to produce a high degree of infertility. Strictly localized inflammation at some one spot in the urethra of specific, and sometimes of apparently nonspecific origin, may produce a urethral secretion which annuls or lessens the motility and vitality of the spermatozoa during ejaculation and before they reach the female. In such cases, appropriate local treatment is frequently sufficient to restore full fertility. An irritated condition of the seminal vesicles may produce the same effect, and is also frequently removable under treatment.

Congestion and swelling of the prostate may occur from many causes, very frequently from mere excess or imperfection in the marital relation. It habitually produces an excess of sticky prostatic mucus which entangles many, or in severe cases, all the spermatozoa and thus destroys their motility before they ever reach the female genitals. Such secretions may also show a biochemical hostility. These cases are again very hopeful under treatment.

CASE 2 (Clinical Records No. 4271).—A physician in the later thirties and a woman, aged 32, married seven years, both reported themselves as in unusually good health, which was borne out by appearances. The husband gave a negative past history, but said that marital coitus had been habitually excessive—six or seven times weekly. The wife was in no way abnormal, except a very sharp anteflexion with spasm of uterosacral and small os. Admixture of a direct specimen of the semen with the vaginal and cervical secretions did not affect the spermatozoa unfavorably. The woman was probably fertile, though the probability of impregnation would be increased by a plastic on the cervix and anterior cervical attachments. A direct specimen of semen showed spermatozoa in abundance and of good motility, but from the first moment of observation the progress of the spermatozoa through the semen was slow. There was a very rapid occurrence of agglutination of the spermatozoa in clumps with entanglement in the mucus. At the end of three quarters of an hour of observation all the spermatozoa were entangled and incapable of progress even in the direct specimen. Local

examination of the male revealed a large, soft prostate. The case was referred to Dr. Paul Thorndike, who confirmed this observation and also found a much enlarged vesicle. He recommended massage of the prostate and vesicle, and reexamination of the semen after treatment was recommended if pregnancy did not follow on the normal condition of the male, a plastic correction on the cervix.

These patients came from the Middle West for an opinion and were not seen again; but the case is selected as striking because the patient was a well trained and active physician who believed his own fertility to be beyond question, after repeated examination of his semen.

This and all the conditions mentioned have been seen, and most of them frequently in young males in first-rate general health.

The degree of fertility in a given male can never be decided without a full examination (as discussed later in the paper), and it is usually<sup>1</sup> unjustifiable to treat or, more especially, to operate on a woman for sterility without first ascertaining the condition of her husband. Many, if not most, male sterilities are curable.

#### AUTOINTOXICATIONS

That sluggish action of the colon with consequent chronic retention of feces may be of itself a sufficient cause of sterility in women has been shown by a not inconsiderable series of cases. It might at first sight appear possible that a direct influence on the uterus and ovaries by the production of pelvic congestion, was the way in which this cause operated; but the absence of significant congestion, as evidenced either by gross examination or by the microscopic characteristics of the secretions, and the presence of symptoms of chronic autointoxication in many of this series of cases seems to place them among the autointoxications rather than among those in which the sterility is due to local conditions.

CASE 3 (Clinical Records No. 4614).—The husband, aged 26, presented a negative history and physical examination. The wife, aged 22, considered herself in good health, but was somewhat pasty looking, and acknowledged lack of energy and resistance. They had been married ten months. The wife presented no symptoms except backache and some general abdominal lameness off and on, increasing during the last six months; some muscular rheumatism, some stiffness and occasional slight swelling in the hands. The general physical examination was negative (including urine), except on abdominal palpation evident fulness over the ascending and transverse colon. The bowels moved freely on alternate days; she was not in the habit of taking cathartics. Genital secretions were essentially normal. Pelvic examination was negative. Marital relations were normal. Postcoital examination was postponed until after treatment of constipation. During the following two weeks great quantities of old feces were unloaded under the use of liquid petrolatum, cathartics and irrigation. During this process the right hand became considerably swollen, stiff and painful though not very tender (owing to increase of autointoxication in process of unloading?) During the next two weeks there was some neuralgia in the left shoulder and arm; the right hand was better; the left hand was now a little swollen. Two weeks later, under continued catharsis and irrigation the hands became practically well; her color was now better; she was sleeping and eating better, and declared herself much less tired. Pelvic examination was now much more satisfactory. Both ovaries were probably a little full. She was given vaginal supposit

1. An occasional exception to this principle may be found in cases in which the husband is inaccessible, and when an operation which would tend to promote fertility is also justified by a local symptomatology, which is sufficient to affect the general health; for example, severe dysmenorrhoea with sterility, both dependent on anteflexion of the cervix and enlarged ovaries.

tory of boroglycerid and ichthyol. She was advised to give continued attention to the bowels; to use vaginal suppositories of boroglycerid and ichthyol five days in succession, planning for coitus on the seventh day each week, for some months, before instituting any further treatment. One month later catamenia failed to appear. The patient is now well advanced in normal pregnancy.

This case is selected for quotation as peculiarly instructive from the almost complete absence of any genital peculiarities and from the absence of any other treatment than emptying of the bowels, except for the brief vaginal depletion. In most of the other cases of the retention series a greater or less alteration of the secretions was present and some direct local treatment was necessary; yet in all the retention of feces has seemed so much the predominating feature, both in diagnosis and in treatment, as to warrant the clinical conclusion that the sterilities were essentially due to this factor and terminated by its relief.

My experience has not furnished me with equally conclusive evidence that general auto-intoxication from distant lesions is by itself a sufficient cause for sterility, most of the cases presenting hostilities in the secretions which required considerable local treatment, and which might have been due to other causes than biochemical alterations from disturbed health due to auto-intoxication; but the cumulative presumption derived from numerous cases leads me to accord much practical weight to this probability and to consider it important to eliminate all such conditions in the management of cases of sterility. This conclusion is reinforced by the experience of both experimental and commercial animal breeders that both good general condition and proper diet are essential to fertility, in both sexes. Animal breeders are emphatic about the advantage of a glossy coat, a clear eye, animated temper, etc., in breeding animals. These correspond, of course, to good complexion, bright eye and the general results of conditions of good elimination in the human race.

#### EMPIRIC OPERATIONS

Sterility is a subject that has not been adequately studied, and the importance of the microscopic study of the conditions that determine it has not reached the mass of the profession or attracted the attention of more than a very few, even among specialists. An unfortunate result of this is that the specialist in sterility sees many cases that have been complicated by previous unsuccessful operations, usually on women. When the organs of a sterile woman show no gross abnormality she is usually advised to try some one of the time-honored minor expedients and is dismissed with that advice; but when some gross and easily detectable abnormality is found she is too frequently subjected to an operation on the mere chance that that abnormality may be causative to the sterility. If performed in the absence of an exact knowledge of the causes and conditions that are really involved in the individual sterility, such an operation is naturally not adapted to their correction; and while it may occasionally yield results, it is worse than wasted in the other cases. Especially prominent among these useless operations are those which are done for the relief of retroversion without recognition of one of the functional derangements of the ovaries which imply nonovulation, or of a preexisting ante-flexion from the existence of short anterior attachments of the cervix.

The futility and injustice of the performance of an abdominal operation for sterility without attention to the needs of nonovulating ovaries needs no mention, yet it is a very common mistake.

The performance of a suspension, whether by sero-serous stitch or by shortening of the ligaments in the face of a forward fixation of the cervix, means necessarily the restoration of a flexion that decreases uterine drainage and thereby increases the conditions productive of sterility; the uterine tension so produced moreover eventually destroys even the anatomic result in a large proportion of cases.

CASE 4 (Clinical Records No. 4011).—A man, aged 34, and a woman, aged 27, had been married a little less than three years. When one year married the wife was referred to an excellent surgeon of prominence in a large city, on account of the nonappearance of conception. She was free from any symptoms of ill health. The surgeon found the uterus in retroversion, but found nothing else. He dilated and curetted, and performed a suspension operation. The couple were seen a little less than two years later. The vaginal secretion was overacid and bacillary. On postcoital examination the spermatozoa found in the vagina were all still. The cervical secretion contained no spermatozoa and was profuse, tenacious and turbid, showing a high leukocytosis and constituting by itself an efficient obstacle to impregnation. The uterus was again in straight retroversion; the anterior attachments of the cervix were organically short, the uterosacrales in spasm. Both ovaries were full and slightly enlarged, the catamenial enlargement persisting during an undue portion of the month and never wholly subsiding. The husband had a negative sexual history, and his general physical examination was negative except that he was living a very confined office life, and was in soft condition. He had been much given to athletics until a few years earlier. His prostate was soft and swollen, the left side being markedly larger. Examination of a direct specimen of semen revealed oligospermia, morphologically well formed, but mostly still and the remainder in feeble motion, most of them entangled by their tails in sticky mucus. There was an extreme excess of crystallized elements in the semen, and it was believed to be hostile biochemically as well as mechanically. Case 4 is recent,<sup>2</sup> but it is selected for citation because it illustrates so many points. The husband was functionally sterile. The retroversion created no symptoms either before the operation or after its occurrence; such a retroversion has little influence on fertility and is unimportant. The fixation of the cervix made it improbable that a mere suspension would effect any improvement in the condition of the uterus. The vaginal secretion was slightly hostile, the cervical was very hostile, and in the anatomic condition of the cervix could hardly be otherwise. The ovaries were functionally deranged. The woman was subjected to an abdominal operation for a harmless retroversion, the ovaries were left untouched, and except for the institution of a dilatation and curettage, which in such an anatomic position of the cervix is useless, nothing else was done, yet the operator is a well known and able man.

Cases almost as flagrant are frequently seen by the expert in sterility. To the credit of the profession, it may be said that they have become rare in most other lines.

Unnecessary and unsuccessful curettings are another extremely frequent element in the empiric treatment of sterility. Many operators seem to believe that if a routine examination discloses no evident abnormality in the female of a sterile mating, it is always fair to curet her. Dilatation and curettage delicately performed, in connection with plastics on the cervix, form

<sup>2</sup> Both partners are now under minor treatment. If the man can be rendered fertile, the woman will need another operation.

an intrinsic part of many operations for sterility but when done by themselves and especially when done on a hit and miss principle, they are seldom efficacious and not infrequently harmful. When less well done and when done without correction of the shape of an underdeveloped cervix, they very often produce trauma and scar tissue about the angle of flexion which distinctly and by itself decreases the prospect of pregnancy at any subsequent time.

The use of stem pessaries is a far too frequent and very harmful expedient in the treatment of sterility. There is no question that the use of the stem is occasionally followed by pregnancy in previously sterile women. Some of the practitioners who use them have claimed as high as 25 per cent. success, though usually in a small series of cases, and from 10 to 15 per cent. is generally credited to this procedure; but all or nearly all of the unrelieved majority are rendered permanently and hopelessly sterile by the results of the stem. When effectively used, the stem produces improved uterine drainage; but it effects this by the production of a pressure necrosis in the portion of the canal where it lies. The few pregnancies that follow its use occur during the comparatively few months in which patency remains; but the mucous membrane has been destroyed, and unless pregnancy occurs immediately, recontraction and decreased drainage again set in. In my own experience, I have never had a success by any method after a stem pessary has been unsuccessfully used. I have seen not a few salpingitides which apparently were referable to the use of the stem.

It is well known that neither uterine fibroids nor even ovarian cystomas are entirely preventive of pregnancy, though it is comparatively rare in the presence of these neoplasms. This is evidently due to the fact that fibroids do not necessarily encroach on the uterine canal and that simple cysts of the ovary do not under certain conditions produce the intra-ovarian tensions which prevent ovulation. When such neoplasms are combined with the secretional hostilities or with non-ovulating ovaries, their possessors are sterile. When the neoplasms are removed by operations which also are directed to the removal of the conditions of sterility, the cases form a class in which the prognosis is especially favorable; but the removal of neoplasms from sterile women without attention to the real causes of the sterility naturally yields only a small percentage of results, and must then too often be followed by plastic corrections which might just as well have been performed at the same time. A single operation with a successful result is always preferable to an operation that is followed by a disappointment, even though a second operation is afterward successful.

One more class of failures remains to be discussed. It is a universally accepted principle that no chain is stronger than its weakest link; but the equally clear fact that no tube is more patent than its narrowest part seems to have attracted less attention, though it will be assented to the moment it is set forth. This principle is again as true of physiologic as of mere mechanical patency, and it is eminently true of the genital passages in many sterile individuals. A localized condition (usually inflammatory) which is either mechanically or biochemically obstructive to the spermatozoa may certainly be so much localized as to exert no special effect on the general health, and yet render the canal as impervious to impregnation as

though such a condition extended its entire length and caused an extreme symptomatology. Male hostility of this class has already been discussed. Biochemical vaginal hostility of bacterial origin, mechanical cervical hostility from inspissated or sticky mucus, tubal hostilities without marked enlargement of the tubes, and ovaries which are nonovulating from retention of the follicles are frequent causes of sterility which seldom produce ill health or even gross lesions. The diagnosis of these conditions can be made only by the microscope. These cases are usually pronounced to be entirely normal, the patients are often assured that they are not sterile in spite of the fact that they do not produce children. These cases belong properly to the expert in sterility and are among the most satisfactory cases that are sent to him. They are cases that the general practitioner, and even the gynecologist who has not made a special study of sterility, can hardly be expected to elucidate. They are frequently complicated by the presence of the stigmata of genital underdevelopment; but, unless this is very marked fertility can usually be restored. They form an important and very hopeful class, but their prognosis is always better if treatment is undertaken early in married life than when the sterility has been long continued.

CASE 5 (Clinical Records No. 4167).—A man, aged 35, and a woman, aged 30, had been six years married. The wife presented no symptoms except occasional sensations in the right lower quadrant when fatigued. There were extreme antelexion of cervix with retracted anterior attachments of the cervix, pinhole os, rather small and slender uterus in retroversion, and both ovaries palpable and probably slightly enlarged. The vaginal secretion was overacid and white. Smears showed a preponderatingly bacillary flora. There was evident biochemical hostility. The cervical secretion was quite normal. Postcoital examination revealed an abundance of spermatozoa in the vagina, all dead after an hour in situ. A cervical specimen showed abundant spermatozoa of good motility. It was presumably a case of moderate vaginal hostility and of ovarian sterility. The anterior attachments of the cervix were released; the os was enlarged by a small bilateral Pozzi operation. The abdomen was opened. The right ovary contained a small calcified corpus; it was resected; the remainder of the ovary was enlarged, mainly by edema, and was scarified. The left ovary contained a flaccid corpus cyst, the size of an English walnut, probably hardly palpable on examination; it was resected. The uterus and ovaries were suspended. The appendix was removed. There was good convalescence and considerable gain in the general condition. During the next six months occasional depletion was carried out with ichthyol and boroglycerid. During the next three months repeated smears showed favorable coecal vaginal flora with only normal acidity. At the end of this time a second postcoital examination disclosed normal motility of spermatozoa in the vagina. Pregnancy occurred immediately after this, and the child was born at term eighteen months after operation.

The general characteristics of this class of cases are an absence of symptoms, except sometimes dysmenorrhea, marked antelexion of the cervix due to a congenitally short Goffe's fascia and other anterior attachments, cervix small with small os, the fundus of the uterus not large, and the intermediate portion of the organ slender. There is poor drainage from the uterus, and the cervical secretion tends to be inspissated and sticky. Except in the dysmenorrhoeic cases, these conditions make little trouble during maidenhood; and in those in which pregnancy occurs soon after marriage, the development of the uterus is completed during pregnancy. When pregnancy does not follow

promptly after marriage, a very acid, highly bacillary, vaginal secretion usually appears, and sterility is established. At this early stage, and if repeated examinations of the ovaries show them to be thoroughly normal throughout the menstrual month, the cervical plastics alone, or in combination with vaginal disinfection and autogenous vaccinations from the bacillary flora, are frequently successful. If such a sterility remains long unrelieved, functional derangement of the ovaries usually ensues, and after persistent disturbance of the ovaries has once followed, a conservative operation on them must be combined with the other procedures if success is to be hoped for. Pregnancy seldom occurs in the first six months after any of these operations. It is most common in the second or third six months, and a considerable percentage of successes do not appear until the fourth six months or perhaps shortly after. Minor treatment and the autogenous vaccinations are often of much importance as after-treatment.

This class of cases varies greatly in the degree to which the several factors are present. Success in treatment rests largely on careful analysis of their relative importance and the adaptation of the operative or other treatment thereto; but these sterilities form a large, interesting and very hopeful class.

#### EXAMINATION, DIAGNOSIS AND PROGNOSIS

The many possibilities, on one side or the other, which are involved in the sterility of a given mating form so complicated a subject that the decision as to which of the many possibilities form the effective cause or causes in a given case, and the formation of a prognosis of what can be expected from treatment, can usually be reached only after all have been considered and examined for.

The examination of a couple should begin with a careful general life history of both, which should be especially directed toward detecting the existence of autointoxications or of an involvement of the testicles or ovaries in past general infections.<sup>3</sup>

The general history should, if necessary, be followed by a general medical physical examination.

A careful sexual history of both partners should be taken. In the case of the man it should include past and present sexual habits, degree of desire, and infections; in the case of the woman, a chronological inquiry into the events of puberty, any changes in the catamenial history, and the phenomena of the marital relation, especially when first assumed.

The local physical examination of the male should include the exclusion of any abnormalities of the penis, and careful palpation of the testicles, of the prostatic urethra, of the prostate and vesicles. When there is a history of past infection or any tenderness on palpation of the urethra, a urethral examination should be added.

In the pelvic examination of the woman, the usual visual and bimanual examination should be followed by a rectovagino-abdominal palpation, which is made with the forefinger in the vagina, the second finger in the rectum, and the other hand on the abdomen. The superior degree in which the shape and relation of the uterine body, and the conditions of the ovaries are determined by this examination can be appreciated only by those who have trained themselves to it. It is

essential to the determination of the existence of spasms in the so-called uterine ligaments (unstriated muscles), a very important item in the examination for sterility; and the functional derangements of the ovaries can hardly be studied successfully in any other way. These examinations should usually be repeated under anesthesia. The use of primary anesthesia by gas-oxygen is usually quite sufficient for this purpose, and is so lacking in disturbing or unpleasant features as to be quite unobjectionable.

These examinations should include not only the usual search for abnormalities but a complete review of every part of the genital organs, including size, shape, degree of development, tenderness, congestion, localized inflammatory conditions and spasms. The study of the lesser degrees of functional alteration of the ovaries may sometimes advantageously include repetitions of the rectovagino-abdominal examination throughout the varying phases of the menstrual month.

Finally, the secretions of both sexes should be submitted to a microscopic examination. Smears should first be made from both the vaginal and the cervical secretions, and the chemical reaction and gross appearances of both should be recorded. The smears should be stained, and their study should include the bacteriology of the vagina and the amount and condition of the contained epithelial cells, with especial reference to the degree of destruction of their cytoplasm. In the cervical secretion the important points are the amount and condition of the epithelial cells, the degree and quality of the leukocytosis, and the thickness and tenacity of the mucus.

It is usually in practice most convenient that a post-coital examination of the woman should be the next step, because if the examination of the vaginal pool shows an abundant number of spermatozoa with a high percentage of first-rate progressive motility, a direct microscopic examination of the male may be dispensed with; but it is rarely conclusive to this effect unless made within the first hour after coitus.

The mucus of the postcoital flow as it escapes from the os should next be searched. Specimens taken by syringe or otherwise from the lower and upper cervix should be examined, and the behavior of the spermatozoa within them should be carefully noted. In a small proportion of cases an examination of the corporeal secretion is desirable; but it is difficult to perform this examination without contamination from the mucus of the cervix, and it is not altogether innocuous. It should be reserved for cases in which the result of the previous examinations seems to render it especially desirable.

If the spermatozoa as found in the pool are not first-rate, an examination of the semen obtained directly from the male and without admixture with the secretions of the female is essential to a determination of his fertility, and experience has shown conclusively that no male should be condemned without the examination of a specimen which has been obtained directly from his urethra by any one of the three possible methods within a few minutes of the examination. The spermatozoa are exceedingly sensitive to chilling, desiccation and very slight overheating. Cases have been seen repeatedly in which the male has appeared sterile after the examination of a specimen that had been ejaculated as short a time as half an hour previously and subjected to transportation, but in which the examination of a fresh specimen with duration tests

3. It is well known that mumps frequently affects the testicles and less frequently and obviously the ovaries. These involvements also occur, though much less frequently, during typhoid. There is also some evidence to show that they occasionally occur in scarlatina, and perhaps in some other infections, though this must be regarded as unproved.

under proper laboratory conditions showed conclusively that the method of collection and transmission had involved what may be called laboratory errors which were wholly responsible for the absence or imperfection of fertility.

After a full consideration of the history, local and general, and of the local, general and microscopic examinations in their relations to each other in both sexes, a diagnosis of cause, and usually, a fairly accurate prognosis of the prospect both with and without treatment, may be obtained; but the conditions involved are so complex that opinions given without such an analysis are usually little better than guesses.

An accurate prognosis is especially important in sterility, since the institution of treatment, and more especially of operative treatment, in cases in which it is judged appropriate, involves a decision that is different in kind from that which is concerned with the relief of ill health.

When an abnormal condition involves a distressing symptomatology and, more especially, when it involves danger to life, it is of course proper for the surgeon to urge on his patient the importance of treatment, whether minor or operative; but the institution of treatment, with its discomforts and expenses, for the relief of sterility alone is one which is essentially at the choice of the patients and which is essentially dependent on the degree of their desire for children in relation to the degree of improvement in their prospects which may be expected from treatment. Their decision must be largely dependent on the prognosis that is given to them, and every effort should be made to render it accurate.

The degree of success that may be expected from adequate treatment of sterilities in general is a question that is frequently asked by the profession; but, although experience shows that a fairly accurate prognosis may usually be obtained in a given case, a general statement is as yet impossible. Repeated attempt at statistical study of all the cases seen has been made, but has been unsatisfactory owing to the character of the subject. There are so many possible causative elements in sterility; the presence of several such conditions within the same case is so common; the prognosis in individual cases varies so widely in accordance with the combinations so obtained, and varies so much again with the duration of the sterilities, the ages of the female patients and often with the effects of previous treatment that they have undergone that an adequate classification of the cases for statistical analysis would require the use of many thousands of instances, and such are not now available. Statistical conclusions drawn without classification would be misleading, while those drawn from cases selected as favorable would be nearly worthless.

Cases that are successful under minor measures are among the most gratifying that are seen; but the causes that effect sterility in this class of cases are not only so variable, but often grade into each other by such indefinite degrees that their classification for adequate analysis by statistical methods has proved to be, for the present, at all events, a hopeless task. The only general statement about results that is so far in any degree worth putting into figures was reached by treating as a whole the operative cases that have been seen since present methods have been used and in which two years have elapsed since operation. In this series, seventy consecutive cases yielded a general result of

42 per cent of successes; but in fairness it must be stated that this collection included a considerable proportion of cases in which the couple decided on an operation after having been given a doubtful or poor prognosis for success (in some cases as low as a 10 per cent. chance), in view of the fact that they were assured that the prognosis was hopeless without it, and because they were willing to take even the smallest chance.

It may fairly be said that in young persons without venereal history or serious congenital defects, and with a sterility of but a few years' standing, the prospect of obtaining pregnancy under treatment is almost always very good. In selected cases it is as high as from 75 to 80 per cent.; but in less favorable cases it ranges all the way downward to those in which it is from one cause or another absolutely hopeless. Each mating must, then, be considered by itself and it is manifest that no general statement of value can be made.

321 Dartmouth Street.

## STONE IN THE KIDNEY AND URETER

FROM THE STANDPOINT OF THE  
CLINICAL SURGEON\*

A. J. OCHSNER, M.D.

CHICAGO

It would seem proper for me in my part of this discussion to avoid a repetition of what is contained in most of the special works as well as in the various monographs on stone of the kidney and ureter, which are so complete and exhaustive that, in connection with the recent papers by Braasch,<sup>1</sup> Eisendrath,<sup>2</sup> Young,<sup>3</sup> Cabot,<sup>4</sup> Eliot,<sup>5</sup> Merritt<sup>6</sup> and others, the field has been splendidly covered. It would seem well worth while, however, for me to consider stone of the kidney and ureter from the standpoint of the clinical surgeon, especially because I have been constantly active in the treatment of these cases since they have been looked on as surgical.

I assisted Prof. Charles T. Parkes<sup>7</sup> in 1887 in the diagnosis and operation of his first case, which was one of the earliest cases treated by operation in this country.

At that time, the characteristic symptoms, which are now generally accepted, were discussed incidentally in textbooks. Morrison had written on the subject and reported cases. Israel was beginning the work in this department which has since brought him international fame, and Jacobson had given some attention to the surgical importance of this subject which had been mentioned by various surgeons in connection with occasional clinical observations.

The stone in the first case of my experience, mentioned above, was the shape and size of a robin's egg,

was perfectly smooth and fitted like a valve into the entrance of the ureter, accounting perfectly for the pain and symptoms of obstruction and for the thickened walls of the pelvis which made location of the stone by palpation impossible. The stone was located by puncturing with a fine sewing needle, which was generally recommended at that time, but which has since been discarded because it leads frequently to the missing of small stones.

My next observation of especial importance occurred in 1888, when I was directed by my chief to keep a colleague under the influence of chloroform at intervals from 10 a. m. to 8 p. m. while a renal calculus was passing through the ureter. For several years, this physician had passed from one to three renal calculi annually. Morphine had no effect on him and the pain was unbearable, so the use of anesthesia was our only hope of giving relief.

A few days later, before this patient had time to produce another calculus, we met another one of Professor Parkes' patients who had suffered from recurrent renal colic, a manufacturer of steam boilers. On asking him whether he had experienced any attacks recently, he stated that he was definitely through with renal colic, and suggested that if the doctors used their intelligence as actively in their profession as boiler manufacturers had to in their business, no one would ever have to experience a second attack unless he had more than one stone in his kidney to begin with. He stated that when his customers complained of their boilers filling up with lime in the form of scales, he advised them to use rain water, and this ended the trouble; so on the same principle he drank freely of distilled water, and had been free from a recurrence of kidney stone and renal colic.

I immediately put our colleague on this treatment, which he continued for twenty-nine years, never having another attack. He died of cerebral hemorrhage at the age of 74.

Since that time, I have made use of this method in an enormous number of cases, always with the same result; and the practice has been followed by many practitioners who have visited my clinic and others who have read about this method of treatment. I have no doubt that the method must have been used before the boiler maker discovered it, but earlier reference to it has escaped my attention, except that the water from certain springs which is almost as free from lime as is distilled water has been used as a prophylactic against recurrence of renal colic from time immemorial, while regions in which the drinking water is loaded with lime salts are notorious for the frequency of renal calculi, as cited by O. S. Fowler,<sup>8</sup> for instance, in India.

A number of observations similar to the following have proved the importance of this treatment:

CASE 1.—A farmer, aged 34, from the limestone region of Wisconsin, came to my clinic suffering from recurrent renal colic twenty-seven years ago. During former attacks, he had obtained relief spontaneously, but this attack seemed more severe. The stone passed on the second day under treatment with morphine and atropin hypodermically, and 2 ounces of glycerin and large quantities of distilled water, all of which were repeated after twenty-four hours. He obtained a disillling apparatus and drank only distilled water for twelve

years without having any further attacks until he drank well water for six months, being too much occupied while building a new house to take the distilled water. This brought on another attack, during which he passed a calculus 1.5 cm. in length. He immediately returned to the use of distilled water and has now been free from attacks for fifteen years.

I have encountered a number of similar cases.

There is a marked difference in opinion as regards the proportion of cases in which renal and ureteral stones will pass spontaneously, some placing the percentage as high as 90, while others place it as low as 10 per cent. (Merritt,<sup>9</sup> Braasch<sup>1</sup>).

This depends, of course, very largely on the class of cases treated. In our clinic the patients who come from the immediate city or vicinity usually have stones that pass under the treatment mentioned above. In all probability, the stones that passed following this treatment would have passed spontaneously before the patients could have traveled a long distance so that only those patients come from a distance whose stones cannot pass for one reason or another, and therefore clinics which receive their patients almost exclusively from long distances must have a far larger percentage of cases requiring operation than clinics in municipal hospitals.

My next case of especial interest, which I saw in 1892, demonstrated a fact which is now mentioned in most articles, and in practically all textbooks treating on this subject:

CASE 2.—A powerful, healthy appearing man, weighing over 200 pounds, about a week previously had begun to suffer from pain in the region of the right kidney which had increased constantly, no relief being obtained from the hypodermic use of morphine. It was thought that the typical uremic convulsions to which he succumbed almost immediately after I saw him were due to the pain, which was confined to the region of the right kidney.

The physician in charge felt certain that the patient had not previously suffered from nephritis and could not account for the uremic convulsions. The necropsy revealed absence of the left kidney. The pelvis of the right kidney contained a pear shaped stone, 2.5 cm. long, with the portion corresponding to the stem inserted in the upper end of the ureter. A pyelotomy during the early stage of the attack would, of course, have cured the patient as has been demonstrated in many cases since that time.

CASE 3.—A woman had a sinus, leading to a nephritic abscess of the right kidney from which a stone had previously been removed, which refused to heal under treatment. In the meantime, the fistula had drained much urine and pus, while the amount of urine secreted by the other kidney, although it remained normal in quality, decreased constantly until less than 100 c.c. were voided daily. After keeping the patient under observation for a sufficient period, and finding it impossible to pass a ureteral catheter into the pelvis of the right kidney, we decided to remove the organ because we attributed her failing health to absorption of septic material, and at the rate she was losing strength, we felt certain that she could not last very long.

Within two days after the operation, the urine passed from the bladder increased markedly, and within two weeks it increased to 800 c.c. This showed in a very marked degree the fact that the remaining kidney is stimulated to greater activity on the removal of the diseased organ, the justification of which has now been thoroughly established.

The next case marks the beginning of a change in the practice in our clinic:

CASE 4.—A woman, aged 60, emaciated and septic in appearance, with typical symptoms of double pyonephrosis with multiple calculi, was treated by drainage of the left kidney and the removal of a number of stones; a month

<sup>8</sup> Fowler, O. S.: Ureteral Obstruction Causing Urinary Stasis, a New Etiology in Kidney-Stones with a New Method of Nephropexy and Sigmoid Ictal Natural Drainage, J. A. M. A. 62: 367 (Jan. 31) 1914.

later the right kidney was treated in the same manner. Both kidneys were tuberculous. The patient was put under hygienic and dietetic conditions, but lost in weight and strength very slowly but gradually. Formerly, no patients of this type had ever recovered in our experience, although we had a series of recoveries in cases in which we had removed one tuberculous kidney even after it had been drained for a time. In this case, both kidneys were in such bad condition that it seemed out of the question to remove one. We consequently started to fill the sinuses and the pelvis with a paste of 20 per cent. bismuth subnitrate in petrolatum, repeating the treatment once a week. The patient showed improvement within a few weeks, increased in weight and strength rapidly, and made a complete recovery.

Since that time, we have invariably treated sinuses leading to tuberculous kidneys with Beck's bismuth paste with a fair number of recoveries.

During the fifteen years ending Jan. 1, 1919, I have treated 146 cases of kidney and ureteral stone in my clinic at the Augustana Hospital.

#### TREATMENT

In case the calculus lies in the pelvis without several branches into the calices, we have found pyelotomy most satisfactory, following the advice of J. B. Murphy,<sup>9</sup> whenever possible, of first splitting the upper end of the ureter longitudinally and continuing the incision into the pelvis.

In branching stones, we have clamped the pelvicle of the kidney lightly, split the cortex longitudinally just behind its midline, removed the stone, and placed heavy catgut sutures through the kidney, tied just tightly enough to bring the surfaces together, and then released the clamp. In pyelotomy, only in cases in which the edges of the pelvis failed to fall together evenly, fine catgut sutures were used. In either case we drained the wound with a strand of gauze and a cigaret drain.

Ureteral stones which could not be delivered through the bladder without traumatizing the ureter, we have removed through an abdominal incision in the linea semilunaris carrying a small rubber drain, a narrow strip of gauze and a cigaret drain through the lower angle of the wound down to the incision in the ureter. In none of these cases have we applied sutures. Only in one case have I removed a stone through a vaginal incision.

#### CONCLUSIONS

1. The size of the pelvic stone will usually determine the possibility of its passing spontaneously.

2. In the ureter, the primary stone, if it gets started, will usually pass. Secondary stones may be stopped by cicatricial contractions which may have been caused at some point by injuries due to the passage of one or more previous stones.

3. A large proportion of stones of moderate size will pass spontaneously or after dilatation of the ureter with bougies, the use of oil of glycerin injections or one of the various methods of dilatation, of which the one perfected by Lespinasse<sup>10</sup> seems most effective.

4. At times, simply starting the stone with a bougie will suffice.

5. In patients suffering from acute renal colic, the use of morphin and atropin hypodermically followed by the ingestion of 2 ounce doses of glycerin with

large quantities of distilled water has seemed to be of value in aiding the passage of stones spontaneously, especially when the patient was immersed in a very hot bath.

6. The prophylactic measure of taking large quantities of distilled water seems to be effective in preventing recurrences.

7. Sinuses remaining after pyelotomy or nephrotomy will frequently heal after injection with Beck's bismuth paste.

8. The clinician who is alert for the discovery of renal or ureteral stone, who takes into consideration the history and physical findings, will rarely miss a correct diagnosis provided he confirms his diagnosis (a) by careful urine examination; (b) by roentgenographic examination with intensified shadows if necessary; (c) by the introduction of ureteral shadow sounds; (d) by pyelography in doubtful cases, and provided he is willing to consider all points as a whole and will place no weight on negative findings by any single one of the various methods employed.

#### DIAGNOSIS

The most important element in the diagnosis is a carefully written history taken by the surgeon himself who is thoroughly familiar with the clinical courses of these cases, because the careful weighing of all the points elicited is exceedingly valuable, while each individual element in the history may be of but slight value.

This accounts for the constancy with which the older clinical surgeons have their diagnosis confirmed by the roentgenographic and other laboratory findings, and also for the fact that we find in the literature so many of the younger surgeons and diagnosticians who lay little value on the history.

It is certain, however, that wide clinical experience must confirm the conclusion arrived at by Young<sup>11</sup> after his extensive studies, that "no single piece of evidence or combination of evidence is sufficient to make an absolute diagnosis."

Next in importance is the roentgenographic examination. The plate should show a distinct picture of the outline of the kidney to be dependable in case of renal calculus.

In case the shadow is not sufficiently distinct, the latter should be intensified.

In case there is doubt concerning the stone's being in the ureter, a shadowgraph catheter should be introduced.

Of course the bowels should be thoroughly emptied before the roentgen ray is employed, and both kidneys should be examined, because, according to Brunsch,<sup>1</sup> in bilateral stone the pain is unilateral in 64 per cent. of the cases. Guyon pointed out the fact many years ago that a stone in one kidney may give rise to pain on the opposite side exclusively, a condition he termed "renorenal reflex."

Cystoscopic examination is especially useful in differentiating between calculus and tuberculosis. The same thing is true of microscopic examination of stained urinary sediment and inoculation of guinea pigs for tuberculosis.

Lucas,<sup>11</sup> in one of the early works in this field, invented an interesting test for ureteral calculus which has not received due attention. The thigh is held in a flexed position resulting in contraction of the

<sup>11</sup> Lucas, R. C.: Lancet, April 2, 1903.

iliacus muscle, which is relaxed suddenly, jarring the ureter containing the stone and causing acute pain. He also gives the following symptoms not usually mentioned: Patients with calculi often have a tendency to micturate frequently during the daytime, while at night they are not disturbed.

In case of obstruction of the pelvis or ureter of the only remaining kidney, the patient in making frequent unsuccessful attempts to micturate develops headache, vomiting and uremia.

He gives the following points for differential diagnosis between tuberculosis and calculus:

Hematuria without pain appears early in tuberculosis; hematuria with pain is constant in calculus.

Pyuria without pain appears early in tuberculosis; pyuria with pain appears late in calculus.

Pus is present in tuberculosis in excessive amount; in calculus it is minimal in amount.

Pain in tuberculosis is diffuse, dull, constant; in calculus it is definite, sharp and intermittent.

Chills in tuberculosis are common; in calculus they are rare.

There is rise of temperature in tuberculosis especially in the afternoon; in calculus it is rare.

Tubercle bacilli in tuberculosis are sometimes present; in calculus they are absent.

The ureter is thickened in tuberculosis, sometimes it is palpable; in calculus it is not palpable.

The remaining conditions to be considered in making a differential diagnosis are movable kidney, oxaluria, acute granular nephritis, papilloma in the pelvis, tumor, gallstones, tuberculosis of the spine, appendicitis, ectopic gestation, sciatica and lumbago, stone in the opposite kidney, seminal vesiculitis, pyosalpinx, and gastric or duodenal ulcer. Phleboliths and calcified tuberculous lymph nodes may be mistaken for stones when one is attempting a differential diagnosis.<sup>12</sup>

#### ABSTRACT OF DISCUSSION

DR. CHARLES HARFSTER, Toledo, Ohio: I watched the work of Professors Israel and Nitze for about two years, and was much impressed by what they said regarding the finality of any test. Regarding the use of the ureteral catheter and the refinements of urologic diagnosis, I will cite one or two cases to illustrate their great usefulness. In cases of bilateral ureteral calculi, with anuria of from two to five days' duration and the roentgenogram showing stones in both ureters, on which kidney are we going to operate? In a case of anuria of five days' duration, with stones showing in the roentgenograms, we were able to pass a number four catheter by the stones on each side. On one side no urine was coming at all, yet the clinical symptoms seemed to point to that kidney as the one that was functioning. If we had operated on that kidney the man would have died. By being able to pass the small catheter on both sides, we cleared up the diagnosis, operated on the right kidney and saved the man's life. Regarding the length of time a per-

son with anuria and stones on both sides may live, one man who refused operation, on whom we had previously done a prostatectomy, lived about twelve days. Of course, we appreciate the worth of clinical evidence, but we should in all cases corroborate our findings by cystoscopy, roentgen ray and all other diagnostic refinements.

DR. V. D. LESPINASSE, Chicago: The symptoms of stone were worked out in the early days of medical practice, as urinary stone is an obvious lesion and these symptoms were called stone symptoms. Stone symptoms are merely symptoms of acute ureteral obstruction, and anything that will obstruct the ureter will cause the same group of symptoms as a stone. So that we must have more than symptoms to make a diagnosis of ureteral stone. Blood and pus in the urine, of course, help a great deal, but most of us nowadays want something objective, something definite that we not only can see ourselves but demonstrate to anybody else, and we turn to the roentgen ray. The roentgen ray very often fails, particularly in the case of the smaller stones in the ureter, and particularly in certain heavy individuals. The point that I want to make is in regard to the diagnosis of these stones that are negative to the roentgen ray. What happens in the urinary tract when a stone is present? There is ureteral dilatation, dilatation of the pelvis of the kidney and its calices, and these facts can be used to diagnose a stone in the ureter, and should be used. A pyelogram and a ureterogram should be made. Obstruction of the catheter at a certain definite point confirms the diagnosis. These points of pelvic and ureteral dilatation have helped me make a diagnosis in several instances where the stone was negative to the roentgen ray and operation produced the stone.

DR. A. J. CROWELL, Charlotte, N. C.: Three points in connection with Dr. Ochsner's paper I would like to discuss: first, the causes of recurrences of stone in the kidney; second, the frequency with which we have recurrence, and third, a plan to prevent recurrence. Dr. Ochsner believes he has clinical evidence that kidney stones are produced by drinking certain mineral water. How any mineral water can be a direct or predisposing cause to stone formation, I do not know. It may act as an irritant, lowering the kidneys' resisting power and make infection more liable. In my opinion, clot, following hemorrhage, or debris as a result of infection, are the principal causes of stone formation. These act as a nucleus on which the salts of the urine are deposited and to prevent stone formation it is necessary to get rid of these predisposing causes. It occurred to me a few months ago, while studying a case of double nephrolithiasis with infection, that, theoretically, to prevent reformation I should first get rid of the infection. With this end in view I irrigated the kidney pelvis with silver nitrate solutions every third day, beginning with 0.5 per cent, and increasing 0.5 per cent, each treatment, keeping this up until the infection subsides. The stones are removed simultaneously by pyelotomy. The wounds heal by first intention. In ten days I resume pelvic lavage with silver nitrate and physiologic sodium chlorid solutions. This is kept up until no evidence of infection is found. I am now treating several cases in this way. I feel that many recurrences can be prevented by faithfully following this plan of treatment. It was new to me and in looking up the literature on the subject I found that no one seemed to have thought of it as a routine plan of procedure to prevent stone reformation. It has been estimated by different operators, that stones have recurred in from 10 to 40 per cent. of the cases. I heard Mr. Freyer, while removing a stone from the kidney of a patient, say that unless the stone was producing considerable clinical symptoms, "leave them alone since we have recurrences in practically every case."

DR. GUY L. HUNNER, Baltimore: Ureteral stricture is the chief cause of most stones in the ureter. Not only that, but stones forming in the ureter may so dilate the ureter above the stricture that the stone will float up into the kidney, where it will, perhaps, get larger and remain, or get larger and start down again and then get obstructed in some other point. The chief point of importance about this is that in operating on any stone in the kidney or upper ureter, we

should pass the graduated or the dilating bougie from above downward, in order to dilate any possible stricture in the lower end of the ureter. I am a great believer in Dr. Ochsner's method of using these pure waters for these cases that have shown a tendency to reformation of stone.

DR. ALBERT J. OCHSNER, Chicago: I am very glad, indeed, that Dr. Hunner and Dr. Crowell brought out these points, because there is no doubt but what infection is a very important etiologic element and, of course, with the presence of strictures in the ureters you are bound to have infection. You cannot have retention of fluid in the bladder or in any cavity without having infection in a relatively short time. An interesting point that I might mention is this: That there are a number of vegetable juices that seem to have a marked disinfecting influence on the infections in pyelitis. In my contact with surgeons in the tropics, in Porto Rico, and in Mexico particularly I found that they can disinfect a pyelitis within a very short period of time. A person who comes from the United States, with a pyelitis, who has been under treatment for months, or possibly years, will be disinfected within a few weeks by the use of large quantities of the milk of the unripe coconut, in the coconut countries, and by the use of the juice of one of the century plants in Mexico. And here in our own country I have, in many instances, secured relief from infection of the kidney and bladder with the colon bacillus by the use of large quantities of watermelon. So that these vegetable juices seem to have the power of disinfecting the urinary cavities if taken freely.

### THE NERVOUS CHILD AND HIS MANAGEMENT \*

E. BOSWORTH McCREADY, M.D.

WILDWOOD, PA.

The well-poised, effective, emotionally stable adult human being is the exception rather than the rule in modern life. Guthrie<sup>1</sup> believes that "neurasthenia probably causes more misery and pain than any organic disease," and Ernest Jones<sup>2</sup> states, that "neuroses constitute, perhaps, the most widely spread form of disease." A recent institutional census<sup>3</sup> shows that on Jan. 1, 1918, one individual of every 405 in the United States was definitely insane to an extent requiring custodial care. Procrastination in locking the "barn door" is proverbial and is particularly common in nervous and mental disorders. For this both the public and the medical profession are to blame, but more particularly the latter. Physicians deride the efforts of laymen toward that little knowledge of matters medical which they consider renders them dangerous to their own well-being, and while this attitude may be advisable under some circumstances, it can be justified only by the physician's electing himself monitor over both the physical and mental health of his clients by placing a higher value on prevention than on cure.

The neuroses and psychoses are seldom of sudden onset, but are usually the end-result of a long series of contributing factors, which have their inception in early life and are recognizable in early life by the conscientious and careful observer. Parental fears are easily allayed when a trusted family physician or con-

sultant, after examining a distinctly hypoplastic nervous child, states that he can find nothing "organically wrong" (meaning thereby, I suppose, that he finds no disease entity) and dismisses the patient with a tonic and a few vague directions about keeping the child out of school, getting him into the country, or giving him more milk to drink with the optimistic assurance that he is just a little nervous and anemic and will outgrow it after a while. As I have before taken occasion to state,<sup>4</sup> "To this attitude of *laissez faire* more wrecked lives are due than to the actual dishonesty of the charlatan." Equally dangerous are the pessimistic prognostications of another variety of routinist, ignorant of the value of a proper combination of medical, hygienic and educational treatment. While some children are born nervous (hereditary causes), some acquire nervousness (disease, habits, etc.) and others have nervousness thrust on them (faulty training at home and at school). To counteract and to remove these causes in their various and combined phases is the duty (and the privilege) of the physician, and if he fails in its exercise he is derelict.

The difficult feeding case is such because the maternal supply of food does not agree with the child, or because the child fails to agree with the food. The latter condition is due to a deficient legacy of vital force, directly traceable to either or both parents, or to developmental disturbances in embryo. The maternal inability to furnish suitable or sufficient nourishment, and the offspring's inability to metabolize it, are often due to identical causes—organic inferiority and subenergization. The proper development of the nervous system is dependent on proper metabolic functioning, and anything that interferes with this—improper or insufficient food, acute or chronic disease, fatigue, physical and emotional, including that from reflex irritation—all lay the foundation for future trouble. Donaldson<sup>5</sup> and Sugita<sup>6</sup> have shown that the human cortex attains its full thickness at about the age of 15 months, and that at this time cell multiplication and cell migration have practically come to an end, and that the changes incident to further growth are those of enlargement of the cell bodies, growth of axons and myelination. Underfeeding and nutritional disorders retard the completion of this higher cerebral organization. "All this," according to Donaldson, "shows that the important events in the postnatal growth of the nervous system occur early in life, and this in turn emphasizes the paramount importance of favorable conditions during the first three years of childhood."

The danger signs are many; and while not all are of equal import, none should be disregarded. In early infancy they are digestive disturbances, fretfulness, extreme sensitiveness to light and sound, convulsions, premature or late closing of fontanel, premature or late dentition, precocity or delay in the development of muscular control, in talking, undue sensitiveness of skin and mucous membranes, thumb sucking, head rocking, thigh friction, and manipulation of genitalia. In early childhood they are constipation, perhaps alternating with diarrhea, anorexia, and perversities of appetite, aversion to particular articles of food, night

terrors, muscular twitchings, tics and muscular incoordination, stammering, lisping, idioglossia, enuresis, tremors of the fingers on extension, restlessness, irritability, perversity sometimes amounting to negativism, phobias, extreme timidity, fatigability, hypermotivity, etc. If unchecked and uncorrected, the foregoing characteristics tend to aggravation as puberty approaches and we may have definite negativism, stereotypy, and the typical "shut-in personality," psychasthenia, and that short circuit of consciousness included in the term "neurosis." From the physical standpoint, the nervous child more than the child of stable nervous system, is likely to present the anomalies, such as marked cranial and facial asymmetry, ocular muscular imbalance, myopia, hyperopia, astigmatism, adenoids and enlarged tonsils, prognathism, irregular dentition, nevi, deviation of the nasal septum, phimosis, etc. He may show evidence of ductless glandular dysfunction, may be obese with short, stubby fingers, or slender with long bones and tapering fingers, may be sexually precocious, or puberty may be delayed, may take on sudden accesses of growth, or may fail to grow at the normal rate. Adler<sup>7</sup> gives a comprehensive enumeration of the defects which may be found in organically inferior individuals predisposed to the neuroses. Eppinger and Hess,<sup>8</sup> discussing vagatonias, which they find a prominent factor in the neurotic make-up, say: "When we discover that vagatonias is associated with so many constitutional anomalies, which are manifestations of inferiority, we naturally are inclined to ask whether vagatonias itself is not a form of constitutional inferiority." Collin and Verdé<sup>9</sup> find that children with "cerebrospinal fragility," to use their term, are exceptionally susceptible to toxic and infectious influences, and they review a long train of phenomena that are due to this. In fact, so closely associated and interrelated are the symptoms of deficient growth energy (hypoplasia) and nervous insufficiency (adynamia) that the mutual and reciprocal action of each is apparent.

It is not necessary that we classify and label nervous children, as has been attempted, into those destined to develop dementia praecox, those who will develop manic-depressive insanity, psychasthenia, neuroses and what not. The mere fact that the child possesses characteristics which stamp him a potential neuropath or psychopath is sufficient. Treatment should begin as early in life as possible, even in the prenatal period, employing every means at our hand to allow Nurture every opportunity for beneficent activity. Nature, in the form of hereditary tendencies we cannot affect; we can only influence her results through Nurture. The nervous child, particularly the one whose nervousness has been thrust on him, disagrees with his environment. Consequently, his environment should be modified to meet his needs. Unfortunately, the average private home, particularly the urban home, is conducted for the convenience of the adult members of the household; the children may fit in as best they can, just so they keep out of the way of their elders at the infrequent times when these have "no place to go." If this is not the case, they are liable to the opposite extreme

of oversolicitude, overindulgence, and inconsistency of management as harmful in its results as the neglect referred to above.

Thus the treatment of the nervous child must begin with a modification of the immediate environment. It is often impossible for the child to improve while he remains in his own household; not necessarily because the home is essentially unfit, but because it is difficult to eliminate the causes originally responsible for the establishment of faulty modes of reaction. Again, no matter how solicitous and conscientious the parents may be, they lack the special training and experience that would enable them to deal effectively with a mal-adjusted child. This they have already proved, by the child's condition, and it is now time for some one with the necessary equipment to take a hand. If the child remains in his home, his regimen should be under the absolute charge of the attending physician; otherwise treatment is futile. Domestic arrangements must be modified and changed as conditions require, sources of friction must be removed, impatience, irritability and undue sympathy on the part of various members of the household must be curbed. The first consideration should be to see that the child obtains sufficient rest. Not only is easy fatigue a prominent symptom of nervous instability, but it is also a potent cause. Most children are overstimulated by the conditions of modern life; conditions which, because they are usual, are considered normal. Fatigue in children brings about a nervous irritability which leads to further effort, giving the false impression that the child is unusually energetic. Constant calls on the reserves of energy which should only be made in emergency, and very infrequently in childhood at least, result in a condition of nervous insolvency even more serious than the adult form. The constant din of the city streets, the vibration of street cars and automobiles, the flickering glare of the movie, the strident blare of the graphophone, the constant hurry and bustle to be somewhere else as quickly as possible—all these have their effect for harm on the delicate sensorium of the growing child.

Equaling the importance of the prevention of over-fatigue is the regulation of the diet. We are accustomed to think of malnutrition as affecting only those of narrow means; yet a large percentage of children from well-to-do homes are undernourished. The schoolchild, in the habit of sleeping until the last minute, comes to the table with time only to bolt one or another emaculated but widely exploited cereal whose only virtue is that it requires a large quantity of cream to admit of its being swallowed. By the middle of the morning his tissues crave more nourishment, which craving is relieved by candy or highly ornamental pastry of low nutritive value. The edge of his appetite blunted, he makes a sketchy lunch, grudging the time that might be used for play. In the afternoon again his appetite is impaired by some easily obtainable carbohydrate food, and at dinner time he partakes of those dishes only for which he has the greatest liking. The result is that his diet, while perhaps not necessarily deficient in calories, is composed mostly of carbohydrates, generating an evanescent energy, but failing to provide for tissue wear and tear, for growth and for storage for emergency. Such diet, also, is poor in vitamins and mineral salts; nervousness in children is often as much a deficiency disease as is scurvy or beriberi.

Fresh air, bathing, regulated exercise, all have an important place in the hygienic management of the nervous child. It is time for us to apply the lessons learned on the stock farm, in the raising of domestic animals and fowls, to the raising of children. The scientific animal husbandman has learned that the three prime requisites for success, the stock being sound, are; diet, fresh air, exercises. He knows that to secure growth and vigor he must feed a balanced ration, that he must furnish sufficient roughage to give bulk to the intestinal contents, that he must give green stuff and other foods rich in vitamins and in mineral salts. He knows that he must feed in proper quantities, and that to gain the maximum of growth and vigor all animals require range, free from crowding, from noise and from confusion. To the urban realist "pigs is pigs"; but to the up-to-date farmer, good pigs and other animals are the result of balanced rations, exercise and fresh air. What observant swineherd has not seen the "runt" of the litter, nosed aside by his stronger and more active brothers and sisters, equal or outstrip them all when given a trough and a run to himself? Our domestic animals are important and valuable, but are they more important and valuable than our children? Should more scientific study and care be devoted to them than to the individuals for whom they exist?

Mention has been made of the difficulty of bringing about proper nervous adjustment in the child's own home. This is doubly difficult when that home is a city home, and most difficult when it is that of the modern cliff-dweller, the apartment or flat. City life is at best an artificial one for any human being; for the nervous child it is poison. There is nothing so conducive to nervous stabilization as well conducted country life. It is here that the nervous child may be brought to realize what Cabot calls "the glory of raw materials," and it is here that the "human plant" may best receive the nurture that it requires. Mere absorption through contact is not, however, sufficient, for "experience and not memory is the mother of ideas." The child, to gain the best results, must return to a fairly primitive mode of life; and though not, perhaps, obeying to the letter the mandate, "Study Nature, not books," must "study Nature, then books." As Brown- ing says:

It was better youth  
Should strive, through acts uncouth,  
Towards making, than repose on aught found made.

The conventional cut and dried methods of the modern schoolroom, depending largely on memory and abstractions, fail to properly hold and direct the attention of the child predisposed to nervousness. The study of nature, of bird, animal and plant life, and contact with the various activities of country life serve to bring about function of normal areas of interest and to eliminate abnormal ones.

Sequin,<sup>10</sup> to whom modern education and modern medicine are more indebted than either realizes, was a strong advocate of the utilization of Nature in the educational system. Holman<sup>11</sup> says:

Of all the great educators of the past, Sequin is the only one who directly attacked the problems of education, from the first, in a purely scientific spirit, and with a purely

scientific training and purpose. It is not surprising, therefore, that he did what neither Pestalozzi, Froebel nor Herbart had done: he showed that the development of mind, in the earliest years, depends on the development of muscles, senses and nerves; and he discovered the means by which this could be best secured. In short, he cast such a new and essential light on the principles and practices of education as only a mastermind can. . . . In some ways his scheme of garden schools is the crown and completion of his whole theory of physiologic education. It is also the application of his theories to normal children and ordinary schools with regard to certain essentials. In the light of present-day enthusiasms for, and experiments in, open-air schools and classes, Sequin is seen to have been a real revealer of fundamentals and a true prophet. No better testimony to the profound truth of his great discoveries could be found than the recent rediscovery of them.

Some general rules formulated by him more than forty years ago for the conduct of garden schools are as follows:

1. Do not teach anything indoors which can be learned outdoors.
2. Teach nothing from books which can be learned from nature.
3. Teach nothing from dead nature which can be observed on the living.
4. Nature is to be the schoolroom and the schoolbook, unless insuperable difficulties prevent.

Sequin's scheme, as outlined in two papers read before the New York Academy of Science in 1877 and 1878, embraced a comprehensive scheme for the utilization of public parks, museums, libraries, conservatories and other public institutions in a system of education which would render the schooling of the masses more active and practical. Unfortunately, Sequin's ideas, as a whole, have not yet been put into practice, though I venture to prophesy that the day will come when we shall see them carried out almost in entirety with modifications made necessary by the time, just as we now have open-air schools, manual training, domestic science, vocational training, physical culture, and other "modern improvements," all of which were described in in Sequin's plan.

A description of a practical method of education for nervous children, based on the theories enunciated by Sequin, I will take up in a later paper.

Wildwood Hall.

#### ABSTRACT OF DISCUSSION

DR. PERIVIAL J. EATON, Pittsburgh: I was very much pleased to hear Dr. McCready's description of the nervous child. Some children are born nervous, but they are in the minority. Some children acquire nervousness. A greater number acquire nervousness than those who are born nervous. The great majority of nervous children are those who have nervousness thrust on them, if we can express it that way. It seems to me that all of us who are interested in children and who study the effect of environment on children know that is so, and it seems to me that one of the paramount duties of the pediatricist is to teach the mothers (and the fathers, too) and when the opportunity arises the rising generation of girls, the potential mothers—the dangers, the shreds, the rocks, on which they so easily founder. The "back to the soil" cry is what should be realized. The best place in which to train children is in the environment of the country, the open space and the fresh air. As Dr. McCready has said, the training of the child should begin at once. If you cannot begin a child's training prenatally you should do so as soon after birth as is possible. If the pediatricist would teach along these lines, there would be a great deal more of good health and soundness of mentality, and above all an increase in the character of our children.

10. Holman, N.: Sequin and His Physiological Method of Education. London, Pitman & Sons, p. 224.

11. Holman, N.: Sequin and His Physiological Method of Education, p. 12.

DR. RICHARD COLE NEWTON, Montclair, N. J.: I believe it was the late Horace Greeley who said the great trouble in bringing up children in modern times is that we bring them up altogether too carefully. We do too much to our children and often interfere with their natural development. In the South in slavery days the negro children were raised very much like animals; they were put in a sort of pen where they crawled or ran about naked and ate out of a trough. There was never anything the matter with them, so far as known. When I was a young man the negro was ostensibly immune to tuberculosis; now he is more susceptible to it than the whites. His infancy was formerly passed in such a way that he escaped tuberculous infection. Now he is subjected to a so-called higher form of civilization with disastrous results to himself.

DR. HAROLD B. WOOD, Providence, R. I.: There is an aspect in the development of nervous and allied conditions which should be considered. The physical condition of the father at the time of procreation is a potent factor in the development of the child and to a relatively corresponding degree as is the condition of the mother during the child bearing period. The public now appreciates the frankness of the physicians in telling them of the problems of combating venereal disease and would welcome needed advice on this other question. Children should be the result of intent and not of accident. Among the better classes they would be the result of intent if the prospective parents were instructed properly. The physical condition of the father at the time of procreation is reflected in the future child. I am not referring to the transmission of venereal disease or of insanity. All of us know instances which prove my assertions. I know of a father who begot two children at times when he was doing very hard mental and physical work and was much below his physical norm. His children, now adults, are much below his physical and mental powers. In another instance, the first child was conceived when the father was below his normal physical condition and was much worried. The second child was intentionally begotten in the middle of a long and happy vacation. The difference in the children is very marked, the second being of a happier disposition, better physical and mental development and much more resistant to disease. The condition of the mother was not a factor in these cases. Physicians should teach prospective parents that there is a time for establishing their families and that the time for procreation should be intentionally selected according to the presence of good physical condition and mental ease of each parent, especially of the father. In the development of eugenics we need prenatal instruction for expectant fathers.

**Vaccination of Cattle Against Foot and Mouth Disease.**—The chief of the public health service in Italy, Dr. Lutrario, publishes in the *Bulletin of the Office International d'Hygiene Publique* 11:266, 1919, an account of successful vaccination of cattle against foot and mouth disease. In 1914 a committee of five leading university professors and four veterinarians was organized for the study of this subject, with government authority and funds. The method which Professor Terni has worked out consists in reinforcing and prolonging by successive inoculations the immunity already contracted by the animals from a first attack. This method has proved effectual on such a large scale that the farmers now ask to have it applied to their cattle. From 25 to 50 c.c. of blood from cattle saturated with the virus are injected by the vein. This is repeated four or five days later, supplemented with 25 c.c. of a 1 per cent. solution of filtered virus. A third inoculation is made eight or ten days later. The inoculations can be done subcutaneously, doubling the amount of the hyperimmunized blood. Another method seems to act as an effectual preventive vaccine; this is the intravenous injection of red corpuscles from an animal with the disease. This also requires three injections. Two animals that had never had the disease and were vaccinated by this technic showed no signs of the disease, to which the controls all succumbed within forty-eight hours, when the animals were placed in a herd affected with the disease in a grave form.

## MALAKOPLAKIA OF THE BLADDER \*

A. I. FOLSOM, M.D.

DALLAS, TEXAS

## REPORT OF CASES

CASE I.—In November, 1917, Mrs. H., aged 43, was referred to me. Her general health was good. She came complaining of a severe irritation of the bladder. There was undue frequency of urination (nocturnal and diurnal), a burning sensation, and difficulty in voiding. This had been more or less continuous for about six years. Eighteen months prior to her visit to me she had passed in the urine a small piece of tissue which had been submitted to a pathologist, who had reported the tissue to be carcinoma.

The woman was well nourished, had lost no weight, and in general had the appearance of good health. The blood count was about normal save for a leukocytosis of mild degree. Vaginal examination revealed nothing of interest except that the vesicovaginal septum was not indurated at all, and no mass could be felt in the region of the bladder, in spite of a previous diagnosis of cancer. Cystoscopic examination revealed a residual urine of 11 ounces, very milky and having the odor of decomposing urine, similar in every respect to the urine of an old prostatic.

The general bladder surface, roof and side walls were grossly trabeculated, showing numerous cellulæ. These surfaces, however, were only mildly inflamed. The trigon and the adjacent areas of the base of the bladder were covered with irregularly placed, smooth, rounded, nodular tumors, varying in size and shape; some round and almost pedunculated, others with broad bases and resembling plaques. These masses had none of the appearance of papillomas, there being no fronds nor villi. None of the growths showed any ulceration, nor did any have the appearance of cancer.

There were two of these masses located directly on the edge of the vesical sphincter; they were evidently acting as ball valves, obstructing the passage of urine and resulting in the residual urine and the trabeculation of the bladder wall. One of the small masses was removed with the rongeur and was submitted for microscopic study to Dr. J. H. Black of Dallas. His first report was that the growth was medullary carcinoma. I objected to this diagnosis on the grounds that, first, the history was not that of malignancy; second, the cystoscopic picture did not warrant such a diagnosis, and third, there was absolutely no induration to be felt in the vesicovaginal septum.

I told Dr. Black that I did not know what the condition was, for I had never seen such a condition before, and did not recall having read of such, but that I did feel very positive that clinically it was certainly not a carcinoma.

Not knowing what else to do, I began the use of d'Arsonval fulguration, and after the third sitting I found a decided improvement in the local picture. Several of the masses burned had disappeared, just as is frequently seen in like treatment of papillomas. This confirmed my previous doubts about the condition's being malignant, and I again opened the subject with Dr. Black. His further study of the tissue and search of the literature brought him to the diagnosis of malakoplakia. The only mention of the condition found in the texts was in Mallory's "Histologic Pathology": "Rarely an organism, apparently of the colon type, gains access to the submucous tissue and causes a mild inflammatory reaction there, consisting chiefly of an accumulation of endothelial leukocytes, which may collect in large numbers so that soft polypoid masses project into the cavity of the bladder, and suggest the presence of some form of tumor. The organisms are sometimes present in large numbers in the leukocytes, which are occasionally multinucleated and often contain other inclusions, such as lymphocytes and red blood cells."

The diagnosis seemed justifiable from the clinical, cystoscopic and histologic findings, so we classified it as such.

\*Read before the Section on Urology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

Fulguration was continued, and in all there were six sittings. The residual urine decreased materially and the growths were nearly all gone when the patient was seen last in March, 1918.

In April, 1919, she again came in for examination, and no residual urine was found. The bladder surface was practically normal, save for the trabeculation and a few slightly thickened areas over the base of the bladder. No distinct masses were seen at all, and in every way the patient felt entirely relieved of her previous troublesome symptoms.

CASE 2.—In January, 1919, Mrs. S., referred by Dr. Henry Clay, consulted me for a very severe bladder irritation—frequency, burning and general discomfort. This had been noticed first about six years previously and had returned at intervals, getting worse and staying longer each time, until, for the last few months the patient had had very little rest day or night.

Physical examination failed to reveal anything of interest except that her general appearance was below par. She was nervous and her blood showed a moderate secondary anemia. Pelvic examination revealed the uterus retroposed and fairly fixed with a fullness posteriorly.

The vesicovaginal septum was soft and showed no induration at all. Cystoscopic examination disclosed the general bladder surface inflamed in mild degree; the trigon and the adjacent areas were seen to present almost identically the same picture as in Case 1. There were numerous round, smooth, nodular masses, varying in size and shape, some flattened and some almost pedunculated. There were no villous growths, nor were any of the masses ulcerated. A small mass was removed and submitted to Dr. Black for examination.

Fulguration was instituted, and almost immediate improvement was noted in the subjective symptoms. Three treatments were given and a decided improvement in the bladder picture was seen. The symptoms were nearly gone, and the patient was sleeping and eating, and in every way felt improved.

Dr. J. H. Black reported: "The tissue removed from the bladder of Mrs. H., is a soft, reddish-gray mass about 5 mm. in diameter. Sections show normal surface epithelium which is everywhere well defined and nowhere shows any infiltration of the subjacent tissues nor any transition into the types of cells found beneath it. Extending through the mucosa and into the submucosa are large numbers of large oval cells which are, in some areas, densely crowded together with little supporting stroma. These cells have a definitely oxyphilic cytoplasm which is occasionally 'foamy' in appearance. The nucleus is fairly small, deeply stained, and eccentric. These cells are apparently identical with the plasma cell so often found associated with other conditions.

"Many large mononuclears are seen together with some small lymphocytes scattered irregularly through the mass. The stroma is everywhere delicate, and many small thin-walled vessels are seen. Only a few polymorphonuclears are found.

"The tissue removed from the bladder of Mrs. S. is macroscopically similar to the above. Sections show the same character of cells and the same general picture. The number of 'plasma cells' is less, while the mononuclears are proportionately increased. Polymorphonuclears are more abundant also.

"Clinically, the condition present in these two patients is reported to be quite similar. Grossly the tissue is the same. Microscopically, the first picture is quite analogous to those described in the literature as malakoplakia save that none of the so-called 'inclusion bodies' were seen. It differs from the section of a case of Mallory's which I have had the pleasure of studying in that it shows somewhat fewer of the 'plasma cells' and more mononuclears. The second tissue is apparently the same condition save that the inflammatory picture is more pronounced. One who studies these slides would, I think, be forced to the conclusion that malakoplakia is a comparatively rare inflammatory condition which, while essentially characteristic, varies somewhat in its cell content as do other inflammatory conditions."

## COMMENT

A reasonably careful search of the literature shows that the first use of the term malakoplakia was by von Hansemann<sup>1</sup> in 1903, but, as early as 1902, Michaelis and Gutmann<sup>2</sup> described the same condition. Since that time twenty-two cases have been reported, all but two of which were observed at necropsy. Zangemeister,<sup>3</sup> in 1906, reported the first case observed during life. The only article in the English language found was by A. M. Pappenheimer<sup>4</sup> of Bellevue Hospital, in which he reports two cases seen at necropsy.

The disease appears to be one of late life, only one case occurring in a child. All other patients were over 40 years old. The majority of these cases have been found in females, including the author's cases. Eighteen have been found in women and six in men.

Opinion is divided as to the part tuberculosis plays. Some maintain there is very close relationship, while others do not consider it of any importance save as an accidental association. Landsteiner<sup>5</sup> thinks tuberculosis is merely coincidental when found. "The histologic and bacteriologic findings preclude tuberculosis, although the microscopic picture lends support." Von Gierke, in a case with tuberculosis of the lungs, intestine and tubes, found tubercle bacilli in the bladder folds, never in the plaques themselves.

Wegelin<sup>6</sup> and Loelke<sup>7</sup> did not find tuberculosis and do not consider it of any importance.

Waldschmidt<sup>8</sup> concludes by saying:

If we assume tuberculous etiology we must assume action of tuberculous virus at a distance not heretofore known. Summarizing twenty cases with necropsy, tuberculosis was the cause of death in six and minor foci were found in five others; in two cases no reference is made to search for such changes; in seven no tuberculous changes were found anywhere; that such infection was found in two thirds of the cases is certainly explained by the frequency of this disease, irrespective of other conditions.

Pappenheimer says:

The number of cases is as yet too few to decide whether the coincident occurrence of tuberculous lesions in other viscera is more than fortuitous.

In my cases no history of tuberculosis was obtainable. No tuberculin test was made; repeated stains of the urine did not detect tubercle bacilli. No guinea-pig test was made. A careful examination did not reveal any evidence of tuberculosis, and I feel that I am safe in saying that tuberculosis was not a factor in either of my cases.

Among those writing on the subject, Gutmann and Michaelis alone consider the condition neoplastic, calling it "a form of benign epithelial neoplasm"; Hansemann does not take a definite position as to the nature of the growth. All other writers are agreed that the lesions are "infectious granulomas of inflammatory

origin." Landsteiner and Störk consider it an inflammatory process, the characteristic large cells being derived from interstitial tissue, though they are unable to determine from what kind of cell. Their phagocytic powers indicate wandering cells.

Gierke and Ellenrieder find a resemblance to epithelioid cells of tubercle and think they originate partly from connective tissue, partly from blood.

Guterbock<sup>9</sup> thinks them similar to large lymphocytes and true fixed connective tissue cells.

Loebl considers them transitions from large granulata cells, not differing from other inflammatory reactions.

Landsteiner and Störk think the histologic picture that of an inflammatory process and propose making it "cystitis in plaques."

Hart<sup>10</sup> would classify it as a chronic, nonspecific inflammatory hyperplasia.

Michaelis<sup>11</sup> suggests that it is a sort of specific granuloma, due to irritation of cellular elements of sub-nucous lymph spaces.<sup>12</sup>

Pappenheimer closes his description of his two cases by saying:

The precise origin of the characteristic large cells is still a subject for speculation. That they are of similar origin to the phagocytic cells seen in other inflammatory processes seems beyond question. Their large size may, as has been suggested by Michaelis, be due to the inhibition of fluid from the urine.

In reporting his second case he says:

Histologically the characteristic structure is obscured partly by postmortem changes in the tissue, partly also by inflammatory infiltration and necrosis. The characteristic

"inclusions" could not be demonstrated, nor were bacteria to be found. Since, however, there is no other known bladder lesion producing a similar macroscopic appearance, the lesions must, for the present, be classed as one of malakoplakia.

#### ABSTRACT OF DISCUSSION

DR. ARTHUR L. CHUTE, BOSTON: I have been very much interested in the report of the case; but as I have never seen anything like it, I can only speculate as to its nature. It seems to me that Dr. Folsom is perfectly right in believing that it must be some chronic inflammatory condition. It does not seem to me that it is of a tuberculous nature; it does not act in the way tuberculous processes do. I shall be very much interested to hear the report of further cases of the same sort to see if they make the condition clearer. It is a new one to me.

#### THE MAXILLOFACIAL SURGEON IN A MOBILE HOSPITAL\*

REA P. MCGEE, M.D., D.D.S. (DENVER)

Lieutenant Colonel, D. C., U. S. Army

JEFFERSON BARRACKS, MO.

When roads are congested with hundreds of thousands of moving troops with all the impedimenta of war, the matter of the weight and the bulk of the equipment for those who operate on wounded men must be carefully considered. Only those things which are absolutely necessary can be carried. The typical front line operating organization is a mobile hospital. The dressing stations and field hospitals are crowded with the work that they are expected to do, which is essentially emergency treatment. There are many patients who might have a chance to recover if they could have specialists to operate on them at once. Many classes of wounds occur that emergency units are unable to handle. The element of time and transportation is a very important factor. Men that could be saved if they could be operated on within a few hours of the receipt of the injury, and many others who are in such a condition that they cannot survive the trip back to the evacuation hospital, can be successfully taken care of in the mobile units. For these reasons the mobile hospitals were developed.

The equipment furnished by the government for the front line work in this department was well planned, but the insurmountable difficulties in procuring especially designed instruments at the beginning of the war defeated the fulfilment of the plans. There was only one remedy: that of the surgeon's taking his own equipment. That is what I did, and I believe it is the satisfactory solution for all specialists in any war in any army.

For plastic surgery a very complete assortment of needles, Hagedorn half curved and full curved, with cutting points, both large and small, is required. Small, sharp pointed gynecologic needles are also required. One complete set of cleft palate instruments, with appropriate mouth gags, at least three good tongue forceps; an assortment of hemostats, particularly small, sharp-pointed ones; several needle holders of varying shapes; one full set of extracting forceps; an

assortment of elevators; two ronguers; one small dental hand drill; wire working pliers; orthodontic wire; modeling compound; a set of knives; a sharpening stone of carborundum, mouth retractors, and a tracheotomy set can all be easily carried and, if carefully selected, will supplement the instruments found in the ordinary hospital equipment.

It was my good fortune to be detailed as maxillofacial surgeon to U. S. Mobile Hospital No. 1, A. E. F., and it is from the experience gained there that I speak.

NATURE OF WOUNDS

Mobile Hospital No. 1 was always in the area between the 75's and the 6-inch guns. Our advanced position made it possible for us to receive many patients as early as two hours after they were hit. These patients were first carried to the front line dressing station, then, by ambulance, to the triage, and from the triage to us. Only nontransportable battle casualties were taken by No. 1. This meant that we received the most desperately wounded men. Nearly all our patients were suffering more or less from shock. Many were in a state of coma. In nearly all cases of shock in which there was a fracture of the mandible, the patient came out of the condition of shock as soon as the jaw was set, because, in these cases, shock is usually due to obstructed respiration.

As these patients came in they were placed in the receiving ward and, according to the nature of their wounds, assigned to the different services. They were usually covered with blood and dirt, almost invariably suffering from extreme exhaustion, and many, particularly those with wounds in the head, face and neck, were suffering from labored respiration.

As soon as possible after their arrival, they were taken to the roentgen-ray department and examined with the fluoroscope for foreign bodies. It was impossible for us to carry a photographic roentgen-ray outfit, and consequently we depended for localization on indelible pencil marks made on the surface of the body.

When the patient came to the operating table, the face was usually matted with blood and powder, and it was very difficult to get him into the proper condition.

We overcame this difficulty by using gasoline to wash the face, and after that shaving as smooth as possible. Frequently it was necessary to have the anesthetic given before the slightest attempt could be made to clear up the face.

Fig. 1—Emergency splint to permit breathing when the patient is lying down.

TREATMENT

The first things to consider are the depth of the wound, the shape of the wound, and whether or not there is a loss of tissue. Not to exceed 1 per cent. of the patients have a considerable loss of tissue other than that in the direct course of the missile. This applies to wounds of the soft tissues and not to bone injuries. Bone injuries in the maxillary region were most severe when caused by high explosive. The Germans did not use true shrapnel. All injuries marked as shrapnel wounds were really high explosive wounds.

In my clinic at Mobile Hospital No. 1, I had only one case of bayonet wound of the face. We found many men wounded with the bayonet in the front line area, but they were all dead.

The control of hemorrhage in these fresh wounds is not so difficult as the control of hemorrhage later in older wounds. We were bothered very little with secondary hemorrhage, largely because the mouths of the American soldiers are the cleanest and healthiest of those of any soldiers in the world. Much of the secondary hemorrhage that was encountered in the British army was due to the tremendous percentage of oral infection among its soldiers. Fortunately for us, the American habit of taking care of the mouth and teeth and the service of the Dental Corps in the Army render septic mouths a rarity rather than a rule.

Cases in which the parotid gland and Stenson's duct were injured presented the possibility of salivary fistula, and my plan in handling them was always to gather up the exposed portion of the duct or gland with sutures, carry the sutures inside the mouth and fix them there, and then close the face wound immediately so that the fistula, when established, would follow the suture line and open into the mouth instead of on the face. It makes very little difference what portion of the buccal cavity the parotid gland discharges into, and if any change was desired later it was very easily effected; but a well established fistula on the surface of the face is an extremely difficult thing to handle.

When it was possible tracheotomy was avoided; but in some cases, before, during or after the operation, it was necessary to increase the air supply of the lungs, and a number of tracheotomies were performed. In those cases in which the patients were tubed immediately on their receipt at the hospital, I always had the ether given through the tracheotomy tube. This is a very convenient method of etherization for operation on the face and mouth, and should be taken advantage of when intubation is necessary.

REPORT OF CASES

CASES IN WHICH RESPIRATION WAS IMMEDIATELY IMPROVED BY EARLY SPLINTING.

CASE 1—J. C. received a gunshot wound in the arm and the face. The bullet traversed the right upper arm, caused a large superficial wound of the neck, and destroyed the body of the mandible from the cuspid to the second molar on the right side. The patient suffered from shock and labored respiration. Preoperative shock treatment failed to get the patient in condition to receive an anesthetic. The neck wound was cleansed; loose bone fragments were

Fig. 2—Emergency splint applied, jaw thrown forward and mouth held open.

removed; the jaw was set, and a wire splint was applied. The respiration immediately improved, and the patient was soon out of shock. No anesthetic was used. September 13, 1918, three sequestrums were removed. September 16, the patient was evacuated in good condition.

CASE 6.—P. B. was wounded Nov. 2, 1918, at 2 p. m., admitted the next day at 12:30 a. m. and operated on the same morning at 2 a. m. He had a gunshot wound of the mouth and the neck. The roentgen-ray finding was negative. A machine gun bullet had entered the back of the neck, to the right of the center, and at the level of the chin; had traversed the neck, the pharynx and the floor of the mouth, and had destroyed bone and teeth from the left central to the right bicuspid, removing bone to within one-half inch of the lower margin of the mandible. There was a severe, hemorrhagic edema of the sublingual glands, driving the tongue backward toward the pharynx. The patient could breathe only when leaning forward, and then with difficulty. The lower lip was cut open from the center to the left mental foramen. The sublingual glands were drained, and a wire suture was placed through the incisions to keep the drainage open. A stab wound was made and a rubber tube drain inserted under the chin; the bone fragments were removed, the lip repaired and tension sutures employed.

Since returning to the United States I have seen this patient; he had fully recovered, with no further operative interference.

#### CASE IN WHICH EMERGENCY LEVER SPLINT WAS USED

CASE 9.—C. H. was wounded Oct. 14, 1918, at 8 a. m., admitted October 15, at 6:45 a. m., and operated on the same morning at 8 o'clock. The roentgen rays revealed a foreign body 8 by 10 mm. under the upper third of the left ramus. There was a compound comminuted fracture of the ramus on the left side, and one of the body of the mandible on the right. The foreign body entered the right cheek, passed through the palate and lodged on the inner surface of the left ramus. Edema of the palate was so great that the mouth could not be closed, and the drop of the fractured mandible prevented normal respiration. An emergency lever splint was applied. The respiration immediately improved, and the patient was able to breathe lying down, for the first time since the receipt of the injury. October 16, the lever splint was removed, and the edema of the palate was found somewhat improved. An open-bite splint was applied, and breathing stopped. The lever splint was replaced, and the respiration became normal. October 18, a local anesthetic was given. I removed a rifle ball from the inner surface of the mandible, evacuated pus, inserted a drain and applied an open-bite splint with a wire anchorage. The condition of the patient was good at the time when he was evacuated.

#### BAYONET WOUND OF THE FACE

CASE 10.—V. E. was wounded Sept. 26, 1918, admitted the next day at 6:45 a. m. and operated on that evening at 7 o'clock. The patient had a bayonet wound in the right cheek which had opened the antrum and fractured the alveolar process of the maxilla from the third molar (left) to the second bicuspid (right), with comminution between cuspids and bicuspids on each side. The roof of the mouth had been broken through into the nose and the antrum. There was a stellate wound of the face. The injury was cleaned and the wound sutured. A drain was inserted, a modeling compound splint with wire reinforcements on the

upper teeth was applied, and a chin cup used. The patient was evacuated on the third day.

#### CASE OF EXPOSED PAROTID GLAND

CASE 11.—S. M. was wounded Sept. 29, 1918, at 7 a. m., admitted September 30 at 6:55 p. m. and operated on that night at 10 o'clock. The roentgen-ray finding was negative. A gunshot wound had perforated his face and fractured, on each side, the body of the mandible, with a loss of tissue in the molar and the bicuspid region. The upper molars and the second bicuspids were shattered. The tongue was more than two thirds severed. The wound in the left cheek measured 3 by 3 inches. The parotid gland was exposed in the wound, and the capsule ruptured. Breathing was difficult. The tongue was repaired, the mucosa of the cheek stitched, the exposed parotid gland caught with a suture and carried through the mucous membrane, and a ligature passed through the mouth and back over the ear. Primary sutures in the face wound and tension sutures with buttons were placed. The condition of the patient required rest before further operation could be attempted. At a second operation, performed October 1, edema of the glottis and the larynx was relieved, and a low tracheotomy was performed. At a third operation, October 3, the jaws were wired and the tube cleaned. The patient when evacuated was in good condition.

#### DESTRUCTION OF ONE HALF THE MAXILLA

CASE 12.—C. O. was wounded Oct. 11, 1918, at 7 a. m., admitted October 15 at 1 p. m. and operated on the same day at 4 p. m. A high explosive shell fragment had torn the right side of the face entirely open and caused a compound comminuted fracture of the upper jaw, complete up to the floor of the orbit. The right half of the maxilla was destroyed, and the palate was destroyed except for a few fragments of bone and soft tissue. The left cheek was without support, owing to the displacement of the remaining fragment of maxilla to the right. The base of the nose was torn away, and the wound was septic. The patient was unconscious. No injury had been done the mandible. I replaced the fragment of

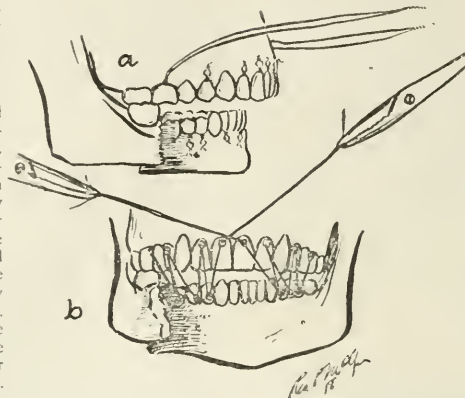

Fig. 3.—Wire splint: a, method of forming wire loops on the necks of the teeth to serve as pulleys; b, wire threaded through the loops.

maxilla, repaired the palate, as far as possible, by closure of the remaining mucous membrane and repaired the mucosa of the mouth. Tissues of the upper lip, face and nose were returned to place and sutured. Button tension sutures were used. An interdental splint was applied and anchored by tension wires from the lower teeth to the head bandage. A modeling compound splint was placed in the nose. Respiration stopped on the table, and I performed a high tracheotomy with good results. A gunshot wound of the outer canthus of the left eye was not operated on because of the condition of the patient.

#### CASE REQUIRING MODELING COMPOUND SPLINT IN AREA OF LOST BONE TISSUE

CASE 13.—H. M. was wounded Oct. 11, 1918, at 11:30 p. m., admitted October 12 at 3:30 a. m. and operated on, that day, at 3 p. m. The injury was a gunshot wound of the chin and a compound comminuted fracture of the mandible. All the bone was gone from the second bicuspid right to the second bicuspid left. The lower lip was detached and hanging by a pedicle from the left side. The bridge of the nose had been shot out. The segments of the mandible were wired into position. Wires were suspended from bicuspid 1 bicuspid, and a modeling compound splint approximating the shape of the missing bone was attached to support the soft

tissues of the reconstructed chin. The chin and the lower lip were repaired. A modeling compound splint was placed on the nose to prevent the turning up of the tip from cicatricial contraction. Button tension sutures were used, and a cigaret drain placed. The patient was two and one-half hours under gas-oxygen analgesia.

SPINAL ACCESSORY NERVE INVOLVEMENT

CASE 14.—M. B. was wounded Oct. 12, 1918, at 10:30 a. m., admitted the same day at 2 p. m. and operated on that night at 11:45. Roentgenoscopy revealed a foreign body, 10 by 12 mm., under the mark on the right side of the nose. It was apparently against the body of the third cervical vertebra. The patient had a gunshot wound of the face; a high explosive fragment had entered the cheek opposite the right first molar, and had ranged inward and backward, fracturing the mandible at the angle on the right side and severing the mandibular artery. The muscles of the pharynx were penetrated. The foreign body was found against the body of the third cervical vertebra. It was removed through the wound of entry, without opening into the buccal cavity. The face wound was stitched and the jaws wired. Immediately on receipt of the wound, voluntary motion in the arms and the legs ceased; the patient was semiconscious. After the operation, the left arm and both legs gradually approached normal. On the second day the patient was fully conscious. The right arm had normal sensation but no motion. The patient could close the right hand and had a slight motion in the wrist. He was evacuated.

METHODS IN DIFFERENT TYPES OF WOUNDS

We had several cases of double fractures of the ramus near the condyles, with the soft palate traversed. In all these instances the men had been shot by Boche snipers. In this type of injury the jaw drops downward and backward and seriously interferes with respiration. If the jaw is set with the mouth closed, the swelling of the soft palate will completely stop respiration. It is necessary to splint the mandible with the mouth open, but with the jaw very considerably thrown forward, to allow the patient to lie down and yet breathe. This was done with a very simple emergency splint of my own invention, made from wooden tongue depressors and orthodontic wire (Fig. 1). All patients with this type of injury will die unless treated early. They invariably come in in a sitting position, leaning forward, breathing with the greatest difficulty, and extremely apprehensive. Those who become unconscious are usually brought in dead, because breathing requires the greatest exertion on the part of the patient. The emergency splint, in every case, allowed the patient to lie down and breathe in the ordinary position (Fig. 2). He was fed with a rubber tube on a feeder through the forks of the splint. The levers were usually left in place for three days and then removed, whereupon the jaw was closed with the wire splint that I used as a routine.

In fractures of the maxilla, complete or partial, whether or not complicated with fracture of the man-

dible, the early treatment is employment of the open bite splint, such as is furnished by the United States government, or the Kingsley type of splint used by the New Zealand troops. The Kingsley type I believe to be the most efficient. In all cases, chin bandages of whatever type are extremely unsatisfactory.

Union in fractures of the maxilla usually occurs much more promptly than union of the mandible; but when we do not get a prompt result, it is much more difficult to treat an ununited fracture of the maxilla.

In all cases of traumatic cleft of the hard or the soft palate, the injury is repaired at once. It is desirable to avoid circumferential wiring or bone sutures whenever a good result can be obtained without them.

Abscessed teeth or teeth that were actually loosened in the line of fracture were always removed.

It is seldom necessary to make incisions in the facial tissues in jaw cases, the wound of entry and the natural opening of the mouth furnishing sufficient access and drainage. Stab wounds under the margin of the

mandible are frequently necessary for drainage. Rubber tubes are always anchored in the drainage area with sutures. Every fractured jaw must be drained at the point of the fracture.

USE OF THE WIRE SPLINT

The wire splint used in my service was made from the ordinary orthodontic wire. Short wires were placed about the necks of selected teeth. These wires were turned with a loop about one-eighth inch in diameter, so that it would act as a ring pulley on each tooth (Fig. 3 a). Two full length wires were used, usually anchored to the upper first molar if present, and if not, to some similarly strong point of vantage. These wires, being doubled, were then worked through the alternate rings

on the other teeth, first, below, then, above; then, below; then, above (Fig. 3 b). After these wires had been placed, the ends grasped with a hemostat, and gentle traction was made outward (Fig. 4 a), which invariably swung the jaw into its correct position, with practically no pain to the patient, and no necessity of manipulation with the hands, no shoving or pushing or pressing to get the fragments disengaged. The wires were then twisted in the median line, so that the jaws were firmly held together (Fig. 4 b).

The great advantage in this type of temporary splint is its ease of application, the ability to apply it without a general anesthetic, and the practically painless setting of the fracture. When an anesthetic must be administered, either for face complications or for wounds of other parts of the body, the jaws should not be splinted with the teeth in occlusion until all danger of emesis has passed. In these cases I always placed the wires ready for splinting, and then, two hours after the patient had recovered from the anesthetic, I drew the

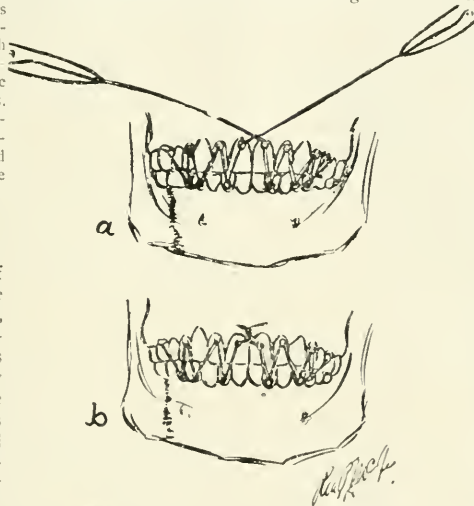

Fig. 4.—a, traction on the wires drawing the fractured jaw into place; b, fracture secured in position.

wired up to close the jaws. In this way all danger was avoided, and time was saved.

Another advantage of this type of splint is that if it becomes necessary to open the jaws quickly, it can always be done with one cut from a pair of scissors. The old type of wire splint, in which two alternate teeth were wired together, made it almost impossible to open the jaws, and, when they had been opened, the entire splinting process had to be repeated; but with the type of splint which I devised, it is simply necessary to twist another length of wire on the end of the cut wire, thread it through the loops, and again close the jaws by traction.

#### PRINCIPLES OF TREATMENT

Fractures of the jaw in war surgery are almost always complicated by wounds of the face. The jaw should first be splinted, or, at least, temporary splint wire should be placed and followed by repair of the facial wound.

Gas gangrene does not occur in the region of the face; consequently, debridement is contraindicated.

All live tissues and all bruised tissues that have a sufficient vitality to recover must be preserved, and the rich blood supply of the face makes it possible for many bruised areas to regain their circulation.

The contraction of the muscles of expression draw the lacerated tissues from their normal positions, and the greatest care must be used to make the correct approximation. Actual loss of tissue sufficient to require flap transfer is comparatively rare. The extensive loss of facial tissue from gunshot injury, so often seen in base hospitals, is more frequently due to shrinkage and adhesions of flesh fragments than to the actual loss from the primary wound.

The routine work was to bring together the mucous membrane before the cutaneous surface was sutured. Tension sutures were used in all extensive injuries to support the approximating sutures and avoid scars and displacement.

When the nose is injured, it should be repaired at once, if possible; and if the injury has resulted in a loss of bone structure, a modeling compound splint should be used to prevent cicatricial displacement.

Patients with the jaw splinted in either the open or the closed position, require liquid diet through a rubber tube attached to the ordinary hospital feeder. Many times the soldiers with their mouths splinted were unable to smoke. This was overcome by placing a glass of water or cup of coffee or cup of chocolate where they could reach it, and by wetting their lips with their fingers they were able to smoke so long as the moisture remained. The process was repeated as often as necessary so long as they wanted to smoke. This gave them a great deal of comfort. It was also possible, in cases in which the lower jaw was fixed or missing, for the patient to hold one nostril closed, and, by moistening the other nostril and putting the cigaret in it, he could smoke very nicely.

The mouth should be cleansed hourly with a warm salt solution. The 5 per cent. *eu-sol* solution used by the British is very effective in these cases. A compressed air spray is important.

Wounds on the surface of the face should have as little dressing as possible.

Wounds of the tongue were numerous. Bone fragments, teeth and bullets were commonly driven into and sometimes through the tongue. In one case the

tongue was more than two thirds severed in the region of the molar teeth. These injuries are not difficult to repair with proper instruments, and in no case was there failure of union.

Local anesthesia with procain was used frequently. This was a saving of time and was satisfactory. One of our greatest difficulties, with our very limited equipment, was to cleanse properly the wounded mouth. This work was carried on as best we could, and our patients were evacuated in good condition; but as Mobile Hospital No. 1 was an essentially front line organization, moving as many as fourteen times during the period of hostilities, our evacuation arrangements were very frequently interfered with, so that patients would have to be taken on motor trucks, ambulances or narrow gage railways, or in any way that it was possible to get them out and get them back. We were in no position to retain them after the period of danger from their wounds had passed. During the campaign, Mobile Hospital No. 1, with a bed capacity of 200, performed in all 6,048 major operations. From this you will see that we did not keep our patients for any great length of time; and owing to the impossibility of arranging proper care for mouth cases during the evacuation, patients with these injuries usually arrived with very considerable sepsis, which they did not have when they left us.

The great points to be observed in the front line work are the conservation of bone, mucous membrane and skin. Drainage must be carried to the extreme. All bone fragments that have live periosteum must be retained. One of the difficulties of this special branch of surgery, as with all others in military service, is the lack of complete understanding of the possibilities and the limitations in front line work as compared with that of the base.

I would suggest that all maxillofacial surgeons be required to be graduates both in medicine and in dentistry; or, in lieu of this, that a maxillofacial surgeon be given a course of training in oral surgery in a dental college, and that a dental maxillofacial surgeon be given a course in general surgery in a medical college. This work absolutely demands both a surgical and a dental training, combined with as much artistic ability as possible.

The conditions for maxillofacial work at Mobile Hospital No. 1 were extremely favorable, because we moved so frequently that we were not hampered with orders, and usually failed to receive detailed instructions until long after their period of usefulness had passed. The commanding officer, Col. Donald Macrae, Jr., gave every support to this department. This was of immense importance, because the specialist in a comparatively new department of war surgery encounters many difficulties that will not occur when a precedent has been established; and, in this particular instance, the precedent was not only the establishment of the specialty of the surgery of the face and jaws, but also the unusual arrangement of placing a dental officer in charge of a surgical department, to handle all cases of the maxillofacial type. Those who follow us in the next war should have comparatively little difficulty in beginning where we leave off.

**Diphtheria.**—Diphtheria is probably a very ancient disorder. There are possible references to it in the Talmud, the Hippocratic collection and later Greek medical writers.—F. G. Clemow, *The Geography of Disease*, p. 131.

POPULARIZING A QUININ FORMULA  
FOR THE TREATMENT OF  
MALARIAL FEVER

BRUCE MAYNE

Biologist, United States Public Health Service  
MEMPHIS, TENN.

WITH COMMENT BY

HENRY R. CARTER, M.D.

Assistant Surgeon-General, U. S. Public Health Service  
BALTIMORE

In the treatment of malarial fevers, the public health officer has seen cause for despairing of obtaining a complete cure. The cooperation of physician and patient in quinin administration seems impossible to secure; yet without this essential, shotgun therapeutics on the part of the physician, and self-medication on the part of the patient are the inevitable results. Still, for some reason, in face of criminal indifference in this regard, malarial fevers are undoubtedly being reduced in severity and in incidence.

The greatest dereliction consists in the insufficiency of the dosage of quinin and the aborted length of treatment. In various hospitals, and in private practice through the malarious districts of the South, the system of quinin treatment varies not so much in proportion to the needs of the individual patient as according to the individual tastes of the medical officer or family physician. In the main, the popular dosage (applied to adults without unusual idiosyncrasy) ranges from 12 to 20 grains daily for active cases, and then when clinical symptoms disappear, the treatment is discontinued without a consideration of subsequent microscopic examinations, and without anticipating the clinical instability resulting in a relapse.

These difficulties open the way to an effort toward standardization. The course of treatment here proposed is offered with a full realization of its inapplicability to special and complicated cases; and it is accompanied with the warning to the lay patient that it is not recommended in attempted self-medication without professional consultation.

The formula that we suggest does not take into account the special question of symptomatology and the algid forms. The severe cachectic cases and the like do not come within the scope of the treatment of this subject. It touches only the preponderance of acute forms without peculiar atypical symptoms. Nor is the matter of method of administration other than that by mouth brought into focus.

One must realize at the outset that the ideal formula must provide: (1) for the relief of the patient—the elimination of clinical symptoms; (2) for the destruction of plasmodia in the peripheral circulation tending toward the prevention of the formation of sexual para-

sites; (3) for the prevention of the production of quinin-inaccessible parasites (so-called resistant or quinin-fast forms), and (4) for the effectual inhibition of the recurrence of clinical symptoms accompanying relapse with the reinvasion of asexual parasites. With these ends in view, this arrangement of administration is proposed:

ARRANGEMENT OF COURSE OF TREATMENT

The course of treatment provides for the application of a minimum of seventy-five days in the administration of 800 grains of quinin bisulphate.

The formula is elaborated in a geometric progression, consisting of four courses of 200 grains each. A scheme of the formula is sketched in the accompanying chart. An analysis of the formula follows:

Scheme of course of treatment; four courses of 200 grains over period of seventy-five days.

1. *Forty grains daily for five days.*—Ten grains of quinin bisulphate should be given four times daily. At the end of this period there should be no severe paroxysms, no chills, and only young rings and mature gametocytes in the blood.

2. *Twenty grains daily for ten days.*—About the middle of this stage the patient should probably be out of bed and clinically and apparently normal; fevers and chills probably absent. With the exception of gametocytes, parasites will not be demonstrable microscopically.

3. *Ten grains for twenty days.*—Arsenic (Fowler's) or other tonic may be prescribed, if indicated. Only gametocytes remain in the microscopic examination. The patient should be on duty or able to resume normal activities, if necessary.

4. *Five grains for forty days.*—In this stage, not the least important, a 5 grain capsule of quinin bisulphate or its equivalent should be taken with a tonic accompaniment if indicated. This stage is marked by the apparent recovery of the patient. At this juncture a continuance of treatment should be strongly urged, especially in the benign types of malaria, for a period of two weeks or more. By this time, a microscopic examination reveals only rapidly disappearing or disintegrating gametocytes which may be considered potentially negligible. The sexual forms of tertian and quartan parasites are not demonstrable at this stage.

This system of medication is considered entirely feasible only with patients subject to practical control. In dealing with young persons and in chronic cases among adults, modified treatment must be given not represented here. It is observed that the weak link in the popularizing of the formula has always been the indifference of the physician and the patient toward continuing treatment long enough to insure absence of subsequent recrudescence of the initial infection. This feature can be overcome only under conditions approaching a military status. It is indicated in this connection that a sustained and effective treatment of malarial fever is equal to or superior to indifferent

quinin prophylaxis. At any rate, it is at present the more necessary of the two to solve on an experimental basis, on a larger scale than has been thus far possible.

#### DIFFICULTIES ENCOUNTERED

As regards the difficulties encountered in the treatment of malaria, probably the most essential point of view is the consideration of the chronicity of this insidious disease. It is a well known fact that the average patient, or, I think I may say, the majority of patients, cannot be induced to take sufficient quinin for a sufficient period to effect a cure, or at least to prevent a relapse in a reasonable time. This is especially appreciated by physicians in the Mississippi Delta, many of whom have unwittingly confessed to me that they themselves have harbored malaria parasites without attempting to rid themselves ultimately; and like the patients to whom they administer, are quite satisfied with a temporary cessation of symptoms to the point of the absence of febrile paroxysms. Therefore, it can hardly be expected that the laity will be readily converted to the proper standard of medication. It is a common experience that the chronic forms of malarial fever are developed through the fact that the patient is subjected to initial small doses of quinin and that the treatment is discontinued when the active symptoms disappear and the patient states that he feels better.

A systematic campaign of publicity along these lines would have far-reaching benefit, both for the physician and for the patients to whom they profess to administer. We cannot ascribe this condition entirely to ignorance, because too many exceptions have been encountered. I believe the term "fatuous indifference" would better apply. Needless to say, this situation has its sequel in the undermining of efficiency to an extent that is probably incalculable. Therefore, the conscientious sanitarian longs for any method that can be devised to ameliorate the conditions brought about through lowered standards.

#### THE LENGTH OF TREATMENT AND THE INITIAL DOSE

In this connection we must not overlook the moot point of what is the proper length of time to administer quinin. The period recommended in this paper may be felt to be inadequate, and its extension to the period of ninety days is judged to be safer. Another objection is anticipated in the heavy initial dosage recommended. This may be reduced, if necessary, to 30 grains of quinin after the second day without further modification of the formula. This change is not advised if the patient shows no distress toward the heavier dosage.

It is interesting to relate that in some experiments conducted at a government hospital in connection with the infectivity of malarial mosquitoes with *Plasmodium vivax*, it was observed that among fifteen persons who received initial infection from mosquito bites, the incubation period and the complete symptomatology could be followed perfectly. In every instance in which the period of treatment was less than two and a half months there followed a relapse. Among the latter were included four physicians who had volunteered for the biting experiments. The moral is obvious. Its application is as difficult as human nature is mysterious.

#### COMMENT BY DR. CARTER

The criticism of the author that the treatment usually pursued for an attack of malaria generally fails to eliminate the infection is true. This is disputed by no one.

It is unquestionably desirable to have a standard treatment in dosage, method of administration and duration of treatment which would (1) give the highest percentage of cures of malarial infections, and (2) be practicable for general administration.

*The two most important bench problems of malaria yet unsolved are to find (1) the best means of determining the existence of malarial infection in man, and (2) the best method of eliminating it.* This paper is an attempt to formulate the latter.

In my judgment, the basis of Mayne's formula for such standardization is sound, namely, heavy doses and confinement to bed in the beginning of the treatment of an acute attack, and continuation of the treatment after the disappearance of symptoms. As to what should be the preliminary high dosage; how long this should continue; what should be the diminution of dose in the continuation of treatment; whether the treatment should be continuous or intermittent and for how long the treatment should be continued, I have, indeed, opinions which are fairly consistent with this formula, but have not sufficient data for them to warrant their exclusive advocacy.

I do not think it would be advisable to publish this formula as being the method of treatment for the cure of malaria, because (1) we do not know that it is the best; (2) we could not say it was better than a considerable number of other formulas that would be at once brought out, some of which, as those advocating intermittent instead of continuous treatment, are radically different, and (3) it does not, so far as I know, rest on direct observation, giving the percentage of cures from its use, either absolutely or in comparison with other methods.

In 1913, a committee of the Southern Medical Association was appointed to standardize the treatment for the cure of malarial infection. It consisted of Craig, Bass, Deaderick, von Ezdorf and Krauss—all good men, unusually good men in that line. No report was made; at least I know of none; and this question was left indeterminate. Bass did formulate a method of treatment, however, for which he claimed much. Deaderick, Krauss and von Ezdorf (I don't know about Craig) were not inclined to admit these claims. Bass had read a paper which, as I recall, embodied much the same views as the one referred to above. He does not now hold his previous opinions of the efficacy of the method of treatment therein advocated.

Within the past three years much clinical experimentation has been done along this line by British physicians, both in England and in the Balkans. I may mention Ross, Stephens, James, Carter, MacFie, D. Thomson and others, men mainly well trained with much malarial experience. They have not been able to agree on any such formula for treatment, and few of them individually make very definite and decided claims for any special treatment.

Stephens, basing his observation on two rather small groups—seventy-two and eighty-seven cases, respectively—concludes that the same method of treatment (in this case 90 grains of quinin in solution on two consecutive days) was decidedly more effective in July

and August than in January to April. In the warm weather 60 per cent. of cures were obtained as against 3 per cent. in cold weather. Cases were accounted cured if there were no relapses either clinical or parasitic within sixty days, blood examinations being made daily.

I mention this just to show how inchoate is the subject from the standpoint of British workers.

I would then regard it inadvisable for the Public Health Service to endorse implicitly any formula as a standard for the treatment of malaria in the present state of our knowledge of this subject. I say this although I am in agreement with the basic plan of this formula and in general agreement with the details, and I am sure that if it were generally used, many cases would be cured which under the treatment they do receive are not cured. I am afraid, however, to recommend that the Public Health Service go on record as endorsing a specific formula for the cure of malaria until we know more about it both absolutely and as compared with other methods.

This subject was one of those put down for investigation by the National Malaria Committee ("research, clinical"), if it ever gets started.

#### PERSONAL OBSERVATIONS REGARDING THE TREATMENT OF GLAUCOMA\*

JOHN E. WEEKS, M.D.

NEW YORK

My object here is to give my personal impressions of the various forms of treatment for glaucoma that I have employed during a period of thirty-two years in the active practice of ophthalmology, all of which time I have diligently searched for efficient means to control hypertension.

The principal determining causes of hypertension as I regard them are:

1. Obstruction to the outflow of fluids from the interior of the eye by (a) inflammatory products, as the presence of fibrin in the aqueous, blocking the spaces of Fontana, or of non-diffusible substances, such as colloids or albuminoids, which do not readily pass through the filtration spaces (anterior chamber usually deep); (b) encroachment of the iris on the spaces of Fontana following increase in the size of lens or increase in the contents of the vitreous chamber (anterior chamber shallow); (c) the incarceration of the iris or the capsule of the lens in a cicatrix after traumatism, or wounds made by the removal of cataract or other operation opening into the eyeball (anterior chamber compromised); (d) development of iris cysts and tumors, or thickening of the iris; (e) increase in volume of the contents of the vitreous chamber by retinal or choroidal hemorrhages, or by intra-ocular growths.

2. Sclerosis affecting the lymph spaces at the sclero-corneal junction, as in lophthalmos or after interstitial sclerokeratitis (anterior chamber usually deep).

3. Increase in intra-ocular secretions, as in abnormal conditions of the vascular system (aortic insufficiency plus extensive temporary increase in arterial tension).

4. Retention of aqueous in the posterior chamber.

In at least 90 per cent. of all patients with "idiopathic" glaucoma, except in infantile glaucoma, there is a history of chronic constipation. The correction of this condition goes far to relieve hypertension.

In regard to range of tension as measured by the tonometer of Schiötz, I have seldom seen a normal eye with a uniform tension less than 12 or more than 27, the usual normal range being from 16 to 25. In pathologic eyes without perforation I have noted a tension of from 1, the lowest, to 130, the highest.

In "idiopathic" glaucoma, very marked variations in tension may take place. Thus, I have noted a tension of 40 in one eye of a patient and 50 in the fellow eye. On the succeeding day the tension was 22 degrees in both eyes, and on use of a 1 per cent. solution of pilocarpin once daily this tension has remained. In the case referred to there is slight nasal contraction of the fields, and the vision is a little less than normal.

#### MIOTICS

The miotics employed are, of course, pilocarpin and physostigmin (eserin). As adjuvants, jaborandi is used internally, opium at times, and also free catharsis. I have not found advantage in the combination of ethylmorphin hydrochlorid (dionin) with these remedies. The pilocarpin and physostigmin are usually dispensed in a sterile 3 per cent. solution of boric acid to avoid rapid deterioration of the solution. I have never experienced any bad results from the use of these remedies, if I may except a transient hyperemia of the iris in a very few cases after the use of physostigmin. Solutions of pilocarpin, if persisted in for some time, produce irritation of the conjunctiva in a small percentage of patients, but never any disease of the eyes.

Miotics have been employed in the way of a preventive as well as a corrective measure. Pilocarpin in strength of from one-third to 1 per cent. is prescribed in many cases in which the tension is at or near the upper limit of normal, in which the anterior chamber is shallow, and in which there is even slight cupping of the whole or a portion of the disk. The pilocarpin is used once a day, at night, on retiring, rarely twice daily, and the solution is freshly made once in two weeks. The treatment is continued a longer or shorter time, as may appear to be desirable.

It is a routine practice to test the tension of the eyes of all patients by digital palpation. If the tension appears to be above normal, or the history or the appearance of any part of the eye indicates hypertension, present or remote, a tonometric measurement is taken.

In all cases of tension above 25, as determined by the Schiötz tonometer, miotics are resorted to and an endeavor is made to keep the tension at or below that degree. The fields of vision for form and colors are taken from time to time, and the degree of vision is determined.

In regard to the effect of miotics, it has been possible in a number of cases of "idiopathic" glaucoma of various forms to keep the tension at about the upper limit of normal, and to hold it there for many years without deterioration in vision or loss of visual fields (Mrs. H., Rochester, nine years; Mr. C. F., New York, eleven years; and many others). In one case, that of Mrs. McC., after a period of two years of hypertension the tension became subnormal and the miotic was discontinued. Three years have passed, and the hypertension has not returned. In quite a high percentage of cases the hypertension may be controlled for a longer or shorter period, and then the fields and vision begin to fail in spite of increase in strength of the miotic, and operation becomes necessary.

\* Read before the Section on Ophthalmology at the Seventeenth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

There are but few cases of "idiopathic" glaucoma that are not more or less affected by the instillation of miotics, although it is frequently impossible to bring the tension down within the normal range, namely, from 16 to 25 mm. As an example of the great reduction possible, the following is a case in point:

CASE 1.—Mrs. S. consulted me, Feb. 5, 1919, with a tension of 110; the cornea was hazy; vision was perception of light. She was admitted to the infirmary. A 1 per cent. solution of physostigmin salicylate was instilled every two hours, and a calomel purge was given that afternoon, a saline the following morning, and  $\frac{1}{4}$  grain of morphin at night. At 2:30 p. m. the following day the tension was 23, and the vision was greatly improved.

In hypertension after cataract or other operation on the eyes, a high percentage of permanent relief is obtained by the use of miotics.

In regard to dosage, the strength and frequency of use is entirely regulated by the necessity, beginning with pilocarpin in 0.33 per cent. solution once or twice daily, increasing to 2 per cent., instilled as frequently as is required, or changing to physostigmin solution (the salicylate being used as a rule) varying in strength from 0.25 to 1 per cent., and instilling it from one to four or five times daily as required. If physostigmin, 0.5 per cent. used three times in the twenty-four hours, does not suffice to keep the tension at or below 25, I insist, with very few exceptions, on operation.

In secondary glaucoma the effect of miotics is seldom so marked as in the "idiopathic" cases. A reduction in tension of from 10 to 20 may often be obtained, but it will probably not be easily attained and is difficult to maintain.

Treatment by miotics in these cases, if the hypertension is above 35, is not of much value, as a rule, although there are exceptions.

For many years I have made it a routine practice, when time and circumstances permit, to try the effect of miotics in all cases of hypertension before advising operation. There are a number of conditions which may develop which cause me to decide that operation is desirable, and, when convinced that operation is the conservative course to pursue, I inform the patient that he must assume responsibility for the consequences if the advice is not followed. A diminution in the field of vision for form or colors, with or without enlargement of the blind spot, is an urgent sign, as is also a slight positive diminution of vision. It is allowable to permit a low degree of hypertension if no falling off in field for form or colors or diminution of vision can be detected, but such patients must be watched with great care to prevent irreparable damage through unexpected exacerbations in tension. Operation is advised if the patient is found to be inclined to irregularity in the use of the miotics, and in cases of contemplated long absence from efficient observation by a competent ophthalmologist.

Experience has convinced me that early operation is desirable. The degree of vision present when a glaucomatous eye is not in a state of congestion is seldom

much better after operation; nor is a contracted field much enlarged. There are, of course, exceptions to this rule, but they are not great in number. Loss of field almost to the fixation point need not deter operation, as the fixation point will be included in the blind portion of the field much more quickly if operation is delayed than if operation is performed. Small retinal hemorrhages do not contraindicate operation if other conditions are urgent.

#### OPERATIONS

The operations to be employed must be determined by the characteristics of the individual case. Buphthalmos and other forms of "infantile" glaucoma are not, as a rule, satisfactorily treated with miotics, but in some cases miotics act very well.

CASE 2.—Miss A. R., aged 9 months, was brought to my office, Sept. 21, 1909, with buphthalmos affecting the right eye. The cornea was cloudy; the pupil dilated and oval; tension, + 2; vision, apparently, perception of light. Pilocarpin solution, 1 per cent., was instilled twice daily, increased sufficiently frequently to keep the pupil small. The cornea gradually cleared and vision improved. The tension decreased until it was but little above that of the fellow eye. Dec. 17, 1917, tension was a little above normal, vision, fingers at 18 inches. A few days later the buphthalmic eye sustained a blow, and detachment of the retina developed. Tension then fell below normal.

Fields in Case 3.—Form ———. Red .....

In buphthalmos, paracentesis may be resorted to in the early stage of the condition. When seen shortly after birth, the cornea will be more or less opaque, with stippled surface, except at the periphery. A small paracentesis performed at the limbus, the opening being made patent every five or eight days for a few times, as required, will cause the entire condition to improve. If followed by miotics, the result will often be quite satisfactory. When the patient has reached the age of from 4 to 8 years, trephining is the operation of choice, a trephine not more than 1.5 mm. in diameter being used. The anterior chamber will be deep, and a conjunctival flap of fair thickness can be obtained. A liberal piece of iris should be excised. A satisfactory case is the following:

CASE 3.—Miss Y. C., aged 18 years, came under observation. March 8, 1915. Buphthalmos was present in both eyes; vision, right eye, was fingers at 18 inches, eccentric; left eye 20/20 —; tension by Schiötz tonometer, right eye 63, left eye 46; right disk pale; the fields were as shown in the accompanying chart. March 9, 1915, trephining was done under ether, a 1.5 mm. trephine being used. June 14, 1917, vision in the right eye equalled fingers at 1 foot, eccentric; left eye 20/30 + +; tension, Schiötz, right eye 22, left eye 21. The fields were as shown. There was a relative central scotoma in the field of the right eye.

Neither iridectomy nor the Lagrange operation in buphthalmos is satisfactory because of the extreme thinness of the sclera and cornea, and because of the difficulty of obtaining a filtrating cicatrix without endangering the contents of the globe. The opening after a trephine operation has a tendency to enlarge by stretching. Consequently, a large trephine should not be employed.

In other cases of infantile glaucoma in which the globe is not enlarged, some other form of operative procedure may be employed.

In my practice, secondary glaucoma is encountered in about 4 per cent. of the cases of cataract extraction. In some of these cases the capsule of the lens appears to be the cause, as in the following case:

CASE 4.—Mr. W., aged 65 years, was subjected to combined extraction for mature senile cataract. Hypertension developed three weeks after the operation, which was not satisfactorily controlled by miotics. Tension reached 45 mm. of mercury. About one-fourth of the anterior portion of the capsule of the lens had been removed by the capsule forceps. The capsule at its upper equatorial area was caught in the cicatrix at the corneal limbus and apparently put on the stretch. Two well marked bands of capsule extended from the middle of the incision downward, diverging to the lower margin of the pupil. The tension was but little influenced by miotics. By means of a narrow cataract knife, the bands of capsule were divided. The divided ends separated widely, showing that they were in a state of tension. The hypertension of the globe was relieved and did not return.

It has occurred to me a few times that after a cataract extraction the iris on one or both sides of the coloboma in combined extraction and extraction after preliminary iridectomy has become incarcerated in the angle of the wound. Hypertension has developed subsequently in some of these cases. If the anterior chamber is opened at a suitable place and the columns of the coloboma on the incarcerated side are freely divided, the hypertension will be relieved in the majority of such cases. There are some cases of hypertension following cataract extraction, not due to either of these causes, which may be relieved by operation. In one patient coming to me after operation for the removal of cataract by a colleague, a trephining, made at the outer part of the coloboma, a 1-mm. trephine being used, gave permanent relief. In a case of simple extraction by me, hypertension developed about six weeks after the uncomplicated extraction. In my absence from the city, Dr. Herman Knapp performed the usual iridectomy, permanently relieving the hypertension. The patient was subsequently under my observation for eight years. The tension of that eye remained normal.

In secondary glaucoma accompanying acute or subacute iritis, the hypertension will as a rule subside spontaneously in a few days. At times, operative procedure becomes necessary. In these cases paracentesis, one or more times, followed by opening the wound every second or third day, is usually sufficient. The paracentesis should be made at the limbus, pushing a narrow flap of ocular conjunctiva before the point of the knife, so that the wound at the sclero-corneal margin will be covered when the knife is removed. Rarely an iridectomy upward is required.

The secondary glaucomas that follow sclerokeratitis, or after interstitial keratitis, are not usually successfully treated by a simple iridectomy. In these cases, since the glaucoma follows the partial closure of the lymph spaces at the sclero-corneal junction by the sclerosing process following the inflammation, a filtering cicatrix must be obtained by some form of operation in order to give permanent relief from the hypertension. Such a filtering cicatrix *must* be obtained in virtually all chronic cases in which the anterior chamber is deep.

The largest percentage of cases of glaucoma is made up, of course, of the "idiopathic" cases, conveniently

described as the acute, subacute and simple chronic cases. The acute cases frequently present a very high tension, ordinarily (if not treated) running a course of from two to three weeks, when the tension sinks approximately to the upper limit of normal, with more or less loss of vision. As a rule, I do not find it necessary to operate at the height of an acute attack, as in by far the greater number of cases the tension can be greatly lowered in a few hours by treatment. The treatment that is usually employed by me is, locally, physostigmin, 1 per cent., every hour, if tolerated (exceptions are very rare); systemically, a calomel purge, morphin hypodermically, and light diet. If after twelve hours there is no diminution in the tension, operation is performed. If the tension is subsiding, operation is postponed until the eye has become as nearly normal as possible, when a broad iridectomy is performed. This operation is with few exceptions all-sufficient in these cases. Posterior sclerotomy before the iridectomy is seldom necessary.

For the subacute and simple chronic cases of glaucoma I prefer an operation that will permit of the formation of a filtering cicatrix. Quite a large number of operations with this aim in view have been devised and practiced more or less extensively. Among them we may mention the operations of Colonel Elliot, Lagrange, Holth after 1908, Hubert, Verhoeff, and the operation of Holth before 1909 (iridencleisis). Ophthalmology owes much to Colonel Elliot and Professor Lagrange for the operations they have advocated, and for the extensive study and painstaking elaboration of their work. I have performed the Elliot trephining operation fifty-eight times. Unfortunately, I had intra-ocular hemorrhages follow in two cases, iritis in six cases, detachment of choroid in two cases, return of tension from blocking of the opening in a number of cases, and late infection in two cases. At present I limit the use of this method to buphthalmos, some cases with deep anterior chamber, and to cases of chronic simple glaucoma, mostly with relatively low hypertension. The Lagrange operation, which I have performed 269 times, is relied on for the forms of glaucoma other than those reserved for the Elliot operation. The operation is performed as described by Lagrange, except that the incision is seldom more than 5 mm. long (Lagrange advises 7 mm.). The shorter incision is employed to avoid the danger of prolapse of the head of the ciliary body or of the lens into the wound, and to lessen the possibilities of escape of vitreous. In this series of cases there has been deep intra-ocular hemorrhage once. The openings have been occluded by the falling forward of the head of the ciliary body in three. There has been loss of vitreous in three cases. Hypertension has recurred in a small percentage of dispensary cases because of inability to have the after-treatment followed up; but in private cases, hypertension has recurred to an extent to nullify the result in only four instances. There has been but one light case of iritis and no case of late infection.

In employing this operation the after-treatment is very important. Massage should be employed daily, beginning forty-eight hours after the operation in all cases in which the tension is not subnormal, for the purpose of gently forcing a very small quantity of the aqueous through the scleral opening, causing the conjunctiva covering the opening to bulge slightly. The massage should be continued a few days or weeks, as

is found necessary, to secure a filtering cicatrix. The patient can be readily instructed how to perform the massage, and the after-treatment can then be conducted without the presence of the surgeon. The results in private patients have been most satisfactory. It is my opinion that the Elliot operation will give a higher percentage of permanent relief of hypertension in patients who cannot have satisfactory after-treatment, as in dispensary practice; but in private practice a greater percentage of satisfactory results, in the class of cases mentioned, can be obtained by the Lagrange method.

Eyes with "idiopathic" glaucoma of the nonacute type are subject to degenerative changes even after the correction of the hypertension, and we must not expect as high a percentage of such eyes to retain the vision present after a successful operation as would obtain after iridectomy for other conditions. The results of early operation are the most satisfactory. Eyes with advanced degenerative changes, particularly the chronic cases in which atrophy of the optic nerve is considerable, not infrequently continue to degenerate, but more slowly, after hypertension has been completely and permanently relieved.

46 East Fifty-Seventh Street.

#### ABSTRACT OF DISCUSSION

DR. WILLIAM CAMPBELL POSEY, Philadelphia: I believe that operation should be performed: 1. In all cases of acute and subacute glaucoma and in all chronic cases on the manifestation of any inflammatory glaucomatous symptoms. 2. In all cases of chronic glaucoma in which there is doubt of the patient's cooperation in the persistence in the miotic treatment throughout the remainder of life. This includes practically all hospital cases and such private cases as may be of a weak and vacillating disposition. 3. In all cases of chronic glaucoma when the patient resides at such a distance from proper ophthalmic care that he is unable to report at sufficiently frequent intervals for the supervision necessary in the proper and safe carrying out of the miotic treatment, or for operation in the event that inflammatory symptoms arise. 4. In all chronic cases under fifty-five years of age, an operation on the most affected eye is advised, miotics being employed in both the operated and unoperated eye for the remainder of life. Operation on the second eye should follow if subsequent observation shows that vision is maintained better in the operated than in the non-operated eye. 5. In all cases of chronic glaucoma, without regard to age or the development of the disease, in which miotics have been given a faithful trial for at least six weeks or two months, as evidenced by the constant maintenance of pupillary contraction to almost pinpoint size, and in which vision and the field of vision show progressive deterioration.

After a very limited experience with the Lagrange operation (eight or nine cases) and a wider, but still in comparison with Dr. Weeks a restricted experience with the trephining operation, I have returned to iridectomy, as both the Lagrange and Elliot operations seemed, in my hands, at least, to be attended with greater danger to the eyes. I speak particularly or remotely after trephining. There are certain cases of secondary glaucoma in which the trephining operation is in my judgment to be preferred to other forms of operative procedure, and I agree with Dr. Weeks in thinking it the operation of choice in lophthalmos.

DR. E. E. BLAAUW, Buffalo: Ellett refers to the silent iritis. Diagnosis of silent iritis can be made, but there is no other symptom whatever. Atropin should be used but I do not know for how long. Dr. Knapp instills atropin right after the operation. The question is, should we do a partial iridectomy or a complete iridectomy. Silent iritis is due to chemicals in the aqueous.

DR. D. T. VAIL, Cincinnati: Conjunctivitis which almost simulates trachoma, renders the continuous use of a drug prohibitive. In one case having this to contend with, and finding it impossible to carry out an operative plan of treatment, I made up a prescription of eserin in the usual way and incorporated in that 1 grain of camphor with sufficient alcohol to dissolve the solution and told the patient to use it and report. He came back after three months without renewal, and the conjunctiva was free from any sign of those follicles which are so characteristic of eserin where it irritates. Since then I prescribe 1 grain of camphor, with sufficient alcohol for solution. I have not used the eserin since. If we are to believe what we are told by Crookes and others, glaucoma following cataract is sometimes due to epithelial cells, or transplantation of them into the anterior chamber, it spreads, and ultimately lyses the cornea and the structures behind it, resulting in an inveterate form of glaucoma, which ends in enucleation. Since returning from India I have employed the Graefe knife which performs a double function. First, we avoid the introduction of these cells to a large extent, and having introduced the knife into the anterior chamber, laying it horizontal to the tangential surface of the cornea, we can find the extreme edge of the angle, something which cannot be done with a keratome.

DR. L. WEBSTER FOX, Philadelphia: We are greatly indebted to Dr. Weeks for his valuable contribution on a subject that has placed all ophthalmic surgeons on their mettle. I wish to act as his supporter in many of the details he has given us, both from the medicinal and surgical viewpoint. We must look on glaucoma cases with fear and trembling. We are dealing with a condition which presents many pathologic phases, and if the patient lives long enough, the case generally ends in degeneration of the vision and eyeball. I have scheduled my cases under four heads: First, cases where there is only a suspicion of glaucoma, and which require internal and local treatment. Second, cases in which local medical treatment (instillations of pilocarpin or eserin) fails to hold the field of vision, and in these cases we resort to operative procedure. I prefer the Elliot method here. If it fails to hold I supplant it by an anterior sclerotomy, and this operation may be repeated until the tension is not only reduced, but kept down. Third, the Lagrange operation, in my experience, is preferable to the Elliot in such cases where the visual field has decreased suddenly and where cupping of the disk is manifest. Fourth, a perfectly performed operation is that where the keratome has been used with a long incision, well back in the sclera, combined with a broad iridectomy. To me the keratome is the one instrument that has so thoroughly proved its value that I am surprised to hear criticism of its use. I only use a Graefe knife in the sclerotomy and Lagrange methods.

DR. WALTER R. PARKER, Detroit: What operation shall we do when we are forced to operate? If any of you had glaucoma, your operation of choice would be an iridectomy. We all know, however, that in some cases equally perfectly performed iridectomies do not give equally good clinical results. If we can select the cases which can be benefited by iridectomy, and leave the other cases to Lagrange or trephining, or other operations, then our operations would succeed better. I have divided these cases into anterior and posterior simple glaucoma. As you all know, there are two general lines of flow of the lymph in the eye, the so-called posterior route and the anterior route. With patulous lymph spaces, the flow will be interior, and there will be a tendency for the lens to follow this flow, and the anterior chamber will be lessened in depth. On the other hand, if the anterior spaces are blocked, and the posterior are patulous, the anterior chamber will remain relatively deep. If the anterior spaces are patulous, the iridectomy will do no good. If the posterior spaces are involved an iridectomy is contraindicated; on the other hand, if the anterior are involved, then it is indicated. I have tried to classify all my simple cases into one or another of these groups. I cannot give you the increase off-hand but the number of cases was much increased after the iridectomies, and held its own in the trephinnings.

DR. JOHN E. WEEKS, New York: In employing this operation the after treatment is very important. Massage should be employed daily, beginning forty-eight hours after the operation in all cases in which the tension is not subnormal, for the purpose of gently forcing a very small quantity of the aqueous through the scleral opening, causing the conjunctiva covering the opening to bulge slightly. The massage should be continued a few days or weeks, as is found necessary, to secure a filtering cicatrix. The patient can be instructed how to perform the massage, and after treatment can then be conducted without the presence of the surgeon. The results in private patients have been most satisfactory. It is my opinion that the Elliot operation will give a higher percentage of permanent relief of hypertension in patients who cannot have satisfactory after-treatment, as in dispensary practice; but in private practice a greater percentage of satisfactory results, in the class of cases mentioned, can be obtained by the Lagrange method. Eyes with "idiopathic" glaucoma of the nonacute type are subject to degenerative changes even after the correction of the hypertension, and we must not expect as high a percentage of such eyes to retain the vision present after a successful operation as would obtain after iridectomy for other conditions. The results of early operation are the most satisfactory. Eyes with advanced degenerative changes, particularly the chronic cases in which atrophy of the optic nerve is considerable, not infrequently continue to degenerate but more slowly, after hypertension has been completely and permanently relieved. Dr. Fox regards glaucoma as a serious condition. Since I have adopted the method described in my paper I feel certain of relieving hypertension in from 60 to 70 per cent. of the cases. Referring to what I would prefer personally, or choose in an operation on my own eyes, I never recommend an operation that I would not consent to or would not have made on my own eyes under similar circumstances.

## THE SOLUBILITY OF INTESTINAL IPEACAC PREPARATIONS \*

TORALD SOLLMANN, M.D.  
CLEVELAND

The reputed value of ipeacac against intestinal amebas was originally based on its oral administration. Its nauseant and emetic actions, however, constituted serious drawbacks to its use. The coating of pills with salol is not always satisfactory, although, with due care, it appears to be quite feasible.<sup>1</sup> The hypodermic injection of emetin hydrochlorid avoids the local actions; but used thus, it often fails to rid the patient of amebas, especially if he is a chronic carrier. Attempts have therefore been made to solve the problem by the use of emetin compounds that, while insoluble in the stomach, would be soluble in the intestine. The basis of these attempts lies in the difference between the reaction of the stomach and that of the intestine.

### EMETIN BISMUTH IODID

Emetin bismuth iodid is described in New and Non-official Remedies and a further description is found in the report of the Council on Pharmacy and Chemistry for 1918.<sup>2</sup> Emetin in this form is only slightly soluble in water and dilute acids, but dissolves quite freely in 1 per cent. sodium bicarbonate. It is evidently some-

what soluble in the stomach, and accordingly produces some digestive disturbances, although these are much less severe than with ipeacac proper.<sup>2</sup>

### ALCRESTA IPEACAC

Alcresta ipeacac is an adsorption product of ipeacac and fullers' earth (hydrous aluminum silicate) especially prepared according to the method of J. U. Lloyd, who discovered that practically all alkaloidal salts are adsorbed by this powder and are thereby rendered insoluble in neutral or acidulated water.<sup>3</sup> This finding was confirmed by Gordin and Kaplan.<sup>4</sup> The alkaloids can again be dissolved by treatment with chloroform in the presence of fairly strong alkalis.

Tablets of alcresta ipeacac were described<sup>5</sup> in N. N. R., 1917, on the basis of the claims of the manufacturers that their alkaloids "are physiologically inert as long as they remain within the stomach, and are rendered active when set free in the alkaline media of the intestine." This was interpreted to mean that they are insoluble in the reaction of the stomach, but become soluble in the intestine.

### RELATIVE SOLUBILITY OF EMETIN BISMUTH IODID AND ALCRESTA IPEACAC IN DIGESTIVE SOLVENTS

An attempt was made to demonstrate the assumed behavior of these preparations in the stomach and the intestine. The gastric reaction was represented by 0.2 per cent. hydrochloric acid; the intestinal reaction by 1 per cent. sodium bicarbonate.

The experiments were made as follows: The powders were shaken thoroughly with the solvent, filtered, and the filtrate acidulated with hydrochloric acid, if necessary, and tested with mercuric potassium iodid (Mayer's reagent). Solution of the alkaloids is indicated by the occurrence of a turbidity or precipitate when the reagent is added.

TABLE 1.—PRELIMINARY COMPARISON OF THE SOLUBILITY OF EMETIN BISMUTH IODID, AND OF IPEACAC ADSORPTION PRODUCTS

	Solubility in 0.2% Hydrochloric Acid	Solubility in 1% Sodium Bicarbonate
Emetin bismuth iodid (0.05 gm. + 10 cc. of solvent)	Slight	Very considerable
Ipeacac—Lloyd's reagent (2 cc. 20% tincture, 10 cc. 0.2% hydrochloric acid, 1 gm. Lloyd's reagent)	None	Very slight
Ipeacac (animal charcoal) (as preceding, except that the charcoal is used in place of Lloyd's reagent)	Considerable	Very slight

The details are shown in Table 1. Briefly, the experiments showed that emetin bismuth iodid is almost but not quite insoluble in the acidity of gastric juice, and that it is freely soluble in the alkalinity of the intestinal juice. This is as was expected. The adsorption product of ipeacac and Lloyd's reagent, however, was insoluble not only in the acid medium but also in the bicarbonate. Charcoal, incidentally, did not adsorb the alkaloids effectively even from acid solution.

The insolubility of the adsorption product in bicarbonate seemed so important a contradiction to the clinical use of the product that the investigation was extended to the commercial tablets, and was modified in various directions.

\* From the Department of Pharmacology of the Western Reserve University School of Medicine.

<sup>1</sup> The investigation was supported by a grant from the Therapeutic Research Committee of the Council on Pharmacy and Chemistry of the American Medical Association.

5. They were dropped during N. N. R. during that year because of "exaggerated, misleading and harmful" therapeutic claims (Report of Alcresta Ipeacac, *J. A. M. A.* **69**:1373 [Feb. 20] 1917).

## SOLUBILITY OF ALCRESTA IPECAC IN ALKALINE SOLVENTS

Three specimens of alcresta ipecac tablets were used in these experiments. One specimen was submitted by the manufacturers in 1915; the others were purchased recently in Chicago and Cleveland. The statements that follow may be regarded as holding true of all three specimens, unless exceptions are mentioned. Several specimens of emetin hydrochlorid were used for purposes of comparison.

It may be mentioned that 0.2 per cent. and 0.5 per cent. hydrochloric acid fail to dissolve any of the alkaloids, even on incubation; that is, the filtrates are unchanged by the mercuric potassium iodid reagent.

## SOLUBILITY IN SODIUM BICARBONATE

The alcresta ipecac samples were powdered and mixed with from 0.5 to 1 per cent sodium bicarbonate, from 10 to 100 c.c. per tablet, and filtered either at once or after being allowed to stand up to four days.

The filtrate (which was always distinctly alkaline to litmus) was then acidulated with hydrochloric acid and tested for dissolved alkaloids by the mercuric potassium iodid reagent. The results (Table 2) were

TABLE 2.—SOLUTION OF IPECAC ALKALOIDS IN SODIUM BICARBONATE

Preparation	Dilution	Concentration of Sodium Bicarbonate	Length of Contact	Result with Merc. Pot. Iod.
Emetin HCl.....	1:100,000	1%	Short	Marked turbidity
Emetin HCl.....	1:100,000	Supersaturated	Overnight	Marked turbidity
Alcresta tablets, 1 tablet				
Samples	per c.c.			
All three.....	10	1%	1 day	Clear
Cleveland.....	10	0.5%	1 day	Clear
Cleveland.....	10	1%	Short	Clear
Cleveland.....	10	1%	1 day at 39 C.	Clear
Cleveland.....	10	1% + 0.5% bilin	1 day at 39 C.	Clear
All three.....	10	1%	4 days	No change at once, but slight turbidity on standing

absolutely negative, with the possible exception of the specimens that had stood four days, in which a part of the bicarbonate may have been converted into carbonate.

Theoretical objection could be made to these experiments on the assumption, first, that emetin is liberated, but is insoluble in bicarbonates, and second, that the reagent is too insensitive to reveal small quantities of dissolved emetin.

Neither assumption is tenable. As for the solubility of emetin in bicarbonate: the experiments of Table 2 show that emetin is sufficiently soluble in bicarbonate for the solution to give a marked precipitate with Mayer's reagent. In fact, a 1:10,000 solution of emetin is not precipitated by the addition of sodium bicarbonate; whereas sodium carbonate or hydrate produce turbidity. Stronger solutions were not tried. The delicacy of Mayer's reagent is such that a drop added to 5 c.c. of the emetin hydrochlorid solutions gives turbidity with a 1:100,000 solution and precipitation with a 1:10,000 solution. It should also be noted that the addition of bile salts does not increase the solubility of the alcresta ipecac in bicarbonate solution.

There is a further possibility, namely, that the emetin is liberated by the bicarbonate from the adsorbent, but for some reason fails to dissolve. This assumption is vague, and even if tenable, there would seem to be no practical advantages in "liberating" an alkaloid, except for the purpose of dissolving it. However, to dispose

of the suggestion, and to check up the results, the alcresta ipecac-bicarbonate mixture or the residue remaining after the filtration of the bicarbonate solution was extracted with ether. The ether was separated, filtered and evaporated, and the residue taken up with dilute acid and tested with Mayer's reagent. The results (Table 3) are uniformly negative and confirm that the emetin of the alcresta ipecac-bicarbonate mixtures is also insoluble in ether.

TABLE 3.—ETHER EXTRACTS OF ALCRESTA IPECAC-BICARBONATE MIXTURES

Alcresta Tablets (1 per test)	Bicarbonate solution (c.c.)	Concentration of Bicarbonate (c.c.)	Length of Contact	Ether Extract of Mixture or Residue	Result with Mayer's Reagent
All three.....	10	1%	4 days	Residue	0
All three.....	10	1%	Short	Mixture	0
All three.....	10	1%	1 day	Mixture	0
Cleveland.....	6	0.5%	1 day	Residue	0

## SOLUBILITY OF ALCRESTA IPECAC IN STRONGER ALKALIS

It appeared from these experiments that the assumption of the intestinal liberation of emetin from alcresta ipecac is untenable. It was therefore thought that a test of the effect of somewhat stronger alkalis on alcresta ipecac might prove instructive. For this purpose, the residues remaining after the fruitless extraction with bicarbonate were treated successively with sodium carbonate, added to 0.5 or 1 per cent., and then with sodium hydroxid, added to 0.5 per cent. The mixtures were extracted at each stage with ether, and this was filtered, evaporated, acidulated and tested as usual. The results are shown in Table 4. They indi-

TABLE 4.—SOLUBILITY OF ALCRESTA IPECAC IN STRONGER ALKALIS \*

Alcresta Tablets	Sodium Bicarbonate, 1%	Sodium Carbonate 0.5 to 1% to Residue	Sodium Hydroxid 0.5% to Residue
All three specimens 1:10 c.c.	Clear	Slightly turbid	Large precipitate
1915	Clear	Very slightly turbid	
Chicago	Clear	Clear	
Cleveland	Clear	Considerably turbid	

\* Reaction of ethereal extracts of the solutions as stated in the columns, with Mayer's reagent.

cate that the emetin, although not liberated by the sodium bicarbonate, is indeed liberated to some extent by sodium carbonate, and much more by sodium hydroxid.

## PRECIPITATION OF ALKALINE EMETIN BY LLOYD'S REAGENT

The assumption that alkaline emetin is soluble in the presence of Lloyd's reagent was further tested directly by shaking alkaline solutions of emetin with Lloyd's reagent. It was found that this removed the alkaloid just as completely as from acid mediums, and rendered it insoluble, not only in watery solutions, but even in ether.

The experiments were made by adding alkalis to a 1:100,000 solution of emetin, till these contained 1 per cent. respectively of sodium bicarbonate, sodium carbonate and sodium hydroxid.

The solution in bicarbonate was clear; that in carbonate had a slight precipitate; that in hydroxid was slightly turbid, with a rose tinge.

Half of each sample was shaken with Lloyd's reagent. The reaction remained alkaline to litmus in

every case. Samples of the mixtures were then filtered, acidulated and tested with Mayer's reagent. The remainder of each mixture was then shaken out with ether, the ether filtered, evaporated, acidulated and tested with Mayer's reagent.

TABLE 5.—LLOYD'S REAGENT OF ALKALINE SOLUTIONS OF EMETIN\*

	Sodium Bi-carbonate	Sodium Carbonate	Sodium Hydroxide
	Direct Test	Direct	Other Ext.
Mixtures without Lloyd's reagent	Marked turbidity	Turbid	Other Ext. Considerably turbid
Mixtures with Lloyd's reagent	Clear	Clear	Clear Very slightly turbid

\* Mayer's test of dissolved alkaloid applied to the acidulated filtrates.

The results, shown in Table 5, prove clearly that Lloyd's reagent binds emetin in alkaline solution.

ACTION OF IPECAC ALKALOIDS WITHOUT SOLUTION

When the insolubility of the *alcresta* ipecac alkaloids became apparent, this information was communicated to the manufacturers. In their reply they conceded this insolubility and added: "We do not state that the ipecac alkaloids are soluble in a solution of the alkalinity of intestine, but only that they exert their physiological effect in the intestine and, as you of course understand, solubility in water is not necessary in order to bring about absorption from the intestinal tract."

These statements cannot be accepted. I doubt very much whether any substance can be absorbed, undissolved, from the intestine. Solubility in water, of course, has no bearing on the case, for I have aimed to imitate the solubility characters of the intestinal fluid.

It appears equally doubtful whether, undissolved, insoluble and adsorbed emetin can kill amebas. I tried to approach this problem by testing the toxicity to earthworms; but the low toxicity of emetin for these animals (they survive 1:10,000) rendered this impracticable.

The pharmacologic evidence indicates quite strongly that the emetin-*alcresta* ipecac is quite inactive in the digestive tract of dogs. Fantus<sup>6</sup> found that a doubled fatal dose of ipecac produced no effects of any kind when mixed with fullers' earth. Eggleston and Hatcher<sup>7</sup> likewise found no effects whatever from doses of *alcresta* ipecac that would have been fatal had a pure ipecac been administered.

This is as far as the positive evidence at present extends. Ordinarily, it would not be expected that a substance that is quite insoluble in the intestine, and that has completely lost its effects on the intestinal cells, which are ordinarily very sensitive to it, should still be effective on amebas, which are ordinarily affected only by high concentrations. Such a contradiction should demand a very careful and critical reexamination of the clinical evidence. As I am not in a position to undertake this, I must leave the subject in this incompleated state.

CONCLUSIONS

Emetin bismuth iodid is only slightly soluble in fluids of the acidity of the stomach, but freely soluble in fluids of the alkalinity of the intestine. These findings

agree with the clinical data, namely, that it is an effective amebicide, but is not altogether devoid of gastrointestinal irritation.

The alkaloids of *alcresta* ipecac are entirely insoluble, both in acid and alkaline solutions of physiologic concentration. The solubility is not improved by the addition of bile salts or of albumin.

The pharmacologic literature of *alcresta* ipecac confirms that the emetin remains entirely inactive.

RELATION OF TEETH, TONSILS AND INTESTINAL TOXEMIAS TO DISEASES OF THE EYE\*

GEORGE HUSTON BELL, M.D.

Attending Surgeon, New York Eye and Ear Infirmary (Eye Department)

NEW YORK

The presence and fatality of diseases whose essence is toxemia make them a subject of prime importance to the whole medical profession. I have selected the subject of focal infections for this paper, for the reason that it is a field in which I have long been interested, having read a paper<sup>1</sup> on this subject before the New York Institute of Stomatology, at the New York Academy of Medicine, in October, 1910. My belief has grown stronger and stronger that there is not sufficient attention paid to focal infections as a real cause of diseases of the eye. The epoch-making work of Rosenow<sup>2</sup> on the transmutation and selective localization of pyogenic organisms in the various tissues of the body has revolutionized some of our ideas of etiology and pathology. The experimental and clinical investigations of Brown and Irons<sup>3</sup> have been especially valuable to us, and we know now that the eye may suffer from such infections, as well as joints, muscles, nerves and blood vessels. Wescott,<sup>4</sup> Haskins,<sup>5</sup> Harrison<sup>6</sup> and others have recently presented interesting articles in this connection.

What I now wish to do is to bring to your attention the grouping of the most potent focal infections which we encounter in the practice of ophthalmology. For the lack of a better classification I call them the "three T's," which stand for teeth, tonsils and toxemia of the intestinal tract.

Every patient who comes to my office must stand the "acid test" of the three T's, and the same routine is carried out, as far as possible, in my clinic at the New York Eye and Ear Infirmary. It takes only a few minutes to subject patients to this examination, provided there is a laboratory man at hand, yet how often it is overlooked and forgotten. If one has the three T's well in mind constantly, there is no chance to overlook any of the great sources of focal infections.

\* Read before the Section on Ophthalmology at the Seventy-third Annual Session of the American Medical Association, Atlantic City, N. J., June, 1912.

<sup>1</sup> Because of lack of space, this article is abbreviated in THIS JOURNAL. The complete article appears in the Transactions of the Section and in the author's prints. A copy of the latter will be sent by the author or by THE JOURNAL on receipt of a stamped address and envelope.

The ramifications of the three T's are so interwoven that it is impossible for me to dissociate them. In thinking of one in connection with a patient the other two always come into my mind. In other words, they go hand in hand. This paper is written with the understanding that, when necessary, syphilis, gonorrhoea, and an occasional sinus or tuberculous trouble must be eliminated or excluded.

#### THE TEETH

Much has already been written, and much more can be written about dental infections as a cause of diseases of the eyes. Too much stress cannot be laid on a thorough examination of the teeth, which includes: (1) inspection of the mouth; (2) palpation of the gums, and (3) roentgenograms of all the teeth, dead or alive, pivots, arches and bridges.

Barker<sup>7</sup> calls attention to the fact that "serious arthritis, osteitis, osteomyelitis, periostitis, myositis, embolic pneumonia, pleuritis, endocarditis, neuritis, neuralgia, iritis, anemia, septicemia and pyemia may, in certain cases, have their origin in oral sepsis." And I believe there is a growing tendency to look on the same etiologic factor as contributory in many instances of chronic degenerative diseases like arteriosclerosis and arterial hypertension.

CASE 1.—A man, aged 22, came to my clinic at the New York Eye and Ear Infirmary, July 15, 1917, with plastic iritis in both eyes. When first seen, both pupils were contracted and the aqueous was cloudy. There was severe pain in both eyes, considerable exudation in the left pupillary space, and marked ciliary tenderness and injection. The patient was ordered into the hospital at once and had the usual treatment for iritis. The Wassermann test was ++++. Inunctions were started. As the teeth were badly decayed, fourteen of them were extracted during his first ten days in the hospital. Improvement was so rapid that I decided to discontinue the inunctions. The patient made a rapid recovery, leaving the hospital at the end of four weeks. He had gained 4 pounds in weight in the nine weeks that elapsed after he had the teeth extracted. His vision is now normal in both eyes. He was given seven inunctions while in the hospital. I proposed to treat him for constitutional syphilis, but wanted first to see what would happen after the removal of these septic roots, before going on with the treatment for syphilis. The result was most happy. I showed this patient to the section on Ophthalmology at the New York Academy of Medicine, Nov. 19, 1917.

CASE 3.—L. F. C., aged 37, sent to me by Dr. H. H. Forbes, July 27, 1917, was complaining of failing vision in the right eye. With correction, he had vision: O. D., 20/200; O. S., 1/20. On examination, I found that he had an exudate choroiditis and large floating opacities in the vitreous of the right eye. His tonsils had been removed by Dr. Forbes. On examining his mouth, I found his gums very much inflamed, and on the right side, at the root of one of the molars, there was a gum boil. There was also a bridge in his mouth. I devised an immediate roentgenogram of his teeth, which showed, for one thing, that there was an old root in the gum of one of the central incisors, which had been pulled long before; also that there was an abscess cavity at the root of two of the upper molars on the right side. The root of the incisor was extracted; also two molars were pulled, and the bridge was removed. All of this work was done in the summer of 1917. The patient's Wassermann test and urine were negative, and he had no internal treatment. The man had been improving ever since the dental work was done; July 5, 1918, he came to me with a vision in the right eye of 20/20 with correction.

Any part of the eye may be attacked as a result of dental infection, but by far the greatest number of

cases show the iris, ciliary body, choroid or cornea to be affected.

Lewis<sup>9</sup> reports two cases of retinal hemorrhage due to bacterial toxins, and sets forth a new conception, namely, that in these cases there occurs an absorption into the blood of a soluble protein poison, usually given off from focal infections, which has a solvent effect on the intercellular cement substance of the cell wall, and that the hemorrhage is not due to alteration of the blood pressure, but to local lysis in the wall itself. It seems to me that Lewis' theory of this new pathology is a correct one, and will in the future explain many obscure cases of recurrent retinal hemorrhages which, in the past, have been diagnosed as due to tuberculosis.

In operations on the eyeball when pyorrhea alveolaris is present, or when I suspect any trouble with the teeth, I always begin by referring the patients to an up-to-date dentist, who at once starts his treatment. When the dentist has finished with the patient, I generally wait from four to six weeks before operating, so as to try to eliminate all toxins from the system. Even in glaucoma I wait, if it is possible, to eliminate the three T's. All of this may seem heroic, but let me assure you that we are dealing with an arch enemy not to be trifled with, and my success in treating patients along these lines impels me to go forward.

#### THE WAY TO "GET RIGHT" ON THE DENTAL QUESTION

To my mind, the way to get at the dental problem correctly is to start with children in the schools, as complete and proper mastication cannot take place unless the mouth is in a healthy condition. Education along dental lines and in dental hygiene is just as necessary as education of the mind. Children who never use a tooth brush are constantly coming to my clinic. All they get here in our public schools in the way of dental hygiene is what they call "the tooth brush drill." What we really need here in New York and elsewhere are dental hygienists or dental dressers, to inspect the mouths of these schoolchildren regularly and systematically; to detect irregularities of the teeth; to detect cavities by probe and mirror; to chart defects correctly; to select temporary teeth for extraction; to clean the scale from the teeth; to extract the temporary teeth, and to apply various tonics to the gums when inflamed and, above all, to educate the children in "dental hygiene." Women who do this work are given a nine months' course at Columbia University; then they stand an examination and are given a diploma as "dental hygienists." These dental dressers are, of course, to work under the supervision of some up-to-date dentist who can inspect their work from time to time. In this way the city would not be put to any great amount of expense, and the children would be well taken care of and receive scientific treatment. This work is all the more important when we stop to consider that at least 70 per cent. of our schoolchildren have defective teeth, that all defective teeth are injurious to health, and that some of them are a deadly menace to their owners.

#### EYESIGHT OF SCHOOLCHILDREN

The dental dressers could also be taught to test the vision of all schoolchildren regularly, and those with defective eyesight could be referred to the clinics, as

7. Barker, L. F.: Oral Sepsis and the Digestive Apparatus, South. J. A. M. A. 7: 481 (Jul.) 1918.

9. Lewis, F. P.: A Bacterial Toxin as the Cause of Retinal Hemorrhage, J. A. M. A. 70: 1813 (June) 1918.

nothing handicaps a child's progress in education more than poor eyesight. Hints and pamphlets on the care of the eyes and the teeth should be published for distribution among the schoolchildren and the mothers. The pamphlets could also outline the diet for these children, and call the attention of the mothers to the harmful effects of sugars and candies.

The publishing of the pamphlets, the issuing of charts to be hung in the schoolrooms, and the preparing of exhibits to be used in the schools are some of the things which the dental dresser could do.

These suggestions of mine are all educational, and should be a part of the regular course of every child from the kindergarten until the day of graduation.

Diseases of middle life are fast increasing. They are microbial, of a chronic, recurring character, and are carried into the blood stream from a few foci, the mouth being the source of the greatest danger.

#### THE TONSILS

The tonsils, on account of their position and structure, are more prone to infection than almost any other organ in the body. Because of their position, they come in contact with the various species of bacteria in the mouth cavity. More important than this, however, is the deposition of these bacteria with the food, in the lumina of the crypts. They therefore receive and transmit in many cases some infectious process.

Ziegler<sup>11</sup> reported a case of marked papilledema in a child, which was persistent for over a year, and which subsided and cleared up after the removal of the tonsils. This septic condition of the tonsils was well illustrated in a case of a physician which King<sup>12</sup> reported. The patient had arthritis and heart and kidney trouble with episcleritis. He was unable to attend to his professional duties. The whole systemic involvement was cleared up by the use of vaccines and the enucleation of the tonsils. I had the pleasure of seeing this physician eighteen months after operation. He had resumed his practice and had had no recurrence of any of his old troubles. He had gained in weight and was feeling fine.

When the tonsils are involved, anything less than the radical treatment is of little value. This was thoroughly demonstrated by Case 5.

CASE 5.—Miss C. R., who first came to me, July 5, 1918, complained of "red eyes," as she called it, and had been under treatment for several years by two competent oculists. There was at this time marked redness and congestion of the bulbar conjunctiva, with some edema and some follicles on the palpebral conjunctiva. I examined the patient's eyes for retraction, and found that her error had been properly corrected. Looking her over for the three T's, I found that her teeth were excluded, but on examining her throat, it developed that she had two large, juicy tonsils which projected way beyond the pillars of the fauces. She was told that nothing could be done for her until her tonsils were removed. That day, the first time I had ever seen her, she was sent to consult a nose and throat specialist, and her tonsils were enucleated the next day. Her progress has been very marked ever since the operation, and now, six months afterward, "the red eyes" have disappeared, and she no longer has any chronic conjunctivitis. She remarked to me, "You are the first doctor who ever examined my tonsils." Think of it, a woman 25 years old with a low grade conjunctivitis, which had extended over a period of several years, who had never had her throat examined!

Osborne<sup>13</sup> thinks that a very large proportion of thyroid disturbance is caused by mouth and throat infections.

Recently Gardiner<sup>14</sup> has called attention to the fact that he has seen two typical cases of exophthalmic goiter which were permanently cured after one year's observation with the rest cure and the enucleation of the diseased tonsils. He also states that Morse was able to cultivate *Streptococcus viridans* from the thyroid glands removed from two typical cases of goiter.

Errors of diet and pyorrhea alveolaris are the starting points of nearly all cases of hyperacidity, hypoacidity and toxemia of the intestinal tract. How often is the dietetic condition discussed with our patients unless they have some obscure eye disease? How often do we demand of new patients coming to our offices an examination of the urine? I hold that every patient should be examined for the three T's and along these lines. How many of us warn patients against the excessive use of cane sugars, glucose and carbohydrates? When we stop to consider that after the Revolutionary War, the estimated consumption of sugar in the United States was only  $7\frac{1}{2}$  pounds per capita per annum, whereas in 1914, the per capita used amounted to about 90 pounds, as Joslin<sup>15</sup> says, "the marked increase in the consumption of sugar is appalling." He continues: "Since 1900 it has increased 17 per cent., and the mortality from diabetes mellitus has doubled in that time. Such a marked alteration in the diet of the nation is noteworthy and deserves attention."

It is in these civilized food products that we must look for the agents that are responsible for autointoxications from which the human race now suffers. The carbohydrates taken as sugars and starches are digested by the ptyalin of the saliva, and amylase, maltase and lactase of the pancreas, and the invertin of the intestinal juice, so that they are all reduced to a state of monosaccharides. Some of them are further broken up by bacteria,<sup>17</sup> with the formation of lactic acid, alcohol, marsh-gas, hydrogen and butyric acid. In other words, there is nothing in the human stomach to render it physiologically assimilable. It is attacked there by bacteria which oxidize it and convert it into highly irritable organic acids and several alcohols. If taken in solution on an empty stomach, or when the food is passing into the small intestine, it becomes a food product, as the inverted ferments of the intestine break it up into glucose and levulose sugars, which are assimilable. If taken, however, with food which must remain in the stomach one or more hours, then sucrose becomes a foreign body, is acted on by bacteria, and its ultimate products become important factors in the production of our metabolic diseases.<sup>18</sup>

As Hawk<sup>19</sup> says, "Chemically considered, the carbohydrates are aldehyd or ketone derivatives of complex alcohols." I think two things, therefore, are necessary for sugar fermentation; undigested sugar free in the stomach or intestine, and the bacteria in sufficient quantity to attack it. Overfeeding with sugar either given as too much food as a whole, or as too high sugar percentage, will cause fermentation. We must bear in

mind that the gastric juice is not only a secretion but also an excretion, and anything that goes into the stomach that will produce fermentation will generally produce hyperacidity and will have a tendency to give us the acid stools.

CASE 7.—A man, aged 20, who came to my clinic with vision: O. D., 20/20; O. S., 20/200, complaining of poor vision in the left eye. There was a circumcorneal injection of blood vessels of the left eye. The cornea was hazy, with few spots on Descemet's membrane, and the pupil was contracted. One could see that the eye was in a state of low grade inflammation. The teeth were negative as far as we could make out, although a roentgenogram of them was ordered. A Wassermann test was also taken. The tonsils had been removed when he was a boy. On getting his personal history, it developed that he had eaten about half a pound of chocolate every day for the last six months. He was a helper on an express wagon and visited many candy stores. He was taken off the sweets and given some atropin and hot bathing for his eye. He continued with his work.

Two weeks later roentgenoscopy of the teeth and the Wassermann test were negative; the urine was also negative, except for ++++ indican. The patient continued to improve, and at the end of three months was entirely well, with a vision of 20/30. One year has now elapsed and he has had no return of his malady. There is no doubt that this patient was suffering from sugar poisoning.

Dietitians are not all agreed as to the value of sugar. I hold and believe that it is a toxic substance, and that children, as well as adults, should be deprived of its use, so far as possible.

We see the baneful effects of candy and sweets in children coming to us with eczematous keratoconjunctivitis, one of the commonest diseases of the eye. It is a common disease in more senses than one, for it is common among the common people. The sight of a dirty and slatternly mother dragging two or more children equally dirty and slatternly, with eyes tightly closed is, unfortunately, too frequent in our outpatient clinics, and forms a sad picture which is familiar to us all. To my mind, the phlyctena, which is characteristic of the disease, is the ocular manifestation of a toxemia arising from some focus situated somewhere in the body. It is interesting to note that all of the children have gastro-intestinal disturbances, and the great majority of them have indican in the urine. This toxemia of the gastro-intestinal tract is brought on by the excessive use of candy and sweets, and bad teeth. Some of these unfortunate children also have adenoids and tonsils, which must be removed. I know that a great many observers claim that there is a good deal of evidence to show that a tuberculous focus exists somewhere in the body. I do not think that their reasoning is sound. I hold that the three T's play the important part in the etiology of this disease. When the cause of the trouble is removed and these children have local treatment for their eyes, they get well.

Hill<sup>20</sup> has found that the stools of breast-fed babies are normally quite strongly acid in reaction, owing to the large amount of sugar and fat in breast milk. In severe cases of sugar fermentation, Hill recommends alkali treatment. He also maintains that a baby can take relatively more sugar than an adult, as the assimilation limit is much higher in infancy. Case 8 is most interesting, as it clearly shows the results of sugar poisoning:

CASE 8.—Mrs. A. G., aged 27, married, came to me, Oct. 1, 1918, complaining of her vision being fogged, and of being unable to read. She had been under my care for her eyes

for several years, and her vision in the past had always been normal. Her vision at this time was 20/200 in each eye. The pupils reacted sluggishly to light. Pressure on the eye-balls gave her pain. Her fields for form were normal with a central color scotoma for red, extending from the blind spot to the fixation point. The scotoma was more or less circular in shape, and not oblong, as we generally see in toxic amblyopia due to tobacco poisoning. There was no contraction of the peripheral field. Both fundi were normal. The optic disks were not swollen or edematous. She gave a history of consuming large quantities of sweets in the form of candy—about half a pound a day—and of drinking at least three ice cream sodas a day. I had a chemical analysis made of the blood and the urine. She was given a dose of castor oil, which has great power to sweep the intestine clean, after which I ordered a strict diet, without any sugars or sweets, and she was given one bottle of Bulgarian bacilli three times a day before meals.

October 6, the report on the blood was that it was normal except for high blood sugar, from 0.15 to 0.18 per cent. The urine showed high specific gravity, 1.027, with a positive reaction for sugar, and high indican reaction. I thought from the start that I was dealing with a case of hyperglycemia, and these tests were still more convincing.

The average glucose content of normal blood is about 0.1 per cent. This increase in the blood sugar was brought about by the increased ingestion of carbohydrates in the form of sweets, for the reason that after the ingestion of large amounts of sucrose or glucose, causing the assimilation limit to be exceeded, and alimentary glycosuria will arise.

November 1, I saw the patient again, at which time her vision was 20/70 in both eyes. The treatment was continued. The urine was examined again for sugar, but was negative. The diet was continued.

The patient was seen from time to time, and on December 1 her vision was normal again and she could read Jaeger No. 1.

This case is undoubtedly one of autotoxemic amblyopia, due to the anomalies of metabolism. The opportunity was afforded for the production of toxic substances through the instrumentality of the sweets. Most candies contain inverted sugars and commercial "glucose," which are readily fermented either by bacterial action or by means of enzymes or activating bodies or agents. It is interesting to note right here that two fifths of all the sugar that is consumed is eaten in the form of candy. The most frequent occurring examples of such a disturbance of vision is found in diabetes mellitus, in which we have constantly high blood sugar.

I hold that every case of retrobulbar neuritis should have a chemical analysis of blood and urine, even if the patient smokes and drinks. Estimations of the blood sugar are, undoubtedly, of great value in the treatment of these cases of toxic amblyopia.

There are two ways in which the sight may become affected in toxic amblyopia—endogenous or exogenous: the endogenous toxins being found in connection with hyperglycemia, diabetes mellitus, uremia, the puerperal state, or a septic process somewhere in the alimentary canal, while exogenous toxins are tobacco, ethyl or methyl alcohol, and numerous other substances.

Collins and Mayou state that the poison either acts on the ganglion cells of the retina or their synapses, or by the production of ischemia which interferes with their nutrition.

It is interesting to note also that Adams<sup>21</sup> of Oxford, in speaking of twenty-nine acute cases of retrobulbar neuritis, states that two thirds of these were in females between 15 and 30 years of age.

<sup>20</sup> Hill, L. W.: Sugar in Relation to Infant Feeding, Boston M. & S. J. 179: 1 (July 4) 1918.

<sup>21</sup> Adams, P. H.: Some Points in Retrobulbar Neuritis, with Special Reference to Prognosis, Brit. J. Ophth. 2: 522 (Oct.) 1918.

It is interesting to note that a substance which has been occasionally found in the lens, and which does not occur under normal conditions, is sugar.<sup>23</sup> Its presence in the lens in cases of diabetic cataract has attracted the greatest attention. Professor Kuhne was able to demonstrate it. It is also interesting to note that Lohmeyer<sup>24</sup> succeeded in demonstrating the presence of sugar in the vitreous taken from two human beings who had just died of diabetes. Deutschmann<sup>25</sup> proves the presence of sugar in the aqueous and vitreous of the body of a diabetic whose lens also contained sugar. This work by these investigators is most timely and most interesting, and only goes to show that sugar can leave the blood stream and may attack any of the tissues of the eye.

#### HOW BAD TEETH AFFECT THE ALIMENTARY CANAL

Pyorrhea alveolaris, or Riggs' disease, is not only a serious condition, but also is very prevalent. This chronic disease loosens the teeth in the gums, or rather strips the gums from the teeth, so that they drop out, and mastication becomes impossible. But even more disastrous to health than the inability to masticate properly are the effects of the continued ingestion of toxic material which the pyogenic germs have developed. This toxic material, and bacteria mixed with the food, pass into the alimentary tract and bring about gastro-intestinal autointoxication which, in turn, is responsible for a large number of grave conditions. This is one reason why the teeth should be thoroughly investigated in every patient coming to us, whether we suspect a septic process in the alimentary canal or not, as pus may be swallowed with the food over long periods, or metastatic infections may occur. Barker says that some cases of gastric and duodenal ulcers are secondary to oral sepsis.

Of course, the examination of the urine of all new patients coming to the office is imperative. It is also essential to have the indican content of the urine. This gives a rough index of the extent of the putrefactive process in the intestine. It is therefore the duty of every physician, whether he be specialist, general practitioner or surgeon, to examine the urine of all new patients coming to his office, and to demand a urinalysis of all old patients once a year. I cannot lay too much stress on the importance of having the urine of all patients examined, and I think that the failure on the part of the physician to do this is simply inexcusable.

Joslin says that "the time is not far distant when the progressive dentist, even, will demand a urinary report of all his patients." I am convinced that the indican reaction is passed over too lightly by physicians in general. Soper<sup>26</sup> says: "I have often noted the good effects produced in certain cases of toxic headaches by sharply limiting the protein and reducing or omitting sugar from the dietary. Patients of this class usually present excessive indicanuria, much colonic flatus, froth, and fermentative feces. Moreover, they are in the habit of consuming large quantities of cane sugar."

Apropos of the carbohydrate element, the work of Pemberton<sup>27</sup> is especially interesting. He produced

good results in cases of rheumatoid arthritis by a radical reduction of carbohydrate in the dietary.

Hagelberg<sup>28</sup> found an abnormally high sugar content in the blood in twenty-six cases of arteriosclerosis. A thorough examination of urine and feces, and a chemical blood examination will give us a reliable index of the putrefactive condition in the intestinal tract.

Why the optic nerve should be affected in some cases of gastro-intestinal autointoxication, the uvea in other cases, the cornea in some and the vitreous in still others, I am not able to state, nor am I able to state just how the conditions are brought about. We must all admit, however, that toxemia may result from chemical changes in the intestinal contents, and that absorption of protein toxins from the intestinal tract does take place, and that the blood stream is the carrier of the infection, the three common foci being the teeth, tonsils and the intestinal tract.

#### SUMMARY AND CONCLUSIONS

*The Teeth.*—1. If the teeth are properly treated from the outset, they will not abscess. If we do our part, Nature will do hers. That is the reason why we must start with the children in the schools.

2. These suggestions on my part are educational, and should be a part of the regular course of every child, from the kindergarten age until the day of graduation.

3. I strongly urge the country to "get right" on the dental question.

5. Modern dentistry is relieving the world of much misery, by the watchful care of the foci connected with the teeth, and the time is not far distant when modern dentistry will be made a department of medicine.

7. While many of the results of oral infection are apparent to the eye, the deep-seated and hidden foci, which are frequently the most virulent, are entirely hidden and can only be revealed by the roentgenogram.

8. Diseases of middle life are fast increasing and, to my mind, the mouth and the diet are the sources of the greatest danger.

9. As complete and proper mastication cannot take place unless the mouth is in a healthy condition, I hold that a dirty mouth is one of the greatest menaces of the human race.

*The Tonsils.*—1. The tonsils receive and transmit, in many cases, some infectious process. Because of their position and structure, the tonsils are more prone to infection than many other organs in the body. Because of their position, they come in contact with various species of bacteria found in the mouth. More important than this, however is the deposition of these bacteria with the food which we find in the lumina of crypts.

2. It has been demonstrated that the tonsils are the principal foci of infection in the throat carriers of hemolytic streptococci.

3. All patients coming to the office should be examined for diseased tonsils.

4. When the tonsils are diseased, anything less than the radical treatment is of little value, as they are carriers of infection.

*The Alimentary Canal.*—1. Focal infections, especially those of the teeth, tonsils and alimentary canal, to use the words of Professor Osborne of Yale, are "no fad," but realities to be looked for and eradicated, if we are to cure our patients.

28. Hagelberg, M. *Berl. klin. Wochenschr.* 39: 197 (Sept. 19) 1916; *abstr. J. A. M. A.* 59: 1753 (Oct. 9) 1916.

2. Errors of diet and pyorrhea alveolaris are the starting points of nearly all cases of hyperacidity, hypo-acidity and toxemias of the intestinal tract. Children are often improperly fed, with the result that about 70 per cent. of schoolchildren have dental cavities; and when decay sets in early, the teeth become septic, poisoning the food eaten, so that systemic infection is frequent. Decayed teeth afford a ready passage into the system for disease germs. Large numbers of children have tuberculous glands which, in my opinion, are incident to such foci.

3. Sugar, chemically, is a solid alcohol. From a local little used product it has become the universal condiment in the food of the civilized races. It is used in man's drink, in his food and as his refreshment between meals, not only in solution, but also in the form of the ubiquitous candies of commerce. We must also bear in mind that two fifths of all the sugar consumed is eaten in the form of candy.

4. Dietitians are not all agreed as to the value of sugars. I hold and believe that they are toxic substances, and that children as well as adults should be deprived of their use as far as possible, as they are chemical alcohols. When the hydrochloric acid of the gastric juice is diminished in quantity (hypo-acidity), as it may be in many cases of functional or organic disease, there is no check to the growth of the microorganisms in the stomach; then the sugars are acted on by the bacteria, and fermentation takes place, with the formation of large amounts of such substances as lactic acid and butyric acid; in some cases a pyloric spasm is produced, thereby more markedly increasing fermentation and acidity with their end-product results. Ilawk says that there are certain of the more resistant spores which even the normal acidity of the gastric juice will not destroy.

5. It is difficult for me to avoid the conclusion that the unrestricted use of all carbohydrates must be deleterious to the human economy.

6. If the sugar poison can invade the aqueous, the vitreous and the nutritive stream of the lens, then why can it not produce an inflammatory process in any of the tissues of the eye? On account of the insidious onset, the cause of the trouble is liable to escape recognition unless the dietetic condition is kept well in mind.

7. We must educate our patients to look after their diet, teeth and tonsils, and impress on them the great importance of having their urine examined once a year. In obscure conditions of the eye, we must go a step farther and have the feces of the patient examined, to see if the stools are toxic, and last but not least, to insist on a chemical examination of the blood, as a thorough investigation of the urine, feces and blood will give us a reliable index of the putrefactive condition of the intestinal tract.

40 East Forty-First Street.

#### ABSTRACT OF DISCUSSION

DR. HIRAM WOODS, Baltimore: I believe absolutely in the possibility of a dental origin of ocular lesions. Dr. Bell has called attention to a matter of great importance clinically, but it is apt to lead us into a lot of speculative pathology. The clinical importance is twofold: (a) Our patients will not get well unless we find the cause of the eye disease; (b) in the present state of our knowledge, little more than a therapeutic experiment is at command. We give the patient the benefit of our best judgment and go over everything we think causative. Then we act. But can we tell, before our

therapeutic test, how near right we are? Dr. Bell mentions a case of obstinate episcleritis. It resisted everything until the pyorrhical condition of the gums was removed. That was the cause. I had a patient with episcleritis who had had all his teeth extracted, except four. The attacks of episcleritis continued. Then another dentist removed all the bridge work. He still has episcleritis. In this case the teeth were not the cause, in spite of the dead roots showing infection. Sometimes we find more than one cause, as one of Dr. Bell's cases illustrated. With pyorrhea or dead teeth in a syphilitic patient, for instance, there is usually nothing in the appearance of the eye to guide us in determining the etiology. If we assume dental origin, we may deprive a patient needlessly of a very useful part of his anatomy. Dr. Bell uses the expression "rheumatic iritis." We should get rid of this term. Both rheumatism and iritis are infections, and do not bear a causative relation to each other. They are due to the same cause. As to the tonsils, they are universally recognized as a portal of entry for infection. Grant distal manifestation of focal infection and a tonsillar cause is admitted. Yet even so, tonsils may be removed for ocular troubles without benefit. It is another diagnostic pitfall. Before the removal of a tonsil solely for ocular disease, there should be, as far as possible, an exclusion of other causes and a bacteriologic examination of the crypt content. Finally, Dr. Bell discusses intestinal autointoxication as a cause of eye disease. He speaks of it as a toxemia. I was much surer some years ago, than now, about the causative relation between intestinal absorption and eye lesions. Dr. Bell is right in associating recurrent phlyctenular ophthalmia with intestinal disorders.

DR. JOHN E. WEEKS, New York: In a considerable number of cases of autointoxication, by regulating the diet, we were able to cure fifty-three out of fifty-five patients who had inflammatory conditions of the deep structures of the eye. Eliminate or limit the quantity of sugar; give meat. We were never intended to eat sugar. It has only been a diet for a couple of centuries. Sugar causes fermentation and the generation of acids, which affect the eye and other structures.

DR. F. PARK LEWIS, Buffalo: I think I have absolutely demonstrated the effect of dental infections in the production of iritis. About two months ago in a case of recurrent iritis, working in conjunction with a group of men, a suspected tooth was found to have a root abscess. It was extracted under aseptic precautions. It was crushed, and from the canal was taken a culture which proved to be almost an absolutely pure *Streptococcus viridans*. Injections were made into the abdomen and the ear vein of a full grown white rabbit and within twelve hours there developed a definite iritis, with little ocular congestion, nor was there any congestion of the retinal vessels. After four days the inflammation began to recede and a large dose was given which killed the rabbit. The eye was then removed under aseptic precautions and a portion of the iris was dropped into culture medium. We reproduced *Streptococcus viridans*. The organism was also found in the iris tissue. This demonstrated absolutely for the first time, as far as I know, the selective affinity of the organism found in dental root abscess for the special structure which had been affected in the individual from which the tooth was taken.

DR. CLARENCE A. VEASEY, Spokane: The most remarkable demonstration of the direct influence of dental infections in the production of ocular disease I have ever had the opportunity to observe was in five cases of ophthalmoplegia interna. One of the patients was treated by the former usual methods for several weeks and others were treated for a somewhat shorter period without the least appreciable improvement. In from two days to one week after the removal of the focus of infection every patient had entirely recovered. Four of the cases were due to chronic infection of the faucial tonsils and one was due to a focal infection in a tooth because of a partially filled canal. In the latter case no pus was found; but a roentgenogram revealed a rarefied area at the root of the tooth, and the canal was then discovered to have been filled only partially. I have also

observed several cases of high blood pressure, some with marked pulsation of the retinal arteries, minute hemorrhages and acute nephritis. These conditions disappeared within a short time after the removal of the focus of infection. My own observations, like those of others, would seem to indicate that many ocular affections, formerly classed as idiopathic, are in reality due to a focal infection somewhere in the body; and in any given case, whether or not there appears an apparent cause, thorough examinations should be made to discover whether in addition to the apparent cause there may not be some focus of infection.

Dr. M. C. ROSE, New York: J. Forbes Ross of London has repeatedly demonstrated that he can modify the surgical scar by increasing or decreasing the potassium salts given the patient. In eye work where prompt, perfect healing is so essential the study of every detail should be our aim. Further confirmation of the value to ophthalmologists of the study of diet can be found in the experiments of A. H. Clark of Baltimore. In the treatment of some of the pus invasions by vaccines, the reaction and coagulability of the blood is so important, that if the blood has not the right reaction, they fail to give results. Give the patient lemon juice and the vaccines will produce results. Experience of over twenty years has shown that every inflammation, from the top of the head to the sole of the foot, makes greater headway in an acid body; so it has been my custom to stop excess of sugar, oranges, grapefruit, wine and beer, reduce the quantity of protein food, and to administer alkalis, such as potassium bicarbonate or sodium bicarbonate; stop when the body is slightly alkalinized. Dr. Mendel of Yale showed how cases of xerophthalmia and other eye diseases developed in children whose diet was defective in fats and vitamins. The eyes were quickly made well by the addition of chicken liver and cod liver oil to the diet. Laboratory workers have demonstrated that the amount of end-products of protein digestion (uric acid, ureacreatinin) excreted by the kidneys may bear no constant ratio to the uric acid, urea and creatinin content of the blood. Clinical workers have demonstrated, with the help of the laboratory, that the excess of the end-products of protein food in the blood bears a definite relation to sickness and disease; and the amount of the end-products excreted by the kidneys often bears no constant relation to the condition of the patient. Creatinin is the easiest of the end-products of protein to be eliminated by the kidneys. So a constant excess of creatinin in the blood from 6 to 10 per cent. shows that the kidneys are hopelessly damaged, and the prognosis must be bad. Creatinin is produced from tissue cells, and Lusk tells us that the quantity of creatinin eliminated is independent of the quantity of protein intake, and the same holds true, as a rule, for uric acid; but urea output can be increased or decreased by regulating protein diet. Since the protein output in the urine may bear no constant ratio to the excess of protein end-products which may be in the blood, and since the excess of protein products circulating in the blood bears a constant relation to certain degenerative diseases of the eye, I would recommend routine blood examinations in degenerative eye conditions.

Dr. FREDERICK F. FEELE, Lincoln, Neb.: Dr. Bell's summary of the present status of focal infections as related to eye diseases deserves consideration. Too much emphasis cannot be placed on the necessity of finding all sources of infections. The fact of a positive Wassermann does not mean that iritis is due to syphilis. Brown and Irons in their report of 109 cases of iritis found that seventeen were due to combined causes. I have seen numerous cases of iritis or uveitis in syphilitic individuals, who had either resisted the ordinary specific treatment or had recurrences, clear up apparently permanently by removal of the teeth or tonsils. A large number of old scleritis patients are without teeth, but I think free from a return of that painful affection. As to intestinal toxemia, as far as I can learn, the view seems to lean more toward the idea that this factor belongs in the same category as rheumatism and is an incident of the same causal agent of the eye disease. Brown and Irons unqualifiedly present this view. They failed to find one case out of 100 in which focal infection was absent,

and conclude that the intestinal toxemias were due to the same focal infection as the iritis. Dr. F. Park Lewis agrees with this view in an article which he read two years ago, in speaking of the etiology of lenticular changes. He states that every patient with striae in the lens is suffering with a greater or lesser degree of intestinal indigestion, with the resultant absorption of toxic products. It seems to me that in view of the well known necessity and value of a certain percentage of sugar in the diet of infants and growing children, it is a reasonable conclusion that a certain amount is allowable in any dietary. Our aim should be rather a well balanced ration in a quantity suitable to the needs of the individual. I assume that if the ordinary amount of sugar is not assimilable, a focal infection might be responsible for such failure. I would in this instance extract the abscessed tooth, but not the "sweet" tooth.

Dr. JAMES J. KING, New York: The importance of tonsillar infection in relation to eye diseases was first impressed on me in 1914. A doctor had a severe tonsillitis in April. Three weeks later he developed episcleritis, multiple arthritis, nephritis, myocarditis and endocarditis. Those conditions persisted for eight months despite treatment by many able specialists. In December, 1914, he consulted me in relation to his tonsils as a causative factor of his trouble. Three eminent laryngologists had told him his tonsils were negative. On taking cultures of the tonsils I found a virulent infection and advised the use of autogenous vaccines and then the removal of the tonsils. This advice was followed, and in one month all of his symptoms had disappeared. Today, after an interval of four and one-half years, he is a well man.

Dr. H. B. LEMERE, Omaha: In the West we practice triology, we extend our practice to the ear, nose and throat, so that we form from our own findings a concrete idea of the nose and throat in connection with eye disease, and I now have added diagnostic stomatology as necessary for proper diagnosis and treatment of eye conditions. Unless we can interpret our own roentgenograms of the alveolar processes, we will fail to get the infected foci removed in many cases. We will have to help, at times, dentists who are not well grounded in pathology, even though they may be skilful mechanically, and this we shall fail to do unless we can discuss intelligently with them the films and the appearance of the alveolar processes. Many of these focal infections are secondary to primary foci; as, for example, infected tonsils from bad teeth or maxillary sinus empyema from an infected tooth, and these secondary infections may in turn cause ocular disease. Dr. Knapp's paper seems to indicate that in sympathetic ophthalmia the injured eye may be regarded in the light of a secondary focus. I want to endorse what Dr. Park Lewis said, that each case must have some one responsible for results, and one man must have authority over and direct all the energies of the workers in the different branches. In a pronounced ocular affection the internist, the laryngologist and the dentist must all be subordinate to the oculist, as the eye condition is the one of paramount importance.

Dr. OLIVER TYDINGS, Chicago: When we recognized that these troubles were only local symptoms of systemic disease, we made a large advance. Fifteen years ago I reported a case of iridocyclitis which had developed for a long time and which I was unable to relieve. The man was cured by a rectal surgeon. Fifteen years ago, in the course of a discussion on a paper by a New York surgeon, I exhibited some instruments and spoke of the enucleation of tonsils. I was informed that my method was exceedingly crude; that it had been used and abandoned some eleven hundred years prior. I am glad to see that some New York surgeons are following in those footsteps now.

Dr. S. LEWIS ZIEGLER, Philadelphia: I do not wish to belittle the importance of focal infections, but I think we should also take notice of the disturbing influence of sub-oxidation. My attention has been called particularly to it as the causative factor in many ocular lesions. The case of papilledema which Dr. Bell quoted from one of my papers as resulting from infected tonsils was due to tonsils that were enlarged and acted as an obstruction to breathing. The

same causative factor existed in several cases of Mikulicz's disease which I published some years ago. There was no bacteremia shown in these cases. The patients were all cured by correction of the respiratory error. In one case it was enlarged tonsils and in another it was nasal obstruction. The question of diet is also very important. In cases of ulcerative keratitis in children it has been my custom for many years to say "no tea, no coffee, no cakes and no candy." I think this error starts in the stomach, passes on to the nose, and thence through the tear duct into the eye. We must, therefore, consider the importance of these underlying conditions as the result of dietetic errors. I think that while the bacteremia problem should be studied carefully, we must likewise consider the chemistry of the system. In other words, if the chemistry of the system is perverted by bacteria, well and good; but we must consider all the factors involved.

DR. GEORGE HUSTON BILL, New York: We all now agree as to the value of eradicating infections in the teeth and tonsils. The question of food intoxication is the most important subject before the medical profession today, as it is the starting point of all our troubles in the gastro-intestinal tract and also the starting point of pyorrhea alveolaris. The human race now suffers more than ever from diseases of middle life and I believe that it is the civilized food products, errors of diet and bad teeth and tonsils that are the causes of the trouble. It is the acid fermentation and acid intoxication produced by sugars and sweets and excessive use of carbohydrates. When sugar is fermented by bacteria, acids are formed. These may be divided into two groups. The volatile acids, such as formic acid, acetic acid and butyric acid, and the nonvolatile acids, such as lactic acid; the volatile acids are formed in large amounts and are the ones that do the most harm. Too much acid causes fermentation, hurries food out of the stomach into the intestines, chemical changes take place, poisons and toxins are formed, which, once absorbed into circulation, cause auto-intoxication. Therefore, we must eat base forming foods. There are a lot of things which we cannot prove in medicine; but that should not deter us from going forward. The process of elimination of focal infections is good enough for me when I can not obtain positive proof. The remedy for all these troubles must be found in the field of the cause. We must investigate the teeth and tonsils and correct the errors of diet. In the treatment of our eye diseases, we should have at our elbow the internist, so as to confer and consult with him. By this means we can hope to attain proficiency in diagnosis and have the proper conception of treatment in all eye conditions.

## AN EXPERIENCE WITH EPIDEMIC MENINGITIS\*

J. S. ROBISON, M.D.

Captain, M. C., U. S. Army  
WINCHESTER, IND.

AND

JESSE R. GERSTLEY, M.D.

First Lieutenant, M. C., U. S. Army  
CHICAGO

In spite of some recent publications, the value of the agglutination test as a check on the efficiency of meningococcus serum has not been given the proper clinical appreciation. Regarding this, our experience with some forty-five cases of epidemic meningitis may be of interest.

When the Army of Occupation entered Coblenz, sporadic cases of meningitis appeared, never two in the same company or neighborhood. All patients, whether brought in late or early in the disease, were at once put on the usual treatment, which consisted of

intraspinal and at times intravenous injections of serum. This product, that of an American commercial firm, was five months old and dated good for another month.

At this time Captain Leon Unger of Chicago, who in France had had considerable experience with this disease, urged that in clinical value the American serum was vastly inferior to that of the Pasteur laboratories.

In spite of our immediate requisition, however, the French serum was somewhat delayed, so that before its arrival we had had ten patients. Our results with

\* The letters in the captions indicate the various serums: A, Pasteur serum, November, 1918; B, Pasteur serum, December, 1918; C, American commercial serum; D, Rockefeller Institute, regular type serum; E, Rockefeller Institute, paratyphoid serum; F, Rockefeller Institute, paratyphoid serum; G, normal horse serum; H, normal salt solution; I, Pasteur serum, 1917.

these were most depressing. Try as we might, in spite of intraspinal injections, often three times within twenty-four hours, the disease progressed steadily and rapidly, absolutely uninfluenced by our efforts. Of the first ten patients, nine died, and the only one who recovered was a young soldier with an exceedingly avirulent infection during the course of which he never lost consciousness. On him, treatment apparently had little influence. He never seemed better or worse or in any way affected by the therapy, but dragged on a rather slow and often interrupted convalescence.

Then came the shipment of French serum. It was dated as manufactured October, November and December, 1918. To our chagrin, however, it failed us completely, and the next patient, like the others, progressed steadily to his death.

A survey of this new serum, however, gave us some hope. The nurse in charge of the ward, Miss Edith Kingsley, noted that in this shipment, by an oversight, a carton of vials, dated 1917 instead of 1918, had been overlooked, and just by chance the first sample taken had come from this particular carton. Of course, we discarded this at once and used the new Pasteur product.

Never have we witnessed such a striking result from a change in therapy. Patients continued coming from all parts of the Army of Occupation to a total of forty-five. There was no change in our technic. Intraspinal injections were given twice, and in the most desperate cases, three times a day. Intravenous injections were only rarely employed. Never has a therapeutic test been more definite, more conclusive. With the advent of the new serum our mortality, almost 100 per cent., changed to a recovery of 100 per cent. Every patient progressed satisfactorily, uneventfully with no complications, to perfect health. Epidemic meningitis, from a gruesome, depressing and repulsive disease, became after only a few treatments a relatively mild ailment.

The agglutinating properties of the various serums were examined by one of us (J. S. R.) without any knowledge as to the clinical results. In the accompanying table the numbers represent cultures of the organisms obtained from spinal fluids of the various

\* From Evans in Hospital No. 2 and No. 49, Third American Army, Coblenz, Germany, Lieut.-Col. Robert B. Hill, commanding.

patients. The agglutinations were done in February, 1919. The clinical observations extended from January to April, 1919.

A later check on the New York State Board of Health serum showed it to be satisfactory both in its agglutinating properties and its clinical results.

CONCLUSIONS

From a study of these forty-five cases, one arrives at the following conclusions:

1. Bacteria may vary according to geographic location. Perhaps our first serum failed because, in its manufacture, strains or organisms indigenous to Germany and France were not included. This, at any rate, is a theoretical possibility.

2. A conclusion of vital clinical importance is that if a patient with epidemic meningitis does not respond at once to intraspinal treatment, one should not temporize. The agglutinating property of the serum against the patient's own organisms should be tested, and if the laboratory evidence is unfavorable, more satisfactory serum should be procured at once.

4235 Michigan Avenue.

THE INFLUENCE OF HIGH AIR TEMPERATURE ON TUBERCULOSIS

HARRY GAUSS, M.D.  
CHICAGO

It is generally taught that man is a homothermal organism, that he has a wide range of adaptability to external atmospheric conditions, that his mean daily temperature varies between 98 and 99 F., this being subject to minor variations according to age, exercise, altered respiration, period of the day, food metabolism, etc. Some observers, nevertheless, have shown that there is a certain relationship between the body and atmospheric temperatures. Hermans<sup>1</sup> records that in crowded theaters and churches his own body temper-

Chart 1.—Average mean daily air temperature, July 20 to Aug. 4, 1916, taken from the U. S. Weather Reports for Chicago; B, principal heat wave; A and C, minor heat waves preceding and following it.

ature rose. Castell and Chalmers<sup>2</sup> observe that if a person, lightly clad and in good health, places himself in the hottest part of an engine room on a steamer in the Red Sea, it will be found that for a short time his temperature remains normal, but in due course of time his temperature will gradually rise to 102 F. or over, when the person breaks off the experiment because of the accompanying general distress, after which his

temperature slowly returns to normal. Haldane,<sup>3</sup> investigating the influence of high air temperatures, observes noticeable elevations in the body temperature when a person is subjected to still, elevated and saturated atmosphere. Likewise, Lee<sup>4</sup> has seen the temperature of a normal adult rise 6 F. during a stay of three and one quarter hours in an atmosphere averaging 104.7 F. with 95 per cent. humidity.

Under normal conditions, heat loss of an average man is accomplished by radiation and conduction, 65

Chart 2.—Temperature chart of a patient from the tuberculosis ward showing rises of 2 F. above his usual course of the disease on days of the principal heat wave and the succeeding minor heat wave.

per cent.; by evaporation from the skin, 15 per cent.; by evaporation from the lungs, 15 per cent.; by heating respired air, 2.5 per cent., and by heating excreta, 2.5 per cent. (Stewart<sup>5</sup>). But when the body is subjected to high temperatures, heat loss from radiation and conduction is reduced to a minimum. The heat regulating mechanism continues for a while to dissipate the heat through the other functions which commonly play a minor part and which thus have the burden of heat dissipation thrown on them. Should the heat regulating mechanism become impaired or fail under the unfavorable atmospheric conditions, heat stroke or heat exhaustion may result.

The direct cause of heat stroke and exhaustion is heat, as given by Rogers,<sup>6</sup> who states that when it is found that heat stroke in India is commonest in the three hottest months and in the geographic groups where heat is fiercest, it seems not unlikely that heat, pure and simple, is the chief factor. The predisposing causes have variously been given. Manson<sup>7</sup> summarizes them as all physiologic depressants, notably intemperance, fatigue, overcrowding, unsuitable clothing, malaria, acute disease, and also chronic organic disease of the important viscera.

The study of the effects of high air temperatures on a normal healthy person may be conducted with reasonable accuracy; but any attempted observation on the effects of high air temperatures on a person having any of the predisposing causes gives rise to a multiplicity of difficulties. Especially is this true if the observed predisposed factor in itself may give rise to an elevation of temperature. However, certain observations made at the Cook County Hospital, Chicago, during July and August, 1916, are worth noting.

During the last five days of July, 1916, Chicago was in the midst of a heat wave which was unusually

compressive. The mean daily temperature for July 27, 28, 29, and 30, was from 90 to 93 F. During this time there was 100 per cent. sunshine, the average hourly wind velocity was 6, and the average relative humidity was 58. The principal heat wave was preceded and followed by minor heat waves whose mean daily temperatures were about 85 F., each being of short duration.

In Chart 1, *A* represents the preliminary heat phase; *B* the principal heat wave, and *C* the succeeding heat phase. During July, 1916, there were admitted to Cook County Hospital 158 patients suffering from heat stroke and heat exhaustion. Among the patients suffering from heat stroke there were admitting temperatures of 110 to 114 F., as reported elsewhere (Gauss and Meyer<sup>1</sup>).

Totally independent, however, of the patients admitted as frank heat stroke cases, there were observed rises of temperature in various patients of the hospital which seemed unusual for the expected course and duration of their disease. Thus, in the contagious ward there were numerous instances of elevation of temperature in children who were convalescent and in whom no rise of temperature was expected. Likewise, in the general medical ward there were observed

to run an even protracted course, and there are few or no crises and lyses to cause marked fluctuations of fever curves. The history of every patient in the tuberculosis ward was examined, and the patients who were in for the entire period of fifteen days from July 20 to Aug. 4, 1916, were selected for observation. Fifty-six cases were thus obtained. The morning and afternoon temperatures of the entire fifty-six patients were averaged for each day and plotted (Chart 3). It is thus seen that in the five days preceding the heat wave, July 20 to 25, the average afternoon temperatures varied between 99.5 and 100 F., in the five days of the heat wave, July 26 to 30, the afternoon temperatures varied from 100.5 to 100.8 F., and in the five days after the heat wave the afternoon temperatures varied between 99.7 and 100 F. The striking factor is that during the heat wave the average afternoon temperature was 100.62 F. compared to 99.8 and 99.86 F. for similar periods preceding and following it.

We conclude that the increased temperatures for July 26 to 30 probably were caused by the high air temperatures and unfavorable atmospheric conditions.

## Therapeutics

### THE TREATMENT OF EPIDEMIC MENINGITIS

Extensive outbreaks of epidemic meningitis in the different armies during the past five years have stimulated an intense study of the disease here and abroad. As a result, much valuable information regarding etiology, epidemiology and treatment have been acquired. It is desirable that advantage be taken of the lessons from this experience in the management of the disease in peace conditions. Up to a short time before the war began a single type of meningococcus was generally accepted as the cause of epidemic meningitis. Dopter was the first to classify meningococcus-like organisms into distinct types. In connection with a recent very lucid description of the manner in which the types of meningococcus came to be recognized, he<sup>1</sup> has described in detail the modifications which have resulted in the treatment of meningitis. Four types of meningococci are now generally recognized, designated as Types A, B, C and D. Type A appears to have been the common one before the war, being found according to Dopter in from 95 to 96 per cent. of the cases. Of the other types, sometimes called parameningococci, B is most common, C and D exceptional. Infections by Type B increased during the first two years of the war, and at the end of 1917 about 50 per cent. of the cases in the French army were of this form. Each of these various types of organism is affected only by its own specific serum. A case of meningitis caused by the Type B meningococcus is not influenced by a serum prepared from Type A organisms. Consequently it has been necessary to prepare serums from each type of organism for use in the treatment of meningitis due to the corresponding type.

For the most efficient serum treatment of epidemic meningitis, two things now appear essential: (1) an accurate biologic determination of the type of organism concerned in the individual case, and (2) the

Chart 1.—Averaged morning and afternoon temperatures for July 20 to August 4 for the fifty-six patients from the tuberculosis ward. The afternoon temperature curve (broken line) bears a relative resemblance to the atmospheric temperature curve.

rises in temperature among some of the old heart and kidney cases, and the same may be said of some of the other wards. In the tuberculosis ward, certain patients had rises of temperature of 2 to 3 F. above that due to the usual course of the disease, which corresponded in time with the principal heat wave and the succeeding phase. Chart 2 is a representative instance. This is offered as an interesting coincidence of increased fever on days of severe atmospheric conditions. There are too many factors that may cause a rise of fever in a tuberculous patient for one to draw hasty conclusions from a single case.

If an observation could be obtained on a sufficiently large series of patients, however, such that the individual causes are of lesser importance than the external factor influencing the whole group, then a satisfactory observation might be made. The tuberculosis ward was selected for this study because it was desired to observe the temperatures in patients for a period of fifteen days; five days preceding, five days of the heat wave, and five days succeeding it; and the tuberculosis ward offered the best material. Most of the patients have chronic advanced tuberculosis, their fevers tend

administration of the serum prepared from the corresponding type. Dopter is not in favor of using polyvalent serum except as a measure of precaution until the laboratory examination has determined the type present in the case. As soon as the type is known, the corresponding monovalent serum should be substituted. He believes that "too much polyvalency might conceivably involve risk of diminished potency." Those who have treated meningitis with serum have observed that occasionally cases occur which are not appreciably benefited by the polyvalent serum used, and in such cases the spinal fluid does not clear up nor do the meningococci decrease in the fluid, as is usual in most cases. Sometimes another make of polyvalent serum may be active, and it is advised to make use of this expedient, with the hope that a strain of meningococcus corresponding to the one causing the infection may have been among those employed in preparing the serum. At best this is not satisfactory. It is much to be desired that serums should be prepared from the several types so that they may be available for cases which do not respond promptly to the polyvalent serums. Accurate differentiation of the type of infecting organism by biologic tests is essential before the treatment can be carried out with a high degree of precision. It has been found that the cases prevailing in a group of individuals both in the meningeal exudate and in the nasopharynx of carriers are usually of one type. Mathers and Herrold<sup>2</sup> found that, in a camp near Chicago, almost 86 per cent. of the cases of meningitis were due to Type A (Group 1), and in the city of Chicago at the same time more than 86 per cent. of the cases were due to Type B (Group 2). If investigation revealed the prevalence of one type in a community or epidemic, a serum high in immune bodies for that type would be reasonably used for routine treatment if it were not feasible to make a biologic differentiation in each case. As the abnormal conditions of army camps disappear, it will be of interest to note whether the prevailing type of meningococcus will again be the Type A, as was apparently the case before the war. Study of cases of epidemic meningitis has served also to emphasize the fact that the meningococci are found not only in the meninges, but also often in the blood, joints, etc. When serum is injected intraspinally, it rapidly passes into the circulation; but it is desirable to secure a greater concentration of antibodies in the blood than is secured in this way. This can be brought about by intravenous or intramuscular injection of serum. It would probably be a useful practice to combine intramuscular with intraspinal injection in all cases. When intravenous injections are used, all precautions to avoid anaphylactic shock should be taken.

Dopter also discusses the procedures to be adopted when serum treatment is unsuccessful. Mechanical conditions brought about by the inflammatory process in the meninges interfere with the free passage of the serum, which thus is limited in its action to a portion of the arachnoid space. In the early stages of meningitis, the serum injected by the lumbar puncture needle passes freely through the spinal and cerebral subarachnoid spaces and the communicating cavities. When the inflammatory exudate begins to organize, obstructions to the flow of serum are formed, and free circulation is interfered with. The obstruction may be

spinal, at the base of the cranium, or at the foramina leading to the ventricles. When the arachnoid space has been blocked, the serum must be injected by routes other than the lumbar one, the site of the obstruction determining the position of puncture. With spinal obstruction, dorsal or cervical puncture is employed. When there is basilar obstruction which separates the spinal from the cranial cavity, the purpose is to introduce serum directly into the arachnoid spaces of the base. This is accomplished by sphenoidal puncture, passing through the most external portion of the sphenoidal fissure. When the meningitis extends from the subarachnoid space to the ventricles of the brain, there is added a ventriculitis or ependymitis. Obstruction is easily produced at the narrow foramina opening into these cavities of the brain. The clinical course in such cases is usually as follows: Early in the history of the case, the symptoms are relieved by spinal injections of serum. After a few days, symptoms recur, temperature rises, headache becomes intense, and the patient becomes drowsy and intermittently delirious. Lumbar puncture yields clear or turbid fluid free from meningococci, which escapes only drop by drop. The patient grows gradually worse, becomes emaciated, muscular atrophies and contractures develop, and death terminates a chronic course. In such cases an early diagnosis of ventricular lesions is rendered more difficult by the fact that at about the corresponding time serous meningitis from the foreign serum introduced is liable to occur and to give rise to almost identical symptoms. Direct puncture of the ventricles involved, and the introduction of serum, is indicated as soon as a diagnosis is made. Experience in direct injection of the ventricles is limited; but accumulating evidence indicates that this procedure will be found of much value in many cases in which cure is not obtained by the usual method of treatment with lumbar puncture.

If an intolerance to serum develops so that serum treatment must be discontinued, two methods of treatment appear to possess some value: One is the production of "fixation abscess" by subcutaneous injection of 2 c.c. of spirits of turpentine. The other is the use of an autogenous vaccine, consisting of from 100 to 500 million meningococci killed by heat at 55 C. Dopter is favorably impressed by vaccine treatment in cases that do not respond to serum.

## THE OAT AS HUMAN FOOD

The sentiment once expressed in the English dictum that oats are food for horses in England and for men in Scotland has persisted in many quarters until the present day. The necessities of war time, coupled with the strongly supported exhortations of the U. S. Food Administration, induced thousands of persons to accept the common cereal grains as of similar values, so far as their nutrient virtues are concerned. But peace time is at hand once more, and the barriers built by the national needs of 1917-1918 are being let down. Old time preferences and prejudices are likely to return to their previous prominence, except so far as the newer lessons have produced a satisfaction with the enforced changes.

Wheat is already rapidly regaining its pristine favor. What will happen to the temporary enhanced popularity of the other cereals remains to be ascertained. In the choice between corn, rice and oats, none of which are preferable bread grains, geographic and racial traditions will doubtless continue to dictate the decision, as they have done so long in the past. We have already called attention to Sherman's<sup>1</sup> demonstration of the excellent utilization and nutritive efficiency of maize (corn meal) when its protein is supplemented with about 10 per cent. of the nitrogenous components of milk. In collaboration with Winters and Phillips,<sup>2</sup> he has prepared a comparable report on the oat proteins. The severity of the test is indicated by the fact that the food consisted essentially of oatmeal cooked with starch in thin, hard "scones" and eaten with apple and sugar, with and without milk. When the diet contained 100 c.c. (3 $\frac{1}{3}$  fluidounces) of milk a day, a daily intake of protein amounting to even less than 0.6 gm. per kilogram of body weight sufficed to maintain a nitrogen balance. Without the supplementary virtue of the milk this record could not be attained.

However, as these investigators conclude, in the maintenance metabolism of adults, as shown by the

nitrogen balance experiments, the proteins of oats and maize are of virtually equal nutritive efficiency. This study by Sherman and his collaborators indicates that "for the purposes of practical dietetics, equal weights of oat and maize proteins may be regarded as essentially equal in value, and even the minimum amount of milk which can possibly be regarded as permissible, in the light of our present knowledge of nutrition, will apparently so supplement the proteins of either the maize or oat kernel as to make them function with an efficiency comparable with that of the average protein of mixed diet in the maintenance metabolism of man." No one will be so rash, at the present day, as to maintain that the cereals per se are perfect foods. Their shortcomings in respect to various nutrient virtues have repeatedly been rehearsed in THE JOURNAL. Nevertheless, the time has passed when we are justified in pointing to any of the commonly used cereals as nutritively obnoxious, as "heating" or as inherently detrimental to health. Science confirms what experience frankly teaches, that all these cereals have a useful place in the human dietary. Maize need not be relegated to the pig-pen, nor oats to the stable.

## THE RAILROADS AND THE PUBLIC HEALTH

To those who regard war as a great disabling mill and contemplate with horror the casualty list of more than a quarter of a million of soldiers in the United States Army during the recent campaign, the statistics of disability and death chargeable to such peaceable agencies as the railroads may be extremely disconcerting. There is food for reflection in the announcement that the railway lines under government control in 1917, employing approximately two millions of persons, mostly men, injured more than 194,000 persons.<sup>1</sup> Approximately 63,000 of the people injured were more or less severely crippled, and more than 10,000 were killed.

These are not figures rendered high by some fortuitous circumstance. The same incidence of railroad casualties is repeated year after year during war and peace alike. According to Census Bureau statistics,<sup>2</sup> the deaths in 1917 from railroad accidents and injuries surpass all others from external causes except in the case of accidental falls and suicides. The casualties of the European war have furnished the occasion for the development of reconstruction plans whereby the disabled are restored to health or returned to careers of comfort and usefulness. An official<sup>3</sup> of the railroad administration has sanely remarked that, having as an example the activities of the government in its efforts to salvage the wounded and sick of the Army and Navy during the war which is just passing, we should be

derelict if we ignored the humane and economic problem raised by railroad casualties.

Aside from such obvious considerations, the railroads are concerned in less direct ways in many other problems that involve the public health. Railroad construction is responsible for many impediments to natural drainage, whereby pits and ditches become breeding places for mosquitoes. In this way the continuance of malaria, a preventable disease, may be facilitated. Inspection of railways in the South has shown this to be something more than a chance supposition.

The danger of pollution of water supplies through the unsatisfactory methods of sewage disposal on moving trains has often been agitated. The committee on health of the U. S. Railroad Administration has directed attention to the less appreciated situation with respect to toilet facilities in stations and terminal buildings. As every traveler in large cities must know, these facilities are used quite as much by the nontraveling public as by the patrons of the railroads. This statement might be extended to include hotels and similar semipublic buildings. Private corporations are thus compelled to face problems in sanitation that they should not be expected to meet. Problems of transportation are intimately connected with the daily lives of the public. The vehicle should be as sanitariously safe as the home.

#### THE INFLUENCE OF THE NERVOUS SYSTEM ON THE SECRETION OF URINE

When nerves supplying the kidneys are sectioned or stimulated, changes in the flow of urine and in the output of its various constituents are likely to occur. These phenomena, long known, have been interpreted by some investigators to indicate a specific influence of the nervous system on the secretory function of the kidneys. Perhaps the most definite assumption in this respect relates to the splanchnic nerves, to which a specific secreto-inhibitory influence has at times been ascribed. When the renal nerves are cut on one side a larger volume of urine flows from the kidney involved. This manifestation, together with alterations in the relative proportions of urinary constituents, has led certain observers to conclude that the changes cannot be explained solely as the result of vasomotor changes; hence they must be attributable to effects directly on the renal cells. Several years ago, Asher and Pearce<sup>1</sup> believed that they had discovered secretory fibers in the vagus nerve, because stimulation below the level of the cardiac branches augmented the rate of urinary secretion. Pearce<sup>2</sup> has subsequently concluded that the results claimed are doubtful because there is no

increase in oxygen consumption (an index of augmented cellular activity) under the foregoing conditions.

The classic example of the salivary glands which respond so promptly and characteristically to nervous stimulation, quite aside from the changes thereby induced in the blood supply, has naturally prepared physiologic investigators to expect a comparable nervous secretory mechanism elsewhere in the domain of glandular performance. The question involved is, furthermore, fundamentally important from many standpoints. The pharmacologist is interested to know whether the nervous system and the drugs whereby he influences the latter can bring about the production of urine through specific cellular action much as do certain chemical substances, like caffeine, which are carried directly to the secretory apparatus by the circulation. The pathologist is also concerned with the precise part played by the nerves in relation to the kidney substance; and the surgeon should also know definitely what a damage to the renal innervation may be expected to occasion. Marshall and Kolls<sup>3</sup> have reinvestigated the problem. Their experimental results show that the changes caused in the secretion of the kidneys after section of the splanchnic nerve on one side are, in all respects examined, similar to those caused by changes in the blood flow through the kidney. Comparable variations can be produced by compression of the renal artery. Urine flow depends more on the rate of blood flow than on blood pressure in the kidney. The effect of section of the splanchnic nerve is an increased blood flow through the kidney, which is responsible for the changes in secretion. Hence, to quote the conclusion of Marshall and Kolls verbatim, it appears that the burden of proof still rests with those who would assign a specific secreto-inhibitory action to the splanchnic nerve aside from the changes which it causes by being the chief vasomotor nerve to the kidney. As long as the changes produced can be explained entirely as vasomotor phenomena, it is unnecessary to invoke a specific secretory action for the nerve.

This conclusion must not be interpreted to signify that the renal nerves are without profound effect on the excretion of the urine. The sole contention is that the effect is not a direct one on the renal cells. Further evidence of the probable correctness of the non-specificity of the nervous influences is found in the fact that adequate renal function has been main-

tained in animals after the kidneys have been entirely extirpated and then replaced. In such circumstances, of course, the nervous connections have been completely interrupted. The facts cited, furthermore, do not in any way negate the current contention that different substances may produce their diuretic effects in unlike ways. It is commonly agreed that in sulphate diuresis, for example, changes occur in the kidney itself, whereas in chlorid diuresis, changes in the blood supply to this organ are primarily responsible. Sulphate diuresis, in which the renal cells are involved, is accompanied by increased oxygen consumption in the kidney—a result not observed in the diuresis affected by chlorids. Similarly, Marshall and Kolls report that after section of the splanchnic nerve on one side, sodium chlorid produces a greater diuresis on the side operated on than on the normal one. Sodium sulphate, on the other hand, produces an almost equally good response from each kidney. Likewise, compression of one renal artery limits the diuresis from sodium chlorid much more than it does from sodium sulphate.

#### NEWLY ESTABLISHED FACTS IN THE PHYSIOLOGY AND PATHOLOGY OF THE DUODENUM

Although the small intestine has long been considered the seat of important functions related to digestion and absorption, the clinical interest with respect to it has usually been primarily medical rather than surgical. Since various digestive secretions pour into the upper portions of the intestine, either from the intestinal cells themselves or from the secretory ducts that enter this organ from the pancreas and liver, the changes that are brought about thereby in the chyme are of considerable physiologic significance for the organism. Surgical experiences have been responsible for the gradually acquired belief that the small intestine is something more than the locus of these enzymatic reactions and food absorption. Extensive resections of the bowel have almost always been attended with subsequent nutritive difficulties; and the untoward consequences of acute obstruction in the small intestine, together with the fact that such interference in the upper portions of the bowel are always more serious than in the portions farther along the alimentary tract, have raised the question of a possible specific nondigestive function of the small intestine and the duodenum in particular.

Not long ago, in referring to the observations published in *THE JOURNAL* by Moorhead and Landes<sup>1</sup> to demonstrate that duodenectomy is compatible with life and perfect health, in the dog, for short periods at least, we pointed out that such experiments, along with many others, definitely disposed of the alleged rôle of

the duodenum in relation to diabetes. Further observations made by Mann and Kawamura<sup>2</sup> at the Mayo Clinic not only verify the conclusions already reached but extend the basis for them. The duodenum was removed from the dog, cat, hog, goat and monkey. Careful studies of the dog did not reveal any noticeable changes following the duodenectomy. The animals remained in good condition. Examination of the blood showed it to be normal with regard to cell counts, hemoglobin, carbon dioxide combining power and hydrogen-ion concentration. The roentgen ray showed the course of a standard barium meal to be virtually the same as in a normal dog. The authors add that experiments on the other species have been too recent to allow conclusions to be drawn, but it would seem that the removal of the duodenum in the hog is as innocuous as its removal in the dog. No data have been secured to show that the duodenum is of great importance in any of the species used.

With respect to the obscure rôle of the small intestine in the development of the toxemia following intestinal obstruction, light is also beginning to emerge out of the controversial darkness that has obscured the subject in recent years. Few subjects in experimental surgery and pathology have been the occasion of such lively debate and marked contrasts of opinion. On the one side was the assertion that the mucosa of the upper duodenum has a specific vital function aside from its ordinary digestive and secretory activities, and that disturbance of this function rapidly causes death. From such a standpoint it would be conceivable that obstruction or injury to the duodenum might upset the essential performance of an organ indispensable to life. The new findings regarding the possibilities of harmless duodenectomy negative such a hypothesis.

Opposed to this assertion has been the assumption that the obstructed intestine is the seat of the formation of toxic products. Here, again, there has been no unanimity as to the genesis and nature of the postulated poisons. Are they the results of a perverted mucosal metabolism in necrotic tissue? Do bacteria play a part in their production? Out of the hitherto prevailing uncertainty which the experimental efforts of a considerable number of American investigators have only slowly succeeded in dispelling, a few salient facts seem to be established. These have been summarized recently by Dragstedt, McClintock and Chase<sup>3</sup> of the State University at Iowa City. It now seems improbable that the mucosa cells are ever concerned with the manufacture of a toxic secretion. The presence of bacteria in the lumen of the intestine is necessary for the production of the characteristic toxic substances, and in their absence these substances do

3. Dragstedt, L. R.; Dragstedt, C.; McClintock, J. T., and Chase, C. S.: Intestinal Obstruction, II. A Study of the Factors Involved in the Production and Absorption of Toxic Materials from the Intestine, *J. Exper. Med.* **30**: 109 (Aug. 1) 1919.

not form. They are produced by the action of the intestinal bacteria on proteins or their split products. In the absence of food, gastric juice, bile or pancreatic juice, these bacteria can produce the characteristic toxic substances from the intestinal juice or from the proteins of desquamated mucosa cells.

It appears, however, that something more than the production of poisonous bacterial products is necessary in the genesis of toxemia associated with intestinal injury or obstruction. These products must be absorbed before they can unfold their toxic manifestations. Various investigators, notably Hartwell<sup>4</sup> and Murphy,<sup>5</sup> have demonstrated that the toxic contents of the lumen of the obstructed intestine are not absorbed through a normal mucosa. As Dragstedt, McClintock and Chase have likewise noted, injury to the mucosa cells, either as a result of the sudden distention brought about by conditions of obstruction or by any other factors that interfere with the blood supply to the mucosa, is an important factor in the absorption of toxic substances from the intestine.

Granting the sequence of events which include the injury to the mucosa, the formation of toxic bacterial products from proteins or their derivatives, and the consequent existence of conditions favorable to absorption thereof, it becomes evident that the exclusion of the bacterial contamination ought to remove the most serious factor in the sequence of detrimental features. Sterile loops have indeed proved nonnoxious where otherwise toxemia might have been anticipated. The hope of securing a destruction of the ever-present intestinal bacteria is not promising. The Iowa investigators report that it is impossible to sterilize the intestine by the use of chemical antiseptics, even when these are applied directly to the mucosa of isolated segments. The burden of drainage, careful manipulation and avoidance of injury as far as possible is thus thrown on the surgeon in the management of the difficulties just referred to.

**Public Health Nursing.**—There should be very close cooperation between visiting nurse associations and boards of health. There must be no friction. Nurses working under private associations doing tuberculosis, child welfare, ophthalmia and venereal disease nursing should realize that their work is a very important part of the board of health work, and that it can be done best by close team work. An efficient board of directors can be of great value to the nurse and the board of health in developing the work and caring for community problems. Cooperation with the doctors is easily established through the general efficiency of the nurses. There is no group of people who value public health nursing quite as highly as the really competent physicians of the community. Nurses and social workers should work together. The nurse should not do social work when there are social workers to do it, and the public health teaching should be done by the nurse—M. McGee, *The Commonwealth* **6**:107 (May-June), 1919.

## Current Comment

### SELF-SACRIFICE IN THE WARFARE AGAINST DISEASE

To facilitate the investigation of some of the threatening infectious diseases that were a source of concern to our medical forces during the war, a number of men volunteered as subjects for inoculation with virus suspected of carrying the etiologic agent of disease. This is not the first time that American manhood has responded so magnanimously to the call of science and preventive medicine. The story of Agramonte, Lazear, Carroll and Reed, who sacrificed themselves in the attempt to discover the mode of transmission of yellow fever, is known to all. While their achievement was not acclaimed with flags or with personal rewards, nevertheless their scientific work and heroism will remain a credit to experimental medicine for all time. Two groups of men modestly made a great sacrifice for their country and for mankind in connection with scientific investigations during the great war. One group offered themselves as subjects for the study of the mode of transmission of trench fever, one of the great puzzles that threatened to work great havoc among the forces at the front. As trench fever apparently is not transmissible to animals, the recourse to human subjects became imperative. The volunteers lent themselves to the demonstration that the blood of trench fever patients is infective, in order to ascertain what element of the blood contains the virus and to discover the relation of the louse to the dissemination of the disease. The story of some of these endeavors and sacrifices has been recorded in the report of the medical research committee of the American Red Cross.<sup>1</sup> It deserves to be told along with the exploits on the Marne and in the Argonne. "Words fail," says the official report, "in attempting to express admiration of the morale and courage of the volunteers. They have more than done their part in addition, by endeavoring to aid in the accuracy of the experiments." Surely such men deserve official recognition for "the sacrifices they have endured in order to save the manpower for the army and to relieve the sufferings of their fellow men." Today trench fever can be controlled. Another volunteer sacrifice has been recorded in the efforts of the army medical staff to find a method of preventive inoculation against measles. No physician need be reminded of the dangers to which this disease subjected millions of men in the two years just past. Here again, in time of need, to quote Major Sellards,<sup>2</sup> who conducted the tests, the individual soldier was found ready and willing to offer his services and accept such risk as was inherent in these inoculations. The nation as a whole may well join a grateful medical profession in reiterating the words of the Surgeon-General to men who, having seen the serious consequences of measles in camp life, for no reward to themselves, gladly accepted the risk simply from a

desire to be of service. Aside from the possible danger and suffering, there was the actual discomfort of long isolation cheerfully and conscientiously borne. To these loyal men has gone this tribute:

The Surgeon General has been informed of the fact that you volunteered for the measles investigation. He desires to express to you his appreciation of the patriotism and devotion to duty that you have shown and to assure you that your contribution to the cause is appreciated by him just as much as was the bravery of the men who went into the fight in France.

#### QUARRY ACCIDENTS IN THE UNITED STATES

Mining has long been regarded as one of the most dangerous as well as laborious occupations. It is characterized by an exceptional liability to accidents which have been a source of solicitude to students of occupational hygiene. Thanks to the serious consideration given to the subject in many countries by those responsible for the public health, as well as by those to whom the accidents represent an economic factor, the introduction of more effectual safeguards has reduced the hazards considerably. Quarrying is usually classed in the category of industrial dangers along with mining. The Bureau of Mines, which now compiles statistics of the quarry accidents in the United States, reports that these likewise are showing a decrease in the fatality rate.<sup>1</sup> In 1917, the latest year for which data are available, more than 80,000 men were engaged as quarry employees. The number killed per thousand 300-day workers was 1.83 in contrast with an average of 2.19 for the five years preceding. The number of nonfatal injuries, however, has not thus decreased. Out of the various causes of injury in and about quarries, falls and slides of rock or overburden take first place, for they are responsible for more than one quarter of the fatalities. Explosives rank second in respect to danger. Like the schoolboy who manipulates firecrackers, the quarry employee is all too forgetful of the charge and returns too soon to the place of hazard. Premature shots also play havoc with each group of persons. Accidents in haulage claimed 16 per cent. of the fatalities, the further causes including a miscellaneous group of sources of occasional danger. To the intelligent employer and foreman such statistics should prove to be a valuable guide toward the field for future safety work.

#### TOXIC POTATOES

It is well known that the green and growing parts of the common potato may contain a toxic glucosid, solanin. The edible part, or tuber, of the potato is not likely to exhibit any significant amount of this substance after it has passed the young stage. From time to time, however, the literature has contained reports of severe intoxications in man which seemed to be associated with the use of potatoes as food. One might readily conjecture in such cases that the vegetable was merely the conveyor of the harmful agent—that some adventitious poison or microbial fac-

tor had become associated with the potato. In most of the cases recorded, chemical examinations of the latter have been lacking for the particular instances in which it was under suspicion. A recent outbreak of poisoning in which the circumstances clearly implicated the potatoes occurred in Leipzig. The symptoms elicited were characteristic and included abdominal pains, vomiting and diarrhea—manifestations described for previous outbreaks. A chemical analysis of a sample of the same lot of tubers was carried out by Rothe<sup>1</sup> at the hygienic institute of the University of Leipzig. The analysis disclosed, the fact that they contained as much as 0.43 gm. of solanin per kilogram of potato, whereas harmless ones usually contain not more than one tenth of this quantity.<sup>2</sup> It should be noted, however, that potatoes which have developed sprouts may, when examined along with the latter, exhibit somewhat larger quantities. In dietary practice, however, the sprouts are removed prior to the culinary use of the tuber. Toxicologic tests on man have demonstrated that as little as 0.2 gm. of isolated solanin may provoke untoward symptoms. This quantity or more might actually occur in the quantum of potatoes that an adult might consume with his meals in the course of a single day. Hence the possibility of solanin poisoning must be reckoned with when potatoes prematurely harvested are used as food.

#### PROPHECY?

The *British Medical Journal*, in its issue of September 20, states editorially that "General Leonard Wood has been nominated as Republican candidate for the presidency of the United States."

### Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

#### ILLINOIS

**Midwife Fined.**—Mrs. Esther Eichenberg, a midwife of Chicago, is said to have been fined \$50 and costs, September 20, for practicing medicine without a license.

**Smallpox at Roodhouse.**—It is reported that sixty-five cases of smallpox have been discovered at Roodhouse, and that state health officials are enforcing strict quarantine and vaccination.

**Second Home Nursing Class Begins.**—The second class in training women in the practical art of home nursing, under the auspices of the department of health of Chicago, started, October 5, at 1358 West Fulton Street, with an enrollment of more than 800.

**Traveling Health Clinic.**—The Cook County traveling health clinic of the Chicago Tuberculosis Institute, during the last four months, has visited thirty-six towns, and has held 111 clinics at which 841 persons have been examined; of these, 352 came for examination of the chest.

**Physician Committed to Jail.**—It is reported that Dr. Franklin J. Oshay of Ladd was arrested and fined \$225 for continuing the practice of medicine after his license had been

1. Fay, A. H.: Quarry Accidents in the United States During the Calendar Year 1917, Technical Paper 213, Bureau of Mines, Washington, D. C., 1919.

1. Rothe, J. C.: Ueber Erkrankungen nach Genuss von solaninartigen Kartoffeln., *Ztschr. f. Hyg.* **88**: 1, 1919.

2. Meyer: Arch. f. Exper. Path. u. Pharmacol. **36**.

revoked by the Department of Registration and Education of Illinois. On failure to pay the fine he was committed to the county jail to serve it out.

**Personal.**—Dr. Walter H. Meents, Chicago, for the last six years instructor in surgery in Rush Medical College, has recently been appointed assistant professor of surgery in the University of Illinois College of Medicine.—Dr. Wilson R. Abbott, Springfield, October 6, succeeded Dr. Leo J. Jacobson as clinician to the Cook County traveling health clinic of the Chicago Tuberculosis Institute.

**Honors to Medical Officers.**—Thirty-one members of the Sangamon County Medical Society who served in the world war were guests of honor at a banquet given by several professional brethren at the St. Nicholas Hotel, Springfield, September 23. Dr. John W. Kelley was toastmaster.—Members of the Peoria County Medical Society gave a dinner at the University Club, October 7, in honor of the members of the society who served in the army during the great war.—The twenty-six medical service men of Vermillion County were honored by a banquet given by the Vermillion County Medical Society, in Danville. Dr. Jasper M. James, Henning, president of the society, presided as toastmaster.

**Recent Developments in Tuberculosis Campaign.**—Appropriations and tax levies totaling considerably more than \$1,000,000, to be used exclusively in tuberculosis work, were made by the boards of supervisors in thirty-two counties in September. In four of these counties tuberculosis sanatoriums are either in operation or well under construction. The funds provided in September will assure the building of fifteen additional sanatoriums next spring. In the remaining counties where the appropriation was not sufficient to provide funds for building next year, the money will be used to finance community nursing service, to operate free tuberculosis clinics and dispensaries and to lay the ground work for sanatoriums to be constructed in 1921. This activity by the various county boards is the result of a far reaching educational, publicity and health promotion campaign conducted by the Illinois Tuberculosis Association and its several local societies. The appropriations and tax levies referred to above are made under the provisions of the county tuberculosis sanatorium law which makes it compulsory on county boards to levy taxes for tuberculosis work whenever the proposal has been carried at a general county election. Among the many noteworthy sections of this law is that which completely removes the tuberculosis campaign from any vestige of pauper relief. The personnel of the board in charge of the funds must have no connection with the management of the almshouse or the county farm and the sanatoriums constructed by the board must be entirely distinct and separate in every way from any institution dealing with indigent cases. It is the spirit of the law that the sanatoriums, clinics and nursing service financed through funds thus provided by taxation following a popular referendum, shall be for the free use of all the tuberculous people of the county in the same way that the public schools, the police and fire departments and the public libraries are for the free use of all the people.

#### MARYLAND

**Personal.**—Harry B. Gantt, Capt., M. C., U. S. Army, Millersville, who for the last two years has been serving on the staff of the Tooting Military Hospital in London, has been transferred to Germany for special duty at Evacuation Hospital No. 27, Coblenz.—George Walker, Col., M. C., U. S. Army, Baltimore, who went to France with the Johns Hopkins Hospital Unit and was placed in charge of sanitation and venereal disease problems at debarkation ports, and who, since the signing of the armistice, has been in England engaged in similar work, has returned home on leave.

**Six Months' Record of Presbyterian Dispensary.**—With a total of 13,308 admissions to the dispensary for the first six months of this year the semiannual report of the activities at the Presbyterian Eye, Ear and Throat Hospital, just made public, reveals a splendid growth in the important work of the East Baltimore institution. During the first six months of the year alone nearly as many patients were treated for all ailments as during 1918, when a total of 15,345 were admitted. Of that number 850 were assigned to beds, where they spent an aggregate of 1,857 days. The unusual number of 4,703 new cases applied for treatment.

**Quarantine Lease Approved.**—The treasury department has approved the new lease with Baltimore city for the quaran-

time station and its continued operation by the U. S. Public Health Service. The secretary of the treasury also renews the agreement on the part of the government to buy the station and its equipment for \$177,000 as soon as Congress makes the appropriation. Under the terms of the new lease the government is to send to the city for persons having smallpox or other maritime quarantinelike diseases and to treat them at a cost of \$1 a patient per day. For the use of the station and grounds, the government will pay the city the nominal rent of \$1 a year during the life of the lease.

**Conference on Tuberculosis.**—Militancy in the state fight against tuberculosis was the keynote of an all-day conference for better health in Maryland held in Baltimore under the auspices of the Maryland Tuberculosis Association during the past week. This meeting formally launched the Red Cross Christmas Seal campaign. Sir Arthur Newsholme, resident lecturer on public health administration in the School of Hygiene and Public Health, was the principal speaker and favored the adoption of the militancy in gaining the attention of the public and the legislators to this campaign for the public health. Dr. William H. Welch also addressed the conference and emphasized the facts that Maryland has always been a leader in the fight against tuberculosis; that the first meeting of the National Tuberculosis Association was held here; that the first tuberculosis exhibit was held here under Dr. Fulton's direction; that the Maryland Association was the first to engage a tuberculosis nurse, which was the beginning of the public health nurse of today, and that Maryland was a leader in institutional segregation of tuberculous patients. At the morning session, Dr. Martin F. Sloan, Baltimore, superintendent of Endowment Sanitarium, startled the conference with the statement that perhaps 27 per cent. of the new cases of tuberculosis developed from influenza and that influenza at the present time was perhaps the greatest single predisposing cause of tuberculosis.

#### MASSACHUSETTS

**The Study of Influenza.**—The establishment of a fund of \$50,000 by a corporation, which suffered heavy losses as a result of the epidemic last year, is responsible for the research work at Harvard University Medical School to prevent the recurrence of the disease. The greater portion of the fund will be used by Milton Joseph Rosenau, professor of preventive medicine and hygiene, and his assistants in research work as to the cause, prevention and complications of the disease.

**Hospital to Open.**—The Brooks Cubicle Hospital, Brookline, a temporary structure with ten cubicles, and named in honor of Dr. William A. Brooks, surgeon general of Massachusetts, who was one of the leaders in last year's fight against influenza, was opened, October 6. The hospital is intended primarily for pneumonia patients, but will be used for influenza patients if necessity arises and will be headquarters for antiinfluenza work throughout the state. Dr. Thomas M. Durrell, Somerville, is chief of the medical staff.

**Hugh Cabot to Leave Boston.**—Dr. Hugh Cabot, Boston, at present clinical professor of genito-urinary diseases in Harvard University School of Medicine, chief surgeon of the surgical service at Massachusetts General Hospital and director of clinics of the state board of health, who went to England in 1916, with the Harvard Unit and commanded General Hospital No. 22, British E. F., with rank of lieutenant-colonel, and was made Companion of the Order of St. Michael and St. George, has been appointed chief surgeon at the University of Michigan, Ann Arbor, and will take up his new duties early next year.

**Personal.**—Dr. Ernest L. Hunt has been appointed director of surgical service and Dr. Edward B. Bigelow, director of medical services at the Worcester Hospital, and will give their entire time to the service of the hospital.—Dr. Henry A. Christian, Boston, Hesse professor of the theory and practice of physics in the Harvard University Medical School, and physician in chief of the Peter Bent Brigham Hospital, has been granted leave of absence to serve for a year in Washington, D. C. as chairman of the division of medical science, National Research Council, and began this work, October 1.—Dr. Isaac Alczar, Roxbury, Boston, has returned after sixteen months' service in Palestine as eye, ear, nose and throat specialist with the American 7th Airborne Unit for Palestine, working under the British Expeditionary Forces.—Dr. Thomas F. Kenney has been appointed chief medical inspector of the public schools of Worcester.—Dr.

Nathaniel P. Freed, Lynn, has been appointed medical examiner (coroner) for the Ninth Essex District to take the place of Dr. J. Armand Bedard, who has resigned to take up Red Cross work in France.—Dr. Joseph B. Howe has been appointed associate medical examiner (coroner) for the Second Berkshire District to succeed Dr. John Flynn, Boston, whose term has expired.—Dr. Joel E. Goldthwaite, who was in charge of the Development Battalion of the Twenty-Sixth Division, was presented with the Distinguished Service Medal by Major-General Clarence R. Edwards, September 20. The citation read, "The award is made for special work in organizing the development section in France."

#### MICHIGAN

**Statistician Dead.**—Herman F. Boldt, Detroit, since 1893, statistician of the local board of health, aged 63, died at French Lick, Ind., September 13.

**Personal.**—Dr. James H. Wellings, after more than thirty years of practice in Lansing, has moved to Hollywood, Calif., where he purchased a winter home some time ago.—Dr. Albert H. Garvin has been appointed head of the new tuberculosis sanatorium for Detroit, which is under construction at Northville.

#### MINNESOTA

**Southern Minnesota Medical Meeting.**—The annual meeting of the Southern Minnesota Medical Association will be held in Mankato, December 1 and 2, under the presidency of Dr. Henry W. Meyerding, Rochester.

**Physicians Plan Sanatorium.**—At a meeting of the Range Medical Association held at Virginia, September 5, the chief subject of discussion was the establishment of the proposed sanatorium for St. Louis County, which it is expected will be erected on the range.

**Personal.**—Dr. John E. Soper, Minneapolis, has been elected chairman of the Theodore Peterson Post of the American Legion.—Dr. Brent V. Bates, Wheaton, has received the Distinguished Service Cross, which was awarded for unusual bravery while under fire, in October last. Captain Bates and a number of volunteer stretcher bearers had been ordered to fall back on account of heavy fire, but remained, and evacuated all the wounded safely before daylight.

**Dreyer Lectures in Medicine.**—A special series of three lectures will be given at the Institute of Anatomy, Minneapolis, by Dr. Georges Dreyer, professor of pathology, Oxford University, at 4 p. m., October 8, 9 and 10. The subjects of the lectures are:

October 8, "Some General Principles in Mathematics and Their Application to Medicine."

October 9, "Their Principles in the Study of Respiration and Circulation."

October 10, "Their Relation to Metabolism in Health and Disease."

#### NEW YORK

**Typhoid on Long Island.**—An epidemic of typhoid fever is reported in Port Jefferson and vicinity, where twenty cases are reported, with thus far, one death.

**New York State's Potential Loss in Population.**—In a statement issued, October 2, Dr. Hermann M. Biggs, state commissioner of health, estimates that the state has sustained a loss of approximately 90,000 population in the past eighteen months, which is attributable to the influenza epidemic and the decline in the birth rate. The marked decline in the birth rate is due partly to war conditions and partly to the influenza epidemic, and the loss due to this cause is placed at 36,000. There was an excess mortality of 51,000 due to the influenza epidemic, which would bring the total loss to nearly 90,000. The birth rates for July and August were 18.7 and 18.8, respectively, the lowest since reliable data have been available. The death rate for July and August was likewise the lowest on record.

#### New York City

**Harvey Society Lectures.**—The first lecture of the Harvey Society series will be delivered at the New York Academy of Medicine, October 18, at 8:30 p. m., by Lieut.-Col. Georges Dreyer, M.D., professor of general pathology in Oxford University, on "Biological Standards and Their Application to Medicine."

**Women Physicians at Academy of Medicine.**—The delegates to the International Conference of Women Physicians

now in session in this city were the guests of the Women's Medical Association of New York City at the Academy of Medicine, the evening of October 1. Dr. Emily Dunning Barringer, president of the association, presided. The guests were welcomed by Dr. George David Stewart.

**Personal.**—Col. Fred H. Albee sailed on the *Mauretania*, October 2, as official representative of the Medical Corps of the U. S. Army to the Interallied Congress in Rome. He expects to return about November 1.—Dr. George W. Jean has located in Santa Barbara, Calif.—Dr. John C. Murphy, for several years visiting gynecologist to St. Johns and the St. Louis city hospitals, has been released from military service.

**Plan to Enlarge Beth Moses Hospital.**—The Beth Moses Hospital at Stuyvesant Avenue and Hart Street, Brooklyn, which will be completed by Jan. 1, 1920, now plans to erect another wing which will provide an additional 150 beds. Up to the present time \$300,000 has been expended on the hospital and another \$150,000 will be needed before the hospital is opened. A campaign to raise this sum was begun, October 1. Dr. Isaac Levin is president of the hospital.

**Health Department Favors Daylight Saving.**—At a hearing held before the board of aldermen, October 3, regarding the proposed daylight saving ordinance, Health Commissioner Royal S. Copeland headed a delegation that advocated the passage of the measure. In his arguments in support of the ordinance he said he represented the 700,000 poor children of the tenements and that this additional hour of sunlight is a great benefit to them. He expressed the opinion that the benefits accruing to public health are alone sufficient ground for the passage of the ordinance.

**Women's Motor Corps Will Assist Health Department.**—Dr. Royal S. Copeland, health commissioner, announces that Col. Helen Bastedo, commander of the Motor Corps of America, has placed at the disposal of the health department the entire transport service of her organization. Dr. Copeland states that the services rendered by the Motor Corps throughout the epidemic of influenza last year in conveying doctors, nurses, invalids, and food supplies was a great help, and that the services of the organization will be utilized in a similar way in the event of an epidemic this year. The facilities that have been made immediately available will be used for the transportation of drug patients to the narcotic hospital on North Brothers' Island.

**Diseases Under Investigation at the Rockefeller Institute.**—The Hospital of the Rockefeller Institute for Medical Research confines its work to selected cases that bear on a limited number of subjects chosen for investigation. In line with this policy a bulletin has been issued stating that during the autumn and winter the diseases that will be the subject of special study are as follows:

1. Acute lobar pneumonia and other acute pulmonary infections, influenza, bronchitis, bronchopneumonia, etc. 2. Cardiac disease, especially the more advanced stages of heart failure. Patients showing completely irregular pulse and suffering from fibrillation of the auricles are especially desired. 3. Acute rheumatic fever, patients with acute polyarthritis and children with recurring endocarditis, pericarditis, and myocarditis of supposed rheumatic origin, and those with chorea, polyarthritis and acute cardiac complications. 4. Nephritis. It is desired to admit patients with acute nephritis and young persons or those in early adult life suffering from chronic nephritis of only moderately severe grade. Physicians desiring to send such patients should communicate with the resident physician.

**Institutional Treatment of Drug Addiction.**—The *Weekly Bulletin* of the department of health of October 4 reports that, though the department's Riverside Hospital in which drug addicts are being treated, has been in operation for only a month, its methods have been attended with marked success. The capacity of the hospital is 323 men and 100 women. To date, more than 500 of these patients have been taken entirely off the drug to which they have been habituated and more than 200 of these, apparently cured, have been discharged to their homes. The treatment consists of elimination and reduction of the drug on admission to from 1½ to 3 grams a day. Morphine is used in the hospital irrespective of the drug to which the patient is habituated. At the end of four or five days scopolamine anesthesia is produced by hypodermic administration, and the patient then taken entirely off his drug, which in more than 99 per cent. of the cases treated has been heroin. The report states that the striking result of the treatment is the demonstration of the rapidity with which the drug may be withdrawn entirely, without disturbance of the patient's well-being and without producing nervous manifestations.

OHIO

**Dr. Holmes to Retire from Practice.**—Dr. Christian R. Holmes, dean of the Medical College of the University of Cincinnati, who is now under treatment in a hospital in New York City, has announced his intention of retiring from practice and will devote his entire time to the work of the college.

**Personal.**—Dr. Otto T. Behrer, Dayton, has been appointed city chemist by the Cincinnati Board of Health, succeeding Dr. E. M. Meyer, retired.—Dr. John McCartney, Girard, the oldest medical practitioner of Trumbull County, was given a surprise party at his home, September 25, in honor of his eightieth birthday anniversary.

**Hospitals Registered in Ohio.**—Registration blanks are now being sent out to all hospitals and dispensaries in the state, asking for details as to number of beds available, kind of cases taken, etc. A bill passed at the last general session of the Ohio legislature requires that this information shall be collected and collated by the state department of health. Maternity hospitals have been registered and licensed in Ohio for a number of years, but this is the first time that full information has been sought concerning the number and kind of hospitals and dispensaries operating in the state.

**District Society Meeting.**—At the annual meeting of the Second Councilor District Medical Association at Dayton, September 25, Dr. Harrie B. Martin, Springfield, was elected president; Dr. Elmer R. Arn, Dayton, secretary, and Dr. Herbert C. Hanning, Dayton, treasurer. A course of graduate instruction under the direction of medical teachers of national repute was conducted under the auspices of the Councilor District Society, September 22 to 26. This course was made available to the 500 physicians practicing in the eight counties included within the district.

**Trachoma Clinic in Portsmouth.**—Surg. John McMullen of the United States Public Health Service is holding a very successful trachoma clinic in Portsmouth. A survey of all the schoolchildren is being made by Drs. Joseph L. Goodwin and Ross Hopkins of the Public Health Service and state department of health, respectively. So far, among Portsmouth schoolchildren less than 1 per cent. have been found to have trachoma, while in the rural schools the percentage has reached 3. More than forty patients were present the first day of the clinic, and the attendance has continued high. This is the second trachoma clinic to be held in Ohio; the first was held at Waverly in Pike County two years ago. There is now evidence that some of the river counties in Ohio are just as much affected by trachoma as are counties in Kentucky, and the Ohio State Department of Health is planning a campaign of detection, education and prevention.

**Public Health Organization in Ohio.**—The counties in Ohio are organizing rapidly under the Hughes Act, a bill passed by the last general session of the Ohio legislature. Each county will be known as a general health district and will have a full-time health commissioner, public health nurse and clerk. Each city having a population of 25,000 at the last federal census will be known as a municipal health district. The mayors of municipalities and presidents of township trustees of a county constitute the district advisory council which appoints a board of health of five members, two of whom shall be physicians, one a lawyer, one a farmer, and the fifth not specified. So far, eighty-four of the eighty-eight counties have organized and appointed a board of health, and in thirty-eight counties the board of health has organized and made a budget. All of the budgets so far reported call for a larger organization than the minimum prescribed by the Hughes Act. The demand for public health nurses is especially large, many counties asking for six or seven. The salaries apportioned for health commissioners are adequate, and experienced men should be secured. These are appointed from civil service lists of candidates examined by the state civil service commission. In only one county has there been definite opposition to the Hughes Act, and provision is made for the state health commissioner to appoint a board of health when the local authorities fail or refuse.

PENNSYLVANIA

**New Society Organized.** The physicians of the Allentown and Eastern hospitals and St. Luke's Hospital, Bethlehem, have organized a clinical society with Dr. Edgar M. Green, Easton, president, and Dr. William L. Estes, Jr., South Bethlehem, secretary and treasurer.

**Hospital Notes.**—The State Hospital, Nanticoke, has received thus far \$40,000 in its drive for \$75,000 for the erec-

tion of the nurses' home.—The Fountain Springs State Hospital raised \$4,000 in one day for the equipment of a new ward.—The people of Pottsville are contemplating the erection of an addition to the home for nurses to cost \$60,000.—Trustees of the State Hospital, Hazleton, are planning to build a nurses' home to cost \$75,000, of which \$25,000 has been given by the state.

**Hospitals Attack Suit Against State Aid.**—September 30, thirty-six attorneys representing hospitals and homes from all parts of the state appeared before Judge Kunkel and Judge McCarrell of the Dauphin County Court at the hearing on the suit instituted to prevent the state from paying funds to sixty-six institutions to which the last legislature voted appropriations. The suit seeks to restrain the state from paying out its funds to the various institutions named, all of which are sectarian, was filed by Willis Collins of Delaware County, representing the antisectarian appropriation association. About \$2,000,000 is involved.

**Personal.**—Dr. Walter Lathrop, surgeon-in-chief of the Hazleton State Hospital, who has been ill for three months and has undergone several surgical operations, has gone to the seashore for recuperation, and the work of the institution is in charge of Dr. Robert A. Ganghan, assistant surgeon.—Dr. Edgar B. Doolittle, Hazleton, who has been seriously ill at his home, is reported to be improving.—Dr. William D. Cleland, Harlansburg, who moved recently to New Castle, has been appointed medical director of the New Castle public schools.—Drs. Calvin L. Johnstonbaugh, Bethlehem, and Irvin D. Metzger, Pittsburgh, have been appointed members of the state bureau of medical education and licensure.—Dr. Lyndon H. Landon, formerly surgeon to the Carnegie Steel Company and more recently connected with Base Hospital No. 115 at Vichy, France, has been elected general and neurologic surgeon on the staff of the Western Pennsylvania Hospital, Pittsburgh.—Dr. Davenport Hooker has been appointed head of the Pittsburgh School of Anatomy and professor of anatomy in the University of Pittsburgh.—Dr. Harry G. Clarke, Pittsburgh, has been appointed superintendent and medical director of the City Poor Farm, Mayview.

PHILADELPHIA

**Nurses to Go to China.**—After serving fifteen months overseas with the Jefferson Hospital Unit, three Philadelphia nurses will leave, October 10, for duty in the Shanghai Hospital.

**Course in Public Health Nursing.**—The Visiting Nurse Society has offered a two months' course in public health nursing to pupil nurses of the hospitals of Philadelphia. Eleven pupil nurses from various city hospitals have already applied. This course is only open to pupil nurses during their last year of hospital training, and should these nurses desire to take up a postgraduate course at the Pennsylvania School of Social Service on their graduation from the hospital, they will be given credit for the work done while attending class at the Visiting Nurses' Society.

**Personal.**—Dr. J. Thompson Schell, chief surgeon of the Northwestern Hospital, sailed for London, October 2.—Dr. Charles K. Mills, chief of staff at the Philadelphia General Hospital and founder of the neurologic department of that institution, has resigned after forty-two years' service. Dr. Mills will continue as consultant to the neurologic department.—Dr. James W. McConnell, head of the neurologic department at the University of Pennsylvania and for many years connected with the Philadelphia General Hospital, has been appointed to succeed Dr. Charles K. Mills.—Dr. Eugene J. Ansis, professor of pathology and bacteriology in the school of medicine at Temple University, delivered the introductory address, October 2, to the students of the department of medicine, dentistry and pharmacy of that institution in the college building, Eighteenth and Buttonwood streets. Dr. Ansis has just returned from overseas service. He was professor of pathology and bacteriology in Baltimore, at the American University for the expeditionary forces.

CANADA

**Personal.**—Dr. Norman K. Wilson has returned from overseas and resumed practice in Toronto confining his work to diseases of the nose and throat.—Dr. Edwin C. Beer, Brandon, Man., lately medical officer to the Royal Flying Corps, has commenced practice in Toronto.

**University News.**—There are more than 400 entrants in medicine in the University of Toronto. The total registration to date in McGill University, Montreal, is more than

200 in all faculties.—Drs. Henry T. Machell, Allan M. Barnes, Geoffrey Boyd, and others have resigned from the teaching staff of the department of medicine of the University of Toronto.

**Hospital Items.**—General Mewburn, minister of militia for Canada, announced in the House of Commons, recently, that that total number of Canadian hospital patients still overseas was 126; he also announced that there were still 6,598 hospital patients in the military hospitals throughout Canada.

—Dr. Duncan A. L. Graham, the newly appointed professor of medicine in the University of Toronto, has been appointed chief physician to the Toronto General Hospital; Dr. John A. Ollie is to have charge of the heart clinic; Dr. Fred W. Rolph of the gastro-intestinal department; Dr. Galdwin W. Howland of nervous diseases; Drs. George S. Young and George S. Strathy of general medicine; Dr. Harold C. Parsons of tuberculosis; Dr. Charles K. Clarke of the psychiatric department; Dr. Robert D. Rudolf of therapeutics, and Dr. William Goldie in charge of indoor patients' ward. No surgical appointments have yet been announced.

#### GENERAL

**Warning.**—It is reported that a man representing himself as a physician is making the rounds of physicians' offices in the East, with an electrical diagnostic set on which he collects a deposit, promising delivery in five days. The delivery is not made. He claims to come from Springfield, Mass., and is said to be wanted by the police.

**Medical Periodicals Delayed by Strike.**—The medical periodicals published in New York City have not appeared for the week of October 4 on account of the strike of certain organizations of printers and employees which have tied up completely the offices in which they are employed. It is expected that 152 weekly periodicals published in New York City will fail to come out this week.

**Relief of Civilian Employees.**—A bill providing that civilian employees of the federal government suffering with tuberculosis shall be admitted to the hospitals of the Army, Navy and U. S. Public Health Service has been reported by the Senate Committee on Public Health and Quarantine with the recommendation that it pass. It was introduced by Senator Morris Sheppard of Texas, and has the indorsement of the U. S. Public Health Service.

**Gynecologists Organize World Body.**—At the conference of gynecologists held in Brussels, Belgium, the last week in September, the International Association of Gynecologists and Obstetricians was organized, and it was decided to hold the first meeting in America, 1922. The following officers were nominated: president, Dr. Franklin H. Martin, Chicago; secretary-general, Dr. Frank F. Simpson, Pittsburgh; counselors, Drs. J. Riddle Goffe, New York, Thomas J. Watkins, Chicago, and George Gray Ward, Jr., New York.

**American Public Health Association Meeting.**—The American Public Health Association will hold its forty-eighth annual meeting in New Orleans, October 27 to 30. Committees of specialists have been organized to answer questions and give advice on milk supply, influenza, public health nursing, tuberculosis, health legislation, water supply, industrial hygiene, child hygiene, malaria, personal hygiene, etc. An important part of the program will be the papers and discussions on the coordination and enlargement of federal health activities.

**Tuberculosis Foes Meet.**—At the meeting of the Mississippi Valley Conference on Tuberculosis, held in Des Moines, Iowa, September 22 to 24, under the presidency of Sherman Kingsley, Cleveland, the following officers were elected: president, Dr. John H. Peck, Des Moines, Iowa; vice president, W. McM. Miller, St. Louis; secretary, Dr. Arthur T. Laird, Duluth, Minn., and counselors, Sherman Kingsley, Cleveland; Dr. James W. Pettit, Ottawa, Ill.; Dr. Ethan A. Gray, Chicago; R. J. Reed, Des Moines, Iowa (re-elected); Dr. Eugene B. Pierce, Howell, Mich.; Dr. Alfred Henry, Indianapolis, and Mrs. P. Wanzel, Armour, S. D.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

Methodist Hospital, Philadelphia, \$1,000, by the will of Louise M. Pepper.

St. Vincent's Hospital, New York, \$5,000; New York Foundling Hospital, \$1,000; Columbus Hospital, St. Elizabeth's Home for Crippled Children, St. Ann's Convalescent Hospital, New York Institute for Blind, Home of Rest for Consumptives, and New York Skin and Cancer Hospital, each \$500, by the will of Margaret A. Howard.

Presbyterian Hospital, New York, \$200,000, and Sloan Maternity Hospital, \$80,000, by the will of General Horace W. Carpenter.

Presbyterian Hospital, New York, \$2,000, by the will of Miss Mary M. Roberts.

**Clinical Congress to Meet.**—The ninth annual meeting of the Clinical Congress of the American College of Surgeons will be held in New York, October 20 to 24, under the presidency of Dr. William J. Mayo, Rochester, Minn. The program includes papers by Sir Anthony Bowlby, London, on "Fractures of the Femur"; Harvey Cushing, Boston, on "Brain Tumor Statistics"; Alexis V. Moschowitz, New York, on "Empyema, with Particular Reference to Its Pathogenesis and Treatment"; George W. Crile, Cleveland, on "Surgical Treatment of Exophthalmic Goiter"; Sir Robert Jones, Liverpool, England, on "Stiff and Flail Joints"; Otto P. Geier, Cincinnati, on "The Physician and Surgeon in the Industrial Era"; Dr. John B. Deaver, Philadelphia, on "The Acute Abdomen"; Major Gillies, R. A. M. C., Sidcup, England, on "Plastic Operations for Facial Burns," and C. Jeff. Miller, New Orleans, on "Radiotherapeutic and Other Methods for Treatment of Cancer of the Uterus."

**Investigation and Prevention of Influenza.**—The Senate Committee on Public Health and National Quarantine has made a favorable report to the senate on a measure introduced by Senator Warren G. Harding of Ohio for the investigation and prevention of influenza and similar diseases. The committee has recommended that the appropriation for this work be \$1,000,000 instead of \$5,000,000 as provided in the measure as introduced. The committee also adopted an amendment providing "that any allotment of funds to universities, colleges or other suitable research institutions shall not be limited to any one school of medicine." The work is to be carried on under the supervision of the U. S. Public Health Service. The medical departments of the Army and Navy are authorized to cooperate in the work of "investigating influenza and allied diseases, in order to prevent their causes and prevent their spread." The secretary of the treasury is authorized to expend a part of the money appropriated for research work on this subject in such research institutions as are qualified. The measure is now on the senate calendar for consideration and may be called up for action at any time.

**Prevention and Control of Drug Addiction.**—A bill to provide aid from the United States government for the several states in the prevention and control of drug addiction and the care and treatment of drug addicts has been reported favorably by the Senate Committee on Public Health and National Quarantine. The measure as amended by the committee appropriates a sum of \$3,000,000 for the fiscal year ending June 30, 1920, and \$2,000,000 for the year ending June 30, 1921, to be available for the various states when they have raised an amount equal to that requested of the federal government. The expenditure of 10 per cent. of the annual appropriation is authorized to collect and spread information in regard to the care and treatment of drug addicts and for administration purposes. The bill has the indorsement of Secretary of the Treasury Carter Glass who has said that "it will meet what must be regarded as a critically serious situation developing out of enforcement of amendments to the Harrison Narcotic Act." The war and navy departments are authorized to transfer temporarily hospital buildings and equipment for the care and treatment of drug addicts. The various state boards of health or narcotic commissions are expected to cooperate with the U. S. Public Health Service in taking advantage of the provisions of the measure. It may be called up for action by the senate whenever the senate is considering general legislation. The bill was introduced by Senator Joseph I. France of Maryland, chairman of the Senate Committee on Public Health and Quarantine, by which committee it was reported favorably.

#### FOREIGN

**Nurses Win Greek Decorations.**—Eight nurses of the American Red Cross have been decorated by King Alexander of Greece with the Medal of Military Merit for their work in fighting the typhus epidemic in Macedonia.

**Mobile Hospital Functioning in Roumania.**—The autochir, the mobile hospital purchased by the American Red Cross for the American E. F., at a cost of \$400,000, has been sent to Roumania. It was intended for France, but the signing of the armistice ended the need there, and when Queen Maria of Roumania appealed for help from the Red Cross, it was decided to send it to the aid of that diseased and impoverished nation. The hospital was sent by ship from America

to Bologna, Italy, and thence on its own wheels to Bucharest under the care of Col. George de Tarnowsky of the American army. The autochir consists of a roentgen-ray truck, an electrogenic group with accessory parts, a heating plant, a rolling machine-shop, an electric lighting plant, an operating room with plate glass cabinets containing every known surgical instrument, ambulance trucks containing beds for twenty patients, four ambulances capable of accommodating six severely wounded or twelve slightly wounded men, tent hospital trucks, an acetylene truck for lighting the hospital, store-room trucks with large supplies of blankets, cots, sheets, dressings and drugs. There is also a large truck which contains sleeping rooms for physicians, nurses and interns. Eighteen huge trucks resembling American moving vans constitute the complete hospital. It has moved up near the Roumanian army, where it is functioning with speed and efficiency.

**Hospitals in Siberia.**—Col. R. B. Teusler, Red Cross commissioner to Siberia, has recently reported on the American Red Cross hospitals in that country.—In response to the dire need caused by the epidemics of typhus, cholera and pneumonia, a new hospital was established at Irkutsk.—There is a 100 bed hospital in Tchilyabinsk in the Ural Mountains, which was opened by the American Red Cross and later became an important base hospital for the all-Russian government.—At Omsk, the capital of the Kolechak government, a 1,000-bed hospital is being operated, and at Petropavlovsk a typhus hospital was equipped and given to the government.—There is a 200-bed hospital at Tomsk, given to the government by the University Clinic and operated by the Red Cross.—At the request of the mayor of Novonikolaevsk, the Red Cross opened a hospital in the Commercial Club of that city, which operated during the typhus epidemic.—Important work in the extermination of contagious diseases was done by the Red Cross workers at Siberian railway stations. Delousing plants, disinfecting apparatus and clothing dispensaries were conducted.—An antityphus train traveled over more than 4,000 miles in Siberia to stop the spread of typhus, and is now being operated under direction of the same American Red Cross workers on the Perm front. The expense of this train was at first assumed by Allied sanitary commissions and was managed by the American Red Cross, which now has assumed the entire responsibility of the train.—At the request of the Czecho-Slovak national council, work was started by the Red Cross in eastern Siberia. A commission consisting of twenty-five physicians and thirty-five nurses was sent at once to that portion of the country. This group has since been augmented, and a large staff is now at work among the Siberian population.

**LATIN AMERICA**

**Election of Officers.**—The Medical Society of Valparaiso, Chile, has elected the following officers: president, Dr. Vicente Dagnino; vice president, Dr. Guillermo Munnich; secretary, Dr. Gastón Lachaise, and treasurer, Dr. Miguel Manriquez.

**Child Hygiene in Peru.**—Under the title "Asociación protectora de la Infancia" there has been formed at Lima, Peru, a child hygiene association. Its officers include the following: president, Dr. R. Neuhans; vice president, Dr. Oscar Miro Quesada; secretary, Dr. Carlos Enrique Paz Soldán, and treasurer, Mr. Carlos D'Almeida Argote.

**Anniversary of the Medical Society of Santiago de Chile.**—The Medical Society of Santiago, Chile, celebrated last September the fiftieth anniversary of its foundation. In connection with the celebration there was published a special number of the *Revista Médica de Chile* which is the organ of the society. The officers of the society for the year 1920 are as follows: president, Dr. Germán Valenzuela B.; vice president, Dr. Luis Vargas Salcedo; secretaries, Dr. Hugo Lea Plaza and Dr. Engenio Cienfuegos, and treasurer, Dr. Juan D. Montenegro.

**Typhus Fever in Chile.**—According to a statement published by the Department of Interior of Chile, there were admitted to the hospitals at Santiago, Chile, from October, 1918, to June 30, 1919, 4,235 cases of typhus fever of which 852 died. During the first fifteen days of July there were 190 cases admitted with thirty-three deaths. During the first six months of the year 1919 the general mortality at Santiago was 9,993 exceeding by 2,249 the number of deaths for the same period in 1918. This increase is due to the present epidemic of typhus fever. The data collected by the Department of Public Health show that the disease has been endemic in Chile for the last thirty years.

**CORRECTION**

**Error in Article on Extra-Uterine Pregnancy.**—In the article by Dr. Alfred C. Beck, Brooklyn (*THE JOURNAL*, September 27, p. 963), the legends of Charts 2 and 3 are reversed. That which appears under Chart 2 should accompany Chart 3, and vice versa.

**Government Services**

**Personnel of the Army Medical Corps**

On Oct. 3, 1919, the Medical Corps contained 4,837 medical officers, a decrease from the previous week of 459. The Reserve Corps contained 3,509 officers. The total number of officers discharged since the beginning of the war is 27,622.

**Foreign Correspondence**

**RIO DE JANEIRO LETTER**

RIO DE JANEIRO, Aug. 30, 1919.

**Statistics of Influenza**

The public health department recently published the full statistics of the epidemic of influenza which swept over Rio de Janeiro in October, 1918. That month, 11,458 deaths occurred in Rio; 6,344 males and 5,144 females; 990 persons from 0 to 1 year old; 752; from 1 to 2 years; 1,159 from 2 to 5 years; 877 from 5 to 15 years, and 7,473 over 15 years. The average death rate was 3.69 per cent. The first cases occurred in the beginning of the month, and by October 12, ten deaths had been reported. The epidemic spread rapidly over the city. Nine hundred and thirty deaths were registered ten days later, after which date the death rate declined, 753 on the 23d, 729 on the 24th, 621 on the 26th, etc., altogether 8,817 in twenty days. The epidemic was not considered past till the middle of November. Up to the middle of November there were still many deaths, after which time the epidemic was considered extinct.

**Brazilian Physician Honored with an Invitation by the President of Bolivia**

Dr. McDowell of Rio de Janeiro, whose works on beriberi, yellow fever, hookworm disease, spirochetosis, ieterohemorrhagic, etc., are well known in both domestic and foreign medical circles, has received an invitation from the Bolivian government to give a series of lectures on tropical diseases.

**New Professor in the Medical School**

Dr. Rocha Vaz was chosen professor in the medical school in the place of the late Miguel Pereira. Thirteen members of the congregation voted for him; five for Dr. MacDowell; four for Dr. Clark, and one for Dr. Romeiro.

**Rural Prophylaxis**

The secretary of the interior has given instructions establishing seventeen posts for the suburbs of Rio de Janeiro,

order to fight hookworm and malaria. All are under the direction of a sanitary inspector who in his turn is subordinate to the head inspector. Once more we are obliged to call attention to the fact that the director of public health has no authority over this service.

#### Absence of Yellow Fever

Since the last letter, no new case of yellow fever has been reported throughout Brazil.

#### Reorganization of the Public Health Department

The commission appointed to elaborate the sanitary code has given its opinion in favor of creating the ministry of health. If the government does not find it convenient to pass such a bill at once, it proposes to establish the federal department of public health, consisting of four divisions: public health service of the capital, maritime and fluvial sanitary defense division, rural prophylaxis division, and public assistance and child welfare division. The president of the department, as well as the heads of the four divisions, will be appointed by the president of the republic, chosen among the prominent members of the medical profession. The commission suggested the organization of an advisory board consisting of the president of the department, the chiefs of the different divisions, the professor of hygiene in the medical school, the president of the National Academy of Medicine, the director of the medical school, and the professor of hygiene and sanitation in the school of engineers.

#### South American Trypanosomiasis

Carlos Chagas read an interesting paper in the National Academy of Medicine, calling attention to some new developments pertaining to the cardiac affection of the disease. A great number of cardiograms were exhibited. Henrique Araújo read an important paper on the same subject in the Sociedade de Medicina e Cirurgia. Araújo is of the opinion that many cases of other infectious diseases have been registered under that name. He called attention to the fact that the cases of Chagas disease with nervous symptoms, endemic goiter and idiocy do not differ greatly from similar ones discovered in other parts of the world. He proposed to add the name of Oswaldo Cruz to that of Chagas, giving it the joint name Cruz-Chagas, as he considers Oswaldo Cruz the discoverer of *Trypanosoma cruzi*. He admits the possibility that a filtrable virus is the cause of endemic goiter and idiocy. Another important item mentioned is that in many regions of southern Brazil and of the Argentine Republic infected triatomas (the transmitters of the disease) have been found in large quantities without one case of the disease having been reported. He does not consider the infection as an endemic of sufficient importance to be combated. *Trypanosoma cruzi* has not been found in more than forty cases within the last ten years.

Vasconcellos stated at the next meeting of the society that Clementino Fraga and Gonçalo Muniz in Bahia, Carini in São Paulo, Kraus, Maggio and Rosenbusch in Buenos Aires had observed that in many regions of Brazil and in Argentina, where infected triatomas were found, no case of Chagas disease has been observed. He called attention to the fact that since 1909, when the first case was verified, up to date, only twenty-nine cases with *Trypanosoma cruzi* in peripheral blood had been declared. Although Chagas affirms that *Trypanosoma* causes anemia, Ezequiel Dias of the Oswaldo Cruz Institute, found that male patients with Chagas disease have 5,725,000 erythrocytes, females 4,925,000, and children 5,027,000 in cubic millimeter.

#### MEXICO LETTER

MEXICO, Sept. 28, 1919.

##### Legislative Matters

There will soon come up in congress for action the bill for the enforcement of Article 4 of the constitution, relative to the practice of professions. This bill requires, as expected, that in order to practice law, medicine, obstetrics or pharmacy in Mexico it is necessary to possess a degree granted after passing an examination in certain studies either at the National University or the universities of the different states. Foreign degrees will have to be submitted for registration when reciprocity has been established with the country in which they were obtained, while, so far as other countries are concerned, it will be necessary for the applicant to submit to an examination. Persons who do not comply with these requisites will be punished according to the provisions of

the criminal code, and finally no person will be authorized to practice his profession unless he agrees to observe and make others observe the provisions of the constitution of 1917. There are some who criticize this new bill; but despite its defects, it should be approved as soon as possible to stop the many abuses of quacks (foreigners in the majority) who find their victims chiefly among the lower classes of the population and who enrich themselves through their brazen system of advertising and the boldness with which they practice medicine when they hardly know its most elementary principles.

Since the year 1857, when the constitution of the republic was adopted, it has been impossible to obtain the enactment of a law regulating the exercise of the different professions, and as a consequence the whole country, and especially the city of Mexico, has been a paradise for quacks and especially medical quacks. As an instance we may mention the case of an individual from Central America who came sometime ago to this country, applied for examination at the school of medicine, and failed to pass, but established his office shortly afterward in one of the most central locations. Occasional instances exist in which regular physicians are also practicing quackery with good financial results; but it does not seem so easy to reach these cases through legislation.

#### Horse Meat and Donkey Meat

Because of the scarcity and the poor quality of the beef now on sale or through eagerness to make money, some people have been devoting themselves surreptitiously to the slaughter of donkeys, mules and horses. As some of these people have been caught and punished, they intend to ask the board of public health that they be allowed to open a slaughterhouse exclusively for horses. The flesh of these animals is not bad, and during hard times we have eaten it here with full knowledge of its origin, and it is known that there is in Havana a society of horsemeat eaters. I do not know anything about the quality of donkey meat.

#### New Medical Journal

The central commission for the study of tabardillo (typhus fever), which was created by a resolution of the medical congress held here to discuss this disease, has begun to publish a bulletin in which appear the most interesting articles on this disease written abroad as well as observations by physicians of this country. This publication is distributed free of charge and can be obtained by writing to the editor, Dr. José Terrés, 5/a. calle de Donceles, 115, Mexico.

#### Personal

Dr. Gregorio Mendizábal has requested to be excused indefinitely from attending the sessions of the Academy of Medicine, of which he has been a member twenty-five years. This society, in view of the high character of the applicant, decided to make him an honorary member. The same physician will celebrate, December next, the fiftieth anniversary of his entering the profession; and on that occasion his numerous friends, pupils and sympathizers intend to show him in some way the high appreciation they have for his services.—Dr. Rafael Raygadas Vértiz, the surgeon, has returned from Bern, Switzerland, where he went to represent the Mexican Red Cross.

#### LONDON LETTER

LONDON, Sept. 18, 1919.

##### Hydrogen Arsenid Poisoning in Submarines

In June, 1916, an outbreak of hydrogen arsenid poisoning in two submarines was observed. Ratings in other submarines before and since have been sometimes affected with mild symptoms, which in view of the proof furnished in these cases may well have been due to traces of this gas in the atmosphere of the boats. The first suspicion of this poisoning being present was due to an examination of the blood of three men who were sent to the laboratory of the Naval Hospital, Chatham, for evidence of carbon monoxid poisoning. They were jaundiced, and this suggested a blood count, which revealed profound anemia. A few days later, Haldane recovered hydrogen arsenid from the battery gases of the boat in question. The two submarines mentioned above did voyages of from four to eight days' duration, and were submerged an average of seventeen hours a day. In the first voyage of each boat the symptoms were not so marked, and the onset was generally delayed until the third or fourth day; and on returning to their base the crews were able to carry on duty or proceed on leave. During the second trip the

symptoms were more pronounced, and started usually on the first or second day out. The severity of the illness forced one boat to return at the end of four days. In an experimental trip of one boat, the onset of discomfort occurred in four hours; vomiting started in fourteen hours, and the boat broke surface at the eighteenth hour after diving. Twenty men out of the twenty-six on board vomited within twenty minutes of opening up the boat. The men themselves attributed their symptoms to the prevalent bad weather, in spite of the fact that many had never been seasick in their lives, or else to an evil smelling oil fuel used in all the boats. That the condition was hydrogen arsenid poisoning is proved by the symptoms not fitting in with any other condition, and by the recovery of arsenic from the urine and hair of the victims. The source of the hydrogen arsenid was at first believed to be in the sulphuric acid used in the batteries, which always contains traces of arsenic; but if so, it was peculiar that other boats had been using acid with a higher arsenic content than that supplied to the boats in question and yet had had no unpleasant experiences. The origin was ultimately traced to an alloy in the battery grids of the affected boats which contained more arsenic than that used in other submarines. The hydrogen arsenid also was found to appear in greater amounts as the batteries got older.

The two symptoms most complained of were vomiting and dyspepsia. Vomiting was the most constant and troublesome symptom. Once it had started it was continuous throughout the trip. In half the cases it was accompanied by burning and gripping abdominal pain. Dyspepsia on exertion was noticed in twenty-four of the thirty cases. It was probably due to destruction of and impairment of the oxygen-carrying power of the red corpuscles, aided perhaps by a toxic action on the heart muscles. There was no evidence of any lung damage. Constipation was rather more often complained of than diarrhoea. The color of the urine varied from brown to blood red. This was due in most cases to hemoglobinuria, methemoglobinuria, or even to whole blood. In a few of the milder cases it may have been caused by bile pigments only. Albuminuria, except in three cases, was always present after admission. It was rarely more than a trace. Casts were found on only one or two occasions. Headache was fairly constant, and in a few men it was the chief trouble, together with insomnia. Jaundice was a constant sign. All the men except four showed mild neuritic symptoms. The symptoms did not manifest themselves till four days after returning from the voyage, but took from two to three weeks to pass off. They consisted for the most part in tingling and "pins and needles" sensations in the hands and feet. The legs were prone "to go to sleep," and a few men suffered from cramps. Among various individual symptoms there were two of interest as showing the affinity of arsenic for any mucous membrane. Two men had scalding and frequent micturition, and one suffered from an irritable conjunctivitis. The final proof that arsenic was the cause of the illness was furnished by the fact that it was found in the urine, hair and nails.

#### Graduate Medical Study

The Fellowship of Medicine has undertaken to carry on its work of graduate teaching in London. Last winter a series of demonstrations and lectures were given and were so widely utilized by American, French and other physicians that a regular weekly bulletin of the hospital facilities available was published. The work is now being reorganized for the coming winter. Its value as a means of encouraging international friendship has proved great. The results have exceeded the expectations then expressed. In the coming session a great expansion of the scope of the work is anticipated. The series of special lectures given under the auspices of the Fellowship at the Royal Society of Medicine began again, September 15. The following is the program so far as it has been drawn up: Mr. W. H. Trethowan, "Feet; Mechanical Disabilities"; Mr. L. B. Rawling, "Surgery of the Skull and Brain—I"; Mr. W. H. Trethowan, "Feet; Paralytic Deformities and Disabilities"; Dr. Hutchison, "Chronic Diarrhoea: Its Varieties and Treatment"; Mr. L. B. Rawling, "Surgery of the Skull and Brain—II"; Mr. A. H. McMillen, "Some Common Disorders of the Fundus Oculi"; Dr. Eric Pritchard, "The Causation and Treatment of Rickets."

#### Lunatics and the War

A further increase in the death rate among lunatics is announced in the fifth annual report of the Lunacy and Mental Deficiency Board of Control for 1918. In the eighty asylums under review, the death rate among males was 25.2 per cent. and among females 16.4 per cent.—an increase of

3.7 per cent. in the former and 2.4 per cent. in the latter case. This steady increase caused the board much anxiety, and it referred the matter for inquiry to three commissioners, who attribute part of the increase to the effect of war conditions, such as reduced supply of food, inadequate staffs, and some degree of overcrowding. The commissioners, however, are of opinion that war conditions alone do not account for the alarming increase of sickness, and that their disappearance will not eradicate the communicable diseases (tuberculosis, dysentery and typhoid), which have obtained so strong a hold on a number of asylums; they have drawn attention to a number of matters of asylum practice and administration which have materially added to the seriousness of the situation and call for special effort toward improvement. The commissioners make a number of suggestions which are already carried out in some asylums. A further decrease is reported in the number of notified insane persons in England and Wales, the figures on Jan. 1, 1919, being 116,703, or 9,138 fewer than twelve months previously. In the three preceding years there had been decreases of 3,278, 3,159 and 8,188, respectively, as compared with an average annual increase of 2,251 for the ten years ending Dec. 31, 1919. The relative percentages of the sexes—males 42.8, females 57.2—show a continued reduction in the proportion of males.

#### Biology and the Locating of Submarines

The British Association for the Advancement of Science has resumed its annual meetings, interrupted for two years by the war. The president, Sir Charles Parsons, delivered an address on Science in War and Peace. Referring to the introduction of the binaural hydrophone for locating submarines, he pointed out that when the vessel is in motion or the sea is rough the water noises from the dragging of the instrument through the water and from the waves striking the ship drown the noises from the enemy vessels, rendering the instrument useless. The assistance of eminent biologists proved invaluable at this juncture. Experiments were made with sea lions by Sir Richard Paget, who found that they have directional hearing under water up to a speed of 6 knots. Also Arthur Keith explained the construction of the hearing organs of the whale, the ear proper being a capillary tube too small to be capable of any useful function in transmitting sound to the relatively large anal organs which are deep set in the head. The whale therefore hears by means of the sound waves transmitted through the substance of the head. It was further seen that the organs of hearing in the whale to some degree resemble the hydrophone. The course now became clear. Hollow towing bodies in the form of fish or porpoises were made of celluloid, varnished canvas, or even thin metal, and the hydrophone fixed in the center of the head. The body is filled with water, and the cable towing the "fish" contains the insulated leads to the observer on board the vessel. When towed some distance behind the chasing ships, disturbing noises are small and enemy noise can be heard up to speeds of 14 knots and at considerable distances.

#### Commissions for Medical Women in the Army

The grievance of medical women who during the war did medical work in the army but were not given commissions has already been reported. A joint deputation of the Women's Medical Federation and the British Medical Association has had before the undersecretary for war the case for giving medical women the same status and commissioned rank as given to medical men doing similar work. The deputation enumerated certain disadvantages under which the medical women worked, such as delay in pay and absence of billeting accommodation. The War Office replied that these were matters of local administration and adjustment and were not dependent on absence of commissioned rank. The complaint that the want of commissioned rank impaired the women's professional status and put them at a disadvantage in meeting commissioned medical officers was not considered valid. The fact that they belonged to the medical profession assured them the position to which they were entitled. As regards increased pay and promotion, it was held that if medical women were to enjoy the advantages from which they were excluded, they must be not only willing but also able to perform the duties of commissioned medical officers. The deputation contended that there were no such duties which could not be equally performed by commissioned women, but the medical authorities of the War Office were unanimously of opinion that there were many essential duties which could not be performed by medical women. No doubt certain duties performed by medical officers could equally well be undertaken by medical women, such as nec-

and surgical duties in hospitals, work connected with anesthetics and the roentgen ray, and the charge of laboratories. But the medical officers who perform these duties have had to undertake general service obligations and have been liable at all times for duty anywhere. To provide that commissioned medical women be engaged only on duties of which they are capable, it would be necessary to provide a special contract for special duties, which would result in immobilizing personnel and would necessitate an increase in establishments. The success of the medical organization in the war has been due in great measure to its mobility. Not only medical units but personnel had to be moved at short notice from lines of communication to battle areas, and even from one theater of war to another. During the last two years it was only thus that wastage could be met and reinforcements provided. Frequently whole hospital staffs were hurried up to front areas to meet sudden casualties and to make good the loss of whole casualty clearing hospitals or held ambulances. If the medical services had been immobilized by granting commissions for special units or areas, a serious situation would have arisen. The authorities held that there were insuperable difficulties in employing medical women in charge of regiments or other units or for duty in field ambulances. The provision of suitable accommodation would be impossible. Women would be out of place in the continual and intimate contact into which a medical officer is brought with a soldier. The command of medical field units involved leadership and discipline, and at times great strain and hardship to which women would be equal only in rare cases. They could not undertake the important duties of sanitation, which necessitate frequent visit to trenches and billets. A medical woman with no companions of her own sex could not be called on to live the life of the trenches. Medical women could not carry out venereal inspections or lecture troops on the prevention of venereal diseases. At the same time the War Office expressed deep appreciation for the valuable services rendered by medical women during a lengthened period of stress and anxiety. They filled a real need, and their untiring devotion earned the gratitude of all ranks.

The joint committee of the Women's Medical Federation and the British Medical Association made the following rejoinder: The reply that belonging to the medical profession assures women the position to which they are entitled is not valid. The medical woman has no status when she joins, and however long she serves, no right of seniority. Whatever her position in civilian service, whatever her length of service in the army, she is junior to and takes orders from any commissioned officer. As to inability to perform certain duties performed by men, each woman of the deputation was questioned, and they unanimously replied that medical women were able and willing to perform, if necessary, all the duties required of men; but they agreed that there were duties that it was desirable to have performed by men, if available. Further, it is argued that the War Office asked women to do work previously performed by men who held commissions. This they have done and therefore they should have been given the commissions that would have been given men for these duties. Commissions have been given to medical men who by reason of physical disability or age were not fit for full service.

## Marriages

WILLIAM J. EGAN to Miss Viola Forster, both of Milwaukee, at Shorewood, Milwaukee, September 25.

HARRY ARTHUR MILLER, Rochester, Minn., to Miss Olga Clara Grabow of Minneapolis, September 27.

MURTON PATRICK MORSE, LeRoy, Minn., to Miss Lydia Oakland of Northfield, Minn., September 6.

EVERETT HERBERT PEA, Vincennes, Ind., to Miss Cicelia Place of Grand Rapids, Mich., August 14.

HENRY MORRIS SCHEFFER to Miss Helen Rosamund Levy, both of New York City, September 21.

JOHN B. WEIKENSIMER, Steger, Ill., to Miss Gertrude Marie Gormley of Chicago, September 20.

JOHN CHRISTOPHER GRABAU to Miss Laura Louise Knoche, both of Buffalo, October 8.

FRANKLYN PIERRE DAVIS to Miss Athie Eliza Sale, both of Enid, Okla., September 25.

## Deaths

Charles Knickerbocker Winne, Albany, N. Y.; Jefferson Medical College, 1859; aged 81; colonel, M. C., U. S. Army (retired), who entered the Army as assistant surgeon in 1861, and was retired as lieutenant colonel and deputy surgeon-general, June 30, 1902, by operation of law, and was made colonel, retired, April 23, 1904, and who during the Civil War was brevetted captain, major and lieutenant-colonel for bravery; died at his home, September 24.

Jacob Dennis Arnold, San Francisco; Washington University, Baltimore, 1876; aged 63; a specialist in diseases of the eye, ear, nose and throat; lecturer on throat and ear diseases in the College of Physicians and Surgeons, Baltimore, in 1884 and 1885; president and professor of diseases of the throat and ear in the San Francisco Polytechnic from 1887 to 1889; died at his home in San Francisco, September 26, from carcinoma of the pancreas.

John Randall Hooper, Baltimore; University of Maryland, Baltimore, 1866; aged 78; organizer and president of the Howard Bank, Baltimore, and later cashier and a director of the Commonwealth Bank; an astronomer of international reputation; who established and headed the astronomical section of the Maryland Academy of Sciences; died at the home of his daughter in Round Bay, Md., September 19.

Walter Morrison Byers, Mohawk, Ind.; Physio-Medical College of Indiana, Indianapolis, 1908; aged 36; a member of the Indiana State Medical Association; while driving his automobile over a grade crossing, near Mohawk, September 20, was struck by a Big Four train, and sustained a fracture of the skull and other injuries from which he died a short time later in the Deaconess Hospital, Indianapolis.

Harry Andrew Sullivan \* Rockford, Ill.; Marquette University, Milwaukee, 1913; aged 31; who went overseas as first lieutenant, M. C., U. S. Army, with Surgical Unit No. 1, saw service in the Verdun sector, and was honorably discharged, July 8, 1919; formerly a well known pitcher of the St. Louis National League; died at his home, September 22, from pneumonia.

Theodrick C. Boulware \* Butler, Mo.; Missouri Medical College St. Louis, 1869; aged 78; a Confederate veteran; for half a century a practitioner of Butler, and for thirty years local surgeon for the Missouri Pacific Railroad; one of the incorporators, directors and for several years vice president of the Missouri State Bank; died at his home, September 6.

Dabney Minor, Cleveland, Tenn.; Vanderbilt University, Nashville, Tenn., 1910; aged 32; who served for ten months in the Medical Corps of the Army as lieutenant with Base Hospital No. 54, overseas, and was honorably discharged, June 2, 1919; was found dead in his office, September 22. It is believed his death was due to an overdose of medicine.

William Henry Campbell, Pueblo, Colo.; Rush Medical College, 1897; aged 51; a member of the Colorado State Medical Society; formerly health officer of Pueblo, and president of the Pueblo County Medical Society; coroner of Pueblo County; died at St. Mary's Hospital, Pueblo, September 18, five days after an operation for appendicitis.

André Rose Girard, West Columbia, W. Va.; College of Physicians and Surgeons, Baltimore, 1883; aged 55; who entered the Army at the entrance of the United States into war, and was honorably discharged as lieutenant, M. R. C., Dec. 12, 1918, on account of physical disability; died at his home, September 23, from diabetes.

Robert Agedius Krost \* Chicago; Northwestern University Medical School, Chicago, 1905; aged 29; assistant professor of pediatrics in his alma mater, and attending pediatrician to Wesley Memorial Hospital, Chicago; died in that institution, October 4, from septic pneumonia following an abscess of the nose.

Curtis Austin, Bagdad, Ky.; Louisville (Ky.) Medical College, 1883; aged 59; a member of the Kentucky State Medical Association; formerly a member of the state board of health; local surgeon of the Louisville and Nashville system; died at his home, August 15, from acute gastritis.

James H. Bristol, Portland, Ore.; Willamette University, Salem, Ore., 1895; aged 51; a member of the Oregon State Medical Association; who was taken ill in the operating room of Selwood Hospital, Portland, September 1; died in that institution, September 11.

\* Indicates "Fellow" of the American Medical Association.

**Thomas A. Kurr**, Fredericksburg, Pa.; Baltimore Medical College, 1902; aged 42; a member of the Medical Society of the State of Pennsylvania, and a specialist in pediatrics; died in the Good Samaritan Hospital, Lebanon, Pa., September 20, from heart disease.

**Adrian Reginald Karreman**, Chicago; University of Michigan, Ann Arbor, 1888; Rush Medical College, 1889; University of Illinois, Chicago, 1890; aged 51; a member of the Illinois State Medical Society; was murdered at his home in Chicago, September 29.

**Smith H. Hess**, Sioux City, Iowa; Rush Medical College, 1865; aged 75; for many years a wholesale druggist of Sioux City; died in the Presbyterian Hospital, Chicago, September 13, from embolism, three days after prostatectomy.

**William Alexander Sympton**, Glasgow Junction, Ky.; University of Tennessee, Nashville, 1892; aged 53; a member of the Kentucky State Medical Association; died at his home, September 4, from chronic interstitial nephritis.

**Jacob G. Streets**, Bridgeton, N. J.; Hahnemann Medical College, Philadelphia, 1866; aged 74; for many years a member of the local board of education; died at his home, September 17, from cerebral hemorrhage.

**Louis Frederick Psotta**, Washington, D. C.; College of Physicians and Surgeons in the City of New York, 1895; aged 51; died in the Emergency Hospital, Washington, D. C., August 9, from angina pectoris.

**Orville McLeod Smith**, Palmyra, Va. (license, nongraduate, Virginia, 1890); aged 51; a member of the Medical Society of Virginia; died at his home, September 16, from chronic disease of the stomach.

**Hiram T. Chapin**, Pittsboro, N. C.; Louisville (Ky.) Medical College, 1886; aged 61; a member of the Medical Society of the State of North Carolina; died at his home, August 31, from cerebral hemorrhage.

**William Clayton Pendergrass**, Clovis, Calif.; Vanderbilt University, Nashville, Tenn., 1899; aged 55; a member of the Clovis City Council; died at his home, September 22, from cerebral hemorrhage.

**James Wilson Cormany**, Mount Carroll, Ill.; Miami Medical College, 1873; aged 70; also a dentist; at one time mayor of Mount Carroll; died in Los Angeles, September 10, from cerebral hemorrhage.

**J. D. R. Williams**, Cardinal, Ont.; University of Victoria College, Cobourg, Ont., 1856; aged 86; at one time acting editor of the *Toronto Globe*; died at his home, August 2, from senile debility.

**Eli Hollingshead**, Seattle; Eclectic Medical Institute, Cincinnati, 1872; aged 86; a pioneer practitioner of Waterville, Wash.; died at the home of his daughter in Seattle, September 11.

**Charles W. Thompson**, Clearmont, Wyo.; Ohio Medical University, Columbus, 1896; aged 62; died at the home of his daughter in Cambridge, Ohio, September 17, from chronic nephritis.

**Axel F. Blomburgh**, Minneapolis; Minneapolis College of Physicians and Surgeons, 1897; aged 52; died at his home, September 7, from carcinoma of the throat.

**Matthew L. Bennett** \* Watkins, N. Y.; Geneva (N. Y.) Medical College, 1866; aged 73; a specialist in surgery; died at his home, August 6, from angina pectoris.

**Wilton R. Stuart**, White Post, Va.; College of Physicians and Surgeons, Baltimore, 1880; aged 64; died at his home, July 24 from cerebral hemorrhage.

**George S. Brigham**, St. Cloud, Minn.; University of Vermont, Burlington, 1870; aged 74; died at his home, August 30, from infection following influenza.

**Morris W. Fellman**, Philadelphia; University of Pennsylvania, Philadelphia, 1894; aged 45; died at his home, September 22, from heart disease.

**Andrew Jackson Dern**, Redlands, Calif.; Eclectic Medical Institute, Cincinnati, 1885; aged 66; died at his home, September 2, from asthma.

**Andrew W. Moore**, Fayette, Mo.; Washington University, St. Louis, 1882; aged 74; died at his home, August 18, from chronic nephritis.

**Mahlon B. Dill** \* Perkasic, Pa.; Jefferson Medical College, 1881; aged 67; died at his home, September 25, from cerebral hemorrhage.

**J. N. Murdock**, Leicester, Mass.; aged 92; who went into business two years after graduation; died at his home, June 12.

## The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE JOURNAL'S BUREAU OF INVESTIGATION, OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE FRAUD ON THE PUBLIC AND ON THE PROFESSION

### MORE MISBRANDED NOSTRUMS

"Rubino Healing Springs Lithia Water."—The Rubino Healing Springs Co., Hot Springs, Va., shipped in June, 1917, a quantity of "Rubino Healing Springs Lithia Water" into Connecticut. This was another of the so-called "lithia waters" which contained practically no lithium. The product was declared misbranded, first because of the false and misleading statements that it was a lithia water when, in fact, it "did not contain a sufficient quantity of lithium to entitle it to be called lithia water" and, second, because of the false and fraudulent claim that it was effective as a treatment for rheumatism and gout. The court entered a judgment of condemnation and forfeiture and ordered that the product should be released to the claimant on payment of the costs and the execution of a bond.—[*Notice of Judgment No. 6005; issued June 17, 1918.*]

"Kuhn's Rheumatic Remedy."—A quantity of this preparation was shipped in November, 1916, by the Kuhn Remedy Company of Chicago. Samples analyzed by the federal

chemists showed the product to be a water-alcohol solution containing essentially potassium iodide, iodine and sugar with indications of small amounts of plant material and aromatics. These findings essentially confirmed those of the state chemists of New Hampshire and North Dakota who reported on the stuff in 1914 and 1916, respectively. The preparation was declared misbranded in that it was falsely and fraudulently sold under the claim that it was a cure for all forms of rheumatism, neuralgia, blood diseases, lumbago, etc., "when in truth and in fact it was not." It was also falsely and fraudulently represented as a preventive of organic heart troubles resulting from rheumatism. In June, 1918, the company pleaded guilty and was fined \$200 and costs.—[*Notice of Judgment No. 6392; issued Sept. 8, 1919.*]

"Lower's Pure Blood Remedy."—Robert H. Lower of Hot Springs, Ark., shipped, in October, 1916, a quantity of "Lower's Hot Springs Pure Blood Remedy." This was analyzed in the Bureau of Chemistry and found to be a weak alcoholic solution containing sugars, small amounts of chlorides, iodides and sulphates (probably as the sodium salts) and vegetable extractives among which were podophyllum and an atropin-bearing drug. The stuff was falsely and fraudulently represented as a treatment or remedy for syphilis, paralysis, catarrh, eczema, malaria, chancroids, sciatia, all kinds of rheumatism and all blood and skin diseases. In June, 1918, Lower pleaded guilty and was fined \$10.—[*Notice of Judgment No. 6353; issued Sept. 8, 1919.*]

"Schade's Specific and Female Regulator."—In January, 1917, Erna D. Schade, who did business as Herman Schade, Chicago, shipped in interstate commerce, a quantity of "Schade's Specific and Female Regulator." In January, 1918,

formation in the case was filed against Schade by the federal authorities in the charge that the product was misbranded. The government chemists reported that the preparation was a water alcohol solution containing chiefly sugar, gummies, essential oils, licorice, and bitter plant extractives. It contained 12.84 per cent of alcohol by volume, but the label declared the presence of 45 per cent of alcohol. The government authorities declared that the claims made for the preparation, to the effect that it was a remedy for retarded, suppressed, irregular, painful and imperfect menstruation, miscarriage, leucorrhoea, "palpitation of the heart," ulceration of the womb, sore breasts, etc., and the further claim that it was a regulator of the "monthly courses," as well as a remedy for hysteria and falling of the womb, were false and fraudulent. In June, 1918, Erna D. Schade pleaded guilty and was fined \$100 cos's.—[*Notice of Judgment No. 422, issued July 20, 1919.*]

## Correspondence

### "PROTEOGENS": DR. BROEMAN REPORTS RESULTS NIL

*To the Editor:*—In the September 27 issue of THE JOURNAL my name was mentioned in connection with the Merrell Chemical Company's "Proteogens" in the treatment of syphilis. The Merrell Chemical Company promised not to use my name at any time in connection with their "Proteogens" injection and they know that the use of my name has been distinctly against my wishes. I feel that in justice to myself, as well as the public, I should report the result of my experiments with their "Proteogens" in private practice.

In explanation I might say that I began the use of their "Proteogens" in April, 1918, and I feel that I now have enough data to give a complete report. I might say that all my results have been practically nil; particularly is this true in my cases of syphilis which all had a four plus Wassermann reaction when I discontinued using this form of treatment.

Very truly yours,

C. J. BROEMAN, M.D., Cincinnati.

[COMMENT.—In connection with the above letter read page 1000 of THE JOURNAL, two weeks ago, September 27.—Ed.]

### "THE INHERITANCE OF ACQUIRED CHARACTERS"

*To the Editor:*—Although you have distinguished company in complaining of the dismal rigidity of the mendelian law, the authors quoted in your editorial of September 13 on this subject are not at all convincing. Their arguments appear to me to be puerile in more ways than one. Fischer says that the children of older parents are apt to be greater intellectually than the children of young parents, therefore they have inherited acquired intellectual characteristics. Was there ever a more typical post hoc ergo propter hoc argument? I doubt whether it would be possible to collect reliable statistics bearing on the question; but, granting the truth of the original statement, what ground is there for Fischer's conclusion? It is analogous to, and just as fallacious as, the old belief in the inheritance of tuberculosis. In both instances the result is due to environment. Of course the children of older and wiser parents are apt to have a broader and less impeding environment than the children of young and over-conscientious couples who are lacking in poise and experience and who frequently suppress or warp the child ego. On the other hand, we have the sad examples of the children of fussy and unpractical old intellectuals in comparison with the children of cheerful, upright, easy-going young people.

Furthermore, I have never seen any grounds for discouragement in the comparative slowness of evolutionary processes as applied to man. Such an attitude seems to be due to a lack of appreciation of the facts. Development through

heredity has no direct relation to the development of the individual; it is the slow conservative method by which minute changes are tried out over long periods of time. It will not yield in the least to the hurry and impatience of modern America.

The brilliancy of the concept of selective evolution has so dazzled the minds of two generations that the relative importance of environment has been overlooked. As a result, heredity has been made the scapegoat for many of the ills actually due to defects in the present social organization. Here again tuberculosis is one of the most striking examples. The individual man is endowed by heredity with possibilities of development so far beyond actual accomplishment that it is as futile to ask for more as for the small boy already glutted with food to cry for more cake. We can change our environment—in the broad sense of the word—as completely as we can change our clothes. Read "Sartor Resartus" once more and be comforted.

LOUIS C. AGER, M.D., Brooklyn.

### POISONING FROM EATING CANNED RHUBARB STEMS

*To the Editor:*—A recent your comment on "Death from Rhubarb Leaves Due to Oxalic Acid Poisoning" (THE JOURNAL, Sept. 20, 1919, p. 928), I wish to place on record ten cases of poisoning from eating rhubarb stems. These were of the peak of 1917—whether early or late canning could not be ascertained. In one family of ten, nine had eaten of the rhubarb. The ages ranged from 2 years to 86; all the patients were violently ill; two, who had had two helpings, had convulsions. The symptoms in all came on within twenty minutes of each other and about two hours after eating. Free use was made of the stomach pump, followed by lime water, and also castor oil. All the patients recovered. This point was evident to me: that the ones who were first treated with use of the stomach pump recovered most promptly. The mother, who had not partaken of the rhubarb, had no symptoms. One other patient in another family two weeks later had similar symptoms from eating rhubarb and promptly recovered. Samples of this rhubarb were sent to our state laboratory. The report was that the samples submitted contained approximately the normal amount of oxalic derivatives.

HARRY W. BENSON, M.D., Oakland, Neb.

### STERILIZE THE THERMOMETER

*To the Editor:*—In view of the possible return of influenza, may I call attention to a matter of hygiene which all consider of importance: I refer particularly to the necessity of thorough sterilization of the fever thermometer.

It is unfortunately still the custom in many hospitals to sterilize thermometers by standing them upright in a solution of mercuric chlorid, phenol (carbolic acid) or alcohol, a solution which is often not deep enough to cover more than half the length of the tube. Before use, each thermometer is hastily wiped off in one motion with a piece of gauze or cotton, starting at the top, the unclean end.

While our knowledge of influenza is what it is, it seems important that we should work and plan on the basis of things known. We know that the pathologic process in the lungs is partly due to gram-positive organisms variously reported staphylococci, streptococci and pneumococci. The variety of these secondary organisms determines the type of lesion.

At Camp Johnston I found pneumococci in the sputum and in the lungs at necropsy of influenzal pneumonia patients, pneumococci which were usually of Type IV, rarely of Type III, and hardly ever of Type I or Type II. Occasionally staphylococci took the place of pneumococci. The influenza bacillus was isolated in a large percentage of the cases.

What impressed me in following the clinical course of the disease was the frequent sudden change for worse in patients who had been admitted mildly ill a few days previously.

Were not some terminal infections contracted in hospitals? It seems possible. Improper sterilization of thermometers may have been one mode of infection.

We need a Semmelweis in influenza to teach us that the nose and mouth of influenza patients should be treated with somewhat the same respect as the genital tract at the puerperium, for it seems improbable that all the infections with gram-positive organisms in influenza come from organisms normally established in each patient's mouth, in view of the fact that the gram-positive organisms that predominate differ in different hospitals. One is inclined to believe that these secondary infections came from other patients. It would seem well, then, to guard the nose and mouth of influenza patients.

Perhaps it is unfair to criticize hospital methods of sterilizing thermometers when most physicians still clean their pocket thermometers by immersion under the tap or by dipping them into a glass of water. Thermometers to be cleaned ought to be laid flat in an antiseptic solution.

RICHARD E. STIFEL, M.D., Cleveland.

## Medical Education, Registration and Hospital Service

### COMING EXAMINATIONS

- ARKANSAS: Little Rock, Nov. 11-12. Sec. Regular Board, Dr. T. I. Stout, Brinkley. Sec. Elective Board, Dr. Claude E. Laws, 803 1/2 Garrison Ave., Fort Smith.
- CALIFORNIA: Sacramento, Oct. 20-23. Sec. Dr. Chas. B. Pinkham, Butler Bldg., San Francisco.
- CONNECTICUT: New Haven, Nov. 11-12. Sec. Regular Board, Dr. Charles A. Tuttle, 196 York St., New Haven. Sec. Homeopathic Board, Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Sec. Elective Board, Dr. James E. Hair, 730 State St., Bridgeport.
- DISTRICT OF COLUMBIA: Washington, Oct. 14-16. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.
- GEORGIA: Atlanta, Oct. 14-15. Sec., Dr. C. T. Nolan, Marietta.
- KANSAS: Topeka, Oct. 14. Sec., Dr. H. A. Dykes, Lebanon.
- LOUISIANA: New Orleans, Nov. 4. Sec. Homeopathic Board, Dr. F. H. Hardenstein, 702 Machesa Bldg., New Orleans.
- MAINE: Portland, Nov. 11-12. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.
- MICHIGAN: Lansing, Oct. 14-16. Sec., Dr. B. D. Harrison, 504 Washington Arcade, Detroit.
- NEBRASKA: Lincoln, Nov. 12-14. Sec., Dr. H. J. Leimbhoff, 514 First Nat'l Bank Bldg., Lincoln.
- NEVADA: Carson City, Nov. 3. Sec., Dr. S. L. Lee, Carson City.
- NEW JERSEY: Trenton, Oct. 21-22. Sec., Dr. Alexander MacAlister, State House, Trenton.
- NEW MEXICO: Santa Fe, Oct. 13-14. Sec., Dr. R. E. McBride, Las Cruces.
- SOUTH CAROLINA: Columbia, Nov. 10. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.
- TEXAS: Galveston, Nov. 18-20. Sec., Dr. M. F. Bennettcourt, Marl.
- WEST VIRGINIA: Charleston, Oct. 14. Sec., Dr. S. L. Jepson, Masonic Bldg., Charleston.

## Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

### SANITATION OF SWIMMING POOLS

To the Editor.—Leading opinions are urgently sought: 1. In regard to the comparative germicidal efficiency of liquid chlorin and the ultraviolet ray, as found in the actual operation of these methods on swimming pool water.

2. Will the presence in the water of 1 part of chlorin (available) to 1,000,000 of water cause smarting of the eyes, offensive smell, etc.? 3. Is the fact that the chlorin acts on the bacteria in the water all the time, and that the violet ray acts only as the water passes the mercury lamp (and not in the pool), an important or a negligible factor?

4. What is the highest number of bacteria (nonpathogenic) that may be found per cubic centimeter and the water still considered clean and safe for swimmers? R. P. S.

ANSWER.—1. It is not possible to make a precise statement regarding comparative germicidal efficiency of liquid chlorin and the ultraviolet ray, as the conditions under which these agents are effective vary widely in actual practice. As well known, a turbid water is not suitable for the latter mode of treatment. The efficiency of liquid chlorin as a germicide is naturally determined by the strength employed as well as by the amount of organic matter in the water.

2. It is possible that one part of available chlorin to 1,000,000 of water may cause smarting of the eyes in some persons; but this is a point very difficult to determine, since the same water without the chlorin may cause smarting under certain conditions. It seems to be true that in some individuals, at least, water containing the stated amount of chlorin causes no smarting of the eyes when applied in the ordinary way. Even a small amount of chlorin may impart an odor to water which is unpleasant to some people. Suggestion and imagination, however, play a large part in the annoyance experienced from this source.

3. These points are important under some conditions, and negligible under others.

4. So far as we know, no standard for the bacterial content of swimming pool water has ever been adopted.

In general, the treatment of swimming pool water does not seem to be practiced in a uniform manner in different communities, and the results of experimental work are not unambiguous. There is no doubt that it has proved difficult to maintain the delicate balance between disagreeable odors and bacterial purity in some instances in which chlorin or chlorin compounds are used. Careful supervision of chlorin application is essential. Manheimer (*Pub. Health Rep.* 33:267 [March 1] 1918) states that ultraviolet light in actual practice has proved ineffective.

### Massachusetts May Examination

Dr. Walter P. Bowers, secretary of the Massachusetts State Board of Registration in Medicine, reports the oral, written and practical examination held at Boston, May 13-15, 1919. The examination covered 13 subjects and included 70 questions. An average of 75 per cent. was required to pass. Of the 29 candidates examined, 23 passed, and 6, including 2 osteopaths, failed. The following colleges were represented:

College	PASSED	Year Grad.	Pct. Cent.	
Pacific Medical College	.....	(1914)	81.1	
Chicago Hospital College of Medicine	.....	(1918)	76.2	
Rush Medical College	.....	(1901)	75.0	
Medical School of Maryland	.....	(1910)	75.0	
Baltimore Medical College	.....	(1905)	75.0	
Boston University	.....	(1919)	76.0	
College of Physicians and Surgeons, Boston	.....	(1915)	75.0	
Harvard University (1915)	82.0 (1916)	76.7, 78.7, 83.0		
Tufts College Medical School (1917)	78.9, (1918)	79.1, (1919)	76.7	
	77.5, 77.5			
Columbia University	.....	(1898)	75, (1914)	81
Long Island College Hospital	.....	(1908)	75	
Syracuse University	.....	(1916)	85.5	
Woman's Medical College of Pennsylvania	.....	(1912)	76.9	
University of Vermont	.....	(1903)	79.5, (1914)	75
	FAILED			
Chicago Hospital College of Medicine	.....	(1917)	70.8	
College of Physicians and Surgeons, Boston	.....	(1916)	71.5	
Middlesex College of Medicine and Surgery	.....	(1918)	72.7	
Laval University	.....	(1917)	72	

### Ohio June Examination

Dr. H. M. Platter, secretary of the Ohio State Medical Board, reports the oral, written and practical examination held at Columbus, June 3-6, 1919. The examination covered 10 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 130 candidates examined, 128 passed and 2 failed. Twenty-five candidates were licensed through reciprocity. The following colleges were represented:

College	PASSED	Year Grad.	Pct. Cent.
Cornell University	.....	(1918)	87.1
Atlanta Medical College	.....	(1908)	76.3
Northern University	.....	(1902)	80.8
Southwestern Homeopathic Medical College	.....	(1908)	76.2
Johns Hopkins University	.....	(1918)	84.5, 85.8
Harvard University	.....	(1919)	86.4
Eclectic Medical College, Cincinnati (1919)	71.1	75.5, 76.6	77.5
	79.2, 80.8, 81.2, 81.5, 82.1, 80.6, 83.7, 81.3, 83.6, 83.9, 84.2, 84.6,		
	85.1, 85.5, 85.7, 85.8, 86.7, 87, 89, 91, 89.7		
Ohio State University College of Homeopathic Medicine (1919)	78.6,		
	81.3, 81.1, 82.9, 83.1, 83.6, 85.5, 85.8, 86.6

Mississippi June Examination

Dr. W. S. Leathers, secretary of the Mississippi State Board of Health, reports the written examination held at Jackson, June 24-25, 1919. The examination covered 12 subjects and included 96 questions. An average of 75 per cent. was required to pass. Of the 21 candidates examined, 18 passed and 3 failed. Twenty candidates were licensed through reciprocity. The following colleges were represented:

Book Notices

THE OPERATIONS OF OBSTETRICS, EMBRACING THE SURGICAL PROCEDURES AND MANAGEMENT OF THE MORE SERIOUS COMPLICATIONS. By Frederick Elmer Leavitt, M.D., Obstetrician to the City and County Hospital, St. Paul, Minn. Cloth. Price, \$6. Pp. 406, with 248 illustrations. St. Louis: C. V. Mosby Company, 1919.

The merit of this work lies in the fact that it is devoted entirely to an exclusive field of surgery which heretofore has not received sufficient attention in the college curriculum. Obstetric emergencies call for immediate action, if the patient's life is to be saved. This presupposes a cool head, and a knowledge of just what to do. There is usually no time to read up or to call a consultant. While it is true that standard textbooks on obstetrics deal with operative methods, the grouping of the subject in a separate book has the merit of emphasis in this important field of practice. The arrangement of the subject-matter is logical, and the treatment quite up to date. The illustrations, by the author himself, are adequate.

A LABORATORY OUTLINE OF EMBRYOLOGY WITH SPECIAL REFERENCE TO THE CHICK AND THE PIG. By Frank R. Lillie, Professor of Embryology, and Carl R. Moore, Instructor in Zoology, University of Chicago. Pp. 66. Price, postpaid, 38 cents. Chicago: University of Chicago Press, 1919.

This publication, which has gone through several revisions, has served for the study of embryology by medical students. The writers believe that a course in embryology for medical students can be presented more effectively by studying the development of each organ system separately than by consideration of the entire embryo at time intervals. This book gives methods of study and outlines the course in embryology specifying the number of hours to be devoted to each phase, the entire course being intended to cover sixty hours. The outlines have been employed in the medical course at the University of Chicago during eight quarters. It is believed that they will prove useful in other institutions.

and Miscellany**

**ESTIMATING THE RATE OF SYPHILITIC  
INFECTIONS IN THE UNITED STATES**

BENJAMIN MALZBERG

Special Agent, United States Interdepartmental Social  
Hygiene Board  
NEW YORK

No problem in public health is of greater importance than the control of syphilis. No other disease requires more insistently the organization of proper agencies to cope with it. Yet the very fundamental of a preventive campaign, an accurate knowledge of the exact prevalence of syphilis, is nowhere to be found. Prevention must be grounded on a knowledge, first, of who is diseased, and, secondly, of how many are diseased. The first is obvious, for how can isolation of the diseased person be enforced and how can follow-up work be maintained, if the very elementary knowledge of who is diseased is lacking? How can action be taken toward the formulation of a plan and organization for the prevention of the spread of disease, unless health bodies have an accurate knowledge of the size of the problem? Mere assumption or a guess as to the prevalence of syphilis is a very unsafe foundation on which to work. It is true that there are numerous estimates as to the prevalence of syphilis, not only in the United States, but also in Europe. But as to results there is very little agreement. This in itself is no indication of error, for it might very well be that the rate of syphilitic infection fluctuates widely, not only for different places, but for different periods of time as well. What is of deep concern, however, is the fact that not a single estimate of the prevalence of syphilis in the general population can stand the test of examination. The estimate is usually high or low, being dependent on the idiosyncrasies and prejudices of the writer. If he is an alarmist, who, because of long specialization, cannot see the woods because of the trees, then he alleges that every other male adult will be infected some time in his life. On the other hand, should the writer be possessed of a conservative spirit, then he will report the rate of infection as small.

For many years it has been the custom to quote and requote a limited number of authorities. Thus, Morrow in

TABLE 1. TOTAL CASES OF SYPHILIS AND OF GONORRHEA REPORTED IN THE CITY OF NEW YORK\*

Year	Syphilis	Gonorrhoea
1912	2,124	2,418

Total	108,836	49,427

\*Weekly Bulletin, Department of Health, City of New York, May 24, 1919, p. 162.

the United States, Fournier in France, and Blascko in Germany have been the sponsors for most of the well-known estimates. We are told that from 10 per cent. to 20 per cent. of the adult population of New York City is infected with syphilis; that 15 per cent. of the Parisian population is similarly diseased; that 45 per cent. of Berlin clerks between the ages of 18 and 28 are syphilitic, or that from 40 per cent. to 60 per cent. of males will be infected some time in the course of their lives. The time certainly has come when such statistics should be either verified or discarded. If in the present state it is impossible to arrive at any estimate concerning the prevalence of syphilis, the fact should be frankly admitted. To quote continually data that are of doubtful value, to say the least, is not a hopeful augur of future success. It is well, therefore, to clear the ground for a thorough analysis of the problem. Let us desist in

the future from the method of amassing a heterogeneous conglomeration of statistics from all over the world, and attempting the well-nigh hopeless task of generalizing from such results.

STATISTICAL METHODS

What are the methods, then, by which accurate results may be achieved? They may all be reduced, fundamentally, to two methods of procedure: The first is the collection and tabulation of cases of syphilis, and the morbidity rate therefrom, by the state and local bureaus of vital statistics. The second is the examination of a cross-section of the population. The former is obviously the more logical method. It is supplementary to the collection of mortality statistics. From the point of view of the statistician, neither set of data would be complete without the other. It would not be fair to state that this is not well recognized by the health

\*The Notifiable Diseases: Prevalence During 1916 in Cities of Over 100,000, Pub. Health Rep. 32: 595 (April 27) 1917.

authorities, for a survey of health regulations throughout the country would at once show a long list of state and municipalities that require the reporting of cases of venereal disease. Yet, that the results therefrom are utterly valueless is well known and admitted by all concerned. At least, the only exception I have come across is the statement of the director of the Bureau of Venereal Disease of the North Dakota State Board of Health, to the effect that "physicians of the state are, as a rule, faithfully complying with the law in reporting cases of venereal disease to the bureau." To the contrary, it is a commonplace that physicians invariably refuse to report cases of syphilis. This attitude results, first, from a failure to recognize the value of morbidity statistics and, secondly, from a desire to protect the patient from any social and moral stigma that may be attached to a venereal disease. However, whatever the motive may be in any particular case, the result is that but a very slight proportion of syphilitic cases are ever reported to the health authorities. This failure is so well known that no effort whatever is made to enforce the law in relation to the reporting of venereal diseases. In New York City an effort is being made to encourage voluntary reporting of cases by the physicians, by offering them the facilities of the health department laboratories in examining and diagnosing blood specimens. Yet despite this, the morbidity rate for syphilis for New York City for the year 1918 would be only 0.3 per cent. if the number of cases reported by the health department were to be accepted at their face value. Nothing exposes the failure to report venereal disease so much as a glance at the figures themselves. For New York City the totals are as given in Table 1.

Physicians and statisticians all know that there must be a far greater rate of infection from gonorrhoea than from syphilis, yet for the period of 1912 to 1913, the ratio of syphilis to gonorrhoea as reported to the New York City Health Department was, roughly, 2.1, a complete reversal of a well established fact. Of course the health department does not pretend that its figures are truly descriptive of New York City.

1. Bull. North Dakota State Board of Health, April, 1918, p. 9.

The fallacy involved in reasoning from the reported cases is further demonstrated, in Table 2, in which the rates show not only that the cases reported are far from the total number of infections, but also that the accuracy of what little notification we have varies widely from city to city. Thus, we find that a method which could give us relatively exact results, if properly utilized, leads us into absurdities when cooperation between the health bodies and practicing physicians breaks down.

#### THE QUESTIONNAIRE

Several attempts have been made to arrive at an estimate by the use of the questionnaire method. Thus a special committee of the New York County Medical Association estimated in 1901 that there were 200,000 cases of syphilis in the city. This result was obtained by analyzing the results received from physicians who were requested to state how many syphilitic patients they had treated during the year. This method is subject to so many errors that the result ought surely to be discarded. In the first place, many of those infected will not report for treatment, trying some self-cure or patented methods instead. In the second place, syphilis has been a choice field for the quack, who would be the last individual to give facts concerning the size of his practice. Then, again, many of the reputable physicians will always fail to reply to a questionnaire. The method of correction usually pursued is to credit them with a number of cases in proportion to the total reported by the other physicians. But is it not apparent that the physicians replying are more likely to be those who specialize to some extent in this field and who will, therefore, be visited by a larger proportion of such patients? To these sources of error we may add that arising from duplication. In view of these facts, any estimate thus established must be rejected, unless associated with other very weighty evidence.

Thus, in whatever form the reporting method is used, it is seen to result in failure. It might be argued, however, that it is possible to estimate the morbidity rate for syphilis by utilizing the death rate. This follows directly from the relation between the death and morbidity rates. Thus, if the death rate is multiplied by the inverse of the lethal rate, the result will be the morbidity rate for the given disease. The difficulties in estimating the death rate are similar to those encountered in estimating the morbidity rate. The physician making out the death certificate, in other words, disguises the real cause of death by naming a secondary symptom. It is possible, however, to evaluate with some degree of accuracy the true death rate for syphilis, by correcting for secondary causes.<sup>2</sup> But as the lethal rate for syphilis is an absolutely unknown quantity, it is impossible to pursue the method further. And again, even though the latter could be discovered, one could not be sure as to which year a death ought to be ascribed, as it might result from an infection as old as twenty years.

#### EXAMINATION OF A CROSS-SECTION

There remains, then, but one other method, the examination of a sample population which must be a true cross-section and representative of every element in the population. One cannot assume, for example, that because 6.4 per cent. of the applicants for a license to peddle in New York City are syphilitic, the same is true of the total population, or that there is a high rate of infection among women in New York City because 40.8 per cent. of the inmates of Bedford Reformatory were found infected.<sup>3</sup> These groups are specially selected and in no way typical of the general population. The same is true of hospital populations, though they approach more nearly the general population in character. Thus, among 18,187 hospital patients coming from all social and industrial classes, and examined at random in twenty hospitals, 19.6 per cent. were found to be syphilitic.<sup>4</sup> But it

would be futile to infer from this that the rate of infection is as high in the general population, because the former class was selected in two ways. In the first place, a hospital group differs in age distribution from the general population and, in the second place, it is undoubtedly selected indirectly through the secondary effects of syphilis, which may attack any organ of the body and cause diseases that are not at first diagnosed as syphilitic. In order to arrive at a reasonable estimate, it is essential, therefore, that a group be examined which is apparently in good health.

Such an opportunity was afforded by the National Army, which was drawn practically at random from the male population between the ages of 21 and 31, a period at which infection is most likely. Unfortunately, no Wassermann tests were given, diagnosis being based entirely on obviously pathologic symptoms at the time of examination in camp. The result is shown in the fact that among 911,840 men examined, only 4,027, or 0.44 per cent., were diagnosed as syphilitic. The ratio for all the venereal diseases was 2.25 per cent.

When the second million men in the National Army were examined, the percentage, owing to more experience and, therefore, greater skill in diagnosis, increased to 5.4 per cent. for all venereal diseases. Applying the ratio found in the first draft, this would mean that 1.06 per cent. of the second million were syphilitic. But both estimates are so far from the mark that they are valueless for all practical purposes, as it is not possible to correct for the amount of syphilis that remained undiagnosed. It is interesting to note, however (assuming that the errors in diagnosis were in proportion throughout the country), that the East South Central Division, consisting of the states of Kentucky, Tennessee, Alabama and Mississippi, showed the highest rate of infection. This was followed by the South Atlantic Division, which consists of the states of Delaware, Maryland, Virginia, West Virginia, North and South Carolina, Georgia, Florida and the District of Columbia. These two divisions showed rates of infection far higher than those for any other section of the country. The lowest rate was found in the Pacific Division, consisting of the states of Washington, Oregon and California.

No one can ever guess when again there will be such an opportunity for examining so large a proportion of the population. It is not worth while expressing vain regrets over what might have been accomplished by a thorough survey. It would be better to devise some practicable method of either securing complete notification of cases of syphilitic infection, or else finding another large cross-section of the population suitable for examination. The former is a problem in public education, the results of which will undoubtedly materialize in the future. But we must obtain some ready method for immediate use. As such, I offer the following suggestion: The policy holders and applicants for policies in the large life insurance companies are selected from the entire population of the United States, comprising elements from the poorest to the richest, the most ignorant to the most enlightened. Would it not be an excellent plan, from the point of view of both the public health movement and the life insurance companies, to give every applicant a Wassermann test? It might be objected that the cost involved would be incommensurate with possible results. But Mr. Arthur Hunter, in an address delivered at the eighth annual meeting of the Association of Life Insurance Presidents, showed that when only the better type of cases with a history of syphilis were accepted, there was still an extra mortality of 80 per cent. due to the disease. Consequently, with the expectation of life thus materially reduced, it would be to the advantage of the company to know who are the persons who would make the poorest risks. Such information, when obtained, could be turned over to the proper health authorities, who would then have a basis of fact, rather than speculation, on which to work.

32 Franklin Street.

<sup>2</sup> This the writer has attempted, and the result will be published in the near future by the American Social Hygiene Association.

### Evidence Sustaining Conviction of Murder

(*People v. Card (Calif.)*, 180 Pac. R. 53)

The District Court of Appeal of California, First District, Division 1, in affirming a judgment of conviction of murder in the second degree, charged to have been committed by the defendant in the performance of a criminal abortion, says that the defendant contended that there was not sufficient evidence connecting him with the commission of the crime, and it was true that the deceased went from his offices to an all too speedy death to permit her statement as to what had occurred while she was in his offices to be given in the form of a dying declaration. But the evidence showed that the defendant maintained offices as a physician and surgeon; that there were several connecting rooms, one of which was his private office, and another was his reception room; that between these two rooms was a system of bells so arranged that a button touched in the reception room conveyed the information to the occupant of the private office that a patient was in waiting, and the touching of a button in the private office by its occupant informed the assistant in the reception room that the patient should be sent to the private office; that these responding bells were rung shortly after the deceased and her girl companion were admitted to the defendant's reception room. The evidence further showed that no other physician than the defendant occupied his private office; that when his assistant was thus advised that he was in his private office and ready for the patient, the deceased was directed to his door; that she returned in a few moments to the reception room to get a sum of money, on receiving which she went back into the defendant's private office; that she remained away from the reception room, where her friend remained in waiting, for the space of about an hour, when she was helped into the reception room by one of the defendant's assistants, and there given over to her friend with the instruction that the patient was to be taken to her home or room and given a dose of salts. She was then in a condition indicating to the point of certainty that during the hour spent in the defendant's private office something had been done to her which had destroyed her immediately preceding state of normal health, and left her weak, distressed, hardly able to walk, and bleeding to an extent which within a short while sapped her life. On reaching her room, less than a block away, she had to be put to bed, and there was then found on her a towel identical with those in use in the defendant's office. She died within a very few hours, her death being due to an abortion performed that day. When the defendant was interviewed by a detective officer, shortly after the girl's death, his demeanor, words and actions were very far from those of an innocent man. The court thinks this evidence was sufficient to justify the finding of the jury holding the defendant responsible for the decedent's death by means of a criminal abortion. A rehearing is denied by the Supreme Court of California.

### Valid State Requirements as to the Branding of Foods

(*Corn Products Refining Co. v. Eddy et al. (U. S.)*, 39 Sup. Ct. R. 325)

The Supreme Court of the United States, in affirming a judgment in favor of the defendants, says that they were the members of the state board of health of Kansas, and that the plaintiff sought to enjoin them from interfering with the sale of its proprietary table syrup called "Mary Jane" on the ground that it was misbranded, and in particular from interfering, because of Regulation 6 of the board, with persons dealing in or selling the syrup within the state of Kansas. The syrup, which was manufactured in Illinois, was composed of 85 per cent. corn syrup or glucose, 10 per cent. molasses, and 5 per cent. sorghum, and was sold in cans which bore labels that stated, among other things: "Mary Jane is guaranteed by Corn Products Refining Co. to comply with the Food and Drugs Act, June 30, 1906. Registered under serial number 2317. Mary Jane. A Table Syrup Pre-

pared from Corn Syrup, Molasses and Pure Country Sorghum. Contains Sulphur Dioxide." Regulation 6 of the state board of health, on the effect of which the attack was centered, in the argument before the court, so far as pertinent, reads:

Manufacturers of proprietary foods are required to state upon the label the names and percentages of the materials used, so far as is necessary to secure freedom from adulteration and misbranding: (1) In the case of syrups, the principal label shall state definitely, in conspicuous letters, the percentage of each ingredient, in the case of compounds, mixtures, imitations or blends. When the name of the syrup includes the name of one or more of the ingredients, the preponderating ingredient shall be named first.

It was urged that since the plaintiff's syrup was a proprietary food, made under a secret formula and sold under its own distinctive name, and since it contained no deleterious or injurious ingredients, the effect of the regulation in requiring the plaintiff to disclose on the label the ingredients and their proportions amounted to a taking of its property without due process of law. But evidently the purpose of the requirement was to secure freedom from adulteration and misbranding; the mischief of misbranding being that purchasers may be misled with respect to the wholesomeness or food value of the compound. And it is too plain for argument that a manufacturer or vender has no constitutional right to sell goods without giving to the purchaser fair information of what it is that is being sold. The right of a manufacturer to maintain secrecy as to his compounds and processes must be held subject to the right of the state, in the exercise of its police power and in promotion of fair dealing, to require that the nature of the product be fairly set forth.

The question of whether Regulation 6 was within the authority conferred on the state board was a question of state law. But the question of whether Congress has covered the field to the exclusion of state regulation is to be determined by what the act of Congress omits, not by what it contains, and by considering whether, in words or by necessary implication, Congress has prohibited the states from making any regulation in respect of the omitted matter; and the court holds that it has not, so far as the issues involved in this case were concerned. The proviso in Section 8 of the federal act that "nothing in this act shall be construed as requiring or compelling proprietors or manufacturers of proprietary foods which contain no unwholesome added ingredient to disclose their trade formulas, except so far as the provisions of this act may require to secure freedom from adulteration or misbranding," merely relates to the interpretation of the requirements of the federal act, and does not enlarge its purview or establish a rule as to matters which lie outside its prohibitions.

### Tuberculosis and Injuries—Experts Differing in Opinions

(*Kansas City Southern Ry. Co. v. Akin (Ark.)*, 210 S. W. R. 350)

The Supreme Court of Arkansas affirms a judgment for \$3,000 damages in favor of plaintiff Akin, in this personal injury case wherein he alleged that there had been tubercle bacilli in his system for some time prior to the injuries complained of, but at the time he received such injuries he was in good health and the tuberculous germs were encapsulated, innocuous and inactive; that as a result of the bruises produced by his injuries his strength and vitality were greatly affected, and by reason of his injuries the tuberculous germs became active, and tuberculosis developed in his spermatic cords and testicles; that on account of this tuberculous condition a surgical operation had to be performed, resulting in the removal of his testicles. Several physicians, to whom a hypothetical question was propounded, answered that the injuries caused the condition of tuberculosis found in the plaintiff's testicles and spermatic cord at the time of the operation, when they were removed. The defendant propounded substantially the same question to experts introduced in its behalf, and also other hypothetical questions based on the testimony in its most favorable light from the standpoint of the defendant, and the answer to these questions was in effect that the injuries did not cause

the tuberculosis afterward developed in the plaintiff's testicles. Wherefore counsel for the defendant contended that the issue as to the proximate cause of the tuberculosis in the testicles was put at large in the realm of speculation and conjecture by the testimony of the experts.

Now as to whether or not the plaintiff was afflicted with active tuberculosis in his arm, which was arrested by amputation in 1906; and whether or not the germs of tuberculosis may be arrested, become encapsulated, inactive and innocuous, and remain in this condition in the system for several years, and then, by reason of some injury to the person, be revived and become active and hurtful, the court says were questions which would require scientific knowledge for their correct solution. These were matters beyond the grasp of the ordinary layman, but peculiarly appropriate for expert knowledge and opinion. Because the experts differed in their opinions on the same state of facts, assuming them to be true, was no reason for relegating to the realm of conjecture and speculation the issue as to whether or not the injury was the proximate cause of the tuberculosis thereafter developed in the plaintiff. The theory on which all expert testimony rests is that, when facts are established with reference to the subject-matter of inquiry which the common observation and experience of the jury would not enable them correctly to understand and interpret, then they may have the benefit of the opinions of those who, by reason of their special study and learning, have peculiar knowledge of the subject. Because experts differ in their opinions as to the conclusion to be drawn from the facts proved does not render the ultimate result to be determined by the jury one of speculation or conjecture. In such cases the question is one not of conjecture and speculation on the part of the jury, but rather a question of weight and credit to be given to the conflicting opinions of experts. If the experts differ in their opinion as to results, then it is the province of the jury to determine which has reached the correct conclusion. A contrary doctrine would result in the elimination of the opinions of all experts, unless they happened to be of one mind, and abrogate the rule of evidence permitting the introduction of such testimony.

Applying these principles to the facts of this record, it was therefore an issue for the jury as to whether or not the injuries produced by the alleged wreck were the proximate cause of the tuberculosis for which the plaintiff claimed damages, and the court did not err in refusing prayers for instructions which sought to withdraw that issue.

#### Suppression of Brothels a Valid Health Measure

(McKinley, et al. v. United States (U. S.), 39 Sup. Ct. R. 324)

The Supreme Court of the United States, in affirming the judgment of the District Court of the United States for the Southern District of Georgia, holds valid the act of Congress of May 18, 1917, which authorized and directed the Secretary of War during the war to do everything by him deemed necessary to suppress and prevent the keeping or setting up of houses of ill fame or brothels within such distance as he might deem needful of any military camp, etc. The defendants, McKinley and another, who were convicted and sentenced on an indictment which charged them with having unlawfully kept and set up a house of ill fame within the distance designated by the Secretary of War, under the authority of the act of Congress, namely, within 5 miles of a certain military station of the United States, contended that Congress had no constitutional authority to pass this act. But that Congress has the authority to raise and support armies and to make rules and regulations for the protection of the health and welfare of those composing them, the supreme court says, is too well settled to require more than the statement of the proposition. Congress having adopted restrictions designed to guard and promote the health and efficiency of the men composing the army, in a matter so obvious as that embodied in the statute under consideration, may leave details to the regulation of the head of an executive department, and punish those who violate the restrictions. This is also well settled by the repeated decisions of this court.

**Uterine Myoma.**—This study is based on the consideration of 251 consecutive patients with uterine myoma subjected to operation; in 102 patients partial and in 144 complete hysterectomies were done; in the remaining five cases the uterus was removed through the vagina. The mortality in the partial hysterectomies was 4.9 per cent. (five deaths); in the complete removal cases it was 5.5 per cent. (eight deaths). Montgomery points out that the existence of the fibroid, through the continued irritation or disturbance of the circulation, increases the danger of complicating infections. Tubal collections are not infrequent, large hematomatous cysts of the ovary are often found, and in many cases extensive adhesions and inflammatory changes greatly complicate the operative procedure. Intestinal, omental and vesical adhesions may so mat the structures together as to obliterate all landmarks and make hysterectomy in such cases one of the most difficult operations in surgery. The operator must be ready, instantly, to change his preconceived order of procedure for one adapted to the unexpected situation for the purpose of preserving and maintaining the important functions of the related viscera.

**Study of an Early Ovum in Situ.**—The specimen described by Williams represents an early human ovum, removed thirty-eight days after the cessation of the last period; it was hopelessly abnormal, and represents the youngest stage of hydatidiform mole with which Williams is familiar; it was in the act of aborting. The complete lack of development of the embryo, the absence of fetal vessels in the chorionic membrane and villi, and the hydatidiform changes in the

stroma of the latter, make it clear that the ovum was hopelessly abnormal, and that abortion was sooner or later inevitable. Furthermore, the specimen is regarded by Williams as a striking configuration of Mall's dictum that primary abnormalities of the ovum are probably the most frequent cause of abortion, and that the attempted abortion in this instance must be regarded as a conservative effort on the part of Nature to rid the organism of a structure which had failed to accomplish its allotted task.

**Premature Separation of Placenta.**—According to Morse the intramuscular lesions of the uterus in premature separation of the placenta are not provoked by an acute distention of the uterine cavity. They depend on obstruction of the uterine circulation. When such an obstruction is provoked artificially in rabbits by ligating the veins of one "horn" of the bicornate uterus, the lesions produced are identical with those in women suffering from this complication of pregnancy. Similar lesions are also observed following simple rotation of the uterus. The primary lesions in placental separation are an engorgement of the decidual sinuses and a hemorrhagic extravasation into the decidua; the intramuscular hemorrhages occur as a secondary lesion in those instances where the circulatory disturbance is excessive. Probably the excessive mobility of the uterus predisposes to a similar though spontaneous acute constriction of the veins of the broad ligament in women advanced in pregnancy. The albuminuria which sometimes accompanies placental separation probably is secondary to the disturbance in the uterine circulation and not an indication of a primary nephritic toxemia.

**Blood Transfusions in Blood Stream Infections.**—In Polak's discussion it is shown that after the bacteria have gained entrance to the blood stream the cellular elements of the blood are rapidly destroyed. The heart, liver, spleen and kidneys show definite pathology and acidosis develops. Small repeated blood transfusions increase the cellular elements, stimulate resistance and raise the blood pressure and hence add to the natural defense.

- Experience with Artificial Pneumothorax.**—This analysis by Parfit and Crombie concerns sixty-three patients for whom induced pneumothorax was undertaken. In the ordinary course of events the outlook was fairly good in only 2 per cent, doubtful in 25 per cent, and bad in 73 per cent of the series. The patients were classified 24 per cent, moderately advanced and 76 per cent, far advanced. Only 6 per cent were clinically unilateral. The disease had been manifest an average of thirty-two months; the extreme periods were ten years, the longest, and three months, the shortest. The object of the treatment was to afford relief from some distressing symptoms in 48 per cent, of the patients. In 52 per cent, there seemed a good chance to check the progress of the disease for a longer or shorter period.

The procedure was undertaken as an urgent measure for the control of hemorrhage in three patients without regard to suitability otherwise. In 95 per cent. of the cases—sixty—it was a matter of election and six of these cases were simplified by the presence of fluid, easily replaced. During the course of the treatment of the whole series of cases, forty-three so-called mishaps occurred as the result of 757 punctures and 634 refills. Subcutaneous emphysema of sufficient degree to warrant a note occurred in eleven cases. Mediastinal emphysema occurred fifteen times in nine patients. Escape of gas into the peritoneal cavity in a patient at the third refill took place after 500 c.c. had been well borne at 8 cm. water pressure. Rupture of the pleural pocket into pulmonary tissue, presumably through a cavity wall, occurred in two cases. Puncture of a bronchus or cavity occurred once with a former patient who had returned for investigation of the condition of the pneumothorax. Penetration of a large vessel occurred once. Traumatic pneumothorax from puncture of the lung occurred four times. Gas embolism occurred in one case along with traumatic pneumothorax. Pleural reflex of very mild nature occurred four times in three cases. Fainting on slight movement following a refill occurred twice in one case with a well established, voluminous pneumothorax. The authors regard this procedure as the most effective form of treatment for the progressive case of any stage, and for indolent, moderately advanced cases. It should be applied without undue delay in those cases which conform to the requirements of selection, after a relatively brief unsuccessful application of other forms of treatment.

**Predisposing Factors in Pulmonary Tuberculosis.**—Having in mind the treatment of pulmonary tuberculosis by the use of artificial pneumothorax, Shaw conceived the idea that if he injected human tubercle bacilli into the blood stream of a rabbit with one collapsed lung, a lesion might develop in the uncollapsed lung. The results were the reverse: the lesion developed in the collapsed lung and in no other organ. That this holds true whether the bacilli are injected into the blood stream or into the trachea of a rabbit having a collapsed lung, was seen from the experiments. Therefore, it is evident that the collapsed lung is not a defense against the tubercle bacillus.

**Fresh Air Treatment of Pulmonary Tuberculosis.**—Branch states that judging from clinical results, the vasomotor stimulation of a judicious water treatment enhances the fresh air effect so much that the final result is improved at least 50 per cent. by its addition to the other treatment. Especially in many cases forbidding exercise all the good effects of the latter are obtained from a properly administered water procedure. There is improvement of the pulse, nutrition, etc., without the injurious exertion incident to exercise. In all cases the procedure should be mild but methodical, and not left to the patient's fancy. The following procedures have afforded most satisfaction in Baruch's work. If the patient is able to treat himself, he may begin with cool water friction daily after leaving his warm bed, well wrapped and slipped for his bath room. Dipping the middle portion of a towel in water at 90 F, he twists it so as to expel most of the water. After unfolding it he grasps each end with a hand, throws it over his back and makes rapid passes in both directions, freshly saturating the towel and wringing it several times. He then wrings the towel out of the water and treats the front of the body and thighs to the point of good friction with it. After drying he should proceed into the fresh air, to reap the full benefit of the vasomotor stimulation. The treatment may be repeated on the same afternoon or the following day according to the urgency of the case, reducing the water temperature each time or less frequently according to reaction until 70 or 65 F. is reached. Then the quantity of water left in the towel may be increased or the application be prolonged. When the patient is unable to treat himself, the cold friction may be used by the nurse with a mitten or towel repeatedly wrung out, the rule being that it is done quickly and thoroughly. It may readily be done in bed. The extremities are omitted. Another more rapid and pleasant procedure is the cold affusion. The patient, while warm out of bed or warmed by a blanket wrapping of ore-

half hour, is seated in a previously warmed bath tub the outlet of which is open. From a small tub or large basin water of a temperature of 90 F. is dipped with a broad mouthed vessel and poured with some force over the shoulders, back and chest of the patient successively. Begin with two affusions over each part, reduce the water temperature daily or twice daily when needed, until 65 F. is reached, then increase the quantity of water used. Dry the patient and send him out of doors. Good reaction is required, or at least an absence of chilliness after dressing. The water temperature is not increased if the patient feels chilly after dressing, but the procedure is made brief and is gradually restored in duration as reaction improves. In the beginning reaction may be promoted by friction, but the aim of all procedures for this neurovascular training is to evoke spontaneous reaction.

- \*Pneumoperitoneum. Method of Detecting Intestinal Perforation. W. E. Dandy, Baltimore.—p. 378.

**Knee Joint Injuries.**—Thirty-two patients of the eighty-two whose clinical history was analyzed by McWilliams and Hetzel did not have a fracture. Eight had simple fractures, while the remaining forty had combinations of comminuted fractures, the patella being fractured in eighteen, the femur in twenty-nine, the tibia in twelve cases and the fibula in one case. Of seventy-three patients operated on for knee joint injuries, of whom final reports were obtainable as to infection, fifty-seven remained clean; in seventy of seventy-six known cases the synovial membrane was completely closed while six were drained into the joint. In general, Willem's treatment was not well carried out. Generally a splint was not used, except in cases where a fracture made it imperative, but the lack of night nurses made active motion at night impossible and in the daytime the patient was left to make the motions by himself. There was no general system, even in the daytime, for forcing the patients to make active motions regularly. Even with this abortive plan, all the operators say that early motion gave excellent results, function having returned well in a short time. The too early evacuations sometimes stiffened the joints irrevocably.

**Treatment of Recent Wounds of Knee Joint.**—Pool and Jopson emphasize that in all cases of wounds of joints by projectiles, except certain perforating (through and through) wounds by bullets, operation should be done. The principles of conservative treatment are thus summarized: complete débridement of the tract of the projectile through the joint; absolute closure of the joint by suture; primary or delayed closure of the superficial parts according to the rules laid down for primary suture of the soft parts alone; finally, early active motion. Thirty-four cases are analyzed.

**Open Operation Through the Knee Joint.**—Open amputation through the knee joint, as opposed to open amputation through the lower end of the femur, Smith claims, offers the following advantages: Fresh bone and marrow cavity are not exposed to infection; there is opportunity for a longer, and in some instances an osteoplastic stump; operative shock is minimal.

**Correction of Deformity in Fractures.**—In Thomas' opinion the roentgen ray is not being used with sufficient frequency to determine the results of efforts at reduction of fracture deformity. He is convinced that sufficient use of it for this purpose would probably demonstrate that reduction of overlapping of fragments in fractures of the shafts of long

bones, without operation, is rarely accomplished. The contraction of the surrounding muscles caused by the irritation of fragments never relaxes until the muscle is permanently shortened by organization of the traumatic exudate which always infiltrates these muscles about the fracture. Probably no known method of extension can effectively overcome this contraction. Thomas claims that most fractures and dislocations of the upper extremity are probably due to falls on the hand. A dislocation is merely a fracture of the skeleton at a joint with displacement of the fragments. In a fall the upper extremity is interposed, palm down and elbow rigidly extended, to break the force of the fall, so that the mechanism by which the force is applied to it is essentially the same in all falls. The common and typical displacements in fractures and dislocations of the upper extremity can be explained more effectively by such a fracturing force than by the theory of the pull of certain special muscles.

**Pneumoperitoneum.**—From personal observation Dandy is convinced that perforation of the intestines or the stomach can be diagnosed by the roentgen-ray findings. The escaping intestinal gases accumulate under the diaphragm if the head is elevated. The roentgenogram shows the diaphragm and liver sharply outlined and a collection of air separating these structures. Localized collections of gas in the abdominal walls, the buttocks, etc., may betray a colon infection and therefore an abscess resulting from a perforated bowel. No intraperitoneal injections of air have been made in patients, although Dandy feels that the procedure is safe and should offer valuable information which may lead to correct diagnoses in obscure cases. By determining the exact shape, size and position of various abdominal structures, a big lead will be obtained not only as to the exact organ which is diseased but also as to the pathology of the organ involved. Many patients may thereby be spared a useless exploratory laparotomy by the disclosure of inoperable conditions, whereas others may be offered specific rather than exploratory operations, or a rational rather than an empiric form of treatment.

**Treatment of Infected Bone Wounds.**—Cotton reviews the work done in these cases at U. S. Army General Hospital No. 10, Boston. The good results obtained are credited to Carrel's technic and the use of surgical solution of chlorinated soda. Three hundred and forty-six patients were admitted. One hundred and eighty-two operations were performed. There was one death; a patient with empyema, who came in moribund, died before he could be operated on. There were two amputations, one for a hopelessly crushed and crippled leg with a septic knee, one deliberately after the wounds had been healed for a limb so badly damaged and paralyzed as to be worthless. There have been no reamputations, no resections and no cases of secondary osteomyelitis after the cleaning operation.

**Method for More Accurate Study of Injuries to Atlas and Axis.** The principal object of George's method is to leave with students some fundamental facts: first, the study of the anatomy; second the variations from the normal.

\*Unusual Case of Granuloma Annulare. A. W. Stillians, Chicago.—p. 580.  
\*Neurodermatoses and Pseudolichens. F. Wise, New York.—p. 590.

**Alkali Reserve in Skin Diseases.**—The authors confined their attention almost entirely to the inflammatory dermatoses. They examined 139 patients of whom eighty, or 59.7 per cent., gave normal values; fifty, or 35.9 per cent., gave values indicating a moderate acidosis, and one, or 0.7 per cent., showed a severe acidosis. This last patient had diabetes complicated with carbuncles. Included in this group were cases of sycosis, acne, psoriasis, eczema, pruritus, erythema nodosum, dermatitis herpetiformis, erythema multiforme and lupus erythematosus.

**Granuloma Annulare: Cure by Means of Radium.**—The odd features in Stillians' case were the entire absence of ringed lesions, the failure to localize on the hands, its occurrence in a patient who has a persistently positive Wassermann reaction, and its superficial resemblance to xanthoma. The administration of potassium iodid, 10 grains, three times a day, and mercurial inunctions, had no effect whatever on the lesions. Salicylic plaster, worn for forty-eight hours, made no impression on the lesions. Roentgen rays administered short of the erythema dose gave no result. The Kromayer lamp pressed on (without blue filter) long enough to cause a sharp reaction, had no effect on the lesions. Radium, filtered through 4 mm. of aluminum, cleared up the ankle and knee lesions promptly, but those on the elbows were stubborn, requiring a larger dose, which was sufficient to leave a scar in one spot, without clearing up the lesion entirely.

**Neurodermatoses.**—Wise discusses a certain peculiar morbid change in the skin, to which a variety of names has been allotted, the most familiar being lichen simplex chronicus, lichen chronicus circumscriptus, neurodermatitis, prurigo circumscriptum and pruritus with lichenification. He also makes a brief report of his own observations, based on clinical and microscopic studies.

**Investigation of Pediculicide Substances.**—A number of derivatives of cresol, preserving the general cresol structure, but diminishing the volatility, were experimented with by Moore and Hirschfelder to test their power to kill lice. The calculated amount of bromin was dropped from a separating funnel directly into glacial acetic acid containing the cresol and a small piece of bright iron wire as a catalyzer. Bromination, as shown by titrating a sample with potassium iodid and thiosulphate, was complete in less than one hour. The mixture was then neutralized, separated and filtered off, washed first with sodium thiosulphate to remove any excess of bromin or bromin that had entered the hydroxyl group, then with sodium bicarbonate and water and finally filtered or separated off. Chlorin was introduced by bubbling into the glacial acetic acid solution of cresol in the presence of iron wire until the calculated weight of chlorin had been taken up. The substances were otherwise treated in the same way as the bromin derivatives. Iodin was introduced in saturated sodium bicarbonate solution in the presence of potassium iodid. A series of monobrominated and dibrominated chlorinated and iodo cresols, orthocresol, metacresol and paracresol was thus prepared in which the halogen had entered the ring. By this mode of treatment the trihalogen compounds of the metacresol only are formed and not trihalogenated ortho and para compounds were obtained. Chlorin was also introduced into monobrominated metacresol and in this way a monobrom, monochlor and monobromid-chlorometacresol was formed and in the same way a dibrom-mono-chlorometacresol. The substances which were found to be best suited to the purpose were the dibrommetacresol which lasted ten days and the dichloromono-brommetacresol which lasted thirteen days. These compounds seemed to fulfil the requisites of the problem so far as a laboratory trial could demonstrate.

**Relation of Pancreas to Diabetic State.**—The experiments reported on by Ervin show that a depancreatized animal as long as six hours after depancreation develops a hyperglycemia and glycosuria just as in the true state of pancreatic diabetes, yet consumes glucose at the same rate as the normal animal. The hyperglycemia and glycosuria are dependent on the rate of synthesis of glucose into glycogen and not on interference with the normal rate of oxidation. Ervin believes that the internal secretion of the pancreas is an enzyme, similar to the external secretion but diverted into the portal blood for the rapid synthesis of glucose into glycogen. The failure of its action is the cause of the state of pancreatic diabetes; a diabetic is one who fails to synthesize the absorbed glucose into glycogen at a sufficiently rapid rate to prevent a hyperglycemia.

**Cholesterol Determinations in Cancer Research.**—Luden's observations suggest that the test for cholesterol is capable of giving valuable clinical information, although it should not be looked on as a specific, diagnostic test, such, for example, as the Wassermann test. It might fitly be compared to the test for albumin in the urine. The test furnishes information concerning cholesterol metabolism; it will, therefore, furnish information about the disturbances of cholesterol metabolism connected with cholelithiasis and carcinoma, for instance. A detailed account of the technic used by Luden is given. This technic is based on the determination of more than 1,500 individual blood samples. The cholesterol content of the blood is influenced by the nature of the diet, the rate of basal metabolism, radium treatment, bacterial infection (ulceration, infectious disease) and hemorrhage. Luden insists that determinations of blood cholesterol should have a place in cancer research. Details of observations made in sarcoma and carcinoma cases are given.

**Isaacson Method for Estimating Glucose.**—The rapid colorimetric for determining glucose in urine, which was published by Isaacson, was tried out by Fennell with unsatisfactory results.

**Floccule Formation Reactions and Wassermann Test.**—McCann investigated the methods of Forges and Meier, Elias, Neubauer, Forges and Salomon, Klausner and Herman and Perutz. From the results obtained the author is convinced that, possibly with the exception of the Herman and Perutz

method, these methods cannot be used with any great degree of certainty to corroborate the Wassermann test, and especially so in those cases where the Wassermann gives a doubtful or incomplementary result.

- \*Treatment and Study of Twelve Nonparetic Neurosyphilites Treated by Intraventricular Injections of Arspenamized Serum. A. L. Skoog, Kansas City, Mo., and K. A. Menninger, Topeka, Kans.—p. 114.
- \*Central Nervous System in Purpura Hemorrhagica. A. Gordon, Philadelphia—p. 144.

**Mechanistic Classification of Neuroses.**—Kempf outlines a system which is based essentially on the integrative functions of the nervous system of which the psychoses are considered to be symptoms and which maintains that the same forces which build up a personality when harmoniously integrated cause its deterioration when unadjustable conflicts occur. These neuroses are (1) acute or (2) periodic or (3) chronic; benign or pernicious; of the suppression, repression, compensatory, regression or dissociation type. Mechanistic differences, common symptoms and common causes are discussed.

**Treatment and Study of Twelve Nonparetic Neurosyphilites.** Serum arspenamized in vivo was used by Skoog and Menninger. The reactions were not severe, as a rule. Marked improvement resulted in two cases; slight improvement in six cases, no improvement in two cases and death occurred in two cases. The improvement showed no tendency to follow diagnostic classes. On the whole, the treatment appears to have given encouraging results. From two to four injections were given in each case, in doses varying from 1 to 40 c.c. Immediate reactions consisted of a slight pulse acceleration, negligible respiratory rate change, headache, pains in the neck, back and limbs, nausea and vomiting. The intensity of the reaction depended to a considerable degree on the size of the dose, the amount of hemoglobin in the serum and the priority of the injection.

**Central Nervous System in Purpura Hemorrhagica.**—According to the findings of Gordon in one case, the lesion affects exclusively the cells of the gray matter throughout the entire central nervous system. The lesion consisted of destruction of cells and formation of vacuoles.

**Etiology of Banti's Disease or Splenic Anemia.**—Kristjanson's studies were made in a case of splenic anemia or Banti's disease in which the spleen was removed. Immediately after the removal of the organ, implants were placed on freshly prepared blood agar, Dorsett's egg medium and Loeffler's blood serum, under most careful aseptic conditions. These tubes were then sealed and placed in the incubator for ten days. On the tenth day very small grayish colonies could be seen in close vicinity to the piece of tissue removed from the spleen in one tube. A smear from one of these colonies showed mostly coccoid forms arranged in small irregular clumps; these clumps, however, did not have the characteristic grouping of the staphylococcus family. Subcultures were made on fresh blood serum slants. In four days a very slight filiform growth, barely visible to the naked eye, appeared. Smears from this growth revealed cocci, similar in appearance and size to those observed in the original culture. This micro-organism retains the Gram stain and is nonacid fast. The effects produced on animals by repeated intravenous inoculations with the organism were marked systemic reactions indicated by rise in temperature and leukocytosis. These experimental inoculations in the dog produced progressive enlargement of the spleen with gradually increased fibrosis and perisplenitis. The histologic changes in the spleens were quite like those occurring in early Banti's disease. Control animals inoculated under identical conditions with staphylococci, colon bacilli and pseudodiphtheria bacilli showed no progressive fibrosis of the spleen but had symptoms of general infection from which they succumbed. As a constant feature, the experimental animals inoculated with the organisms isolated from the spleen in Banti's disease gave a positive complement fixation, using a bacterial antigen and the sheep's hemolytic system. The biologic characteristics of the organism are given in detail.

**Influenzal Appendicitis.**—Warfield discusses cases presenting a syndrome which simulated appendicitis but which was not appendicitis. It was influenza beginning with intestinal symptoms. Cases are cited.

\*Gunshot Wounds of Scalp: Neurologic Signs Presented. G. Jefferson.—p. 93.

\*Biologic Effects Due to High Explosives. A. Carver and A. Dinsley.—p. 113.

Development of External Form of Human Cerebellum. J. W. Langelaan.—p. 130

**Gunshot Wounds of the Scalp.**—The observations recorded by Jefferson are based on a series of fifty-four unselected average cases of scalp wounds as seen at the base in France. A large number of the patients showed generalized signs; a history of unconsciousness, complete or partial, with vomiting, nausea, headache, and exaggeration of the tendon jerks generally. Only five patients out of the whole series showed no positive neurologic signs at all. In ten more the only symptom complained of was headache, but this was often so severe and the patients were mentally so dull for a short time that it was evident that the brain had received a severe shaking up. One fourth of the patients allege that they were actually unconscious for brief periods, while another fourth were stunned, frequently being knocked down by the impact of the missile. Headache was present in forty-five cases, definitely absent in six, and not noted in three. Giddiness, was the next most common sign, only being noted on gross changes of posture, and therefore later in convalescence when such active movements began to be attempted. It was never a serious factor. Vomiting occurred in eight cases and nausea was, or had been, present in thirteen. Tendon jerks were exaggerated in twenty cases, and of these eight presented increase of both arm and leg jerks. Increase of the arm jerk always portended a graver injury, and cerebral injury was always suspected when they were active. True ankle and patellar clonus, continuous and regular, was never found, but a few beats, from two or three to six, occurred in seven cases. But when present on one side only, even this mild form has a value. In none of these series was there any injury to the skull, yet there were eleven definite local contusions of the motor cortex, four of the visual, and two more in which a motor lesion was associated with a sensory disturbance of the hand. Three presented jacksonian seizures, and three were trephined on the neurologic evidence; in two an extradural clot was found; in one, nothing abnormal was noted. There were signs of contralateral injury by contrecoup in four cases.

**Biologic Effects Due to High Explosives.**—The present tendency to regard the neuroses of war as of exclusively emotional origin is objected to by Carver and Dinsley. They plead for a more general recognition of the underlying physical basis demonstrable in a considerable proportion of them. It is held that the neuroses of war be brought about by the action of "purely emotional shock," by the action of "purely physical shock," and by a combination of these two factors. The combination is the most common occurrence.

Treatment of Bulbarzias by Tartar Emetic. A. Innes.—p. 340.

Case of Hydrocephalus. S. Lodge.—p. 342.

Flat Foot. H. Smith.—p. 343.

**Rabies and Antirabic Treatment.**—Semple states that if a dog shows signs of rabies within ten days from the date of inflicting the bite, the person bitten should receive antirabic treatment as soon as possible after the condition of the dog had declared itself. A person severely bitten on the head, face or neck would not be justified in waiting ten days to know whether the animal was infective or not. A delay of ten days, or even four or five days, in a case of that kind

might be disastrous, as it might then be too late for successful treatment; the safest course to adopt in such cases would be to commence antirabic treatment at once, and as soon as it became evident that the dog was not infective leave it off. In a rabies infected district a person bitten by a stray dog which subsequently disappeared and was not again seen or heard of should receive antirabic treatment as a precautionary measure. In a rabies infected area it would be a mistake to destroy a healthy looking dog immediately after it had bitten any one, because then all information regarding his condition would be lost unless the carcass or a portion of the brain was sent to a laboratory for experimental tests, which would mean a delay of from four to five days, up to a period of three weeks, or possibly longer, according as to whether Negri bodies were looked for and found, or the inoculation of an animal carried out.

**Disordered Action of Heart.**—In Venning's opinion the strain of warfare, mental and physical is the chief cause of the symptoms of D. A. H. The causation of next importance is infective diseases, and the majority of these were contracted in civil life, rheumatic fever being the worst offender.

## Bulletin of Naval Medical Association of Japan, Tokyo

April, 1919, No. 23

Tumor Resembling Sarcoma of Kaposi. K. Maruta.—p. 1.

\*Symptoms Soft Chancre and Vaccine Treatment of Inguinal Bubo. T. K. Kana.—p. 3.

\*Cancer Diagnosis from Urine. K. Takei.—p. 3.

**Cause of Cold Abscess of Thoracic Wall.**—Shiozawa maintains that these cold abscesses may be caused by a typical tubercle in the connective tissue in the environment of the rib, when there was no change in the bone or the cartilage itself. Out of twelve specimens examined by him, pathologic changes of the rib or the cartilage were present in four while in the remaining eight cases he could establish the existence of typical tubercles in the environment of the rib with no change of the bone or the cartilage at all, the proportion of the former to the latter being 1 to 2. The principal site of the latter affection which showed the typical pathologic features ascribed to tubercle, corresponding with the predisposed locality for the caries of the rib, was in the subpleural tissue between the costal pleura and the interior intercostal muscle. All the patients from whom these specimens were taken had some tubercular change in some other part of the body, but its relation with the cold abscess of the thoracic wall was not established.

**Vaccine Treatment of Inguinal Bubo.**—Kurita treated eighteen patients who had inguinal bubo associated with normal soft chancre by a vaccine made of Ducrey's bacillus. This treatment had a good effect, mitigating the pain of the bubo and the bubo in its first stage was dispersed by the sixteenth day on the average. The advanced bubo and the so-called abdominal bubo were also affected beneficially by this treatment. The only untoward symptoms resulting from the use of the vaccine were pain at the site of inoculation and fever with headache, shivering and giddiness.

**Cancer Diagnosis from Urine.**—The sulphur reaction of Salomon and Saxl as done by Takei gave positive results in 81.7 per cent. of cancer cases, 57.14 per cent. of suspected cancer cases and 16.0 per cent. of cases not associated with cancer, while Kuchel's method was positive in 80.66 per cent., 54.55 per cent. and 26.66 per cent. respectively. Takei claims that from the clinical point of view, the first method is a little more accurate than the second. The sulphur method is less expensive than Kuchel's, but the first method is more complicated and takes longer for its completion than the second, the first taking two and a half days, while the second is completed in one day. The quantity of urine needed for the first method is larger than for the second, and albumin contained in urine, if any, must be removed entirely before carrying out the test, while there is no such trouble with the second procedure. In the first method the degree of reaction varies with the nutrition of the patient examined and the pigment of urine and drugs taken by the patient must be taken into account while in the second these factors are almost negligible.

**Aortic Disease in Soldiers.**—Cotton has analyzed the case histories of fifty soldiers with signs of aortic insufficiency. The points which Cotton makes are these: Aortic disease is compatible with good exercise tolerance; when there is an equal degree of distress after effort the increase in pulse rate is the same in patients with slight aortic incompetence, in aortic disease with free regurgitation where there is no venous congestion, and in D. A. H. cases in which there are no signs of structural disease.

**Increase of Alkalinity of Blood in Shock.**—Moore claims that the outlook on the chemical conditions in shock is all wrong, and this is why the invariably underlying presence of "acidosis," to which at first much attention was given, became later neglected. All cases of serious secondary shock show so-called "acidosis," but this acidosis is not "acidosis," it is "alkalosis." So all the attempts of physiologists to mimic it have been abortive. When the pressure of free carbonic acid in the blood is decreased then alkalinity rises and kidneys and tissue cells remove alkali from circulation. It is for this reason that the circulating bicarbonate decreases, and so lowered titration figures are obtained, but the blood is more alkaline. A fall in bicarbonate reserve to one-third of normal can be caused by a small fall in pressure of carbon dioxide and accompanying increase in alkalinity. When primary shock occurs from sudden heart failure, from emotional causes, hemorrhage, pain, or some such stimulus, there is cerebral anemia and unconsciousness. There is a general cessation of metabolic activity at first and a shutdown later to about one third of the normal rate. If there be a closure down in the tissues to one third, what must happen if the lungs go on working at their normal rate or even at one half their normal rate? An excess of carbon dioxide over that produced must be removed in the lungs and the blood go alkaline, and this is what occurs in secondary shock. During the period of fainting both heart and respiration are held in abeyance, the heart perhaps more than the respiration, and there is a venous condition which favors recovery, but later there is a condition in which respiration exceeds circulation and the blood becomes more alkaline and carries shock to the nerve centers and heart. If as a result of a primary shock the circulation is only working at one third its usual speed, and the respiration is going on at the usual rate, the amount of carbon dioxide produced will only be one third of the normal, while elimination proceeds at normal rate. The result must be that the alkalinity of the blood increases, and any such increase leads to heart failure. Hyperpnea need not necessarily be an antecedent factor to conditions such as toxic products from wounds and muscle cerebral shock. In the main, the condition depends on relative rates of circulation and respiration, although other conditions of injury and fatigue of nerve centers, undoubtedly play a part.

**Etiology of Veldt Sore.**—During the Egyptian and Palestine campaigns chronic sores, very resistant to local treatment, on uncovered parts, became a great scourge, especially among mounted units. Craig investigated these lesions in 197 cases. The micro-organisms constantly present in the cultures were: (1) staphylococci (*S. albus*), rarely *S. aureus* or *S. citreus*; (2) diptheroid bacilli, of two morphologic types: (a) A small straight bacillus, staining uniformly with methylene blue, gram-positive but decolorizing with ease, showing no polar differentiation with Neisser's stain. Usually these small forms were present in moderate number and lay parallel in pairs. (b) Forms morphologically identical with the true Klebs-Loeffler bacillus. Craig believes that type (a) is an immature form of (b). Inoculation experiments showed that the small form was equally as toxic as the large form and developed into the latter. One or other of these types was found in 129 out of 197 sores examined, 67.5 per cent. During the period of investigation diptheria both of throat and nose had been prevalent among the troops. The evidence Craig collected at that time showed that there is a close correlation between the incidence of faucial diptheria and the occurrence of the "desert" sore, the causal agent in each case being the true Klebs-Loeffler bacillus.

**Inoculation Against Spanish Influenza.**—Grey's experience in the South Sea islands impressed him with the value of antipneumostreptococcal inoculation as a prophylactic against Spanish influenza. A full dose of the vaccine used by Grey contained 125 millions of *Micrococcus catarrhalis*, 50 millions each of pneumococci, streptococci and a gram-positive diplococcus. Experience showed Pfeiffer's bacillus to be unnecessary as a constituent of a vaccine directed against this epidemic, and in view also of the risk of a negative phase, Grey thinks it is clearly unwise to use it in any community where the epidemic is already well under way. Grey gives a full dose (50 millions each pneumococci and streptococci) every five or six weeks, and never gets more than the mildest reaction.

**Cases of Intestinal Obstruction.**—Romanis cites two cases in which there was enormous distention of the cecum, and it was gangrenous, due to obstruction from cancer in one case and an impacted gallstone in the other. In a third case he removed 14 feet of ileum which had become gangrenous from strangulation in a small hole in the lower part of the mesentery. The patient made an uninterrupted recovery, and after the first week rapidly put on weight until in four weeks he was heavier than before the operation. At first there were six or seven loose motions daily, but when seen four months after the resection, he was having two soft motions daily and doing his full day's work with ease.

Retroversion of Gravid Uterus. R. B. Eccles.—p. 530.  
Spontaneous Cure of Strangulated Inguinal Hernia. W. F. Stiell.—p. 530.

**Hyperadrenalism as a Cause of Pyloric Stenosis.**—Pirie suggests that the spasm inducing hypertrophy of the pylorus is primarily due to hyperadrenalism before birth, and that other subsidiary postnatal causes determine the persistence or recurrence of the spasm. This condition is due to a lack of balance between the secretions of the various endocrine organs in the process of their development and involution, which may result either in a relative or an absolute hyperadrenalism. The amount of hypertrophy present at birth is insufficient, except in rare instances, to cause symptoms of obstruction. This is clearly evident from the clinical history of the great majority of cases. But there are certain conditions which will cause spasm after birth sufficient to complete the obstruction in an already stenosed orifice. This combination determines the onset and severity of the symptoms. That some of these patients recover without surgical

intervention is due to the fact that the subsidiary conditions are amenable to palliative treatment, and are of greater moment in producing obstruction by added spasm than the congenital stenosis itself. And there is sufficient evidence to justify the opinion that the two chief contributory causes of spasm, phimosis and secretory inhibition, are directly associated with the congenital hypertrophy. In cases of true congenital stenosis circumcision without any other form of treatment has relieved the symptoms immediately for varying periods of time. As to the effect on the stenosed pyloric orifice of changes in the stomach itself: Any local irritative conditions or inflammatory changes will produce swelling of the mucosa. In many of the cases, perhaps all, there is some change of the nature produced by the undue retention and, thus, fermentation of food. Ordinarily these changes would not cause obstruction, but added to congenital pyloric stenosis, they hasten the formation of the vicious circle, and the perpetuation of the obstruction is due to the more rapid secretory arrest. It is also likely that phimosis, while in itself an important cause of spasm, hastens the appearances of symptoms of obstruction in the same way.

**Medical and Surgical Treatment of Hypertrophic Stenosis of Pylorus.**—When surgical interference is necessary in these cases, Gray and Pirie advocate Rammstedt's operation: In their opinion, it will, in the near future, take the place of every other surgical method devised for the cure of hypertrophic stenosis of the pylorus. In all other cases palliative treatment should first be adopted as follows: (1) peptonized milk in appropriate quantities; (2) gastric lavage; (3) circumcision; (4) subcutaneous infusion of physiologic sodium chlorid solution and 2 per cent. glucose, when necessary; and possibly (5) administration of chloral hydrate. If there is no relief of symptoms in forty-eight hours, operation should be performed without delay. In the majority of cases palliative treatment is to be persevered with for from ten to twelve days. Failure to improve after this point constitutes an indication for operation in boys, but not necessarily in girls.

**Retroversion of Gravid Uterus.**—In this case Eccles replaced the uterus by the knee elbow position and then introduced a Smith-Hodge pessary to keep the uterus anteverted. There was complete atony of the bladder, and the catheter was passed every six hours for eight days. The patient made an excellent recovery. At the end of the fifth month of pregnancy Eccles removed the pessary. Four months afterward the patient gave birth to a fine, healthy male child, the labor being quite normal.

**Archives de Médecine des Enfants, Paris**

**Normal Weight and Stature of Children.**—Puig has been investigating conditions in Spain in this line, and has arranged his work for comparison with similar data compiled in other countries. His investigations included two groups of 2,229 and 1,845 children in the Barcelona district. His tables confirm the findings elsewhere that girls weigh more than boys at a certain age but after 15 the boys rapidly gain the supremacy. The peculiar feature about his statistics is that this superiority in weight and height begins much earlier and lasts later than in other countries. It is apparent early as the fifth year, and continues to increase to a difference of 7 kg. in weight in favor of the girls at 14, and of 4.66 cm. of superior height. At 13 the girls were 64 cm. taller than the boys. This difference between the sexes was noted in the Boston statistics only from 11 to 14 and never surpassed 1.9 cm. (Bowditch); in Germany from 12 to 14, with a maximum of 4.1 cm. Quételet's table of figures, from Brussels, is the only one in which the boys surpassed girls in height constantly and at all ages.

**Importance of Change of Air in Treatment of Whooping-Cough.**—Cameseasse asserts that—in his experience, at least—of the so-called children's diseases run a milder course in the country than in the city. He has also found that a com-

plete change of air not only attenuates but usually cures completely all cases of whooping-cough. It is necessary, however, for the change of air to come at about the fifteenth day for it to be effectual. Later than this no influence from it is apparent, and earlier than this it does not modify the disease, but a further change of air about the fifteenth day then will prove effectual as usual. He urges that provision be made in the country to receive whooping-cough children from the city sent out at about the fifteenth day of the disease. He proposes for Paris that two sanatoriums should be established for the purpose at about a two-hours auto drive from the city. The number of inmates may vary from zero to a thousand in different weeks, and there would be many advantages in providing accommodations for the mothers to accompany some of the children. When the number of admissions is low, the convalescents might be given the privilege of a longer stay in the country. He adds that Paris records 500 deaths from whooping-cough annually, and that most of these children might be saved if provisions of this kind were made for them.

**Cryptogenous Fever from Thyroid Instability.**—This article was summarized Aug. 16, 1919, p. 562, when it appeared elsewhere.

**Urticaria Treated by Antianaphylaxis.**—Summarized on p. 562.

**Congenital Stenosis of the Esophagus.**—Comby reviews Brennemann's and other recent publications on this subject, and remarks that congenital atresia of the esophagus seems to be frequent in America. He does not agree with those who think that there is any chance for the survival of these children. Even when successful, operative correction of the anomaly would be so difficult and complicated, he says, that the outlook is hopeless—*Il faut accepter l'inévitable*.

- Deep Lipoma of the Arm. R. Villar.—p. 338.
- Does Intractable Tertiary Aid in Prophylaxis of Influenza? Roumaillac.—p. 339.

**Prolapse of Gravid Uterus.**—Andréodias reports the case of a woman of 31 who for ten years, from immediately after her first pregnancy, had had the cervix of the uterus protrude from the vulva. At the age of 24, a malformed infant was born. At 27 a laparotomy with hysteropexy only transiently relieved the prolapse. The protruding cervix was 8 or 10 cm. long and during her third pregnancy it became ulcerated. In four similar cases in his service the pregnancy went to term in all and delivery was spontaneous. The period of dilatation was longer than usual, and laceration was common. In his four cases labor lasted from four and a half to fifteen hours, and there was no morbidity.

**Wire Treatment of Genital Prolapse in Elderly Women.**—Venot refers to cases in which the degenerated tissues do not permit effectual reconstruction of the pelvic floor. He has applied in such cases in elderly women a method of suturing the walls of the vagina by *cerclage* with a silver wire. With a curved needle he passes a wire around the lower end of the vagina and knots it to make a ring preventing further egress of the genitals. The vaginal wall is first separated from the urethra and loosened up through a small transverse incision in the urethrovaginal wall and a second incision in the posterior vaginal wall, these incisions materially facilitating the passage of the curved needle. The knot of the wire is at the anterior incision where the ends are tied

over the handle of the Reverdin needle, to ward off danger of drawing the wire too tight, and the knot is pushed in to one side. The wire can be easily removed at need.

- \*Delirium and Psychoses with Influenza. A. Porot and A. Hesnard.—p. 141.  
 \*Action of Mustard Gas on Upper Air Passages. R. Moreaux.—p. 146.  
 \*Retention of Urine from Atony. Uteau.—p. 150.

**Delirium and Psychoses with Influenza.**—Porot and Hesnard insist that the delirium and psychoses accompanying or following influenza are the most typical example and synthetic illustration of this form of acute infectious mental pathology which requires general care rather than special institutional care, the clinician rather than the alienist. There is no essential difference between the brief delirium and the psychoses which may drag along for weeks or months on account of some predisposition or reinforcement from secondary factors. The delirium with influenza may not accompany the fever but develop later when the lack of nourishing food, the secondary auto-intoxication and the exhaustion from the disease combine to sap the vitality, especially after alcoholic or other excess and intoxication. The initial disorder is connected with an organic condition, and this latter is what determines the indications for therapeutics.

**Retention of Urine from Atony.**—Uteau eliminated all the usual causes for the retention of urine in a group of cases in which the only objective sign was the insufficiency of the bladder musculature. Whether this is cause or effect is still a question. It is possible that in certain circumstances emotional inhibition might breed a habit. The prognosis is favorable; a cure is generally realized in a few days under the influence of systematic catheterization and silver applications. A special feature of these cases is that the residual urine fluctuates in amount from day to day. It is generally clear, and the sphincter tonus seems to be normal.

### Presse Médicale, Paris

Aug. 25, 1919, 27, No. 47

- \*Significance of the Thrill. L. Bérard and C. Dunet.—p. 469.

 \*Reconstruction of the Angle of the Lips. L. Imbert.—p. 472.  
 \*Access to the Inferior Maxillary Nerve. E. Gascard.—p. 472.

**Significance of the Thrill.**—Bérard and Dunet present evidence to demonstrate that the thrill occurs when a blood wave is passing through an abnormally narrow canal or opening between two cavities each of which has a different pressure. The thrill is not exclusively a mechanical phenomenon; it is also a vital phenomenon in that the active contractility of the coats of the arteries is a factor. The thrill with an arteriovenous aneurysm is stable and is always accompanied by a continuous murmur, reinforced during systoles. The thrill of arterial origin alone is variable. The disappearance of the compressor element or of the spastic element is responsible for it. There may with it also be a murmur with systolic reinforcement.

 \*Cataplexia: Urable Dementia. A. Austregesilo (Rio de Janeiro).—p. 288.

**Anatomy of Completely Divided Spinal Cord.**—Marinesco declares that the war experiences with completely severed spinal cords seem to have completely demolished Bastian's theory that reflex functioning is practically abolished after the cord has been severed in the lower part of the cervical or upper part of the dorsal region. This is true only of a brief primary period. Marinesco and others have demonstrated that the cord recuperates an actual autonomy. This does not seem to be the resumption of its former activity but a new activity of its own, which reproduces only rudimentarily the activity of the divided spinal cord in the dog. It is an inferior kind of activity which differs from normal activity and from that of decerebrated animals and of pathologic obstruction of the spinal cord-cortex route in man. There is no doubt that the fibers of the spinal cord can regenerate, but this anatomic regeneration is not systematized. It does not lead to reconstruction of nerve routes which would ensure the resumption of useful transmissions. Regeneration seems to be possible not only of the roots but of the white substance, but all the experiments and experiences to date demonstrate that the regeneration does not permit resumption of the old functioning. The activity of the spinal cord after complete separation from the cerebellum and brain is a new activity, pertaining exclusively to the spinal cord itself. The innervation of the extensors of the legs depends on the supra-medullary centers, and these extensors do not regain their reflex activity. All the activity of the "spinal man" is in the sphere of the flexors. The flexors regain their tonus and function in a synergic manner, but their temperature is below normal, and electric tests show a different response from normal. The assumption seems plausible therefore that there is an autonomous activity of the spinal cord. It is manifested by defensive movements, but these defensive movements cannot be identified with the reflex defensive movements of the decapitated frog, as they are purposeless and could not serve in any way for actual defense reflexes.

**Familial Atrophy of the Optic Nerve with Tremor.**—The parents were healthy and also four of the six children, but one brother and sister developed visual disturbances suddenly at puberty and they rapidly progressed. The symptoms closely resemble those described by Leber as characteristic of hereditary atrophy of the optic nerve. There are also certain other nervous symptoms, incoordination in the movements of the eyes and asymmetry in the innervation of the face in the young man. In the young woman there is tremor besides, including even the trunk when seated, and all the finer coordinated movements are slow and awkward but the gait and reflexes seem normal. There is pronounced mental impairment in this case. The patients had been apparently normal until puberty. The cases resemble some reported by Behr; his were all in boys, and evidently congenital.

**Tendon Transplantation for Radial Paralysis.**—The success in the case of which an illustrated description is given justifies, it is stated, tendon transplantation as a routine measure for peripheral paralysis. It gives as certain and as prompt functional results as can be obtained with orthopedic apparatus, to say the least.

**Cataplexia.**—Austregesilo's article was reviewed, Jan. 11, 1919, p. 154, when it appeared elsewhere.

### Correspondenz-Blatt für Schweizer Aerzte, Basel

 \*The Factory Physician. Koller.—p. 1214; Ed. A. Ziegler.—p. 1216.

**Influenza in the Pregnant and Parturient.**—Geymüller's experience with influenza in forty-two pregnant women and in eighteen parturients confirms the frequently disastrous influence of these conditions on the course of influenza. The proportion of pneumonia cases was larger, and half of the pneumonia cases terminated fatally. Spontaneous abortion was frequent, probably the result of the excessive amount of carbon dioxide in the blood. The delivery in turn has an unfavorable influence on the pneumonia. After the childbirth, an attack of influenza offers no special danger, the involution processes not being appreciably modified by it.

\*Importance of Weather Conditions as Influencing Development of Acute Noncontagious Diseases. A. Campani.—p. 685.

**Meteorologic Conditions as Influencing Certain Diseases.**

—Campani accepts the term "cyclonosis" to express the three groups of symptoms which seem to have some connection with the weather. The first group includes headache, sensations of heat, irritability and tendency to epistaxis and to hemoptysis; the second group includes intestinal catarrhal disturbances, sleeplessness and loss of appetite, while the third group comprises rheumatoid pains, painful joint disturbances, pains in old scars, etc. He compares in eleven tables the morbidity and the meteorologic conditions during a recent nearly two year period at Verona in northern Italy, his data including 24,528 cases of recorded disease exclusive of acute contagious diseases. The morbidity was least in the windy periods, especially in winter, while the highest morbidity accompanied periods of cloudy skies. As a general rule, he says, the best conditions for health seem to be during or immediately after the great atmospheric convulsions and the fair weather that follows them. The morbidity is highest during the periods of stagnation preceding storms, with a constant temperature, generally rather above the mean, the sky cloudy, and only weak atmospheric currents. The greater the fluctuations in the temperature of the twenty-four hours, the less the morbidity, and the less the fluctuations the higher the morbidity, especially when the humidity is high. The northwest winds in winter and the southwest in summer seemed to be the most favorable for the health in general. The influence of the weather on the development of plants and crops is so evident that he is convinced that physicians may well study the subject in the interests of patients. It might be well to add study of the appearance of sun spots, the variation in electric conditions and even the phases of the moon as these may affect the action of certain ferments.

\*War Motor Psychoneuroses. G. Pellacani.—p. 275.  
\*Tonic Ulnar Spasm of Eyelids. A. Mendicini.—p. 286.

**The Romanowsky Stain.**—Romanese has worked out, he says, a simple and reliable substitute for the Giemsa method. The results seem to be the same with it as with the original Giemsa fluid, while the ingredients are inexpensive and always at hand. He dissolves 0.75 gm. methylene blue in 50 c.c. of 95 per cent. alcohol and 50 c.c. of glycerin, and adds 3 c.c. of a 10 per cent. solution of sodium carbonate in distilled water, and boils for fifteen minutes. Then he adds 35 c.c. of a 1 per cent. alcoholic solution of eosin and boils fifteen minutes. It is then removed from the fire and alcohol is added to bring the total amount to 100 c.c. It is then set aside, covered closely, for a week.

**Stain for Tubercle Bacilli.**—Gasbarrini has long contended that the acids used to decolor the bacilli with the usual

technic are too powerful and detract from the effect. To avoid this he uses methylene blue in excess in a solution of 40 c.c. lactic acid in 160 c.c. distilled water, and adds to this at the time of using four parts of alcohol (95 degrees). This both decolors and recolors at the same time, with the finest and most constant results. It has shown up tubercle bacilli in sputum, urine and stools when the Ziehl gave negative findings, and the accuracy of the lactic acid method was confirmed by the course of the cases. The nonacid resisting bacilli can be differentiated more readily, and the whole procedure takes less time than the ordinary technic.

\*Hemolytic Splenomegaly. L. Castaldi.—p. 325. Cont'd in No. 27, p. 313.

**Hemolytic Splenomegaly.**—Castaldi reviews the few cases on record of what he calls Banti's hemolytic splenomegaly, and describes a case personally observed in a man of 27. There was no pain and but little jaundice accompanying the intense anemia. The blood count showed 2,105,000 red and 6,305 white corpuscles, hemoglobin 45 per cent. and the color index 1.07, with 53.5 per cent. polymorphs; 0.5 per cent. eosinophils and basophils 4 per cent.; large mononuclears 4 per cent. and 41.5 per cent. lymphocytes; no myelocytes, and no nucleated erythrocytes. The case thus fits into the frame of Banti's ahemoipctic hemolytic splenomegaly. In the nine similar cases on record the spleen was removed in seven and with excellent results in every instance. As no improvement was realized under medical measures, Castaldi advised splenectomy but the patient refused this and roentgen treatment was applied, with brilliant success. Ten exposures of ten minutes each were given in the course of forty-five days and the outline of the spleen subsided from 21 by 16 to 12 by 11.5, while the hemoglobin ran up to 80 and the erythrocytes to 5,600,000 and the weight increased by nearly 5 kg. The patient would not wait for further treatment but has kept well during the four years since, including nearly three years of military service. The case teaches the necessity for a trial of thorough roentgen treatment before resorting to splenectomy in such cases.

\*Septicemias. A. G. Guimarães.—p. 73.  
\*Case of Hydramnion with Twenty Litters of Fluid at Seventh Month of Pregnancy. Martino de Azevedo.—p. 88.

**Septicemias.**—Guimarães expatiates on the advantage of taking a culture from the blood in every febrile state, no matter how mild it may seem. The results should not be

classed as negative until the cultures have been taken at different periods in the fever. It has been his experience that infection occurs mostly by way of the veins, and that the pus cocci are most frequently to be incriminated, and that the prognosis with them is almost always fatal in adults, and to grave in children. There are always symptoms from the septicemia, but they vary widely in different cases. The staphylococcus may proliferate in bile. Septicemia with anaerobes is rare. In the majority of cases the pneumococcus is found in the blood after it has localized in the lung, but in one of his cases the pneumococcus was isolated from the blood before it had localized anywhere. In acute cases of septicemia, if an abscess forms, the prognosis becomes more favorable.

### Archivos Españoles de Pediatría, Madrid

- \*Fractures of the Femur. F. Criado Aguilar.—p. 321.  
\*Weight and Stature of Schoolchildren in Spain. P. Puig y Roig.—p. 327.  
\*Alumun Milk in Infant Feeding. A. Muñoyerro and Bravo Frias.—p. 354.

**Treatment of Fracture of the Femur.**—Criado declares that the treatment of fracture of the femur is still open to improvement. The current methods of continuous extension are not based on correct principles although they may give more or less satisfactory results, but he claims that the plaster bandage he uses is irreproachably efficient and can be absolutely depended on. He gives minute directions for applying it without the slightest compression at any point. He first applies the bandage to the pelvis, winding it to cover perineum and anus, leaving only the genitals exposed. Then the leg below the knee is wound in the same way, including the foot, the patient lying supine. No attention is paid to the fractured region while the pelvis and leg are thus being wound, except to keep the thigh in a generally good position. When the leg and pelvis are thus wound they are held firm by assistants while he reduces the fracture, watching for the disappearance of the deformity of the muscle, the good position of the foot, and the normal length of the limb, comparing it with the sound mate. When the femur is thus in normal position, he draws a horizontal line on the pelvic bandage, at about the anterior superior iliac spine, and another at the middle of the bandage on the leg, and measures the space between, cutting a piece of cardboard exactly the length of this space. This cardboard measure is entrusted to an assistant, possibly a member of the family, and the thigh is then wound with the bandage, measuring with the cardboard constantly to keep the two lines the same distance apart so that the limb will retain its normal length. The thigh and knee are wrapped in cotton and the plaster bandage is applied over this, smearing more plaster on the pelvis and leg bandages to make the whole solid. When the plaster hardens, he cuts out an opening for the anus and for the heel. The plaster bandage holds the whole limb in its normal position and length by the extension and counterextension from the plaster hold on the dorsum of the foot and the perineum, thus preventing any contraction of muscles. The patient can be up and about with this bandage if care is taken not to fall.

- \*Ethnic Enlightenment of America. C. E. Paz Soldán.—p. 125.  
\*Etiology and Pathogenesis of Cholecystitis and Cholelithiasis. Rivas Morales.—p. 127.

**The Eugenization of America.**—Paz Soldán reiterates that *governar es sanear, es eugenicar*, and that America calls for eugenization and biosocial progress. He insists that the scientific societies, especially the national academy of medicine in the different countries, should inaugurate a campaign to enlighten the public in regard to racial and eugenic duties as a new and exalted form of patriotism. He appealed to the Academia de Medicina at Caracas to consider taking the lead in this work. The Academia warmly endorsed this plan of ethnic enlightenment as the synthesis of a vast program of life and prosperity for the human being on this western continent, but it declined to take the lead in the movement as it was not in a position and did not have enough prestige to inaugurate an important crusade of the kind, but it promised to serve valiantly and devotedly in the ranks.

### Medicina Ibera, Madrid

July 5, 1919, 8, No. 87

- \*Criticism of Modern Methods for Extraction of Cataract. I. Barraquer.—p. 1.  
\*Early Diagnosis and Operative Treatment of Cerebellopontine Lesions. W. López Aibo and D. García Hornaache.—p. 5.  
July 12, 1919, 8, No. 88  
\*Electrocoagulation of Bladder Tumors. F. Miravet.—p. 17.  
\*Radium in Dermatology. L. Rodríguez and F. Sierra.—p. 21.

**Cerebellopontine Lesions.**—López and García remark that they could find only one article on this subject credited to a Spanish author among the 300 articles they consulted. They have encountered at the public hospital of Bilbao four cases of lesions pressing on the cerebellopontine tissues. The patients were three men between 29 and 32 and one woman of 24. The disturbances may be ascribed to trigeminal neuralgia at first, and it is important to examine with minute care the functions of the fifth, sixth, seventh and eighth nerves. In their cases the evacuation of the pus in the one case of cerebellopontine abscess was followed by a complete cure, but two other patients given operative treatment succumbed to respiratory paralysis. Treatment for syphilis had been pushed in some of the cases but no benefit was apparent. In one of the operative cases a cerebellopontine extension of a tumor in the left half of the cerebellum had been assumed, but the space was found empty. Hemorrhage from the lateral sinus compelled tamponing and this entailed a destructive process with hemiplegia and the patient died six weeks later; no necropsy.

**Electrocoagulation of Bladder Tumors.**—Miravet reports favorable experiences with electrocoagulation of bladder tumors, and commends it as simple and practical. As it does not require general anesthesia, the patient can live his usual life throughout the course. A single application usually cures completely the smaller tumors. The principal advantage in cancer cases is that it checks the tendency to hemorrhage, but he has had a number of cases in which the malignant tumors retrogressed to a certain extent, and in one case to a complete clinical cure.

**Radium in Dermatology.**—Rodríguez has applied radium treatment in 122 cases of cancer of the skin during the last ten years, and 119 of the patients were radically cured. All are free from recurrences to date. The three failures were in patients who had been previously treated vigorously with the roentgen rays; one had an ulcerating roentgen dermatitis. He has applied radium in 147 cases of lupus and many of these patients with lupus of thirty or forty years' standing were cured. A preliminary cureting seemed to promote the action of the radium. Among other lesions that subsided under radium were leukoplakia and lichen planus of the tongue, and he regards treatment of these as very important as they predispose to malignant disease.

### Prensa Médica Argentina, Buenos Aires

June 20, 1919, 6, No. 2

- \*Tardy Inherited Syphilis. M. R. Castex and N. D. Rosso.—p. 25.  
\*Craniotomy for Bullet Wound. R. V. Hernández.—p. 27.  
\*Localizations in the Brain by Light of Biologic Psychology. E. Mouchet.—p. 28.  
\*Study of Pulmonary Tuberculosis as Part of Curriculum. A. Cetrinolo.—p. 30.

**Tardy Inherited Syphilis and Abdominal Disease.**—Castex and Rosso give minute details of nine cases with numerous roentgenograms which confirm that various gastro-intestinal affections may be traced to inherited syphilis. They say that such cases are comparatively numerous, and a frequent type is the gastroduodenal ulcer. A circumscribed perivisceritis, causing pain in the epigastrium, is also relatively frequent. Chronic inflammatory processes in and around the sigmoid and the rectum may be a tardy manifestation of inherited syphilis. Chronic peritonitis with effusion is sometimes traceable to it also, but when this is the case other serous membranes are usually involved and some of the viscera may be diseased. It may be impossible to differentiate these tardy syphilitic lesions from tuberculous changes, but the improvement under tentative treatment as for syphilis clears up the case. Some of their cases presented Lane's kink and Jackson's membrane as syphilitic lesions of this category. Lane called attention to the benefit from calomel in cases of kink, but he ascribed it to the action on the liver.

**Localization in the Brain by the Light of Biologic Psychology.**—Mouchet is professor of abnormal psychology at the University of La Plata, and he remarks in the course of this study of the localizations in the brain that we are less certain about them now than we were a few years ago. Instead of a lot of pigeon-holes for different functions, psychology is progressing toward acceptance of the great unity of our mental life although recognizing zones of special functioning. He insists that we must not depreciate the importance of the white substance of the brain; injury of the former may modify functioning as seriously as injuries of the cortex. He explains how the blood not only nourishes and warms the brain and maintains the pressure, but it also brings hormones to act on it. The hormones are likely to be very important for the functioning of the brain cells. When the stimuli from the hormones predominate, our action is instinctive; when the stimuli from the nerves predominate, our action is under the control of the mind, but the brain is always under the influence of both. When an action is repeated through generations, it comes to be performed with less and less attention from the senses. The hormones alone are able to accomplish it. He asserts that the hormones poured out into the blood "are responsible for the states we call love, desire, appetite, etc. If we remove the glands that secrete the hormones involved, the instinct is lost, and the mental state we call eunuchism is entailed. This hormonal basis underlies the emotions and the intelligence which orient and civilize instinct. Each one of us is kindly or malicious, an imbecile or genius, brave or cowardly according to his entrails and his humors. The hormones are the primary cause of instinct, the voice of our ancestors; our eyes and ears direct and civilize the hormonal action." The hormones act on the brain throughout. The mental states which are the result of their stimulating action cannot be localized at any special point but must involve the whole of the brain mass. The point where a nerve starts, and the region immediately around it, naturally become more or less specialized in the direction of the movements of the muscle innervated by that special nerve, or in the sensations transmitted to that point by different nerve impulses. But with hormones, there can be none of this isolated, partial action. "This explains the unity of our world, of the whole of the workings of the psyche. It is the unity of the Ego in opposition to the unity of the external world, the Non-Ego."

†Intradermal Tuberculin Injections in Diagnosis and Treatment of Tuberculosis in Children. J. P. Garraban, p. 35.

‡Extensive Colectomy for Cancer: Recovery. N. Tagliavacchi, p. 37.

**Syphilis from Clinical Standpoint.**—Palacio reiterates that recent research has shown that between latent syphilis and extremely active syphilis there are many grades and phases, and a new field of observation has opened up here, just as we have learned recently to appreciate better the extent of

endocrine disturbances. Many of the manifestations, early and tardy, of inherited syphilis have been misinterpreted hitherto, but, on the other hand, it is not right to give mercurial treatment bit or miss. The other children in the family should be examined in dubious cases. The lack of a history of abortions in a family does not exclude syphilis; in some families with a syphilitic taint, fecundation seems to be exceptionally active. The virulence of the taint seems to diminish with the length of the interval since the parental infection. The Bordet-Wassermann test should be complete and not be called on to substitute the history of the case and examination of the patient. When a new infection, such as pulmonary tuberculosis, is superposed on an inherited or acquired syphilis, treatment of the latter may modify the soil, reinforce the defensive powers and enable the patient to throw off the superposed infection as the syphilis yields to treatment. This may give the erroneous impression that the specific treatment has cured the superposed infection. A syphilitic lesion in the lung usually locates in the base, and preferably in the middle lobe of the right lung. There is usually a marked tendency to sclerosis, while the general health keeps good. A tuberculous process developing on a syphilitic soil generally displays a fibrous tendency and only examination of the sputum will tell whether a pulmonary affection in a syphilitic is the work of the syphilis or of the tubercle bacillus.

Palacio adds, "When a syphilitic develops cancer (and the majority of cancer cases are syphilitic), if there is not extreme cachexia, mercurial treatment may improve conditions to such an extent that the physician may doubt the diagnosis of cancer." The lesions of syphilis are liable to locate at points where traumatism has reduced the resistance, and this may explain the lack of recuperation or the delay in healing after a trauma. This has been strikingly demonstrated in certain cases of war wounds; the syphilis by rendering the tissues and the vessels in the region abnormally frail and nonresistant, interferes with normal healing. It is possible, he adds, that certain cases of death under chloroform were in persons with inherited syphilis and consequent endocrine anomalies. Specific treatment before the anesthesia and administration of epinephrin might have tided the patient past the danger point, and aided in the healing of the operative wound. Emotional stress or extreme fatigue may rouse a latent syphilis and cause its localization in the nervous system, the initial symptoms of general paresis appearing soon after. If they are not recognized at once and proper treatment instituted, irreparable lesions may soon become installed.

He warns that treatment should be commensurate with the "age" of the special lesion in question, but sclerosis does not regress, and the most that can be hoped is to arrest the process. Syphilis, like tuberculosis, may flare up during a pregnancy. Palacio explains reinfection in syphilis as due to invasion of exceptionally virulent germs during a phase of extreme latency of the original syphilis. Syphilitic nephritis is distinguished by unusual amounts of albumin in the urine, and mercurial treatment is directly indicated. The albumin decreases and diuresis increases after one or two injections.

**Intradermal Tuberculin Treatment of Children.**—Garraban reviews the experiences with 653 children from 2 to 16 years old given tuberculin intradermally both for diagnosis and in treatment. As a diagnostic test, he found it more reliable than the skin Pirquet test, especially with latent tuberculosis. In case of glandular disease or nodule erythema or suspicion of hypersusceptibility in general, he advises to use only 0.00001 gm. of the tuberculin instead of the usual 0.0001 gm. A positive reaction in an infant is an almost certain sign of active tuberculosis, and a repeated negative reaction in older children almost certainly excludes tuberculosis. The intradermal route for tuberculin treatment of children seems to be also likely harmless. There do not seem to be any contraindications, and it is not necessary to take the temperature; estimation of the proper dose is a simple matter by the aspect of the local reaction. As to the efficacy of tuberculin treatment, he does not share Combe and Jeanneret's optimism. In

some cases no effect was apparent; in many others it "seemed" to be effectual. He advises it as an adjuvant or when fundamental climatic and hygiene treatment is not available.

\*Proposed Code of Ethics.—p. 507.

\*The Epidemic of Whooping Cough at Capcá. M. A. Rueda Vargas. p. 543.

Treatment of Syphilis. M. A. Rueda G.—p. 551. Cont'n.

**Proposed Code of Ethics.** This code was drawn up by the Sociedad de Pediatría de Bogotá to be presented at the Fourth National Medical Congress of Colombia to convene in August at Tunja. The code is almost identical with the one adopted in 1918 by the Academia Nacional de Medicina of Venezuela which was very fully described in THE JOURNAL, Sept. 21, 1919, p. 1013. The obligation of physicians to attend their confrères free of charge and without discrimination as to nationality is more explicitly stated in this new code, and a colleague is defined as (1) those who have completed the required course of study; (2) those who have obtained the diploma of physician or surgeon, and (3) those who are dependent in any way on the medical profession. The code continues "The physician should prescribe gratuitously for the colleague's family, that is, for his parents, wife and children provided they do not have a financially independent position. This obligation does not cease with the death of the colleague." It is stated further that at a consultation "no opinions or prognostications should be expressed except as concurred in by the consultants at their conference, and which cannot injure in the slightest the reputation of the attending physician in charge of the case." The hours for day calls are from 8 to 8; for night calls from 8 p. m. to 6 a. m. The Venezuela code made elaborate provisions for a "Tribunal of Honor," but there is no reference to anything of the kind in the proposed code. It closes with the suggestion that it is a duty of *compañerismo profesional* to keep a list of clients who elude payment for medical services, so that other physicians in the same locality can be informed. The code further omits the Venezuela clauses saying that the physician should not make an examination of a married woman unless her husband is present or some one appointed by him, and that a general anesthetic should not be given without the presence of at least two physicians. The code reiterates all the Venezuelan denunciations of *industrialismo médico*, of secret division of fees, and of "the preparation, sale, or promotion of the use of secret medicines."

**Whooping Cough.**—Rueda reports an epidemic of pertussis of unusual severity, the incubation being only three days at most and the spasmodic cough appearing at the fourth day after the initial symptoms. The paroxysms of coughing recurred five or six times an hour, the child being so exhausted in the interim that it lay inert and did not react to any stimuli. Some of the paroxysms of coughing lasted four minutes, the children becoming cyanotic and various complications developing, including epistaxis, conjunctival hemorrhages, hernia, prolapse of the rectum and bronchopneumonia. The latter always proved fatal in these cases, the paroxysms of coughing keeping up in the pneumonia. One child developed a gangrenous process in the mouth which proved fatal. He describes one case in which an artery in the brain of a child of 2 ruptured during a coughing paroxysm, fifteen days after the first symptoms. In one child of 8 the pneumonia dragged along for six weeks and left a condition strongly suspicious of tuberculosis. No cause for the special gravity of the pertussis could be discovered. Vaccine therapy seemed to have an attenuating influence in some cases, the paroxysms becoming less frequent and less severe thereafter.

\*Lessons from Laparotomies. S. Cardenal.—p. 314.

Bronchopulmonary Sprochetosis. Remigio Dargallo.—p. 323.

**Grafts of Dead Tissues.**—Soler reviews here the work of Senece and Nageotte as he watched their experimental research in this line and its outcome. It has been repeatedly described in these columns, and the way in which the graft kept in alcohol for a month grows into its new bed. The connective tissue persists, but all the other cells are resorbed and new ones take their place so that the dead tendon, for instance, recovers its vitality. One man, among others, with an ingrafted tendon to remedy an extensive defect had regained the use of hand and fingers and no one would have suspected that his arm had been crippled.

**Improved Technic for Transperitoneal Cesarean Section.**—Ruiz clamps two forceps on the anterior wall of the fundus of the uterus, about 10 cm. apart, and walls off the rest with napkins. Then he makes a small incision in the center and works through it with his fingers and the handle of the bistoury, separating the fetal membranes from the wall of the uterus. The membranes are not distended as they have ruptured and the fluid has escaped by the natural routes beforehand; he has aided this by having the woman stand up while he lifts with his finger the presenting part of the fetus. Then he fits over the uterus a square of impermeable tissue, about 40 cm. square, cut in the middle so that the edges of the opening thus made can be turned down over the edges of the incision in the uterus, thus covering them completely, and the whole is held in place with forceps. The field of operation is thus completely isolated and all that can be seen is the fetal membranes. These are then incised, the fetus extracted, the square of impermeable tissue removed, and the uterus sutured before the napkins are touched. In conclusion he sutures each of the edges of the lower part of the incision in the parietal peritoneum to each side of the suture in the uterus. This shuts off all communication between the interior of the uterus and the peritoneal cavity, even if the suture should not hold. This suturing does not fasten the uterus firmly to the abdominal wall as a peritoneal ligament soon develops, and this permits ample movement.

**Lessons from Laparotomies.**—Cardenal mentions among other lessons learned from his 2,100 laparotomies that it is not enough for medical students to study the anatomy of the normal abdomen. They should be given opportunities to study pathologic anatomy. They should never miss an opportunity to see "cases, cases and ever more cases." The peritoneum defends itself better than tissues of the connective-tissue type against mild infection, but when the infection is too strong for it, the invasion proceeds more rapidly and fatally than with any other tissue in the whole organism. Another important element in the pathology of the abdomen is the abundance of nerves throughout the entire area of the visceral peritoneum, ramifications from the solar plexus, intimately connected with the cranial nerves which preside over the respiration and circulation. This makes it imperative to reduce to the minimum all exposures of the peritoneum, and keep the viscera in an isotonic medium throughout any intervention, with the minimum of damage to the delicate endothelial coat of the peritoneum as on this depends its resisting power and its wonderful agglutinating power which allow the healing of a wound in a few hours.

With operations in the epigastric zone, the great danger is from bronchopulmonary complications and he ascribes this to a paralyzing influence on the bronchi by reflex action from injury of the sympathetic during the operation. This may occur without infection from the wound, as he has seen these bronchopulmonary complications develop when the wound was healing smoothly and aseptically. On account of the pain, the patient breathes as gently as possible and this, superposed on the reflex inhibiting tendency, reduces the already inadequate ventilation of the lungs and thus gives the saprophytes in the mouth, etc., a chance to proliferate and set up infection. The only means to ward it off is scrupulous cleanliness of the mouth and teeth before the operation, and exercises in breathing, especially deep inspirations, after the operation, favored by the semiseated position.

Lavage of the stomach wards off acute paralysis of the stomach; it has been most frequent in his experience after gallstone operations. He does not wait for the patient to

vomit or develop fever, but rinses out the organ when there is repeated malodorous eructation and the patient feels distressed. He repeats the lavage every six or eight hours and normal peristalsis usually is soon restored. Vomiting of black blood is combated in the same way, and conditions are usually brought back to normal.

He adds that he has several times found the first part of the ileum adherent in a vertical position to the posterior aspect of the stomach, as if Nature was about to do gastro-enterostomy. He reiterates that procrastination kills more persons than any disease, and that this is true of ileus and appendicitis in particular. The patient himself, his family, his physician, and even the surgeon may procrastinate from day to day, and the hour for successful intervention slips past. He adds, "In case of doubt, make an opening into the bowel above. Anything is better than to let the patient die from the poisons generated in the obstructed bowel, and do not be misled by alternations of euphoria and symptoms of obstruction." He incises on the median line to close an artificial anus, and cuts the intestine, leaving unmolested the loop fastened to the abdominal wall. After the side-to-side entero-anastomosis has been completed, he passes a forceps through the artificial anus, into each of the stumps of the bowel adherent to the wall. Seizing the free end of the stump he draws it out through the anus, inverted, like the finger of a glove. This brings the entire mucosa all outside the abdomen, the whole looking like the umbilical cord of a newly born infant. There is nothing left inside the abdomen except a small funnel lined with peritoneum. This serves as a drain for a time and gradually heals up. The portion drawn out can be allowed to dry up and drop off, like the umbilical cord, or it can be cut off later when the opening has healed over beneath. All that is left can be finally buried under the skin if desired. In the after-treatment, it must never be forgotten that retention is the great enemy to be combated.

\*Nature and Treatment of Accidents from Arsenical Treatment of  
Syphilis. V. Pardo Castello.—p. 395.

**Accidents from Arsenical Treatment of Syphilis.**—Pardo remarks in the course of this general review of his own and others' experiences, that what is called the nitritoid reaction cannot be ascribed to anaphylaxis, as a preliminary small injection before the main injection of the arsenical preparation did not attenuate or modify in any way the severe so-called nitritoid reaction in five cases in his experience. On the other hand, injection of a small amount of epinephrin warded it off completely in persons previously subject to the reaction in a severe form. This seems to sustain the assumption that this reaction is due to the vasodilator action of the drug. Serous apoplexy or hemorrhagic encephalitis is one manifestation of this nitritoid reaction, probably the result of dilatation of the vessels in the brain. In a case of this kind the serous apoplexy developed three days after a second injection—0.30 and 0.45 gm. of neo-arsphenamin—with convulsions and a comatose condition. Rapid recovery followed two intramuscular injections of epinephrin. The urine confirmed the vasodilation of the viscera, numerous red corpuscles being found in the sediment. Edema at the base of both lungs was also manifest. The condition is not restricted to the brain, and hence the term serous apoplexy is more appropriate than encephalitis. In conclusion, Pardo remarks that time has reduced the list of contraindications to merely advanced nervous and heart lesions with lost compensation and extreme cachexia. He cites a case in which the needle broke off in the vein and was swept away, compelling an operation to recover it.

The Problem of Tuberculosis. C. Ferreira.—p. 684.

**Large Ovum.**—Pérez reports the successful delivery of an apparently healthy child weighing 5,530 gm. at birth. The mother of 24 had had one healthy child and two abortions and gave a negative Wassermann reaction, but a year or two before had responded positively to the test and had taken a course of mercurial treatment. Both of the parents were medium sized. All the membranes were unusually large so that the case was one of "large ovum" (7,530 gm.) and not merely an extra large fetus. There is every probability that syphilis was a factor in the disproportionate size of the ovum.

**Serotherapy and Vaccine Therapy of Tuberculosis.**—Milano refers to the prepared serum and vaccine made according to Ferrán's theories in regard to the different stages of the tubercle bacillus before it becomes the actual tubercle bacillus as we generally recognize it. He claims that by seizing it in the first of its three phases and vaccinating against it, the organism becomes immune to this phase, and hence there is no chance for it to contract the infection in the succeeding phases as the indispensable first link is missing. The Ferrán theories were recently described in these columns, Aug. 9, 1919, p. 460, and Oct. 4, 1919, p. 1074.

**Intestinal Metastasis of Malignant Chorio-Epithelioma.**—Faulin discusses the metastasis of chorio-epithelioma and reports a case which seems to be unique, the metastasis of the chorio-epithelioma developing in the ileum, about a year after the hysterectomy. The first signs of the malignant disease had been noted seven months before this, vesicles being expelled from the uterus which was only cured at that time.

Personal Displacement of the Testicle with Inguinal Hernia. W. P. J. H. Geyl.—p. 2272.

**Negative Wassermann in Ocular and Cerebral Syphilis.**—Smit declares that we must not pay much heed to negative Wassermann reactions in syphilis affecting the nervous system and the eyes. The response with blood was constantly negative in 12 of the 14 cases he has encountered in the last three years. In half of them the blood vessels and in the other half the cornea or the heart seemed to be primarily affected. In only 2 of the 12 was there a history of known syphilis. In 2 of the cases in which the syphilis had run an insidious course, it flared up with stormy symptoms during an intercurrent infectious disease, as also in 2 others who were not given the Wassermann test. One of these developed apoplexy after typhoid, with oculomotor paralysis, tabes, diabetes insipidus, prostatitis and weakness of the heart; another after pleurisy had diabetes insipidus and multiple adhesions in the pleura, with shriveling of the lung. Tabes in one case seemed to retrogress under twelve intramuscular injections of mercury peptonate, from 0.01 to 0.03 c.c. in 3 c.c. of water. Notwithstanding the negative response to the Wassermann test, the radical improvement under mercury confirmed the diagnosis of syphilis.

**Famiae Edema in the Netherlands.**—Beyermann states that twelve of the inmates of the insane asylum at Medemblik developed in 1917 and 1918 edema and other symptoms which suggested scurvy or purpura except for the remarkably slow pulse and the absence of changes in the gums. Conditions returned promptly to normal without other measures than the addition of fresh vegetables to the otherwise unmodified diet.

Measurement of the Blood Pressure. L. Kaiser.—p. 105.

**Epidemic Meningitis.**—Orbaan relates his experiences with eighteen cases of epidemic meningitis in the military hospital at Harderwijk. No permanent paralysis of cranial nerves was observed in the thirteen survivors. One man was left a carrier of meningococci in the spinal fluid although the nasopharyngeal secretions seemed sterile. In another case the symptoms developed with lightning-like rapidity; the antiserum was used without delay and recovery proceeded with almost equal haste. Orbaan found it extremely useful to separate the men into groups to examine for carriers. When a group was found free from a carrier, all the members of the group were allowed their freedom. By separating into constantly smaller groups, it thus proved possible to reduce to a very small number those requiring isolation. The average was always from 1 to 4 per cent. of carriers, and when these carriers were isolated the building seemed to be freed from the disease. A counter-proof as to the importance of carriers was furnished by his examination of a group of 250 returned Belgians among whom there had never been any cases of meningitis. Careful search failed to reveal a single carrier among them.

\*Roentgen Treatment of Cancer. S. Nordentoft.—p. 1307.

To Determine Specific Gravity of Small Amounts of Urine. H. C. Hagedorn.—p. 1319.

**Roentgen Treatment of Cancer.**—Nordentoft has long been preaching and practicing the treatment of malignant tumors with a single intensive exposure to the roentgen rays, striking hard and thoroughly once for all. It is a risky thing, he says, to apply roentgen treatment when some other physician has given one or more exposures before. The question then is whether to leave the patient to die of the cancer or run the almost equally dangerous risk of roentgen necrosis; in this latter case there is usually some discredit for the physician. He now refuses to treat any patients with brain tumor who have been previously rayed. He relates some cases to show the danger from wasting time on medical measures with a tumor in the throat or nose, and says that the regional glands in the neck with a tumor in the pharynx should not be operated on without microscopic examination. In one case described, a girl of 17 had a sarcoma of the femur subside under roentgen treatment and also a large metastasis in the temporal region. The primary focus in the femur flared up anew but again subsided under roentgen treatment and a metastasis in the mastoid process retrogressed spontaneously. The girl is now apparently perfectly well and looks healthy, but new metastases are liable to develop at any time. Our conceptions of metastasis require revision, he says, as recent research has demonstrated that metastases occur much earlier and on a more extensive scale than hitherto deemed possible, but that they are unable to develop as long as the resisting powers keep at a good level. The spontaneous retrogression of the tumor in the mastoid process in this case justifies the hope that other metastases might undergo the same fate.

He refers in conclusion to the use of autovaccines, saying that the effects of raying a tumor are equivalent to an auto-vaccination on a large scale, and with much more thorough incorporation than with injection of any possible vaccine. But no immunization against new attacks results, and this shows, he says, how futile such vaccines must be in therapeutics.

## THE ARTIFICIAL FEEDING OF ATHREPTIC INFANTS \*

W. McKIM MARRIOTT, M.D.  
ST. LOUIS

The term "athrepsia," as used in this paper, refers to that well known condition of extreme malnutrition of infants otherwise known as "marasmus," "infantile atrophy," or "dekomposition."

### PATHOGENESIS OF ATHREPSIA

The essential factors in the pathogenesis of the condition, as determined by recent investigation, are discussed elsewhere,<sup>1</sup> and they need now only be referred to briefly. The condition of athrepsia may be considered as the end result of an insufficient intake or of a failure to utilize food in sufficient amount to supply the demands of the body; in other words, a condition of virtual starvation. In this condition the volume flow of the blood, that is to say, the amount of blood flowing through a given portion of the body per minute, is diminished. This diminished volume flow, it has been shown, is dependent, in part at least, on a decreased blood volume, seemingly the result of a decreased protein content of the plasma and consequent inability of the blood to maintain its water content. There is an atrophy of the blood as well as of the rest of the body.

### PRINCIPLES OF TREATMENT

The obvious remedy for the condition is food, and very considerable amounts of food, for the energy requirement of such infants is high, and there is the need for replacing much lost tissue. Many of these infants will not begin to gain until they have received as much as 150 or 200 calories per kilogram of body weight, but unfortunately the tolerance for food is low. The intestinal tract and digestive glands supplied by an atrophied, poorly circulating blood are functionally weak. Digestion and absorption of food is necessarily poor. Unabsorbed food remaining in the intestinal tract of a weak infant is "gunpowder" which requires only the proper "match," bacterial or otherwise, to precipitate a catastrophe.

We are confronted then, with the problem of feeding a large amount of food to an infant whose intestinal tract may be incapable of caring for even small amounts of ordinary food.

### THE INJECTION OF GLUCOSE

Food may, of course, be introduced parenterally, but this method of administration has definite limitations. Carbohydrate, in the form of glucose, is the only food that it is practicable to administer parenterally. Pure amino acids or fat emulsions are theoretically suitable for intravenous administration, but are not practical in the present circumstances. Intravenous injection of glucose is a valuable and temporary expedient when the need for food is imperative. The few extra calories introduced in this way occasionally seem to be sufficient to turn the tide in favor of the infant.

Something may be done toward increasing the tolerance of the infant for food. This tolerance, of course, rises as the nutrition and circulation improve, but it is possible to shorten to a great extent the period of repair. This is accomplished by increasing the blood volume and as a result, the volume flow. This may be done by blood transfusions or by the intravenous injection of a gum acacia saline mixture.<sup>2</sup> It is necessary to repeat the transfusions or injections at fairly frequent intervals. Whether or not these procedures are carried out, we still have before us the necessity for providing a food which contains the elements essential to nutrition and which can be fed in large amounts without causing gastro-intestinal disturbances. Breast milk, of course, meets the indication; but breast milk is not always available.

### USE OF LACTIC ACID MILK

It has been a matter of common experience that infants suffering from gastro-intestinal disturbances are able to take larger amounts of milk artificially soured by lactic acid organisms than they can of sweet milk. We have come to regard buttermilk and protein milk as our chief reliance in the feeding of infants with gastro-intestinal disturbances. Buttermilk, that is to say, fat-free lactic acid milk, is low in caloric value; and although a useful food during a period of lowered tolerance, is not a food on which an athreptic infant will gain weight consistently. The caloric value may be increased by the addition of sugar and starch, and favorable results from the feeding of such a mixture have been reported. Protein milk is also a food invaluable for certain purposes, but of relatively low caloric value; and even when enriched by sugar addition it is not especially well adapted to the feeding of markedly athreptic infants, particularly those under 3 months of age, for any length of time.

\* From the Department of Pediatrics, Washington University, and the St. Louis Children's Hospital.

<sup>1</sup> Read before the Section on Diseases of Children at the Seventy-sixth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

1. Marriott, W. McKim: Proc. Am. Ped. Soc., 1919.

<sup>2</sup> The solution used is composed of gum acacia, 10 gm.; glucose, 5 gm., and physiologic sodium chloride solution, enough to make 100 c.c. The solution should be centrifuged a short time before using, as a slight sediment tends to collect. From 10 to 20 c.c. of the solution per kilogram of body weight are injected very slowly into the sinus or into a surface vein.

In selecting a food for athreptic infants, we determined on a lactic acid milk as a basis. There would seem to be no very good reason *a priori* why the fat or, at any rate, all of the fat, should be removed from lactic acid milk. Surely the 2.5 per cent. of fat in protein milk is perfectly well tolerated. Buttermilk is ordinarily fed undiluted to even young infants with fairly good results, thus demonstrating that the concentration of sugar, protein and whey constituents contained in whole milk is not in itself harmful. A certain amount of fat can be tolerated by almost any infant, especially in a lactic acid milk mixture. On this assumption we have fed undiluted lactic acid milk containing amounts of fat up to the amount contained in whole milk, and have been convinced that the great majority of weak, athreptic infants tolerate extremely well undiluted whole lactic acid milk in fairly large amounts, one fifth of the body weight or more per day. For infants under 2 months of age we have usually fed the lactic acid milk somewhat diluted, but the evidence is not conclusive that such dilution is essential.

#### ADDITION OF CARBOHYDRATE

Having demonstrated to our satisfaction that whole lactic acid milk is well tolerated, we cautiously tried the addition of carbohydrate to the lactic acid milk in order further to increase the caloric value. The sugar selected for such a purpose must be one which does not readily undergo fermentation or which, if fermentable, will be so rapidly absorbed that but little fermentation can occur before absorption. The dextrins are not readily fermentable; they are easily split into maltose and glucose by intestinal enzymes but apparently not more rapidly than the end product can be absorbed; therefore little fermentable material is present in the intestinal tract at any one time.

Glucose itself is absorbed with astonishing rapidity, as has been demonstrated by intestinal loop experiments on animals. On the other hand, glucose is very readily fermentable, and for this reason has not been extensively used in infant feeding. Weill and Dufourt<sup>3</sup> have fed considerable amounts of glucose to infants in the attempt to render the stools acid, but in no case was it possible to do so, presumably because the glucose was absorbed before a great deal of fermentation had occurred. The products of the action of lactic acid organisms on glucose are quite innocuous. On theoretical grounds, it would seem that if glucose were fed in combination with lactic acid milk there would be a fair chance of its being absorbed before being attacked by intestinal organisms capable of producing harmful fermentation products. Experiments *in vitro* have shown that in such a mixture the common bacterial inhabitants of the intestinal tract are unable to flourish. In view of the considerations just mentioned, it would seem that a mixture of glucose and dextrin would be an ideal form of carbohydrate for our purpose. Maltose is usually present in ordinary mixtures of glucose and dextrin. In moderate amounts it is well tolerated by infants.

#### THE ADVANTAGES OF CORN SYRUP

Commercial "glucose," otherwise known as "corn syrup," is a mixture of dextrin, glucose and maltose. Of the total carbohydrate present, dextrin makes up approximately 55 per cent., the remainder being maltose, 30 per cent., and glucose, 15 per cent.<sup>4</sup> From its

composition, such a mixture would seem to be well adapted for the purpose desired. An additional advantage of corn syrup is that it is cheap and is obtainable everywhere. We have added carbohydrate in the form of commercial corn syrup to the whole lactic acid milk fed to athreptic infants, and the results were as would have been anticipated. There was little or no tendency to diarrhea, even when as much as 10 per cent. of carbohydrate was added. The stools remained firm, formed and pasty, averaging from one to three a day. In the case of some infants there seemed to be almost no limit to the amount of carbohydrate that could be added to such a milk mixture. Thus we have added a sufficient amount of carbohydrate to cause a distinct glycosuria and have continued the feeding of such large amounts for long periods of time without there being the least tendency to diarrhea or vomiting, and this in the case of extremely weak and emaciated infants, previously suffering from prolonged diarrhea. Not only has it been possible to add this form of carbohydrate to whole lactic acid milk mixtures with impunity, but corn syrup in 5 per cent. solution may be given almost ad libitum between feedings as a means of supplying further calories.

#### METHOD OF PREPARATION OF LACTIC ACID MILK AND CORN SYRUP MIXTURES

Whole milk is sterilized by boiling, cooled to room temperature, inoculated with a culture of Bulgarian bacillus or other lactic acid producing organisms, and incubated over night. A properly prepared whole lactic acid milk is thick, creamy and homogeneous. Too long a period of incubation or too high a temperature results in the separation of curds and whey.

The corn syrup we have used has been an ordinary commercial variety. Such a syrup contains from 80 to 85 per cent. of carbohydrate by weight or, as its specific gravity is high (approximately 1.40), it contains from 110 to 120 per cent. of carbohydrate by volume. The thick syrup is somewhat difficult to handle and to mix with milk. It is more convenient to prepare a diluted syrup. Mixing 45 volumes of the thick syrup with 55 volumes of water gives a thin syrup containing approximately 50 per cent. of carbohydrate. One hundred c.c. of this by volume may be considered as containing 50 gm. of carbohydrate. Such a thin syrup is measured in a graduate and added to the whole lactic acid milk. The mixture should not be agitated sufficiently to separate the fat as butter. The mixture is not further sterilized, but is kept in a refrigerator until used. As such mixtures are very thick, a nipple with a large hole must be used in feeding.

#### THE FEEDING OF THE MIXTURES

In feeding formulas of the type described, it is advisable to begin with a mixture of equal parts of whole lactic acid milk and buttermilk (fat-free lactic acid milk) or, in the case of infants convalescing from diarrhea, on buttermilk alone. If such a mixture is well tolerated, the proportion of whole lactic acid milk in the mixture is increased until straight whole lactic acid milk is fed in most instances. The addition of the syrup is then begun, 3 per cent. of sugar being added at first; if no diarrhea occurs, the sugar percentage is gradually increased, depending on the infant's tolerance and on the amount of food necessary to cause a gain in weight. Fairly large amounts of the corn syrup can often be given to advantage.

3. Weill and Dufourt: *La Nourriture* 2: 65, 1914.

4. W. S. Teller and J. L. Teller: *J. Indust. and Engin. Chem.* 7: 1009, 1916.

The number of ounces of the milk mixture given at a feeding should be approximately the same as if breast milk were fed. We have used four-hour feeding intervals almost exclusively.

#### RESULTS OBTAINED

Up to the present time, we have fed the enriched whole lactic acid milk mixtures to forty infants varying in age from 1½ months to 18 months, the majority being between 2 and 5 months of age, at the time the feeding was begun. The period of time over which different infants received the formula varied from four days to eight weeks.

All of the infants were undernourished—the majority markedly so. About half of those observed had recently suffered from diarrhea. Four were syphilitic; fifteen suffered from other infections during the period they were on the formula. The infections included pyelitis, otitis media, pertussis and bronchopneumonia.

Little difficulty was experienced in making the infants take the food. Some older infants refused the food at first, but later took it eagerly. There were mechanical difficulties in feeding two infants with cleft palates. They did not at first seem able to swallow well the very thick mixture; later they took it without difficulty.

The amount of carbohydrate added to whole lactic acid milk varied up to 10 per cent. or over, the total sugar content up to as high as 15 per cent. The total added carbohydrate has been as high as 3 ounces a day. The amount of added carbohydrate has been greater in our more recent cases, as we have become convinced of its relative harmlessness. The result, as far as improvement of the nutritional conditions were concerned, have been distinctly better with the increased amount of added carbohydrate.

Vomiting, other than the spitting up of very small amounts immediately after a feeding, was unusual. In almost every instance it could be accounted for by the onset of an acute infection. Two infants with cleft palates vomited if the food was forced, and one infant with syphilis of the central nervous system vomited at intervals. This infant also had convulsions from time to time, and it seemed a reasonable assumption that the vomiting was of central origin.

#### THE CHARACTERISTIC STOOLS

The characteristic stools of the infants fed on the mixture described were light brown, formed, and pasty when mashed with the spatula. The number averaged from one to three a day. Several infants had stools looser than normal for a day or two at a time, but the stools again resumed their usual character without a change in food. Two infants with bronchopneumonia, one with pyelitis, and one very athreptic infant dying in collapse, developed a diarrhea during the last few hours of life. Aside from these four, only three infants developed a sufficient degree of diarrhea to warrant a change of formula, and all were returned to the same formula after a period and did well. Two of these had at a previous time suffered from diarrhea while on breast milk. None of the infants developed a condition at all suggestive of "intoxication."

#### THE GAIN IN WEIGHT

A gain in weight of the infants fed on whole lactic acid milk mixtures began when a sufficient caloric intake was reached, and generally continued steadily

for days and weeks, interrupted only by acute infections. Some infants continued to gain even through febrile periods. The number of calories required before an infant would gain weight consistently was often high. Few infants whose weight was as low as 50 per cent. of the normal weight for the age gained on less than 160 calories per kilogram, and many required 200 calories or more. The gain in weight of these infants was not due to a process of "water logging." The gain continued over too long a period, and the flesh was firm and elastic. There was no tendency to edema, and none of the excessive flabbiness observed in condensed milk babies which one might expect in infants fed on a high carbohydrate intake. It might be well to draw attention to the fact that although the food here described contains a high percentage of carbohydrate, it is also high in protein and in fat, the relative proportions not being unlike those of ordinary milk mixtures. It is essentially a concentrated food, and therein lies its chief advantage. If an infant can take only a limited number of ounces at a feeding and only a limited number of feedings in the twenty-four hours and yet requires a large caloric intake, the only solution is to give him a food containing a large number of calories per ounce. The mixtures described have a fuel value of from 25 to 30 calories to the ounce, a larger amount than is contained in breast milk or in any of the usual milk formulas that could be fed with safety.

#### CONCLUSION

We wish to emphasize the fact that we do not consider the type of feeding here described as a panacea for infants. Whole lactic acid milk enriched with the carbohydrates of commercial corn syrup is simply a type of food that enables one to administer a considerable amount of nutriment in an easily assimilable form to infants needing a large amount of food but having an intolerant gastro-intestinal tract. Aside from this, there are no mysterious virtues in such a mixture.

#### ABSTRACT OF DISCUSSION

DR. FRITZ B. TALBOT, Boston: There is much in Dr. Marriott's paper which gives food for thought. One point he brought out, which I think bears repetition, is that children under weight require more calories per kilogram of body weight than the child of normal or average weight. That is borne out both in practice and in the basal metabolism. There is one point, however, which he neglected to state in his paper, and as he read it I thought of atrophic children I have seen, most of whom have subnormal temperatures. If such children are warmed up they frequently commence to gain weight, if they get enough calories. It must be remembered that if the amount of sugar is raised beyond a certain point it will not be absorbed and diarrhea will result. Of course, Dr. Marriott is dealing with another type of sugar than what is ordinarily used, and it is quite conceivable that the limit of absorption of this sugar is higher than that for those in ordinary use.

DR. ALFRED F. HESS, New York: About one year and one-half ago, I had an opportunity to feed some children on corn sugar. At that time, as you know, there was a great want of sugar in the community, and the Division of Chemistry in the Department of Agriculture, Washington, asked me whether I would see how corn sugar was digested by infants. I tried about twelve infants on the regular milk mixtures with the addition of 5 per cent. corn sugar instead of the ordinary cane sugar. These babies varied in age from about 2 months to 1 year. They were kept on this sugar for a period of about three months, and they all did exceedingly well. After the war was over and the shortage of sugar no

inger existed, we went back to cane sugar. I did not use the syrup, but just used the ordinary cane sugar. It is always cheaper than cane sugar and could be sold for a great deal less, but is always less than the cane sugar. Dr. Marriott has raised the question of whether this sugar is a desirable letter. If it is absorbed to a greater extent it is of course of greater value. This can be determined readily by metabolism experiments.

Dr. J. P. CROZER GRIFFITH, Philadelphia: I asked the chief resident physician of the Children's Hospital of Philadelphia several months ago what diet he would choose if he were obliged to select one kind of diet for these marantic babies. Without hesitation he answered, "buttermilk." By this I mean the usual buttermilk mixture with flour and sugar, which is now being used so much by physicians, and I hope will be used more and more because it is such a valuable preparation. I was very glad, indeed, to hear Dr. Marriott's paper corroborate my own experience with the lactic acid preparations of milk, and regarding the ability of the child to take a high percentage of carbohydrate. With the ordinary preparation of buttermilk, wheat flour and saccharose, referred to, the carbohydrate runs up to 10 or 11 per cent., or even more. I have had a decided fear of the high percentage of fat which Dr. Marriott has been using, believing that one of the values of the buttermilk food was the small amount of butter fat in it. However, experience must be the teacher in that matter, and Dr. Marriott's observation seems to show that the fat after all can be borne better than we supposed. It will be interesting to test this further. Dr. Marriott spoke about the food preparations containing lactic acid being more digestible. This has been my own experience. The fact that it is often difficult to have the parents prepare buttermilk properly at their homes makes me desirous, in hospital practice, of placing the infants on some other food as soon as possible. We have tried often to get away from the buttermilk mixture by making one of similar composition by using skimmed milk instead of buttermilk; but repeatedly we have found it was not tolerated as well. The only difference was that of the lactic acid content present.

Dr. C. G. KERLEY, New York: Dr. Marriott's method of using lactic acid milk impressed me very favorably. I have used a great deal of lactic acid milk and protein milk but never after the fashion that the doctor has followed. I have usually employed the fat free lactic acid milk or one with a low percentage of fat in intestinal disorders, under which conditions it is extremely valuable. When the diarrhea subsides, other feeding is instituted. I have not been successful in using lactic acid milk as a general diet in young infants. I confess I would not have had the courage to use the milk in quite the strength that Dr. Marriott used it. I will be much interested in giving this scheme a trial. As regards the carbohydrates, it is quite necessary in feeding very delicate malnutrition infants to give a high percentage of carbohydrates. I usually prescribe the carbohydrate equal to 10 or 12 per cent, this being made up of the sugar that is in the milk, lactose or maltose and starch. Thin, emaciated infants, very much under weight, require from sixty to sixty-five calories to the pound. As regards the milk used in these cases, I prefer the evaporated unsweetened product. I find this much easier of assimilation than fresh cow's milk, regardless of the way in which it may be handled.

Dr. JAMES HOYT KERLEY, New York: Dr. Marriott undoubtedly has had splendid results with his carbohydrate feedings in marasmic infants. It seems to me, however, that the trouble is often caused by the protein. The casein in cow's milk forms a hard curd, while in mother's milk it forms a flocculent curd. I have had great success with evaporated milk, in which the milk has been heated to a high degree, and the protein molecule was broken into many fine particles, which do not form the hard curds in the infant's stomach as is the case with cow's milk. An ounce of evaporated milk is equal to two and one-half ounces of cow's milk, so there is no difficulty in keeping up the caloric value. Dextrin-maltose or lactose is added to the evaporated milk mixture in suitable proportions to obtain the requisite percentage of carbohydrates, just as is done with the lactic acid milk.

Dr. H. F. HELMHOFF, Chicago: I have been very much interested in Dr. Marriott's results, especially as we, too, have been interested in the sugar tolerance of atrophic infants. During the summer of 1915 we used this product in one of our stations in feeding about 125 babies with very good success. We used it as we would use a sugar and flour mixture. The difficulty of preparing the food with the syrup in the homes was such that we found it practically impossible to use it. If Dr. Marriott can show us how it can be used in the homes, it certainly would be a help in our infant welfare work, because it seems to me, from what he has said and from our experience, that it would be a cheap and very excellent food to use in infant welfare work.

Dr. LEWIS WIERB HILL, Boston: One of the most important things in infant feeding is a proper understanding of the use of the sugars. Often we feed altogether too little carbohydrate to our babies, being afraid of producing sugar fermentation. I was, therefore, greatly interested to hear Dr. Kerley say that he often uses from 10 to 12 per cent. in feeding his babies, as I do myself in many cases. Some years ago Dr. Talbot and I investigated sugar metabolism in a baby by gradually increasing the amount of sugar in the food, from 5 to 14 per cent., and keeping the other food constituents constant. We found that the feeding of high sugar increased the nitrogen and salt retention up to a certain point (14 per cent. sugar), when the baby developed a diarrhea. The way that high carbohydrate works beneficially is probably by sparing the protein, and by allowing the baby to store and retain more nitrogen and probably more salts than he would on a low carbohydrate diet. I am in the habit sometimes of feeding my babies on a rather low protein diet, just enough to cover the nitrogen needs, and supplying most of the fuel in the form of carbohydrate, usually as a mixture of dextrin-maltose and lactose. Several years ago Dr. Dinn and Dr. Porter worked along these lines at the Infant's Hospital in Boston, and they found their babies could take from 10 to 12 and even 14 per cent. sugar in many cases without any harm, and with marked gain in weight. I believe that in constipated babies, especially those with small alkaline, rather foul stools, we need not be afraid of feeding high sugars. The baby must be watched carefully, of course, during the high sugar feeding, and if spitting up or diarrhea develops, the sugar must be reduced. The point is, however, that many babies do a great deal better on a high sugar diet (much higher than is ordinarily given) than on a low or a moderate amount of sugar, and we should not follow slavishly any set rule as to the maximum sugar that should be fed to babies.

Dr. THOMAS C. McCLEAVE, Oakland, Calif.: I was very much interested in Dr. Marriott's paper, because I have been pondering how we can give more carbohydrate to certain children. I would like to ask as to the intervals of feeding he has used in these children, and to put in the form of a suggestive question the possibility that perhaps the secret of his being able to give these children the large amount of fat that he is able to give them is dependent on the particular type of mixture he is giving them. It seems to be the whole success of his scheme. He has described his mixture of corn syrup, dextrin, maltose and dextrose. The whole explanation of the success of his scheme is dependent on the composition of his mixture.

Dr. W. McKIM MARRIOTT, St. Louis: The point raised is quite interesting in the light of some of the work we have been doing. I mentioned the fact that in the pathogenesis of this condition there is a greatly diminished volume of the flow of the blood sometimes down to as low as one-eighth of the normal. As the flow is increased by feeding, the subnormal temperatures rise and the infants begin to gain. In the preparation of these milk mixtures in the home we find the vacuum bottle convenient. The whole milk is boiled, cooled down to incubator temperature, inoculated and poured into the vacuum bottle and left over night. In the morning it is ready for use. As to the feeding intervals, we have used four hour intervals, six feedings in twenty-four hours; none more frequently than that. With those four hour feeding intervals we were able to give up to 280 calories per kilo-

gram, so it was not necessary to feed any more frequently. I draw attention to the fact also that these mixtures are quite elastic. One does not have to use the undiluted milk and add so much carbohydrate. The milk may be diluted, or the fat diminished. Of course, I realize that children of this type are likely to develop diarrhea and have to be watched. We made it a practice in the hospital to have the stools saved and to have the resident informed if there was a loose stool, so although we were feeding very high carbohydrate we felt that if we could stop it at the time one loose stool occurred no particular harm would be done.

## VACCINOTHERAPY IN ACUTE AND CHRONIC BACILLARY DYSENTERY\*

P. NOLF

Chief of the Division of Infectious Diseases, Belgian Army

BRUSSELS, BELGIUM

In a previous article we gave our observations of the epidemic of bacillary dysentery of the summer of 1917.<sup>1</sup>

In 1918, especially during August and September, the malady reappeared in the Belgian army with almost as many cases as in the preceding year. In a total of something over 500 cases about 20 per cent. were severe or very serious cases and 80 per cent. were light or moderately severe cases.

In the lighter forms we were able to add nothing to our previous observations either as regards symptomatology or bacteriology. For the grave types the bacteriology was likewise essentially the same. No more than in 1917 could the most malignant forms be attributed to the Shiga bacillus, and the marked predominance of the Flexner bacillus and *Bacillus* Y in 1917 was so much greater in 1918 that in no case were we able to isolate the Shiga bacillus, and in only three cases were we able to obtain agglutination of the Shiga germ. In all three of these there was also agglutination of the Flexner bacillus in high dilutions.

From the symptomatologic point of view, our 100 serious or very grave cases could be divided into two nearly equal halves, one half being choleraic. These are the cases in which the diarrhea is accompanied by vomiting, which not only increases the loss of fluid from the body, but also prevents its restoration by the ingestion of drinks. In a certain number the vomiting came on early, appearing very shortly after the first diarrheal evacuations.

### CONDITION OF THE PATIENTS ON ADMISSION

The greater number of the sick were brought to us in an alarming state with weak, rapid pulse, a tendency to cyanosis, coldness of the extremities and more or less general muscular cramps. The treatment employed departed in nothing from that given in the aforementioned article.

The administration subcutaneously of from 1 to 2 liters of isotonic saline, together with a fluid diet, plays the chief rôle in the treatment. Frequently after twelve hours the appearance of these cases was much improved, and in a few days definite cure followed. The same rapid change for the better was observed in

the cases of 1917, so that we are seriously tempted to affirm that in the choleraic form of bacillary dysentery improvement tends to be rapid, provided the dehydration is combated from the beginning. Perhaps we must attribute our good result to the fact that, on account of the fulminating character of the symptoms at the very outset, the patients of this class came under vigorous treatment at the earliest moment.

In the other half of the serious cases, there was no suddenness in the onset, no dehydration, no collapse; but the gastro-intestinal disturbances were more resistant. The stools were persistently liquid, mixed with mucus or abundant mucopus and blood. There may, indeed, be hemorrhage of dangerous magnitude. The fever does not abate in two or three days, but persists and may last for several weeks, assuming the remittent or intermittent type. Owing to the fever, the pain, the intestinal disturbances and the loss of blood, the patient becomes progressively weaker and more emaciated. It is the ulcerative form of bacillary dysentery. In the fatal cases the patients become veritable skeletons before death supervenes. In the less unfavorable cases, the general condition is not so seriously affected, but the intestinal disturbances persist, and the disease veers toward chronicity, with alternating periods of relatively satisfactory health and more or less numerous recrudescences. As indicated above, this ulcerative form only rarely follows the choleraic form.

### FUTILITY OF SPECIFIC SEROTHERAPY

The treatment of ulcerative dysentery gave us only temporary results so long as we had recourse to the methods of the books. Specific serotherapy proved futile. Therefore, because of the inefficacy of these methods, we had, toward the end of the epidemic of 1917, employed vaccinotherapy in the chronic cases that remained. When possible to isolate a dysenteric germ from the intestine, we made and employed an autogenous vaccine; otherwise we used a vaccine of a Flexner bacillus type made from a gelose culture killed by heat. At this time the vaccine was administered subcutaneously, in progressively increasing doses, the initial dose being usually 10,000. To obtain the desired result it was necessary to raise the dose frequently to from 5 to 10 billion. These large amounts of sterilized culture are regularly well tolerated, though often during from twelve to twenty-four hours after the injection, one observes a little fever, headache and lassitude, with more frequent and less consistent stools, sometimes slight colic, and at the site of injection a little infiltration with moderate pain. All these sequelae soon pass away and, as a rule, disturb the patient but little. There are, however, exceptions to this rule. Thus, one patient, A. de M., bore every dose up to 5 million without reaction; but the next dose, being 10 million, resulted in a marked lighting up of the disease, with a moderate fever (maximum evening temperature 38.6 C.) which persisted for nine days, and the reappearance of the diarrhea (up to twelve liquid stools a day). After that he went on to recovery without further administration of vaccine. These first results have been given in our report of the epidemic of 1917.

### VACCINOTHERAPY IN OLD CHRONIC CASES

In the winter of 1917-1918, we still were receiving cases of chronic dysentery of which the onset dated back several months or several years. We applied

\* Read before the Section on Pharmacology and Therapeutics at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

<sup>1</sup> Nolf, Colard, Dulière and Roskam: L'épidémie de dysenterie bacillaire de 1917 au Front belge, Arch. méd. belges, May, 1918.

the same treatment, but with this difference, namely, that the initial dose was regularly a million germs, and that the dose was raised progressively up to from 5 to 10 billion. The results obtained continued to be favorable. In every case the general condition was improved, and the intestinal symptoms steadily decreased. In the majority, the cure was complete and definite. At times there seemed to be complete cure at the end of the treatment, but at a later period the symptoms returned. In some cases the stools, although regular and only one or two a day and without blood and mucus, yet remained soft, and there persisted a little intestinal instability and discomfort. Case 1 is an instance of this kind:

CASE 1.—A. D., man, aged 32½, admitted, Jan. 29, 1918, for double parotitis, at the age of 26 had had enteritis for six months, with diarrhea and mucus and blood in the stools. Since then he had had frequent slight recurrences. On admission the stools were normal. February 8, all the local and general symptoms of parotitis had disappeared; yet though he was still in bed and on a diet of milk, rice, bread and two eggs, he was suddenly attacked with diarrhea. February 10, he had ten stools in twenty-four hours, with mucus and considerable blood. He became rapidly weak, and had anorexia and vomiting. The stools failed to show a dysentery bacillus, but the blood agglutinated Flexner's bacillus in a 1:200 dilution. February 16, the vaccine series was begun with 10,000 subcutaneously, and the intestinal hemorrhages soon ceased, traces of blood being found for the last time, March 4, after an injection of 300,000 given the day before. March 18, the patient had a soft stool, and the treatment was continued. During the months of April and May he received several doses of from 3 to 5 billion, and after a dose of 10 billion in June he seemed cured. In November he was seen again and reported himself well, but with a slight instability of the intestine.

We should probably have continued the subcutaneous method of administration of the vaccine, had we not, in other affections, particularly bacteriuria due to the colon bacillus or the staphylococcus, observed that the intravenous method of administration was more efficacious and more rapid in its effects. We therefore began the administration of the vaccine by the intravenous route in bacillary dysentery. Our first observation is that of Case 2:

CASE 2.—P. S., man, aged 26, admitted, July 1, 1918, for a benign grippal pneumonia, had suffered in 1917 from acute enteritis, of which he was not completely cured, and was tender to pressure over the sigmoid colon. The serum agglutinated the Flexner bacillus in the dilution of 1:300, and the Shiga bacillus in the dilution of 1:50. Bacteriologic examination of the stools was negative, July 8, 12 and 20, but July 25 showed the Flexner bacillus. Since July 6, a series of subcutaneous treatments with Flexner vaccine had been carried on, and, August 4, an autogenous vaccine in a dose of 1 billion was employed. August 7, 14 and 17, doses of 10 billion were given. At this time there was a notable improvement in the patient and in the stool, which had frequently contained mucus and a little blood. But as the stools were not yet quite normal, a series of intravenous injections was begun, an initial dose of 1 million being given August 17, and the series terminating, August 25, with a dose of 10 million. The patient was completely cured, August 31.

The history of this patient furnishes elements for judgment of the efficacy of intravenous vaccino-therapy in dysentery. The subcutaneous doses of from 3 to 5 billion had given him no fever, but he had reacted to each of the 10 billion doses with an elevation of temperature to 37.6 C. The intravenous doses of 1, 3 and

6 million produced no fever. Fever appeared, however (37.6 and 37.8 C.), after each of two intravenous doses of 10 million.

From the point of view of its ability to provoke a febrile reaction, the dose when given by vein was equivalent to 1,000 times as much as administered subcutaneously. But the complete disappearance of the intestinal disturbances, which the subcutaneous doses of 10 billion had not given, was accomplished by the intravenous dose of 10 million. As recently reported by the patient, the cure has remained permanent. There were other patients who gave the same general results.

#### THE INTRAVENOUS METHOD IN ACUTE DYSENTERY

These successes induced us to try the intravenous method in a number of the cases of acute dysentery of the summer of 1918. We applied the treatment not only to those with confirmed ulcerative dysentery, but also to all those in whom the course of the disease made one fear the development of the ulcerative form, that is to say, in every case in which, after one week, a dietetic and drug treatment had not brought about a cure, or at least promise of a speedy cure.

The doses were given at four day intervals, the initial dose being regularly 10,000 germs, then 30,000, then 50,000, then 100,000, etc. In general, the betterment of the patient did not long delay. The fever dropped by lysis, with some recrudescences more or less marked on the days of the vaccine therapy and the next day; and the intestinal symptoms improved coincidentally. In many cases of moderate intensity a complete cure was effected when the dose of 500,000 was reached. In the more refractory cases, it was necessary to push the vaccine up to about 10 million.

In fifty-two cases treated in this way, we had only two deaths. All the other patients left the hospital cured, except two whom military necessity forced us to send away too soon. We have no doubt that in these two cases also the continuation of the treatment would have resulted in a cure in a relatively short time. By vaccino-therapy we were thus able to avoid the dangerous tendency toward chronicity which in 1917 was produced in a considerable number of our patients. This last result we considered particularly gratifying.

The complete record of the epidemic of bacillary dysentery of 1918 shows a complete cure, at the latest in a few weeks' time, in 500 cases, except only two patients who died, and two who left before the cure was completed.

Cases 3 and 4 are two further reports of acute dysentery treated by intravenous vaccines:

CASE 3.—C. B., soldier, aged 27, admitted, Aug. 11, 1919, for an acute dysentery that began August 9, had much colic, and in twenty-four hours had twenty stools consisting of blood and mucus. There were no muscular cramps or vomiting. His serum agglutinated the Flexner bacillus at 1:200 and the Shiga bacillus at 1:200, but did not agglutinate *Bacillus Y*. The temperature ranged between 38 and 39 C. until August 22, in spite of a rigid medicodietetic treatment. By August 23 there were still eight liquid stools a day, always composed of blood and mucus. August 21, an intravenous dose of 30,000 germs was given. After August 26 the temperature remained normal, and on that day the patient had two formed stools, coated with a little mucus. The dose of vaccine was rapidly increased till it reached 10 million germs, September 14. From that date the stools had a perfectly normal appearance, and the patient left the hospital cured, September 19.

CASE 4.—C. M., soldier, aged 34, admitted, Aug. 22, 1918, was taken sick, August 19, with acute dysentery. He had sixty mucosanguinolent stools in twenty-four hours, and suffered from violent abdominal cramps. There were no muscle spasms and there was no vomiting. The serum agglutinated the Flexner bacillus 1:300 and the Shiga bacillus 1:50, but did not agglutinate *Bacillus Y*. The fever fluctuated between 38 and 39 C. until September 4, dropped slowly until it reached normal, September 13, and then the next day shot up and continued to rise until September 21, when it was 38.6 C. This secondary access of fever may be attributed to vaccination, which was begun, August 26, in a dosage of 30,000 and rapidly pushed to the higher amounts. September 15, the patient received 1 million germs; September 19, 3 million, and September 23, 5 million. After September 5 the stools were more fecal in type. From September 14 to 21, they numbered one or two a day and were formed. They continued thus until September 26, when the patient was discharged cured.

#### CONCLUSIONS

I believe I am justified in concluding from these observations that vaccinotherapy and more especially vaccination intravenously is the most effective therapeutic method in bacillary dysentery in its chronic forms and in the acute forms that show little tendency toward cure. It appears also that the method is more efficacious when it is applied early. The intravenous route has the advantage that it permits results from doses one-thousandth the size of the subcutaneous doses. Not having had occasion to try this method in cases of Shiga bacillus dysentery, it is impossible for me to speak of its utility in this form of dysentery.

In acute dysentery, intravenous vaccinotherapy cures quickly in cases exhibiting protracted fever and lasting diarrhea with hemorrhagic and slimy stools, these being the cases that are refractory to other therapeutic methods, including serotherapy.

#### A PROTEST AGAINST THE RECKLESS EXTRACTION OF TEETH\*

WALTER C. ALVAREZ, M.D.  
SAN FRANCISCO

Day after day I see people who have had half a dozen or more teeth extracted. Their former physicians had promised them great things; in some cases had even guaranteed a cure, but here they are still suffering and now greatly discouraged. Many have no chewing surface left, and the remaining teeth are often so distributed that the only thing to do is to remove them and put in plates. To my mind one of the saddest features is that, in many of these cases, an experienced physician might have foretold the unsatisfactory outcome and might have warned the orthopedist or the dentist to proceed cautiously and conservatively. The arthritis may plainly have been gouty or tuberculous, the headaches may have been due to nephritis or to advanced arteriosclerosis, and the pains in the shoulders may have been due to degenerative changes in the aortic arch. Sometimes I have secured the roentgenograms which were used in deciding which teeth were to come out and have been unable to find more than one or two roots which after years of experience I would call infected. In some, downward projections of the antrum had evidently been mistaken for abscesses. In others, it seemed to me that the

physician, quite oblivious to any possible value of the teeth to their owner, must have ordered their extraction simply because he believed it a panacea for most diseases.

I believe we have lost our heads over this thing and that the time has come to call a halt. Men have obtained such beautiful results in some cases by extracting teeth that some of them are now trying to explain most diseases on the basis of these focal infections. In practice, they pull the teeth first, and if the patient returns unbenefited, they can then look to see what is the matter with him.

As the enthusiast often regards the conservative as a man who must be ignorant of the wonderful results which can be gained by using his methods, I wish to say that since 1911 it has been practically a routine procedure in my office to roentgenograph all suspicious teeth, and I have had hundreds extracted. I would emphasize the fact that I have seen my share of the miracles described by my radical friends—I, too, have seen inflamed joints go down over night; so-called tuberculous glands disappear as suddenly; headaches leave for good, and so on; but these things have not blinded me to the fact that for one miracle I have seen many failures and disappointments. My radical friends who, from their writings, would seem never to have had any failures may perhaps ascribe my unfortunate results to conservatism and to the choice of poor dental surgeons. Although this argument may apply in regard to those cases in which I ordered the extractions, it can hardly apply to those people who were "cured" by these same radicals but who, after a period of relief, are again going the rounds of doctors' offices.

We must recognize these failures; we must face them squarely and study them with particular care. Many people are not benefited by the extraction of teeth no matter how thoroughly it is done, and no good can come from further refinements of that technic. In the middle ages if a man died it was because he had not been bled enough, or because it had not been done from the right vein. Today we know that bleeding is useful in only a few conditions. Similarly, the day will come when focal infections will not be dragged in to explain all ills of the flesh. Seeing that there are these possibilities of failure, we must be more honest and conservative with those who put their lives in our hands. By all means let us continue to look for alveolar abscesses but, if we are to keep the respect and confidence of the public, if we are to avoid damage suits, we must be more careful what we promise some of our patients in return for a toothless mouth. Before deciding whether any or all of the suspicious teeth are to come out, the physician must look the patient over from head to foot. If he is young and sound, and if he has a dangerous arthritis, endocarditis or severe headache for which no other cause can be found, I believe we are justified in insisting on a thorough removal of the diseased tissues. When, however, the patient is old and failing; or when we find high blood pressure, arteriosclerosis and nephritis, let us be careful. Focal infections may perhaps contribute to the development of these chronic degenerative diseases, but I feel sure that they are not the only or even the principal cause. Certainly my experience has been that although the removal of the teeth will sometimes seem to give the patient a new lease of life, the arteries continue to harden, the pressure continues to rise, and sooner or later the symptoms return. Hence it is that

\* Read before a joint meeting of the San Francisco County Medical and Dental Societies, May 5, 1919.

in these cases we should carefully consider all the factors involved. If the infected teeth are not serviceable, if they are loosened, perhaps hanging to wobbly bridges, or if their crowns are gone, there need be no question as to their removal. But if they are strong and serviceable, if the areas of rarefaction are small and questionable, and particularly if restoration by bridges will be impossible, let us be frank with the patient. Let us tell him that the proposed extraction is more or less of an experiment; that we will not promise him anything; but if his troubles are annoying him so much that he wants to leave no stone unturned in his treatment, he can try it.

It is one thing to order a dozen extractions when a man lies crippled with an acute or chronic arthritis, and another to order them because he feels nervous, has no energy, has indigestion, or has pimples on his chin. In the first place the patient is desperate, he is willing to take any chance to get well and will more readily forgive mistakes that arise through overzealous efforts than mistakes arising through lack of interest and neglect. In the second case, he is in no mood for big sacrifices; the treatment, even if successful, may cause more annoyance than the disease, and the physician may come in for a great deal of blame.

We must be careful, also, what we promise to those who, in addition to their root abscesses, have other sources of infection which cannot be so easily removed. I refer particularly to chronic bronchitis, sinusitis, prostatitis and urinary infections, all of which may persist in spite of expert treatment. We may perhaps have trouble, too, on account of pelvic inflammation and gallbladder disease.

The radical group of dentists tell us that most of our failures to cure are due to the fact that we have not removed all of the diseased tissue from the jaws. They would like to open up the jaw widely and dissect away the alveolar process until the tooth can almost drop out of itself. Naturally these men have a certain amount of right on their side. I, too, have seen a number of cases in which diseased bone or the abscess itself was left by the man who extracted the teeth. There are some people in whom the roentgen ray shows a widespread change in the bone around the diseased teeth, and in these cases I think it is probably advisable to remove enough of the inner or outer plate so that the operator can see what he is doing. I feel sure, however, that in the average case, a good extractor can remove the abscess, sometimes entire, hanging to the apex of the tooth.

Many of our patients will return still complaining of their old troubles even when the roentgen ray shows that the removal of diseased tissue has been complete. In some cases the bacteria which may originally have entered through the jaws seem to have obtained so firm a hold on the joints, the heart valves and other tissues that they will not leave simply because their old port of entry has been closed. In other cases, irreparable damage has been done and the joints cannot return to normal even after the disappearance of the infection. We must remember, moreover, that focal infection is probably not the only cause of arthritis, and our clinical study of this condition will not always begin and end with the search for pus.

I believe the main reason for our disappointments is that in many cases the alveolar abscesses seem to exercise no demonstrable influence on the patient's health. Time and again I have seen powerful, and

healthy looking men with large alveolar abscesses which they had carried probably for most of their lives. They maintained that they had never had a headache or a twinge of rheumatism, that, in fact, they had never needed a physician. When such a man remains disabled after an injury we often try to rehabilitate him by removing the abscesses. Naturally, we often fail, simply because we take away something which has never had anything to do with the case. It may be, sometimes, that these sacs are as much outside the body as is a calcified tuberculous gland in the lung. When further bacteriologic work has been done we may find that some of them are sterile, the bacteria having died out just as they do in pus-tubes. Particularly in the case of the smaller areas, the necrosis may never have been infectious in origin but may have been produced by the chemicals used during the preparation of the root canals.

Many of the dentists have become so frightened over the terrible results which they think must follow every root infection that they are refusing to fill any root canals at all. They feel that the risk to life and health is so great that a man should immediately sacrifice every dead tooth in his head. Certainly the thousands of people who for the last thirty or forty years have been chewing contentedly on dead teeth (without signs of root infection) should be grateful that these radical ideas did not prevail when they were young. The trouble with many of our dentists today is that they do not know enough about the wonderful defenses of the body against bacteria. These defenses are particularly efficient in the mouth, where, in spite of the rich flora and the continual trauma, wounds heal with surprising rapidity. Bacteria are constantly getting through the first line of defense only to be stopped at the second, and I see no reason why the body cannot in many cases protect itself perfectly from the activities of a few invaders which have reached the apex of a tooth.

#### CONCLUSION

In view of the fact that the most thorough removal of focal infections often fails to cure arthritis and other diseases, let us be more honest and conservative with our patients. Let us be careful what we promise them. Let us save serviceable teeth whenever possible. Above all, let us do unto our patients only what we would have done unto ourselves if their teeth were in our heads.

177 Post Street.

**Conservative Treatment.**—Further, in your treatment I advise you to be conservative. Don't be "blown about by every wind of doctrine"; don't take up every new thing which is brought forward in the way of treatment. Private practice is not the sphere in which to try experiments; new methods should be tried in hospital, where they can be tried under exact conditions. Do not conclude that the new thing is, necessarily, the right thing. As Clough said,

"Old things need not be therefore true,  
O brother men, nor yet the new,  
Ah! Still awhile the old thought retain,  
And yet consider it again!"

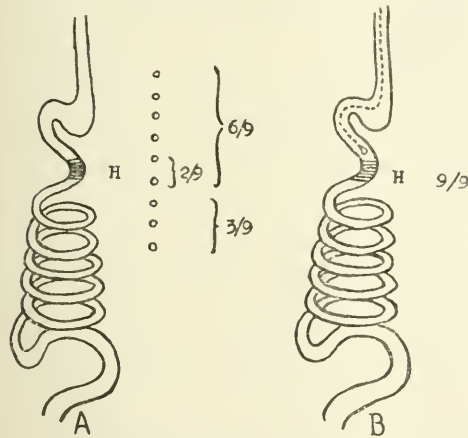

The old treatment has stood the test of time, and has, probably, in most cases, justified itself up to a point. Be sure, therefore, that the new is going to be better than the old before you adopt it. There are some men who are forever rushing after new gods, after every fresh synthetic remedy or after vaccines, for example, which they apply to their patients with only a partial understanding of their action.—Robert Hutchison, *Some General Principles of Therapeutics, The Practitioner*, September, 1919, p. 164.

THE INTRA-INTESTINAL TUBE TREATMENT OF HOOKWORM INFECTION

JOHN L. KANTOR, Ph.D., M.D. (NEW YORK)

First Lieutenant, M. C., U. S. Army; Gastro-Enterologist, U. S. Army General Hospital No. 14  
FORT OGLETHORPE, GA.

Since we now know precisely the human habitat of the hookworm—namely, the first portion of the jejunum, with extension along the intestine in both directions in the severer infections—it follows that the parasites can be removed with the greatest dispatch by a method which would permit of the direct introduction into this region of a maximum concentrated dose of a drug chosen for this purpose. I believe that this can best be accomplished by means of the intra-intestinal tube treatment as devised and carried out by the gastro-intestinal service of this hospital during the past year. Up to the present writing (June, 1919), more than 250 of these treatments have been administered. The results, which seem to be

The shaded portions, H, H, represent the region occupied by the hookworms. A represents the digestive tract in a hypothetical "mouth" treatment with the drug given in three capsules, one every hour for three hours. The nine capsules are arbitrarily represented as dissolving opposite the levels indicated by their position to the right of the "tract." In case, for example, two of the capsules dissolved exactly opposite the infected area, four capsules above this point, and three below, the patient would receive the maximum benefit from two-ninths of his dose, some benefit from six-ninths of his dose, and none at all from the remaining three-ninths. In the case of the "tube" treatment, B, the patient is represented as receiving the entire dose, nine-ninths, with correspondingly increased efficiency.

superior to those obtained by methods heretofore commonly used, will be given in detail in a subsequent statement.

RATIONALE OF THE "TUBE" TREATMENT

Hookworm treatment, as generally practiced in the army, is based on the administration of a vermifuge (nowadays chiefly oil of chenopodium) by mouth, in capsules. It is obvious that just as soon as these capsules are swallowed, the physician loses control of his drug, so far as the significant factors determining its efficacy are concerned. That is, there is no way whereby he can cause the liberation of the full dose, or of any definite part of it for that matter, at the exact point where it will do the most good. Depend-

ing on the motility of the digestive tract of the patient (which varies widely in normal individuals) and on the solubility of the capsules selected to contain the oil, there is always the possibility that:

1. A considerable portion of the dose may be lost by the capsules dissolving *below* the site of the parasites; or,

2. The dose of oil may be too greatly diluted by secretions if the capsules dissolve *above* the site of infection.

On the other hand, it is equally clear that an ideal "tube" method would have the following theoretical advantages:

1. The drug would be delivered directly at the site of infection.

2. The full dose given the patient would be brought into action.

3. Instead of being given in fractions over a long period, the dose would be delivered *en masse*, its work accomplished quickly, its elimination pushed that much sooner, and the danger of cumulative toxic absorption correspondingly lessened.

In the accompanying illustrations an attempt is made to show graphically the differences between the two types of treatment.

DESCRIPTION OF THE TUBE TECHNIC

After several modifications the following procedure was adopted: The evening before treatment, the patient is given a light supper, chiefly rice and milk. There is no preliminary catharsis. The next morning, at about 7:30, the duodenal tube is swallowed on a fasting stomach and the patient is kept on his right side until the bucket has passed the pylorus.<sup>1</sup> The exact time at which the intestine is entered can be determined by the accompanying differential tests:

DIFFERENTIAL TESTS

Bucket in Stomach	Bucket in Duodenum
1. Aspiration through the tube withdraws a clear fluid, seldom bile-tinted, generally positive to Congo paper.	1. Aspiration withdraws golden yellow, viscid bile, negative to Congo paper.
2. If a definite amount (say 15 c.c.) of water is injected, and the injection is followed by a syringe-full of air to clear the tube, the greater part (more than two-thirds of this water) can be withdrawn on the next aspiration.	2. The water injected flows on into the intestine and but a small amount (less than one-third, if any), can be recovered by aspiration.
3. Injection of air is not followed at once by borborzgm.	3. Injection of air is followed at once (in some cases) by borborzgm.

As soon as Congo-negative bile is obtained, and water cannot be recovered as described above, the patient is ready to receive the drug. This is injected directly with the syringe (preferably of glass, and of about 30 c.c. capacity) and is followed by a barrel or two of air to insure the expulsion of the entire dose from the tube. So far in our work, the drug (oil of chenopodium) has most commonly been given in a dosage of 3 c.c. It is quite possible that 2 c.c. may be sufficiently potent. Work on this point is in progress. Of course, it need hardly be mentioned that doses used in the army should receive appropriate modification, when necessary, for introduction into general medical practice.

1. With the buckets (Einhorn, Rehnus) used on this service this usually took place within three hours, infrequently, until very recently, the writer was not familiar with the very surprising phenomenon of Dr. Jutte. The tube used by this worker is said to pass the pylorus very quickly.

Following the injection, a period of six minutes is allowed for the diffusion of the oil throughout the worm-bearing area. At the expiration of this interval, 2 to 3 ounces of a warmed saturated solution of magnesium sulphate are given transduodenally. The object of this flush, which we regard as a very essential part of the treatment, is to remove the drug quickly from the very highly absorptive small intestine in order that undue toxic effects may be avoided. That this is actually accomplished is indicated by the observation that the majority of patients have a copious watery stool containing oil (and sometimes worms) within half an hour following this procedure. The regularity with which this sequence follows is one of the most striking features of the treatment.

It may be stated parenthetically that this flush method of control opens the way to the safe use of drugs in doses ordinarily considered dangerous. At different times, we have administered as much as 4 c.c. of oil of chenopodium, 12 grains of santonin, and 12 gm. of oleoresin aspidii without undue disturbance.

After the salts are given, the tube is removed and the treatment is complete. In most cases from three to five stools follow the first. If a sufficient number do not result, further catharsis may be administered by mouth. The patient is generally sick during the day of treatment, but by supper time (5 p. m.) he is ready for a light meal, and "feels as good as ever" the next morning.

#### PROTOCOL OF AN ILLUSTRATIVE CASE

- 9:05 a. m., Rehfuss tube swallowed.  
10:33, oil of chenopodium, 3 c.c. per tube.  
10:40, magnesium sulphate, 90 c.c., warmed, per tube.  
10:42, tube removed.  
11:20, first stool: oil, 68 worms.  
12:00, second stool: oil, 56 worms.  
2:25 p. m., third stool: oil, 40 worms.  
3:45, fourth stool: oil, 19 worms.  
4:40, fifth stool: oil, 12 worms.

#### SYSTEMIC EFFECTS OF OIL OF CHENOPODIUM: ANALYSIS OF SYMPTOMS

Owing to the precise method of administration offered by the tube technic and to the fact that the drug is readily absorbed by the duodenal mucous membrane and diffuses very rapidly throughout the entire body, we have been able to make some interesting observation on the systemic ("toxic") effects of oil of chenopodium. Moreover, since we had in our material some returned gassed soldiers, as well as several pneumonia convalescents, we had the opportunity of collecting some special data concerning the effect of the drug on the respiratory tract. From this experience we have gathered the impression that oil of chenopodium seems to exercise an appreciable selective action on certain systems of the body that have been sensitized by previous disease or injury. This peculiar susceptibility we have observed in the case of the respiratory system, as stated and in the auditory apparatus and in scar tissues resulting from wounds.

In the average case, the systemic action of oil of chenopodium is observed regularly within some twenty minutes after its administration by tube. The patient then begins to experience the well-known sensation of "tingling," "numbness," "burning," and "pins and needles," throughout the body, particularly in the palms and soles. At about the same time vertigo may be complained of and nausea as well, the latter often

being precipitated by the removal of the tube. The period of discomfort seldom exceeds four or five hours.

The technic first used (which was subsequently modified) called for free preliminary catharsis, a waiting period of from ten to fifteen (instead of six) minutes after the injection of the oil, and a copious transduodenal flush of a liter (quart) or more of plain water (instead of the 2 to 3 ounces of salts finally recommended). Of the first 100 patients treated by this original method, fifty-eight showed no reaction except, in some cases, a moderate degree of tingling, vertigo and weakness. The remaining patients showed varying kinds and degrees of symptoms, but in no case have we so far found evidence of permanent damage. It was in our second series of 100 cases that the change in technic described above was instituted, forty-five patients being treated by the simplified method. A distinct improvement was observed, no less than sixty-five patients showing no ill results from the procedure. A correspondingly better showing is looked for in a series consisting entirely of cases treated by the simplified technic finally recommended.

*Digestive System.*—Of the twenty-seven patients who vomited in the first series of 100 cases, the majority did so when the last few ounces of water were being injected through the tube. In some cases the tube itself was expelled with the water. On several occasions from two to ten hookworms were discovered in the vomitus. In the forty-five cases treated by the preferred method, the incidence of vomiting was reduced to only 17 per cent. We found no evidence that the introduction of oil can be directly "felt" by the duodenal mucosa. In fact, at no time was the abdominal discomfort so frequently mentioned by others a feature in our own experience. It is my belief that this phenomenon is due entirely to ineffectual, delayed or violent purging, and that it is best overcome by direct, transduodenal saline catharsis.

*Auditory System.*—Associated with the very common dizziness there is a certain amount of ringing in the ears. There were eight patients, however, among our first hundred, in whom the latter symptom was marked and persisted longer than the day of treatment. By some individuals deafness also was complained of. In three of the eight cases a distinct history of previous injury or susceptibility was obtained. In the first patient, the tinnitus persisted in the side that had been affected by high explosives in France; in the second there had been a bilateral mastoid operation, and in the third there was a history of quinin neuritis of the auditory nerve lasting for one month six years previously. In the present series the longest duration of ear symptoms was nine days. Objective examination of the auditory apparatus was negative.

*Respiratory Tract.*—There were eight cases<sup>2</sup> in which violent, spasmodic, nonproductive coughing followed the injection of oil of chenopodium. All but one of these patients was the subject of an existing or recent disorder of the respiratory system. There were three patients convalescent from bronchopneumonia, two patients who had been severely gassed in France, and one patient who had chronic bronchitis. What is the cause of this phenomenon? That it is not the result of irritation from the tube itself is clear from the fact that whereas the apparatus is retained

2. These and subsequent figures refer to the incidence in our first series of 100 cases.

at times for hours, the cough does not commence until just about ten minutes after the oil injection. Similarly it is obvious that the effect is not due to direct irritation from inhalation of the vapor, because in that case it would follow instantaneously on the medication. On the other hand, the onset after ten minutes seems best explained by the theory that it takes just about this length of time for systemic absorption and the beginning of excretion of the drug through the expired air. As soon as this oil-laden air reaches the more sensitive parts of the respiratory tree (bronchi and trachea) in these susceptible individuals, the cough reflex is liberated and persists, presumably, until the oil excretion ceases or the irritation subsides. We have observed this paroxysm to continue as long as eight or ten hours.

*The Skin.*—Some degree of palmar tingling is the rule. Wounds with scar tissue show special susceptibility to a persistence of this symptom. Often the burning subsides in the sound member on the day of the treatment, but continues for another twenty-four hours on the injured side. There was one case of profuse sweating of the hands associated with the tingling.

*Nervous System.*—A mild euphoria with general excitation was observed in three cases. This resembles similar symptoms in alcoholic intoxication. In three other cases there was a lethargic state with toxic sleep and considerable prostration which lasted until the morning following the treatment. In this condition, hot coffee enemas were used with good results. The pulse remained uniformly of good quality. There was one case of nervous chill following the treatment.

*Circulatory System.*—Only one instance of circulatory collapse was encountered. This occurred in one of the first cases and followed the largest dose that we have given. Forty minutes after 5 c.c. of oil had been administered by tube, an increasing general reaction was followed by a sudden severe collapse with almost imperceptible pulse and cold perspiration. Active stimulation with the application of external heat brought about recovery in a couple of hours. For the next thirty-six hours there was retention of urine.

*Urinary System.*—One or two patients complained of increased frequency of urination and of pain in the back. Unfortunately our attempt to study the urine concentration, the phenolsulphonphthalein excretion, and the blood urea, proved abortive. Although we saw no evidence, so far as we went, of renal damage, we are not prepared to say whether this system escapes entirely.

#### SUMMARY

1. The intra-intestinal tube method is recommended as the method of choice for the cure of hookworm infection, on the grounds that it is more efficacious, safer and, once the duodenal bucket is in place, quicker, than the methods at present in vogue.

2. The procedure is simple and consists of the following essential steps: (a) introduction of duodenal tube; (b) injection of oil of chenopodium through the tube; (c) injection of saline flush to prevent toxic absorption of oil.

3. The specific toxic effects of drugs can be studied under the precise conditions of tube treatment. Oil of chenopodium seems to have a selective action on tissues sensitized by previous disease or injury.

## OBSERVATIONS ON THE WORK AT QUEEN'S HOSPITAL IN ENGLAND\*

GEORGE MORRIS DORRANCE, M.D.

PHILA DELTA

The hospital at Silecup, England, possessed the advantage of beautiful situation, being in the country just outside of London, away from all disturbing factors. Its organization had reached a rare degree of perfection when we arrived there, and the members of its personnel treated us with the utmost courtesy, going out of their way to see that every opportunity for study and observation was accorded us.

A unique plan was practiced in the arrangement of the different services. The division was so effected that there were sections under English, Canadian, Australian and New Zealand surgeons. This plan stimulated a healthy rivalry which assisted materially in the excellent results obtained.

The record system employed is worthy of mention. Every case was carefully studied and accurate records were kept of each patient. All symptoms, examinations and operative procedures, with photographs, were conscientiously recorded. By the method used by Captain Johnson, the roentgenologist at Silecup, it was possible to take duplicate roentgenogram plates of any given area. This system was later adopted by the American Expeditionary Forces. No attempt was made to conceal or excuse failures. The records were open to all, and the surgeons were frank in discussing their mistakes.

The patients admitted to the hospital were those suffering from injuries at least three weeks old. At first many of them had been operated on previously at the front, but experience taught the surgical staff, and later I had the opportunity and privilege of agreeing with them, that no case should have more surgery at the front than that immediately necessary for the conservation of tissue, unless the patient could be kept permanently by the surgeon performing the primary operation. In the vast majority of cases, time and tissue were lost when the plastic operation was begun in the front line hospitals.

Fractures of the maxillae were for a time treated at this hospital, but subsequently, with the increasing amount of plastic work to be done, patients with these injuries were referred to the Crayden Jaw Hospital, only those in the very severe cases, and those requiring plastic work in conjunction with their fractures were retained.

The rule followed in the treatment of fractures, except in the New Zealand section, was to remove all the diseased teeth and the teeth in the line of fracture. The British soldiers' teeth, on the whole, were in extremely poor condition, necessitating extraction very frequently, thus increasing the difficulties of the oral surgeon.

Fractures of the lower jaw, with loss of bone substance and teeth behind the first molars, were the most difficult to treat because of the tendency of the posterior fragment to ride upward and outward; to overcome this tendency, a saddle was placed on the intermaxillary splint to hold the fragment downward and inward in its proper position.

\* Read before the Section in Surgery of the Society of American Surgeons at the American Medical Association, New Orleans, La., June, 1919.

Major Pickrell devised an ingenious method to prevent the posterior fragment from riding upward and outward. He introduced a screw through the zygoma into the coronoid process, in this way retaining the fragment in its normal position. After union had occurred, the screw was removed.

Mr. Collier showed that in fractures of the lower jaw in the molar region, when bone substance was lost, he could avoid a graft by extracting the corresponding teeth of the upper jaw, thus letting the posterior fragment slide forward. His results were very good. One rule we all learned: To obtain union, all teeth in the line of fracture must be extracted.

#### PLASTIC SURGERY

In plastic work, this hospital holds an enviable position; the originality of the surgeons, coupled with their excellent technic, established principles in plastic surgery which will last forever. Major Waldron, of the Canadian section, was the first to use the Esser inlay, that is, the buried skin graft. This was later modified by Colonels Gilles and Newland, so that instead of introducing the graft from without, it was inserted from the inside of the mouth.

A later modification for obtaining mucous membrane for the mouth was the introduction of the free skin graft. The procedure consisted in incising the mucous membranes or scar tissue of the mouth and making a cast with modeling compound of the cavity thus produced. A Thiersch skin graft was placed over this cast of modeling compound, the latter being held by a dental appliance which had previously been cemented to the teeth. This method failed only in exceptional cases.

Colonel Gilles, the most experienced operator in the British section, frequently used a double tubed pedicle flap taken from the scalp or the chest. The advantage of the double pedicle flap is that it can be transplanted for a long distance without danger of the pedicle becoming infected. He insists that the flap, as in all plastic work, be taken from the area nearest the surface to be covered.

Cartilage grafts were preferred by all the surgeons to free bone grafts in the reconstruction of the nose and supra-orbital margin. It was found that the free bone grafts often became absorbed. No sutures were used through the cartilage to hold it in place.

Previous to our arrival, the staff had run through the entire gamut of methods of nasal construction and had adopted the Indian method as the one of choice, using in every instance a layer of skin for the inner lining. The septum was preferred for nasal support. In the event of its destruction, one or both of the turbinates were selected (if either or both were available), and a free cartilage graft was implanted high up on the forehead, in the area from which the flap was to be taken.

For the correction of shrunken eye sockets, Major Gilles implanted cartilage in preference to performing Mule's operation, in which gold or a glass ball is used, as the inlay became part of the tissues and did not act as a foreign body. The eyelids were restored by an epithelium inlay, with very good results.

Pedicle bone grafts, for example, those of the lower border of the jaw attached to the diaphragm, gave better results than the free bone grafts. Free grafts taken from the rib and tibia periosteum, with a small amount of bone attached, and known as osteoperi-

osteal flaps, were used; all gave fairly uniform results. Practically all the surgeons used catgut for ligatures and for suturing the tissues, silk-worm gut and horse-hair being used to close the skin.

Artificial noses were not favored because of their appearance and discomfort, and the necessity of constantly changing and tinting them. Practically all the patients preferred the plastic operations.

The anesthetic used was ether or chloroform, or a mixture of both. In a large number of instances, the anesthetic was administered by rectum, ether being always used in these cases. Very little local anesthesia was used.

#### SUMMARY

In my experience at Sidcup the things most impressed on my mind were the system of records, the care with which the case was studied before operation, the originality of the operators, and the courtesy and patience shown to those of us who were fortunate enough to be assigned to Queen's Hospital for study.

2025 Walnut Street.

### ORAL AND PLASTIC SURGERY IN THE INTERMEDIATE SECTION OF FRANCE\*

OBSERVATIONS OF A CONSULTANT\*

HERBERT A. POTTS, M.D.

CHICAGO

The exigencies of war always distort and change the ideas and ideals of the civilian soldier, and he is at once confronted with problems that seem insurmountable. It was a difficult task for him to reconcile his dominant idea, of serving the wounded soldier to the best of his ability, to the existing military conditions which many times seemed to overshadow his professional duties; and he was often compelled to sit with folded hands awaiting the arrival of orders, equipment, supplies, etc.

Consolation must be had from the fact that in a very short space of time a movement was successfully "put over," the magnitude of which he will never fully realize, and from the consciousness that he was ready and willing to do his part in the "biggest thing that has ever happened."

For study and comparison a vast amount of work must be done to bring the various data into form which will permit the deduction of logical conclusions. I have ventured to classify some of the case records (the few of which I have copies) from which, together with my observations in the hospitals of Orleans, Blois, Tours, Chateauxaux and Issoudun, I shall endeavor to make some deductions.

#### RATE OF FORMATION OF BONE UNION

We will first consider the time elapsing between the date of injury and the patients' arrival at our base hospital:

Of thirty-five cases of fracture of the jaws of varying degrees of severity, twenty came into our hands within one week after injury. Our treatment of these comprised the removal of teeth, roots and foreign bodies from the line of fracture, the establishment of adequate drainage, and splint-

\* Read before the Section on Stomatology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

ing or immobilization. Seventeen of these cases were well along toward a bony union, demonstrated clinically and by the roentgen ray, at the end of twenty-seven days (average).

The three remaining cases of the twenty were very severe, with extensive loss of bone and much comminution of fragments, and with severe involvement of the soft parts. Satisfactory progress with bone formation was demonstrated in these at the end of 120, ninety and sixty days, respectively.

One case seen during the second week after injury was splinted and a bony union attained within four weeks.

One case seen in the third week had a bony union with trismus; there was no displacement and no loss of bone. Under an anesthetic, impressions were taken, splints constructed which were cemented in place, and by means of rubber bands, the jaws forced apart. At the end of seven days the patient could open his jaws to the fullest extent.

Of three cases seen in the fourth week, one was ununited, owing to roots of teeth and sequestrums in the line of fracture, after the removal of which the fracture healed rapidly under a splint.

Another, which had healed in malocclusion, was improved by an artificial denture.

The other case of this group was a fracture of the upper jaw which progressed rapidly after adequate drainage was established and after it was splinted.

Of four cases seen in the fifth week, one was united in malocclusion; this was refractured and splinted, after which it healed rapidly. The three other cases were injuries of the soft parts.

Three cases seen during the sixth week all healed rapidly after the removal of dead bone and drainage.

One case seen after ninety-three days healed rapidly after the removal of dead bone and splinting.

One case, seen 180 days after injury, being fractured at the symphysis, became solid after the wearing of a splint for four weeks.

One case seen 365 days after injury presented a suppurating sinus with a partial bony union; this closed rapidly with new bone formation after the removal of the second bicuspids, whose root extended into the line of fracture.

These few cases demonstrated the crying need of immediate reduction of fragments and restoration, as far as possible, of the dental occlusion, with the retention of fragments and with the teeth held in normal position by means of splints on the upper or lower jaws, or both, which might, if need be, be held in occlusion by a removable mechanical appliance.

Displaced fragments may be held in place by temporarily wiring them together, or by circumferential wiring, or in selected cases, by external pressure. The open-bite splint is at times of service.

I have seen very few cases of trismus following these injuries unless there were foreign bodies within the substance of the muscles of mastication. The mild cases due to neighboring inflammation readily subsided.

#### TECHNIC FOR REMOVAL OF FOREIGN BODIES

In this connection, I might mention the technic of the removal of foreign bodies as practiced at Base Hospital No. 202 by Capt. L. H. Graves and Roentgenologists Jones and O'Dea. I do not recall the name of the method, but it consists of a table beneath which is a movable roentgen-ray tube, the vertical ray of which is directed upward through the foreign body. The fluoroscope, also adjustable and at right angles to the vertical ray, is lowered on the part. The movement of the tube marks the excursion of the body on the fluoroscope. Blunt artery forceps are then placed on the skin at the supposed depth of the foreign body. The tube is again moved, and if the excursion of the tip of the forceps coincides with the excursion of the foreign body, it is exactly at that depth. The forceps

are then held to mark the spot on the skin, the headlight of the operator is turned on, and a buttonhole incision is made in the skin. The forceps are introduced, and under the fluoroscope are carried by a boring motion to the body, which is grasped by the forceps and extracted directly under the eye. From one to five minutes is consumed by the whole operation, and there is no mutilation of the tissues. More than 400 foreign bodies were in this manner removed, with 100 per cent. success.

#### NERVE INJURIES

I have seen a few patients with injured hypoglossal nerves, but the injuries were either too near the condyloid foramen or too near the entrance of the nerve into the tongue to permit surgical procedure on them. The same may be said regarding the seventh nerve, as it was usually severed within the petrous portion of the temporal bone, or too near its foramen of exit, or too near its exit from the parotid gland, so that it was not promising from a surgical standpoint.

After noting the difficulty which a patient with a severed hypoglossal nerve experiences in eating and talking, I should hesitate very much before utilizing the hypoglossal to repair the facial nerve.

The sliding of the jaw to one side on opening the mouth, after injuries to the neck of the ramus, seems to be due to impaired external pterygoid function, which may be the result of muscular or external pterygoid nerve injury, and usually improves or is recovered from entirely. We see the same phenomenon at times to a mild degree following nerve blocking of the second and third branches of the trigeminus.

Injury of the third branch of the trigeminus in a fracture of the jaw is the rule rather than the exception and is negligible.

#### CHARACTER AND EXTENT OF INJURIES

It seems from subsequent observation of cases that even when there is extensive destruction of soft tissues, one should not delay in the reduction and fixation of the remaining bony fragments in the best possible position. This applies also to the periosteum which molds the bony new growth rather than forms it.

It seems also that anything more than a very feeble effort at primary repair of the soft parts is likely to be a failure, and that the wide open wounds after having been freed of all foreign bodies and injured tissue do better than the ones in which an effort at repair has been made.

Under constant and efficient care for a few days or weeks, secondary closure with a view of limiting scar formation may be attempted; but before attempting extensive plastic surgery, one should wait until all infection has disappeared and until the bacteria and their spores which have been incarcerated within the scar tissue have been killed.

At the earliest possible moment after injury all foreign bodies, including detached bone fragments and tissues injured by the missiles, should be cleanly dissected out, as the lacerated soft tissues do not retain their vitality and subsequently become culture mediums for bacteria.

Wide open wounds, even when extensive suppuration was present, due to lack of frequent dressing, cleared up more quickly than even partially closed ones. Careful Carrel-Dakin management, especially if the wounds did not communicate with the oral cavity, was the method of choice.

Reduction of fractures, immobilization and retention of fragments, together with adequate drainage, established with the idea of its continuance much longer than in wounds of other parts of the body, were the aims of the maxillofacial staffs within the intermediate section, and a suppurating sinus which continued more than six weeks from the time of injury was an indication for operation and removal of the usual sequestrum, after which the suppuration quickly subsided, cavities in the bone and overhanging ledges of bone being removed.

The retention of bone-forming elements in normal position, especially the periosteum with its attached osteoblasts, even in the presence of suppuration, is very important. I suspect that many cases with extensive loss of bone substance which were splinted for transit overseas, and which seemed to be cases requiring large bone-grafts, were found to have bony union by the time the patients landed, or at least had so far regenerated that very small grafts were required.

When the general order came to evacuate all cases, our aim was to splint them in the best possible occlusion, using splints which could in an emergency be quickly released, allowing the patient to open his mouth, or avoid accident by using an open-bite splint.

The general order stopping all operations except in cases of emergency prevented our doing many plastic operations which we were at that time ready to execute.

The feeding of these patients at times presented difficulties, but usually the friendly cooperation of head nurses, cooks and the Red Cross, enabled us to procure an abundance of proper food for them. A variety both in kind and preparation was also provided.

Some few patients came to us with their jaws wired together, and most of them were in good shape. It was no doubt the best means at hand, but dangerous.

I am inclined to think that the better practice would have been to expedite the transportation of the patient to the base hospital without any attempt at reduction or immobilization as the presence of any sort of appliance is at times misleading to the surgeon. He thinks that as an appliance or wire is about the teeth, the patient has been properly attended to, and may be inclined to procrastinate in sending him to the oral surgeon who, when the patient does come, finds that there has been union either fibrous or bony, in malposition, and that reduction on account of the delay is more difficult, demanding at times a refracture before proper splinting can be done.

#### A TRIBUTE

I must pay tribute to the wonderful spirit, implicit trust and confidence of the American soldier; his placid mental state and fortitude were marvelous.

There were eight tables in our operating room at Orleans and when the trains of wounded arrived eight patients were put on the tables, eight rested on the floor, and as fast as one was taken from an operating table another was placed on it. This routine was kept up until the last one was operated on and dressed. There was never a whimper or complaint from any of them. They even assisted when being placed on the table, and took the anesthetic in the most quiet way imaginable without a word of remonstrance or sign of fear, really a phenomenon almost never seen in a civilian hospital. In the wards also there were no gouches, and they appreciated to the fullest extent the efforts of officers and nurses in their behalf. My hat is off to the doughboy.

## THE BROAD TAPEWORM, *DIBOTHRIOCEPHALUS LATUS*, IN MINNESOTA

### ADDITIONAL RECORDS\*

WILLIAM A. RILEY, PH.D.

Chief, Division of Economic Zoology, Department of Agriculture,  
University of Minnesota  
MINNEAPOLIS

Cases of infestation of man by the broad, or fish tapeworm, *Dibothriocephalus latus*, have been regarded as rare in the United States. Nevertheless, Stiles<sup>1</sup> states that over thirty cases have been recognized here, chiefly among foreigners. At least four cases have been reported since that time, and I have knowledge of seven cases from Minnesota which have not been recorded.

Indeed, I am inclined to believe that there are sections of Minnesota in which it is by all odds the commonest of the large tapeworms of man. This seems true in some of the sections settled largely by Scandinavian, Finnish and Polish immigrants. Cases have been reported repeatedly as occurring among these nationalities, but have been regarded as imported. Such, indeed, most of them clearly are.

In 1906, Dr. W. S. Nickerson<sup>2</sup> reported three cases that had occurred in the practice of Dr. Owen W. Parker of Ely, Minn. The patients in two of these cases were Finlanders, but the most significant fact was that the third was a child of Finnish parentage, who was born in Minnesota and had never been outside the state. The father came to this country in 1891. Three years after coming from Finland he passed a tapeworm (*Dibothriocephalus?*). The infested child was born, April 15, 1902, in Ely, Minn. At the age of 2 years, he ceased to thrive or gain in weight, became anemic and suffered from abdominal pains. In August, 1904, his mother noticed segments of tapeworm in his stools and called the physician, who successfully treated him. Up to the time of this report, the child had remained perfectly well.

The tapeworm expelled measured 7 feet in length and was a "typical specimen of *Dibothriocephalus latus*." The scolex measured 1.75 mm. by 0.9 mm.

In the words of Dr. Nickerson, "This latter case is of exceeding importance, since there can be no question that the infection occurred in Minnesota, and it, therefore, demonstrates the fact that the broad tapeworm now has a foothold, at least locally, in this country."

So far as I have been able to learn, Dr. Parker's case is the only recorded one of *Dibothriocephalus* infestation of man in this country which is not clearly explicable on the theory that the parasite was an importation. Indeed, in spite of the apparently clear-cut nature of the evidence, the general point of view of medical men is that expressed by Kopelowitz,<sup>3</sup> who says:

There is very little evidence at present to justify an assumption that native foci of infection exist in this country.

For this reason it seems desirable to place on record two additional cases which have come to my attention

2. Nickerson, W. S.: The Broad Tapeworm in Minnesota, J. A. M. A. 46:711 (March 10) 1906.

3. Kopelowitz, J. C.: *Bothriocephalus Latus* Infection in Missouri, with Report of a Case, J. Missouri M. A. 12:502 (Oct.) 1916.

in the course of some studies on the subject. In both of these, the available data are very meager, but the essential fact bearing on the question is clear: In neither case was there any doubt that the condition originated in Minnesota.

CASE 1.—A Minneapolis boy, aged 8 years, had been suffering from gastric trouble. On treatment, a specimen of *Dibothriocephalus*, 7 meters long, including the head, was expelled. It is preserved in the collection of the Department of Pathology of the University of Minnesota, under the number 0-17-404, but with only the significant note that the patient was born and had lived for all his life in Minnesota.

CASE 2.—A young Chippewa Indian child, on the White Earth Indian Reservation in Mahanomen County, Minn., is the second case which has come to my attention and which is even more significant than the first. Here again many data which would be of value could not be obtained, but this much is known: The child had never been away from the reservation, but was infested by a *Dibothriocephalus*. On treatment more than 3 meters of proglottids were recovered. Unfortunately the head was not obtained, or at least was not preserved. The narrowest neck segments present measured 1.5 mm. in breadth. The eggs of the worm agree very well in measurement with those of the typical *Dibothriocephalus latus*, measuring from 65 to 70 microns by 50 to 55 microns.

Such information as is available regarding the first of these cases I owe to Dr. M. Barron of the Department of Pathology of the University of Minnesota, who treated the patient. That regarding the second case was obtained through the courtesy of Mr. P. A. Starr, teacher in the Indian School at Naytahwausch, who aided me in confirming reports and who put the specimen at my disposal. To each of these I wish to acknowledge my obligation.

An unfortunate misstatement of Nickerson's conclusions has gained wide currency, evidently due to errors in the reports by Singer<sup>4</sup> (who cites "Nicherson"), and of Kopelowitz,<sup>5</sup> 1916, who says:

Nicherson has frequently found the larvae of *Bothriocephalus latus* in fish caught in the Great Lakes.

In reality, Nickerson was very careful to avoid making this statement. He does state that:

Larvae of *Dibothriocephalus* do occur in American fishes. I have obtained them from fish caught in the Great Lakes; but without feeding experiments to rear the adult worm from the larvae, it is impossible to determine the species of *Dibothriocephalus* and the probability is in favor of such larvae being of some species other than *latus*—the parasite of man (italics mine).

Recently, Hall and Wigdor,<sup>6</sup> have described a bothriocephalid tapeworm from a dog at Detroit. Four specimens were collected. As they differ from *Dibothriocephalus latus* and from related species which have previously been reported from the dog, the writers regard the species as new, and propose for it the name of *Diphyllobothrium (Dibothriocephalus) americanum*.

Dr. W. L. Chandler, of the Michigan Agricultural College, has also collected a worm of this genus from a dog at East Lansing, Mich. The worm when found was not in condition for study, but careful measurements of eggs have shown that they average considerably smaller than those of *D. latus*, being about 62 by 37 microns, as compared with about 70 by 45 microns for the latter species. Unfortunately, none of

the strobilae of *D. americanum* had eggs present, and it is therefore impossible to state whether Chandler's specimen should be regarded as of this species.

Hall and Wigdor call attention to the fact that the bothriocephalid larvae, or plerocercoids, found by Nickerson in fish from the Great Lakes may have been the larvae of their dog tapeworm. "The idea is of interest, as bothriocephalids parasitic in man are commonly capable of parasitizing dogs, and vice versa. It may be, herefore, that fish caught in the Great Lakes and consumed here in Detroit, and elsewhere, are parasitized by a plerocercoid other than that of *D. latus* but possibly capable, nevertheless, of parasitizing man."

I have received a number of complaints of "wormy bass" and other fish in the lakes of northern Minnesota, and in several instances, physicians have stated that the parasites were tapeworms transmissible to man. This conclusion obviously was based on a knowledge of the life history of *Dibothriocephalus latus*, or of Nickerson's report. On investigation, it was found that the supposed tapeworms were larval trematodes encysted in the flesh of the fish. In the case of several small-mouthed black bass, taken from Bass Lake, Mahanomen County, in early September, there were in the viscera numerous protocephalid tapeworm larvae which have been identified by Dr. George R. La Rue, as those of *Protocephalus ambloplitis* (Leidy).

However, the possibility that there may occur in this region bothriocephalid larvae other than those of *D. latus*, but equally capable of developing in the human host, is strong. Their development in the dog is suggestive, but the question as to their relation to man can be settled only by direct experimentation as opportunity offers.

## 1. CYSTICERCUS OF THE VITREOUS 2. CONGENITAL MULTIFOCULAR CYSTS IN RELATION WITH THE RETINA 3. ANTERIOR LENTICONUS

### A CLINICAL COMMUNICATION \*

G. E. DE SCHWEINITZ, M.D.  
Colonel, Medical Section, O. R. C., U. S. Army  
PHILADELPHIA  
AND  
MEYER WIENER, M.D.  
ST. LOUIS

The clinical observations on which this communication is based were made in the Ophthalmic Service of United States Army General Hospital No. 14, Fort Oglethorpe, Ga.

### CYSTICERCUS OF THE VITREOUS

CASE 1.—*History*.—An unmarried woman, aged 19, born in Ireland, who had been a resident of the United States for thirty four months, and whose family and personal medical history, so far as it was possible to obtain it, was unimportant, had always been a healthy girl, and with the exception of measles at the age of 14, had had no illness. Ten months prior to the examination she had noted blurred vision of the left eye. This gradually increased and was associated with the appearance of white, cloudy masses floating in front of the eye. At the expiration of five months they ceased to be apparent, and she was no longer able to distinguish even bright light.

5. Hall, M. C., and Wigdor, M.: A Bothriocephalid Tapeworm from the Dog in North America with Notes on Cestode Parasites of Dog, J. A. Veter. M. A., 63: 355-367, 1918.

\* Read before the Section on Ophthalmology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

*Ocular Examination* (July 14, 1918).—Vision of the right eye was 20/20; of the left eye, nil. The palpebral fissures were equal in width, the muscle rotations normal. The right pupil responded promptly to light and in accommodation, the media were clear, the disk slightly reddened in outline, and there was a slight pulsation of the inferior retinal vein. A single chorioretinal artery was noted on the temporal side. The general vascular system was normal and the refraction slightly hyperopic.

The pupil of the left eye dilated readily, and there were no gross changes in the iris; but in the lower portion of Descemet's membrane were a number of punctate deposits and two or three small dots on the anterior capsule of the lens, indicating previous points of adhesion between it and the margin of the iris. The vitreous was moderately cloudy, and there were a few fixed vitreous opacities in the anterior portion of this body. From the upper and inner quadrant a gray reflex was visible, indicating a choroidal infiltration, or perhaps a retinal detachment. Owing to the cloudiness of the vitreous directly in advance of this area, it was not possible to discern accurately, or focus on, any retinal vessel. The region of the disk was visible through the hazy vitreous, and its position could be differentiated by its color; but no vessels were distinguishable.

Quite anterior in the central field of the vitreous, and well in advance of the retina of the macular region, there was a large globular mass, light gray, with a slightly darkened center. The outline was regular and its border almost transparent. It was translucent toward the center, and it was from 6 to 7 disk diameters in width. From its lower border there protruded a tubular extension transversely wrinkled, which terminated beyond a slightly constricted neck into a head, on which two bright dots, and the position of the hooklets, could be distinguished. Distinct peristaltic movements of the cyst were visible and the movements of the protruded head, neck and body were often very active. At times the head was withdrawn within the sac, very much as might be the case with the head and neck of a diminutive turtle.

During a number of observations on the days following the discovery of the cysticercus, the conditions did not materially change, except that in various movements the observations could be improved. Thus, sometimes the head was situated directly downward, sometimes downward and forward, and sometimes more to the temporal side. Depending evidently on differences in the density of the vitreous opacities, the walls of the cyst, particularly those on the temporal side, were more clearly demonstrable. In short, the movements of the parasite, to use the language of Saltzmann, presented an everchanging and interesting spectacle. Naturally, the diagnosis of cysticercus of the vitreous was readily made.

*General and Laboratory Examinations.*—The patient was a well-nourished, rather pale girl, who in a few months prior to her examination had lost weight, and quite recently her appetite had been impaired and she had suffered somewhat from nausea. But the general examinations of the heart, lungs and abdominal viscera were negative, with the exception that one roentgenogram indicated a slight thickening in the region of the gallbladder. On repetition, however, of this examination, the roentgenologist was unprepared to say that this appearance was of pathologic significance. The urine showed no pathologic content; the blood count was, red blood corpuscles, 3,450,000; white blood cells, 5,000; the Wassermann test of the blood was negative. An examination of the stools revealed the presence of ova, but no segments of the worm. It was supposed that these ova were those of *Taenia saginata*, but, as is well known, the eggs of this tapeworm and those of *Taenia solium* so closely resemble each other that they cannot be distinguished microscopically, and the ophthalmoscopic appearance of the hooklets leave no doubt that the ocular intruder was *Cysticercus cellulose* (Fig. 1).

*Operation.*—After keeping the patient under observation for two weeks, during which there was a manifest increase in the vitreous density and descemetitis, it was determined to operate, after the patient had been fully informed as to the chances of operative success and failure, and also fully

informed that if the parasite was not removed the eye was doomed to a destructive inflammation. The following operation was performed by Dr. Wiener:

An incision was made in the conjunctiva with scissors between the external and inferior rectus muscle, beyond the ciliary body and parallel with the corneal margin. Next, the sclera was incised longitudinally with a Graefé knife, the incision being 1 cm. in length, passing through the sclera, choroid and retina. At once fluid vitreous exuded. Guided by means of an electric ophthalmoscope, forceps were introduced into the opening and the cyst grasped and its removal attempted. This, however, was impossible owing to the fact that it promptly ruptured, and further efforts were not made. The wound was closed with conjunctival sutures and a dry dressing applied.

For three days there was no reaction, when pain developed in the eye, lasting for about an hour. A small point of adhesion to the iris and the lens in the upper and outer quadrant was discovered, but there was no ciliary injection. The lens, however, was quite milky in appearance. Convalescence proceeded uneventfully, and four days after operation the patient was discharged, the eye being free from irritation but the lens cataractous.

Twenty-eight days after operation, the eye suddenly became very painful, the conjunctiva was intensely congested, and there was marked ciliary injection, the iris being dull, dark, and slightly greenish in hue. The patient was advised to permit the enucleation of the eye, to which operation she consented. Following this operation there were no complications, and at the expiration of a proper period an artificial eye was adjusted, and it was noted that the patient's general condition began very rapidly to improve.

Dec. 11, 1918, or practically six weeks after the enucleation of the eye, the patient reported that a hemorrhage had occurred from the socket. She was immediately examined, and a clot of blood found at the apex of the orbit. This hemorrhage was coincident with a menstrual molen. About 1 ounce of blood was lost, but no further hemorrhage occurred. She gave the history that on one previous occasion menstruation had been associated with epistaxis. Since this date there has been no report of any complication.

According to H. B. Ward,<sup>1</sup> three different species of tapeworm larvae are known to occur in the eye and its adnexa, namely, those of *Taenia solium*, *Taenia cecchinococcus* and the bothriocephalid tapeworms. Of these, *Cysticercus cellulose* is the most common.

Referring to the frequency of ocular, and especially of retinal and vitreous involvement, Vosgien's figures,<sup>2</sup> quoted by Ward, may be reproduced. Among 807 observations tabulated by Vosgien as recorded for a definite location, 372 were concerned with the eye, and of these, 120 of the retina and 112 of the vitreous. None the less, in individual experiences the cysticercus is not common. For example, in the often quoted figures of von Graefé, there were ninety cases in a total of 80,000 patients with eye diseases.

Extra-ocular cysticercus is of comparatively slight importance. The intra-ocular situation of the parasite may be in the anterior chamber, in the posterior chamber, even in the lens, but naturally, a cysticercus in the posterior segment of the eye, that is, under the retina and in the vitreous, is the one that presents the greatest clinical interest.

As Ward points out, the large number of cases in which this parasite has been found in the retina is noteworthy; moreover, such as are recorded as free in the vitreous body are in the majority of instances seen there after they have escaped from beneath the retina into the vitreous. Indeed, observers have main-

1. Ward, H. B.: Ocular Parasites, American Encyclopedia of Ophthalmology, 1:2:9265, 1918.

2. Vosgien: Le cysticercus cellulose chez l'homme et les animaux, Paris, 1911.

tained that the parasite always makes its first appearance behind the retina, the cysticercus having gained entrance into the vessels of the choroid, and from there has passed beneath the retina, which it detaches from the choroid. Von Graefe, however, was of the opinion that the parasite was able to develop floating in the vitreous, and Fuchs, as will be recalled, states that the cysticercus may find its way into a vessel of the retina or the ciliary body, from which position it may enter the vitreous directly without a preceding detachment of the retina.

The natural history, etiology and distribution of the tapeworm need not be discussed, as they have been dealt with fully in many articles. Among those easily accessible are the one by Saltzmann,<sup>3</sup> and in quite recent times the one by H. B. Ward,<sup>2</sup> already referred to.

Naturally, the lodgment of a *Cysticercus cellulosae*, which is the larval stage of *Taenia solium*, or pork tapeworm of man, can exist only where *Taenia solium* is found. At one time this was most frequent in northern Germany, but even here, owing to the improvement in meat inspection, etc., there has been a noticeable diminution of this form of tapeworm infection. So far as we are aware, *Taenia solium* has not been found in native Americans, but only in those who have emigrated to this country, and even so, it is very rare among them.

In general terms, the fertilized eggs of the adult tapeworm are distributed with the feces of the primary host. By some chance, for example, drinking contaminated water, eating vegetables which have been grown in land that has been fertilized with fresh manure, or dwelling in close community with persons who are suffering from tapeworm and whose habits are uncleanly, the infection is communicated, and the eggs reach the stomach of the new host, where they are hatched, and the embryo, reaching the intestinal canal, gains access to the surrounding tissues, where it may remain or be picked up by the lymph or blood circulation and sent to a distant portion of the body.

As has already been pointed out, the passage into the eye is most frequently through the vessels of the nasal tract, but the parasite may also reach the vitreous through a retinal vessel. After the embryo reaches its final destination, it develops into a bladder worm, which, if it is simple, is called a cysticercus, *Cysticercus cellulosae* being the bladder worm, or the larval stage of *Taenia solium*.

It is stated that it usually requires at least two months before the suckers and hooklets of the adult form are visible.

It is rare that an intestinal tapeworm and an ocular cysticercus are coincident, but such coincidence has been reported. It is also most unusual that more than one cysticercus shall be present in the eye; however, two in one eye have been reported by Alfred Graefe, and Schöbl observed three cysticerci in the same eye. In our patient, upward and inward there was what appeared to be a detachment of the retina. It is possible that this indicated the location of a subretinal cysticercus. Most unfortunately, the enucleated eyeball was mislaid or lost by some one in the personnel of the laboratory. Otherwise this point could have been decided, as well as a report of the pathologic histology of the globe included.

When Ward wrote his article on ocular parasites (it was published in 1918) four cases of cysticerci of the eye had been reported in the United States. Two of these presented only iris involvement, and two occupied the retinal-vitreous system.<sup>4</sup> It is possible that the cysticercus in our patient had been subretinal and escaped into the vitreous; but certainly when under observation it was entirely free in the vitreous and well in advance of the central area of the retina.

Operative experience has taught that a subretinal cysticercus is most easily secured; next, one that is fixed in the vitreous; but the chances of success when the bladder worm is free in the vitreous are exceedingly slim. The last named condition was the case in our patient, who none the less was advised to submit to operative procedure, because in the absence of it the eye is practically sure to go on to a progressive iridocyclitis with destruction of the eyeball. Occasionally, however, cysticerci may live in the eye from two to four years, and a few cases are on record in which the residence of the parasite within the globe occupied a much longer period of time.

#### CONGENITAL MULTILOCULAR CYSTS IN RELATION WITH THE RETINA

CASE 2.—A man from the Dental Corps, aged 22, was referred to the ophthalmic service because of defective vision of the left eye. There was no history of injury and no evidence of constitutional disease. This defective vision had existed from childhood, and at the time of examination vision equaled light perception. The media were clear, the disk was pale and sharply outlined, and to its outer side there was a small crescent of choroidal disturbance. The arteries were small and straight, the veins normal in size, color and outline. In the macular region a large, white, atrophic spot, slightly greater in diameter than the disk area, was visible. Protruding from the upper half of this area there was a large cyst formation, in shape somewhat resembling an observation balloon. Its summit was best studied with +4.50 D. On the surface were a number of small vessels. It was transparent

3. Saltzmann: The Entozoa of the Human Eye. System of Diseases of the Eye, edited by Norris and Oliver 4: 843, 1900.

4. Turnbull: Cincinnati M. News 12: 373, 1910. Miner: M. Rec., Dec. 26, 1891.

and it covered about three fourths of the atrophic macular area.

Extending from the lower temporal edge of this cyst for a distance of about 3 disk diameters there was a narrow, transparent tube carrying two atrophic vessels. This tube resembled in appearance and size a manifest canal of Cloquet. The canal terminated in a wide-spreading cyst mass, which was less transparent than the one in the macular area, and fully four times as large. It possessed the shape of a rounded cone, with the base gradually losing itself in the peripheral part of the temporal quadrant of the retina. On its superior surface there were numerous small cysts, or vesicles, and some which were confluent. The surface of the mass was covered with vessels, which were for the most part atrophic. In the lower quadrant of the field the retina was elevated 2 diopters.

The entire middle and lower field of the fundus was occupied by retinal pigment deposits, unassociated with any atrophic spots, with the exception of one to the nasal side of the inferior temporal artery, just below the disk, and two less pronounced ones still farther below. The vision of the right eye was 20/20, and the eyeground was entirely normal (Fig. 2).

The lesions portrayed in the accompanying water color are subject to several explanations, none of which is entirely satisfactory. That edema and degeneration may result in cysts or cystic spaces in the retina is well known, and such conditions have often been found in the examination of enucleated eyeballs, the so-called Iwanoff cysts back of the ora serrata being good examples. That retinal cysts form in association with separation of the retina of long standing is also well known, and it has been suggested by Leber that some of the cases of detachment of the retina clinically recorded were really instances of cystic degeneration. Derby,<sup>5</sup>

in reporting a probable cyst of the retina and noting that clinical observations in this regard are rare, refers to Gunn's case of congenital microphthalmos and cyst of the retina, to Collins' observation of a retinal cyst which was shown to have developed between the outer and inner nuclear layers, and to Thompson's description of a cystic detachment of the retina. One of us (de Schweinitz<sup>6</sup>) has recorded a cyst of the retina in association with detachment of the retina. It is interesting that in Derby's, Thompson's and de Schweinitz's cases the cysts partly overhang the disk. Incidentally, our case does not belong in this category.

Among the many anomalies of, and associated with, persistent hyaloid artery,<sup>7</sup> various types of cysts, small and large, have been reported. Rarely, the origin of

this vessel, instead of being the usual one, is from a point more or less distant from the optic disk. For instance, in Schöhl's<sup>8</sup> case it arose 1½ disk diameters down and in from the papilla as a translucent cone with a broad base, which suggests a cystic process, and proceeded from the apex in two strands, one of which ended in the posterior surface of the lens.

In Silcock's<sup>9</sup> case the source was from a macular coloboma, and the strand reached the posterior part of the lens.

Is it possible that the balloon-like cyst in our case, from which a cord carrying two vessels passed to the temporal portion of the retina, terminating in the large multilocular cystic area, may be an eccentric vestigial hyaloid vessel with a bulbous expansion at its origin, bent over and twisted away from an approach to the posterior surface of the lens, to be fastened as is portrayed in the illustration? Choroiditis, such as we observed, probably congenital, has been reported in a number of examples of persistent hyaloid artery and its anomalies. We frankly think this theory of the appearances in our patient's eye has little if anything to commend it, but it is mentioned because of the numerous anomalies that have been reported in connection with the remnants of a hyaloid vessel and its sheath.

Doubtless the whole process is best explained by assuming that in intra-uterine life there developed some type of hemorrhagic retinochoroiditis, and that cystic changes occurred in the secondary exudative processes. There seems no doubt that the balloon-shaped mass is a cyst, and the large area in the temporal periphery of the retina almost certainly represents a mass of exudation which elevates the retina (it may have started in the chorioid) and in this elevated retina multilocular cysts have developed. What the nature of the underlying mass is we do not pretend to state, although in this connection it may be worth while to refer to a case observed and reported by de Schweinitz and Shumway<sup>10</sup> which ophthalmoscopically suggested a new growth, a glioma, indeed, but on examination proved to be a detachment of the retina, with extensive dropsical cystic degeneration of the rod and cone visual cells. It may be that the large area in the temporal part of the retina should be classified as an example, in limited space, of exudative retinitis, as described especially by Coats, with cystlike changes on its surface.

ANTERIOR LENTICONUS

CASE 3.—A recruit, aged 20, was referred by the camp infirmary for examination because of defective vision which had existed from infancy. It was possible to see him only once. Vision, right eye was 8/200; left eye, 10/200. It was not possible in the brief time at the disposal of the examiners to ascertain whether any spheric or cylindrical combination could improve vision. Each lens presented a pronounced anterior cone, which could readily be seen by ordinary daylight, looking through the anterior chamber, especially from the side, and also when the pupils were dilated. During this dilatation it was noted that the lenses were small and slightly hazy, except in the region of the zonula. Fundus examination by the indirect method detected no abnormality. The tip of each cone almost touched the posterior layer of cornea (Fig. 3).

So far as we are aware, only two cases of anterior lenticonus have been reported, one by Webster,<sup>11</sup> in which the conicity resembled that of a conical cornea. Without atropin, the following lenses raised the vision, which was 15/200, to 20/200, namely,

$$\begin{aligned} \text{O. D.} & - \frac{1}{11\frac{1}{2}} \\ \text{O. S.} & - \frac{1}{2} \text{C} - 1 \frac{1}{10} \text{C, axis } 135 \end{aligned}$$

After atropin, the vision of each eye was 20/40, the right eye accepting a + 1/10 and the left eye a + 1/10 C + 1/24 c. axis 135.

The second case is the one recorded by Van der Laan<sup>12</sup> under the name anterior polar crystalconus: the patient, a man aged 23, the anomaly being said to have developed slowly during eight years. There was a conical protuberance of the lens into the anterior chamber, occasioning through its center a high grade myopia, while through the periphery of the lens the refraction was hyperopic. The cone is said not to have differed in any way from the ordinary lens substance.

Neither of these reporters, in the abstracts which we have been able to consult, undertakes to give any explanation of this lenticular anomaly. As is well known, examinations of posterior lenticonus have usually demonstrated a rupture of the posterior capsule, and certainly displacement backward of the nucleus is a constant feature. Both of these observations of anterior lenticonus antedate the discovery of posterior lenticonus, first made in a human being by F. Meyer in 1888. Referring to this fact, Louis Dor<sup>13</sup> suggests that there may have been an error in observation, the reporters having been deceived by reflections, whereby they mistook a posterior conicity for an anterior lenticonus. Dr. Wiener, who examined the patient whose brief clinical history has just been reported, is confident that the conicity was an anterior one, as stated, so pronounced that it projected almost to the posterior surface of the cornea.

1705 Walnut Street—Carleton Building.

ABSTRACT OF DISCUSSION

DR. F. H. VERHOEFF, Boston: I have seen only one certain case of intra-ocular cysticercus. Since my opportunity for seeing rare cases has been unusually great, the condition must be extremely rare, at least in the vicinity of Boston. This case was shown to me by Dr. Greenwood. The cyst was remarkably similar in size and situation to that described by the essayists. Microscopically, I have examined two cases. A specimen from one of these, a case of preretinal cysticercus, was sent to me several years ago by Professor Fuchs. The other case occurred in the practice of Dr. Marlow who removed the eye and submitted it to me for examination. This cyst was entirely subretinal, and occurring in a child, led Dr. Marlow naturally enough to make the diagnosis of glioma retinae. In each of these cases the cyst was ruptured and a marked chronic inflammatory reaction of essentially the same character had been set up. There was complete separation of the retina with formation of cyclitic membranes and formation of cicatricial tissue on the inner surface of the retina. Surrounding the cysts the infiltrates and exudates consisted chiefly of plasma cells, eosinophils, and endothelial phagocytes. Pus cells were notably scanty. In Fuchs' case there was a layer of fused endothelial leukocytes lining the external wall of the cyst. In my case the choroid was markedly infiltrated with plasma cells and eosinophils, but in Fuchs' case it was almost free from infiltration, due no doubt to the fact that the cyst was preretinal. From these cases I should judge that it is the content of the cysts that causes the inflammatory reaction, and this fact no doubt explains the reaction which followed the operative interference in the essayists' case. In regard to the case of retinal cysts reported by the essayists, I may say that I have never seen a similar case. In fact, so far as I can recall, the only case of retinal cysts that I have seen clinically was that reported by Dr. Derby and referred to by the essayists. I have frequently found retinal cysts, however, in eyes that have been removed for chronic inflammatory conditions associated with separation of the retina. These cysts seem always to be due to splitting of the retina in the layer of Henley, that is, to separation of the neuro-epithelium of the retina from the nervous portion, and are thus in a way, analogous to vesicles of the cornea or skin.

I found them once in a case of glaucoma secondary to contusion of the eye. This case was so unusual that I am passing around a section from it. The essayists offer several possible explanations for the cysts in their case, but state that none is satisfactory. The explanation, however, that they consider the least satisfactory appeals to me the most strongly; namely, that the cysts have resulted from a partial persistence of the hyaloid system associated with an abnormal development of embryonic tissue. Their suggestion that the case is in any way related to retinitis with massive exudation seems to me improbable.

As to the case of anterior lenticonus: I recall seeing a similar case about fifteen year ago, but I am unable to find the record of it. The essayists wisely refrain from attempting an explanation of this condition about which so little is known, but in a discussion such caution does not seem to be considered necessary, so that I venture to suggest two possibilities, first, that the condition is due to persistence of the conical shape of the embryonic lens vesicle, or second, that it is due to delayed separation of the lens from the cornea.

DR. ALEXANDER DUANE, New York: Apart from the very rare cases of extreme anterior lenticonus, such as the authors have described, we occasionally see cases in which the condition exists to a moderate degree, not incompatible with fair sight. I can recall two such cases of moderate, progressive anterior lenticonus, both observed in women between 20 and 30 years of age. In both there was well marked, somewhat irregular corneal astigmatism with the rule and a total astigmatism against the rule, the latter increasing in the one case from 2.50 D to 6 D in nine years, and in the other from 4 D to 7 D in over three years. In both the ophthalmoscope showed the characteristic, small central area of metamorphopsia, shifting with movements of the eye more rapidly than the corneal reflex. In both fairly good and serviceable vision was secured by cylindrical glasses. In both also the condition was more marked in the right eye. Somewhat analogous to the congenital cyst noted by the authors was the peculiar condition I have elsewhere described, in which there was an egg shaped pigment bordered coloboma of the choroid, to one margin of which was attached by threads resembling the byssus of a mussel a slender and elongated, very delicate and transparent, apparently tubular bag, which, running straight up in the vitreous, lay parallel to the retina and about 1 mm. in front of it. At its upper end this structure tapered off into a point, to which was attached a hook-like appendage. This peculiar body differed entirely in appearance, situation, and direction from a persistent hyaloid artery, nor was it in any way like a retinitis proliferans. It remained unchanged all the time the patient was under observation (eight years). The only other fundus change was a faint, striate atrophy in the region of the macula, causing a central scotoma, which reduced the vision of 17/100. It is, perhaps, a fact of some interest that this patient was rejected for life insurance, because the examining physician had taken his coloboma of the choroid for an albuminuric retinitis. Perhaps also cystic was the condition which I have reported as occurring in a child, whose eyes, otherwise normal in appearance, showed shrunken, rudimentary optic discs, practically complete absence of the retinal vessels, and at each macula a sharp-cut round ring, which I took to be the base of a translucent protrusion of the retina, although I could not actually demonstrate this, since there were no vessels or markings, on which the presence of retinal structure over the area circumscribed by the ring could be predicated.

DR. ALLEN GREENWOOD, BOSTON: Dr. Verhoeff has asked me to discuss briefly the case he mentions, a case which was observed early, due to the fact that the cyst was between the macula and the disk, and when first seen appeared to be the size of a grain of rice, and about that shape. It was nearly round when I saw it. It projected only one or two diopters, and two or three days later it was down below the level of the macula, and later it crept up and covered the entire optic disk. It increased in size until it was about one and one half times the size of the disk, and protruded 5 D. It was easy to see that the eye would be lost by the growth of this cysticercus. Those of you who have tried to pick anything off the optic disk with a pair of forceps in one hand and an ophthalmoscope in the other can realize the difficulty—I had a pair of double reverse action forceps, where one blade revolves in the other. By making an incision between the external and the interior rectus, I brought the tip of the forceps to a level with the cyst and saw that the blades were each side of it, then I closed the forceps and removed the top of the cyst. Immediately the forceps were closed the fluid flowed into the vitreous and I got only the top part of the cyst itself. It required two operations for in the first one the vitreous clouded from hemorrhage. I made the puncture with a Graefe knife, but on account of the hemorrhage I had to wait two days before operating a second time. The patient was fine for about a month, could see finger movements, and the interior of the eye was clearing when she had an intra-ocular hemorrhage, pain for two or three days, the lens pushed forward, the anterior chamber was shallow, and the lens became opaque. The eye quieted down and remains as good as an artificial eye.

This is the only case of cysticercus I have ever seen.

DR. A. E. DAVIS, New York: I wish to report briefly a case which came under my own care. I kept this gentleman, aged 57, under observation for a number of years. He died recently. He suffered from migraine, and always had poor vision. The ophthalmometer showed astigmatism with the rule 2 D axis 90 plus 180—right eye, with the rule 2 D axis 75 plus 180—left eye. The patient, however, accepted a strong cylindrical glass against the rule, as follows:

R. V. = 20/200 : 20/50 w-5 D = -2.50 cyl. 90° L. V. = 20/200 : 20/30 w-1 D = -3 C 75°  
Reads Jaeger 1 from 9" to 15" w-1 D = -2.50 cyl. 90° Rt. plus 3 cyl. 165° left.

Because of the great discrepancy between the astigmatism, as indicated by the ophthalmometer, and that found on subjective examination, some trouble with the lens was suspected, an incipient cataract, perhaps. On examination with the ophthalmoscope, no opacity of the lens whatever was found, but a transparent protuberance of a conical shape on the front surface of the lens of each eye. The corneas were perfectly clear, except for a very minute opacity just to the outer side of the center of the left. The shadows reflected from the pupil resembled in a marked degree the shadow-crecens seen in conical cornea.

DR. S. D. RISLEY, Philadelphia: Simply as a matter of historical interest I thought this might go on record in the transactions of this section: While making some historical studies last year, I took pains to go over the printed book in which the cases reported had been kept by the secretary of the Philadelphia Ophthalmological Society, which was founded in 1871, and lived three years. During that time a general surgeon, Dr. Richard Levis, presented to the society a case in which the cysticercus in great abundance was found in the orbit under the internal rectus muscle.

DR. GEORGE E. DE SCHWEINITZ, Philadelphia: Operative success in intra-ocular cysticercus depends largely on the position of the parasite; success has most often been obtained where it was subretinal. If free in the vitreous the effort to secure the parasite is most difficult.

DR. MEYER WIENER, St. Louis: I had no difficulty in putting the forceps around the part of the cysticercus which I desired to grasp. I could see it very plainly, and see the forceps passing around the cyst. I had no hemorrhage, but when I closed the forceps and tried to withdraw it, it was the same sensation as if you took a pair of forceps and tried to pick up a piece of jelly. It closed over the cyst but there was nothing there between the points of the forceps.

**Vaccination Against Typhoid in Spain.**—Professor Peset, director of the Instituto Provincial de Higiene at Valencia, delivered by request last December an address on this subject at the Paris Faculté de médecine. His figures show that active work has been done in this line in military and civilian circles in Spain and fine results accomplished. In the army at Tetuan in 1914, for example, there were no deaths from typhoid among the 12,000 vaccinated and only 2.61 per thousand cases developed. He relates a number of striking instances showing the protection conferred by the vaccination; the one or two persons in large families who refused vaccination were the only ones who contracted typhoid during an epidemic, notwithstanding that there was no isolation, one of the vaccinated even sleeping with the typhoid patient. At Cheste, there was not a case of typhoid among the 1,200 vaccinated while there were 171 cases among the 4,800 non-vaccinated. Similar figures are cited from the epidemic at Moger in 1915, no cases of typhoid among the 363 vaccinated and 300 cases among the 7,631 nonvaccinated. Also from the epidemic at Torrente in 1917, no cases of typhoid among the 3,330 vaccinated and 407 among the 5,011 nonvaccinated. During 1918 vaccination of the members of the family whenever a case of typhoid developed at any point arrested the infection before it had a chance to assume epidemic form. Various types of vaccine are used. His address is reproduced in full in the *Laboratorio* of Barcelona 3:97 (March) 1919.

THE ACTION OF RADIUM ON  
CATARACTS\*

MARTIN COHEN, M.D.

Professor of Ophthalmology, New York Post-Graduate Medical  
School and Hospital

AND

ISAAC LEVIN, M.D.

Clinical Professor of Cancer Research, University and Bellevue  
Hospital Medical College; Chief of the Department of  
Cancer Research, Montefiore Home and Hospital

NEW YORK

Until recently there was no agent known that could in the slightest degree change or influence the natural course of the development of a cataract from its period of incipency to maturity. Surgery had reached a high degree of perfection and was followed in the majority of cases by a clinical success which meant restoration of vision. Surgery, however, does not influence or change the development of the lenticular opacification but simply removes the entire lens.

A great many attempts have been made to influence the development of cataract by chemical means, but as yet without success. In the last decade, however, a great deal of progress has been reported in radium therapy as applied to various pathologic conditions, and the field of usefulness of the biologic action of radium in the domain of therapeutics is constantly widening. Furthermore, a great many eye conditions, such as trachoma, vernal catarrh, and various tumors of the eyeball and adnexa, have been treated with radium without in any way impairing the normal structure of the eyeball or impairing its function.

One of the writers, who has done some research on the subject of chemotherapeutics of the cataract with entirely negative results, raised the question whether one might not expect that the radioactive substances may exert an influence on the development of the cataract. An *a priori* consideration of the subject showed the likelihood of such an influence by the radium rays.

As admitted by the best authorities on the subject, the capsular epithelium is most probably the starting point of cataract. Indeed, it is inconceivable that the change, or the precipitation, as it were, of certain soluble ingredients within the lens which result in the formation of the opacifications could take place without a change in the structure of the barrier membrane, which the capsule is; and since the capsule is essentially a product of cell life, the change in the barrier must be due in the ultimate analysis to an abnormality in either the structure or the function of these cells.

There is ample biologic and clinical evidence that radium produces various and very deep changes in cellular functions. In tumors and granulomas, the action of the rays consists in the inhibition of the proliferating capacity of the cells; in conditions like exophthalmic goiter, it influences and alters the functions of the cell. It is thus evident that the radium rays may alter or influence the capsular epithelium in such a manner as possibly to render the whole capsule less permeable for the abnormal agents within the general circulation or in the neighboring tissues, which later on entering the lens produce the opacifications; or else the change in the membrane may consist in its

enhanced ability to exosmose certain substances from the lens, and the lack of the latter may result in formation of opacities.

A thorough search of the literature showed that there had been no attempt made by any investigator to influence cataract with radium, with the exception of Koster.<sup>1</sup> This investigator applied radium to a great variety of eye diseases, apparently in a large number of cases. While he does not state definitely the number of cases of each disease treated, he reports on over twenty diseases, and as regards some of these diseases he distinctly states, "I have treated as many as twenty or more patients." Among others, he reports on treatment of cataract, with negative results, but states that in a case of cataracta catarulea—the star form in the anterior cortex—the opacities fell to pieces and disappeared entirely after five sittings of one hour weekly.

The method of radium therapy employed by Dr. Koster is not in accord with the modern conception of the subject. None the less, he apparently obtained favorable results in certain conditions, and there was no deleterious effect observed on the retina or on the other ocular structures. Dr. Koster used a glass tube filled with radium which he placed, uncovered and unprotected in any way, directly to the scleral conjunctiva. This is a dangerous method, since all of the soft rays remained unfiltered and could irritate and burn the adjacent tissue. In this connection, it is remarkable that an amount of radiation which would have surely caused a burn on the skin did not cause a burn of the scleral conjunctiva. It must be admitted that he used much smaller quantities than are employed at present. The therapeutic results obtained by Koster, notwithstanding his inadequate methods, the harmlessness of the procedure, which was shown by him as well as by the investigators who treated epitheliomas of the eyelids, and also the theoretical considerations mentioned above encouraged us to commence this investigation.

## METHODS EMPLOYED BY THE AUTHORS

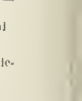

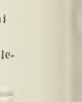

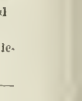

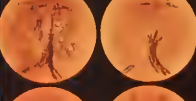

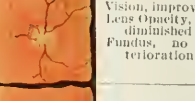

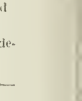

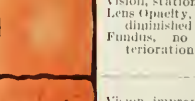

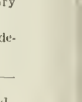

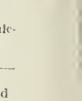

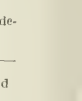

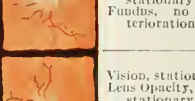

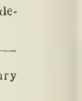

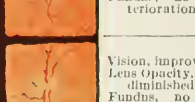

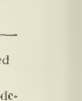

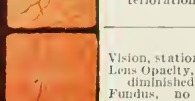

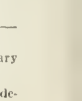

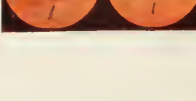

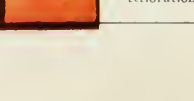

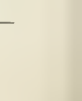

The methods employed were very similar to the technic of deep radium therapy which one of us is using at present in the treatment of malignant tumors and various other conditions. For a clear understanding of these methods it is necessary to explain here very briefly certain physical characteristics of radium.

Radium emits alpha rays, beta rays, and gamma rays. The first two act only as a general caustic on all the tissues found on the surface to which the radium is applied. The hardest beta, and especially the gamma rays, have a selective action which causes their efficacy in the treatment of deep conditions. The selectivity of the rays consists in the fact that they may influence pathologic structures while leaving the neighboring normal tissues practically intact. These gamma rays represent only about 1 per cent. of the total amount of radiations. When Koster employed in his tube 2 mg. in gamma radiations to do the work, there were possibly not enough soft radiations to injure the normal tissue; but, on the other hand, he had only an extremely small amount of gamma radiations to do the actual work. In modern technic, ten, twenty and more times the amount of radium used by Koster is employed. With the aid of various means which it is not necessary to discuss here, all the irritating soft

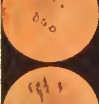

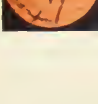

\* Read before the Section on Ophthalmology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

rays are filtered off and only the selectively acting gamma rays are utilized. The actual technic consisted in covering the radium with brass, photographic paper and gauze, and placing it over the closed eyelid. The distance between the radium substance and the eyelid was about 2 cm. The application usually lasted two hours.

The main difficulties that an investigator encounters when he attempts to test the efficacy of any measure on the development of a cataract is the fact that the disease is frequently very slow in progressing and may remain stationary for a long period. It is even assumed by some authors that occasionally a cataract may spontaneously improve for a time. None the less, it is the experience of every ophthalmologist that by far the greater number of senile cataracts follow the usual course and mature in a period of from six months to two years.

A statistical analysis of 131 cases reported by Dr. Nevens of the Liverpool Eye and Ear Infirmary is very characteristic of the usual experience. Of his cases, seven, or 5 per cent., matured in less than one month; twenty-six, or 20 per cent., matured in a period of between one and six months; thirty, or 23 per cent., matured within one year; thirty-five, or 27 per cent., matured in two years; nine cases, or 7 per cent., in three years; seventeen, or 13 per cent., in between three and seven years; and seven cases, or 5 per cent., in between twelve and twenty years, thus giving a total of 75 per cent. that matured within the first two years and only 18 per cent. that took more than three years to mature.

It is thus clear that in a certain number of consecutive cases selected for study, not less than three fourths of such cases, in the natural course of events, would reach maturity within two years, and would consequently have to show a good deal of progression within the first year.

The material used for the present investigation consisted of all the cases of immature cataracts seen by one of us in his routine clinical and private practice during the time of the investigation, twenty-four cases being included.

Twenty patients had senile cataracts of the usual type. In the majority of the cases, both eyes were affected, but only one eye, which was less mature, was treated. Four cataracts were complicated; one was due to a retinitis pigmentosa, one to an iridocyclitis, and in two instances chronic glaucoma was present. An iridectomy was performed in the latter cases, but the cataract was not due to any trauma. None of the patients suffered from true diabetes or nephritis, with the exception of one who showed sugar, traces of albumin, and a few hyaline casts. The type, extent and location of each cataract is noted on the accompanying chart.

Three of the patients received applications of radium for one year; three for eleven months; two for ten months; two for nine months; six for eight months; two for seven months; three for four months, and three for three months.

The result of the radium treatment in these cataracts as regards vision and lens opacification is as follows: There was a combined improvement in the lenticular opacification and vision in twelve cases; lens opacification disappeared in one case without improvement in vision; opacification diminished in five cases with stationary vision (in one case vision decreased); opaci-

fication was stationary but vision improved in three cases; both vision and opacification remained stationary in three cases. In a word, twenty-one cases, or 87.5 per cent., showed some improvement.

The method of procedure in the examination of these cases consisted of the usual methodical examination of the eye, including also an examination of the urine, and physical and blood examinations when deemed essential.

The examination of the visual acuity and the drawings of the lenticular opacities required especial attention to several details, as follows: The illumination of the room and the test charts was of the same character at each examination. Several corresponding letters, numbers, and illiterate charts were used. After the results of the visual acuity test, functional test, and the refraction were determined and recorded in each case, the pupils were dilated with a 1 per cent. homatropin solution for the purpose of examining the details of the fundus and also for a detailed drawing of the opacification. A combined focal examination was made of the lenticular opacity, namely, with a condensing lens and a corneal loop, and then a drawing of this opacity was recorded. The cataract was next observed with the Loring ophthalmoscope through its aperture, the patient always fixing a definite object in space, in order to procure a good view of the entire opacification, and a drawing of it was made. A 20-diopter lens was then inserted in the aperture of the ophthalmoscope for a drawing of the finer details of the lens opacification. In order that the latter examination should be accurate, a distinct fixed opacity of the lens was noted at a definite angle with a strong convex lens in the ophthalmoscope. Then another drawing was made of the opacification; this drawing also served as a guide for future examinations. Finally a drawing was made of the fundus details with the aid of a Loring ophthalmoscope. In a certain number of cases an electric ophthalmoscope was necessary to view the fundus, as the opacity was very dense. Four drawings were made of each case before radium was applied, and subsequent drawings were made at stated intervals.

The chart presents graphically the type of the cataract, the extent of the opacification, the length of time during which the treatment was continued, the number of treatments given, and the results obtained, so that it is hardly necessary to give in the text a detailed history of each individual case. Therefore only some of the cases which present salient features will be discussed in greater detail.

#### REPORT OF CASES

CASE 1.—*Senile Cataract*.—Examination before the application of radium gave the following results: The patient was able to count fingers at 1 foot. With focal examination the lens had a diffuse grayish appearance; with the ophthalmoscope a faint fundus reflex was obtained through the periphery of the lens. Five days after treatment began the patient could count fingers at 3 feet; ophthalmoscopic examination of the lens showed it to have a diffuse grayish aspect, while from its periphery a large fundus reflex was visible. Seven days after the beginning of treatment the patient could count fingers at 4 feet; oblique examination showed the lens to be of a grayish color, having a few whitish dots and small striae scattered near the central area; the ophthalmoscope revealed a much larger fundus reflex, with distinct sector striations radiating from the periphery of the lens. The improvement obtained remains to date, and consequently there has been no progression of the disease during a period of ten months. It is of particular interest to note that in this case

the vision today, ten months after the beginning of radium application, is better than before the radium treatment began; furthermore, a nearly complete fundus reflex is now obtainable, whereas before the application of the radium only at a narrow rim around the periphery was a faint reddish reflex transmitted from the fundus.

**CASE 3.—Complicated Cataract (Retinitis Pigmentosa).—**The patient gave a history of syphilitic infection occurring seventeen years previously. He received antisyphilitic treatment for several years, but had had none for two years before coming under our observation. The Wassermann blood reaction was positive. Disturbance in vision was first noticed thirteen years before; the vision gradually deteriorated, regardless of frequent syphilitic treatment. The first examination was made on May 19, 1918. The vision of the right eye was 20/200; with the left eye the patient counted fingers at 3½ feet. The field was markedly contracted concentrically; the fundus details, though cloudy, showed the typical picture of the disease. Ophthalmoscopic examination of the lens and fundus showed a distinct fundus reflex, which allowed the lenticular opacifications to be studied; they consisted of anterior and posterior cortical opacifications; the anterior had a sector arrangement, the posterior was curvilinear, and in between these opacifications a fine granular appearance was seen with here and there evidences of small globules or vacuoles. One week after the beginning of the radium application the left eye was examined, and the condition found was as follows: Vision equaled counting fingers at 7 feet. The fundus details were more clearly seen, the striations were less apparent, and the vacuoles or fine globules were more evident. No change was noticed in the papilla or in the retinal pigment. Nine days later the examination showed the vision to be 20/200. Ophthalmoscopic examination of the lens showed a larger area free from opacification; there were fewer striae, and the fine globules were more evident. Twenty-six days after the beginning of treatment the vision was 20/100—1; ophthalmoscopic examination showed more of the fundus, the striae were finer and appeared more tortuous, and the opacifications showed a distinct sector-like arrangement. Apparently the vacuoles were less numerous than at the previous examination (later they gradually disappeared entirely). This objective appearance remained stationary, but the vision improved to 20/70, Jan. 9, 1919, and has so continued to date. While this cataract is not a purely senile one, the pathologic condition in this lens is probably identical with that found in senile cataract. If the lenticular opacity were due to the syphilitic infection, one would have expected some improvement from the antisyphilitic treatment; but despite such treatment the vision deteriorated until radium applications were instituted, after which the lenticular opacification diminished and the vision improved.

**CASE 6.—Senile Cataract.**—The patient's left eye had been under observation for the previous eleven months. Examination before radium was applied showed the vision to be 20/30. Lens examination with the ophthalmoscope showed mainly an isolated peripheral opacification. The fundus was normal. Radium was first applied, June 20, 1918, and has been continued uninterruptedly to date. The lenticular opacity and vision gradually improved. Nov. 12, 1918, ophthalmoscopic examination with the aperture gave a faint shadow of the opacification, which had formerly been very evident with this method. Detailed study of the lens indicated that the opacification was less dense than before, owing to the disappearance of some of the striae and of some of the finer granules which bordered the larger opacifications. The vision was 20/15, and the fundus remained unaltered. This case represents a diminution in the opacification of the lens. The vision, which was useful at the beginning of the application, is now practically normal, and has been in this condition for the past ten months. A point of especial interest in this case is that the right eye, which had a matured cataract when first observed, received several applications of radium during the first month. It was then extracted without any technical difficulties, and a very good functional result was obtained; the patient, who is a baker, claims that he could do his

work better before, when he had one blind eye and the other with a vision of 20/30 than he can today when the right eye is aphacic and the left has a vision of 20/15.

**CASE 7.—Senile Cataract.**—The patient has been under observation for the past ten months. The first examination was made, July 11, 1918. The vision at that time was 20/100. The lenticular examination showed three prominent radial sectors and peripheral curvilinear opacifications. Between these striae a moderate amount of opacification was apparent. The vision gradually improved under radium treatment, being 20/30, Sept. 9, 1918; but the opacifications, which had remained unaltered to this date, did not disappear until March 12, 1919, when a redder fundus reflex was distinctly apparent in this area. The important point in connection with this case is the fact that whereas the improvement in vision began a few weeks after the first application of radium, the diminution in the opacification did not appear until eight months after the beginning of the treatment, indicating that the action of radium may be continuous and cumulative in cataracts as well as in malignant tumors. In this case also the other eye, with a mature cataract, was treated before extraction. No technical difficulties were encountered during operation, and a good functional result was obtained.

**CASE 15.—Senile Cataract.**—The vision was 20/30; hypermetropia, 0.75; corrected to 20/20. Lenticular examination showed a broad peripheral curvilinear opacity. The fundus was normal. The patient complained mainly of floating opacities in the vitreous, which were muscae volitantes. The first radium application was given, Sept. 26, 1918. March 18, 1919, the vision was 20/15. The lenticular opacity was less dense and defined, while the floating opacities had entirely disappeared. After treatment it is common for these patients to observe that these muscae volitantes have disappeared.

**CASE 17.—Senile Cataract.**—The urine examination showed sugar, albumin and granular casts. The patient could count fingers at 6 feet. The lenticular opacity consisted of an extensive opacification of varying density. The fundus examination showed a blurred disk margin. Radium was applied, Dec. 27, 1918. Feb. 22, 1919, the vision was 20/70. The lenticular opacity became less dense in its central area and also on its nasal aspect. March 23, 1919, the vision was 20/50; the lens condition and the fundus were not altered. In view of the striking improvement in vision, and by analogy with Case 7, it is quite likely that in the next few months the opacification in this case will show further diminution.

**CASE 18.—Senile Cataract.**—Dec. 25, 1918, the patient's vision was 20/40+1. The lenticular opacity consisted of numerous small granules in the anterior cortex. The fundus showed a few grayish spots on the nasal side of the disk, of vascular origin. Feb. 20, 1919, the vision and fundus were unaltered, but the granules were distinctly less numerous. February 27, after repeated examinations, the small granules could not be seen. The vision and fundus were unchanged. The importance of this lies in the fact that the disappearance of the small granules after two months of treatment indicates that an early small cataractous formation may be cleared up by radium.

#### COMMENT

It is extremely difficult to obtain a correct estimate of changes occurring in the course of the development of a pathologic process which is so extremely chronic and protracted as a cataract usually is. Nevertheless, it appears to us that some of the phenomena observed are so striking and characteristic of the influence of the radium rays on the processes that it is impossible to conceive of them as mere coincidences.

Of the twenty-four cases studied, in 87.5 per cent. there has taken place some change for the better. As a rule, this improvement occurred in the first few weeks of treatment. After that, the condition usually remained stationary during the period of observation. But it must be understood that it was the improved condition which remained stationary, and in no

instance within the 87.5 per cent. did the lenticular opacification retrograde to the original condition as found before the initiation of the radium treatment.

In studying the changes which took place in the treated cataracts, three phenomena, depending in these patients on the function of the cataractous lens, were considered; namely, the vision, the appearance of the lens, and the visibility. By vision, was meant the amount of visual perception obtained by the patient through the cataractous lens; by the appearance of the lens, was indicated the amount and character of opacification found in the lens on an examination by the aid of transmitted light and by focal illumination; by visibility, was meant the ability of the ophthalmologist to perceive a more or less clear image of the details of the fundus through the cataractous lens.

A study of the results shows that in a certain number of cases both the vision and the amount of opacification were definitely improved; in a second group of cases the opacifications diminished, but there was no improvement in vision; in a third group, the vision was improved, while there was no change observed in the amount of opacification. In a few cases of this group an impression was gained that a brighter fundus reflex was obtained after treatment.

It is self-evident that the patients in the first group were improved. It is also easy to understand that an improved or diminished lenticular opacity may not be accompanied by any improvement in vision. The amount of vision which a cataract patient possesses depends more on the location of the opaque area within the lens than on the extent of the opacification. Striae, sectors, and large granules situated in the peripheral region may not impair the vision at all; while a smaller area of opacity situated in the center of the lens may very markedly affect the vision though not a great deal of the lens is involved. It is thus possible that certain striae or granules may diminish in size or completely disappear without in any way improving the vision. The greater objection may be raised that both the improvement in vision and the brighter fundus reflex are characteristics of too subjective a nature to be considered as clinical improvements without the supporting evidence of a change in the objective findings in the lens opacification; none the less, it must be granted that it is quite conceivable physiologically that both the vision may be improved and the fundus may appear brighter, and still no objective change in the picture of the lenticular opacification be noted.

If for the purpose of our discussion we regard a normal lens as analogous optically to a transparent fluid, then we may consider a diffuse lenticular opacification as analogous to an opaque emulsion consisting of minute granules evenly distributed in a transparent fluid. When the number of these granules is very great, or in other words the diffuse opacification is very dense, then no red fundus reflex can be obtained; when the number of granules is less or the diffuse opacification is not so dense, then we observe a faint reddish reflex from the fundus. Furthermore, when an objective finding has shown that such a red fundus reflex has become brighter, such a phenomenon can only have been caused by the disappearance of a certain number of the minute granules from the opaque lens. That these minute granules may disappear under the influence of radium is evident from the fact that in a certain number of our cases much larger granules disappeared under treatment.

This diminution of the quantity of the granules must be followed by both a brighter fundus reflex and some improvement in the vision of the patient.

We therefore maintain that while the best results were obtained in those cases in which there appeared an improvement in all the three phenomena described, we must also consider as improved clinically those cases in which there was direct improvement only in vision or in visibility. On the basis of such calculation there were in all twenty-one cases improved.

These twenty-one cases, or 87.5 per cent., represent such a high percentage of the cases treated that it is impossible to consider the result a mere coincidence. Furthermore, with the exception of one case, it was possible to maintain this diminution of the opacification as well as the improvement in vision and visibility during the period of observation, which was in every case not less than a few months, and in view of the fact that the majority of cataracts mature within a period of two years, most of the cataracts treated should have shown a certain amount of progression.

The time of observation is too short to determine whether this initial improvement can be maintained under treatment at stated intervals, or whether sooner or later the radiation will cease to be effective and the cataracts go on to maturation; but the results thus far obtained are very striking.

The biologic phenomenon that the course of development of a cataract may be, temporarily, at least, altered or inhibited by the action of the rays is fairly well established by this study. Furthermore, this investigation leaves no doubt as to the harmlessness of this agent. In order to establish the fact that any amount of the most intensive radiations leaves untouched the other structures of the eye outside of the lens, many of the patients were given longer and more frequent applications of radium than were actually needed. Moreover, in the beginning of the study larger quantities of radium were employed than are being used at present, and still there was no ill effect.

It is of importance to add here that five cases of matured cataract were also treated with large amounts of radium in order to ascertain whether a preoperative radiation would interfere in any way with the technic or the functional results of a subsequent operation. These patients were then operated on. No difficulties were encountered in the course of the operations, and the postoperative results were as favorable as the results in the nontreated eyes.

We therefore submit that, since there is no other agent in the therapeutic armamentarium which can influence the development of cataract in any degree at all; since surgery at its best leaves an aphacic eye which for practical purposes is frequently less satisfactory than the partial vision of a patient with an immature cataract; in view of the further fact that it is absolutely established that radium does no injury to the eye and does produce some, if ever so slight, biologic alteration in the lens, it is imperative that these clinical investigations of radium therapy in cataracts be continued by competent investigators, the subsequent results checked, and a definite conclusion reached.

#### SUMMARY

1. The application of radium to the eye is harmless.
2. There is diminution of lenticular opacifications under the influence of radium.

3. Should a cataractous lens become matured subsequent to radium treatment and should then an operation be required, no difficulties will present themselves.

4. It is therefore advisable to submit a sufficiently large number of immature cataracts with useful vision to a proper course of radium treatment so that a correct estimate of the value of the method may be obtained.

#### ABSTRACT OF DISCUSSION

DR. ISAAC LEVIN, New York: I am merely a radium therapist, and it is not for me to pass judgment on the clinical results. In fact, I will take it for granted, for the sake of argument, that we have thus far shown nothing, and that I stand today exactly where I did one year ago when Dr. Cohen asked me whether it is permissible or advisable to try radium in cataracts. When a new agency in therapy is applied to the human organism, the first requisite is "do not dare to do any injury." That must be borne in mind. I want you to understand that radium application, in the quantity, quality and dosage as used today in therapy of malignant diseases, does not injure any normal tissues of the organism with the exception of the epithelium of the skin, of the leukocytes, of the spermatozoa and the graafian follicles. All other tissues of the body resist the rays and are not injured by it. Nerve tissue, ganglion cells of the brain and the structures of the eye, are the most resistant tissues to the action of the rays. There is ample evidence in the literature as well as in my own work, that the largest amounts of radium employed in therapy do not destroy or injure normal tissues of the eye. I shall cite a case to illustrate this contention. I have a patient at the Montefiore Hospital who is suffering from sarcoma of the right upper jaw and the antrum. For the last year large doses of roentgen ray and radium were applied. The radium tubes were buried in the tumor, right near the orbit. The bone of the floor of the orbit is destroyed by the tumor so that the radium tube was lying for twenty hours at a time on several occasions right under the right eye. The roentgen rays were applied in the mouth also close to the eye. The eye remains absolutely normal now after one year of treatment. Thus intensive radiations correctly applied do not injure the eye. The next question is, how does the radium affect the lens? There is ample experimental evidence that it does not injure a normal lens. What may its influence be on a cataractous lens? We maintain that radium arrests the development of the cataract, and consequently has a beneficial influence on the condition. But even if further investigation should show that it has no such effect on a number of cases, it still does not injure the remainder of the organ. Therefore, the radium application in incipient cataracts should be employed for a number of years and thus a true estimate of the method obtained.

DR. ALLEN GREENWOOD, Boston: For the past fifteen years I have been following out a line of treatment which I have realized lessened my operative work in cataract cases to a marked degree. In my experience lenses showing a few spicules down and in are little affected and develop slowly; this is true also of nuclear opacities occurring in the highly myopic, and cases in which, besides the spicules, there are nebulous clouds or fine granular spots throughout the lenses, which are the vast majority of cases that interfere with vision. I give a hopeful prognosis and at once institute the following treatment: One per cent. solution of dionin (ethylmorphium hydrochlorid) is dropped into the affected eye three nights out of each week, and after a few months three nights out of every other week. It is well known that the continuous use of dionin will be of little value, but used as above, this drug, which is the one which most markedly affects the lymph circulation and hence the capillary circulation, exerts a decided influence on the nutrition of the lens. The often repeated effect of this improvement in circulation will frequently dissipate lenticular opacities and retard their future development.

DR. E. L. JONES, Cumberland, Md.: Some time ago I published a pamphlet on "The Usefulness of Dionin in Early Senile Cataract," and another one on the arrest of cataract in its early stages. I have used this treatment for more than ten years and I have a number of patients whose vision after a lapse of ten, eight, and six years, still continues to show improvement, and it was brought about through treatment of this character in the early stages of the disease. It is of little use in the later stages. In cases of reading vision, a few doses of dionin will clear up the dust formation or mist; but while the cataract will clear up the spicula remain. The cataract is like a thicket, with leaves on the twigs and branches in the summer time; and after the summer, the leaves fall off and the twigs and branches remain. That is comparable to the spicula. I use dionin with mercuric cyanid, and it works well in a majority of cases.

DR. JOHN E. WEEKS, New York: We all recognize that cataract is due to an interference with the nutrition of the crystalline lens. The epithelium of the anterior portion of the capsule is defective, as shown by Hess. There is the development of granules and minute hyaline globules forming liquor morgagni, and in addition there is erosion of the fibers of the lens to some extent where the gray spiculae are found. A disappearance of the cloudiness of the lens by absorption of the granules and the globules is sometimes observed. This is all we can hope to produce. We cannot cause the opacities due to erosion of fibers to disappear. In my opinion increase in the nutrition of the crystalline lens, either by improving the patient's general condition or by increasing the circulation in the anterior segment of the globe, may cause an arrest of development of cataract in some cases, a retardation in the development in some, and will be without effect in others. For the last thirty years I have been working on this hypothesis. I have used drops consisting of glycerin, boric acid and water. The glycerin produces a hyperemia of the anterior segment of the globe at every application, and may be used indefinitely without harm. I have discarded dionin, as it produces stimulation only over a short period of time. Dr. Greenwood has permitted an interval to elapse after using it three times, so that when used again it produces a further stimulation of the circulation. He has reached results similar to my own. It is immaterial what agent you employ provided it is harmless and sufficient stimulation is produced. I have observed the results of the use of glycerin in considerably more than 1,000 cases in private practice, records of which are in my office. The results have been satisfactory in perhaps a higher percentage of cases than that reported by Dr. Cohen as having been obtained in the treatment with radium.

DR. F. PARK LEWIS, Buffalo: There is an element of danger in allowing the impression to go out that this is a remedy for cataract and that it can be used without danger. I am not sure about that, for certainly it cannot change the metabolism of the lens and at the same time do no harm. Furthermore, I do not think we should employ a remedy empirically, which does not take into consideration the origin of the disturbance. The metabolic changes which have taken place in the lens are frequently the result of toxins in the system, from focal and other infections in the teeth or tonsils. Any remedy is unscientific which does not take into account the cause of the trouble which we are trying to control.

DR. S. D. RISLEY, Philadelphia: For many years I have been interested in the etiology of cataracts. I presented my first paper on the subject in 1889. The paper was based on eighty-six cases of beginning opacity of the lens, in each of which the record was sufficiently complete for analysis. During the intervening years, following a careful study of the eyes of the schoolchildren in Philadelphia made from 1878 to 1881, I recognized fully the importance of choroidal disease, since it was present in all of the eyes which had become myopic in the schools. Therefore, when any patient came into my office, after this fact had been grasped, no matter what the age of the patient, I treated the choroidal inflammation often by persistent and prolonged use of atropin and corrected any existing refraction error. It was very soon

observed that patients with incipient cataract, were greatly benefited by this treatment. Not only were they relieved from asthenopia, but the swelling and opalescence of the lens grew less and the sharpness of vision as shown by the test card often improved. While I have never seen spicules or banks of opacity disappear, in any case, I was convinced by these studies of the importance of choroidal disease over the nutrition of the avascular tissues: the lens, the vitreous body and the cornea. All cases of refraction error had therefore been treated by more or less prolonged use of mydriatics and careful correction of refractive defects and abnormalities of binocular balance. In eighty-six cases I found incipient cataract, as I have stated. The records were sufficiently complete for analysis, and there had been found refraction defects, choroidal disease and degenerating vitreous. To my surprise and gratification the opacity of the lens had not advanced after the treatment. The vision in many cases had improved; the asthenopia had disappeared, and the eye remained well after many intervening years. This experience was first published in 1889. Many hundreds of persons have been treated since, but added experience has but served to confirm the views then expressed. The essential fact in all this was the importance of uveal disease as a factor in the impairment of the nutrition of the avascular structures of the eye: the vitreous body, the crystalline lens and the cornea. In a large percentage, constituting the majority of the cases coming under study, the choroidal disease was associated not only with commencing opacity of the crystalline lens, but with a degenerating vitreous; dilated anterior ciliary vessels and uncomfortable eyes with failing vision. So frequently were the anterior ciliary vessels dilated, that I have come to regard this condition as an indication of uveal disorder. It soon became obvious also that the uveal disease was often but a local expression of some systemic disorder, as cardiovascular disease with kidney involvement. Indeed, I believe that the uveal tract of the eye is as liable as are the kidneys to participation in systemic dyscrasias, and therefore, that the treatment of these affections is often quite as important as any local measures which may be adopted.

In addition to the prolonged use of the mydriatic, of which I have no dread, even in aged people, I have often used at the same time twice daily, weak solutions of phosostigmin ( eserin) salicylate, especially where the anterior ciliary vessels were engorged. This drug has been used because I believe it contracts the blood vessels and so stimulates the circulation which would be quite in accord with the suggestion made by Dr. Weeks.

Dr. G. J. SAVAGE, Nashville, Tenn.: Several things can be done in incipient cataract. I endorse practically everything they have said; but there are two things they have not said, and my experience with one of these for twenty-five years makes me a strong believer in its efficacy. One of the two suggestions comes from Dr. Woodruff, and that is, "Why may not the Crooke lenses do these patients some good?" The other thing I have been using for twenty-five years in every case of incipient cataract. It is a cell-building dose of mercuric chlorid and potassium iodid. Cataract will not develop when there is normal nutrition in the anterior segment of the eye. Anything that will improve cell-activity in this part will help the cataract condition in its inception. One one-hundredth grain of mercuric chlorid and 1 grain of potassium iodid after each meal for five weeks, and then one week of rest, and then five weeks of treatment and one week of rest, and so on, will check the cataractous changes which have just begun, in many instances.

Dr. A. S. GREEN, San Francisco: Following my return from India five years ago, and since then, I have been using Smith's method for the treatment of incipient cataract. This consists of a subconjunctival injection of 15 minims of mercuric cyanid, 1:4,000. Intense swelling of the conjunctiva results which subsides in from four to ten days, but the redness does not disappear inside of a month. In addition to this treatment, however, we prescribe an eye-bath consisting of a 1 per cent. solution of potassium iodid, every morning and every other night. On the alternating night the patient uses one drop of a 2 per cent. solution of dionin, which is

gradually increased to a saturated solution. This treatment is kept up for six months. Smith makes this point, that there is little use in giving this treatment when vision has fallen below 50 per cent. It is a treatment that can be given by any ophthalmologist, and the improvement in our hands has been as good as those reported with radium.

Dr. EDWARD JACKSON, Denver: To go back to radium, perhaps the lack of interest in that phase of the subject has been due to the feeling that it was not available for most of us to try. I think it is important that any treatment that purports to influence a cataract should be investigated, and that the profession should arrive at some conclusion as early a time as possible, as cataract cure without operation is all that is necessary to attract public attention to any proposed means. The possibility is before any one to use radium. It is not necessary to have a radium institute, or to be where large amounts of radium are accessible. The radium emanation has all the physical, electrical and other properties of radium salt, and will very soon be available anywhere in the country. No radium reaches maturity, that is, after thirty days it remains with very little change for a long time; but the radium emanation given off from large amounts of radium has the same properties; but it loses its property very rapidly. I think in four days it loses one half of its efficiency; and at the end of one month, it is practically inert. Since the close of the war it is possible to furnish the radium emanation anywhere. Of course, the physician can arrange for its use; on a certain day he can receive his supply and use it in a considerable number of cases. In that way it becomes practicable for a large number of us to employ and to experiment with this method. One half of the radium of the country is manufactured in Denver, and it was impossible for any of us to get any of it until the close of the war.

Dr. S. LEWIS ZIEGLER, Philadelphia: I think that we should place on record a warning against the statement that radium cannot injure the eye when used in close contact with the cornea. Those who have seen a roentgen-ray burn of the cornea know that it is one of the most persistent and painful lesions. I have seen but one case, that of a surgeon who was wholly incapacitated by the intense pain. Relief could only be gained by enucleating the eye, although good vision was still present. The analogous action of roentgen ray and radium should make us pause, therefore, before recommending this agent to be applied by those who may prove to be careless and ignorant in its use.

Dr. MARTIN COHEN: I have been under the impression, possibly wrong, that from reports dionin and mercuric cyanid and other products have not been as efficient as they may appear. If the products do what is claimed, then radium is only an aid. The twenty-four patients were examined consecutively, and after treatment of three, four and five weeks, they have responded with objective results which I have tried to show on the screen. If radium is effective in epithelial growths and degenerations then it seems the cataract problem might be attacked from that point. We know that radium does not injure the capsular epithelium in normal frogs' eyes. As regards affecting the cornea, we believe that if properly applied to the cornea radium will produce the results mentioned and cause no ill effects to the structures of the eye. We are interested in this problem from the scientific standpoint, and stated that radium is applied only in early cases of incipient cataract, and that some benefit was obtained by the absorption of the lenticular opacities.

**Is Your Community Fit?**—Is malarial fever a health problem in your community? Has a survey been made by experts to advise as to proper methods for control? The Anopheles mosquito, carrier of this disease, may be breeding in collections of water which need draining, filling, stocking with fish, or other measures for mosquito control. Control malaria in your community and you may find you have less labor shortage, the physical well-being of your people may show a marked improvement, and your community may enjoy a great economic uplift.—*Pub. Health Rep.*, April 25, 1919.

EARLY FUNCTION AFTER WAR  
WOUNDS OF THE EXTREM-  
ITIES \*GEORGE W. HAWLEY, M.D.  
NEW YORK

In injury or disease of the extremities, surgery is dealing with a motor. When a man injures an arm or a leg, what he is chiefly concerned about is the restoration of that motor to its previous functional capacity, or as near the original as possible. The patient is not interested in the methods employed, but in the recovery of a valuable motor. Theoretically, the surgeon is supposed to have the same point of view; but he has devoted more time to the methods of immediate surgical relief, and has not been thinking always in the terms of motor function. This is quite natural, because in surgery of the head and trunk the services of the surgeon are usually at an end after the completion of the operation. After the wound has healed he is more or less powerless in his attempts to exercise control over the function of the deep-seated, stationary, internal organs.

The conditions are very different in surgery of the motor-skeleton, where skeletal, joint and muscle function are so much under the direct control of the surgeon, and where delay, neglect, and failure in the after-treatment count for so much in the ultimate result. Just as the delay in hours in beginning motion after orthotomy for septic arthritis by the Willems method means so much for the success or failure of the treatment, so also does delay often affect other injuries of the limbs. Instead of the labors of the surgeon being chiefly operative, they involve exacting and time-consuming service outside of the operating room.

It is not too much of an exaggeration to say that there has been little comprehensive effort up to the present time to salvage the potential cripple. What has been done to limit the disability in unavoidable deformities and to prevent unnecessary disability in avoidable deformities? Who will venture an estimate of the number of avoidable deformities among the 700,000 war cripples in France, or among the army of industrial cripples produced in this country every year?

In civil surgery it is still more or less the custom to treat a fracture as a broken bone, and not as a motor with a broken part. It is not uncommon in many excellent hospitals for much, if not all, of the treatment in these cases to be carried on by members of the junior staff. The interest of the surgeons and all concerned is frequently limited to the early immediate surgical treatment, and, as every one knows, many patients are sent to their homes to work out their own salvation as best they may. In civil surgery there has been no real compulsion to obtain complete and early recovery in extremity injuries. No agency exists to compel the profession, the hospitals or industry to effect an intelligent salvage of the potential cripple.

In this respect, civil surgery has much to learn from military surgery. Theoretically, in military surgery the army organization demands that the wounded or injured soldier be treated primarily with the object that he be returned to active military duty in the shortest

time, or eventually discharged with the least degree of permanent disability. Unfortunately, however, no machinery existed in the military service to accomplish what military necessity required, and none had been developed in civil practice. It was necessary to create the organization and develop the technic of execution. Such an organization was created in the United States Army, and the process of fitting it into the general scheme has been in operation during the past year.

While the problem of the restoration of the function of the damaged motor-skeleton is not a new one, no one has fully understood the importance of early motion, or the evil results of delay. In civil practice, nearly every one has been more or less conscious of the unfortunate results of failure to begin motion early, and every one is familiar with the convalescent stiff joint; but only among war cripples can one appreciate the appalling results of neglect, in wounds not only of the bones and joints, but also of the soft parts.

To Depage is due the credit for demonstrating the value of early active motion in the treatment of war wounds, and to Willems for his mobilization treatment of joints. To those who have had occasion to observe and direct the efforts to reestablish early function in recent wounds of the extremities, it is no exaggeration to say that the results have been, on the whole, little short of marvelous; but much has yet to be learned and a great deal of care must be exercised in the application of motion to recent injuries of the motor-skeleton.

## ABSTRACT OF DISCUSSION

DR. WILLIAM W. PLUMMER, Buffalo: The subject of Dr. Hawley's presentation reduces itself practically to agreement and confirmation. In the matter of after-results from the secondary closures, the results as shown by him are obvious; and those who had the opportunity to be at General Hospital No. 9 last summer and see some of this work know that there is no short cut to happiness in the matter of getting such results. What impressed itself on me was the necessity for close study of detail in the treatment of these cases. Any of the results obtained in any of the hospitals in France, if comparable to these, were only attained after the case had been carefully and industriously followed by the men in charge of the various wards; and with all the advantages of the various treatments that we found useful and standardized, it boils itself down to the man doing the work. There was opportunity to see, a short time ago, in sharp contrast, a large group of men undergoing physical therapy in which this group was being developed by the purely mechanical method of supervised passive exercise, and another group in which the men were doing the exercise, as the British say, "on their own." There was no comparison in the results. Those that were supervised were getting good results quickly; and the others, who were depending on apparatus and that sort of thing, were not.

DR. JOEL GOLDBLUM, Boston: One or two points should be remembered in the treatment of these badly infected wounds and in the use of the Carrel-Dakin method of treatment. Without any question, it is the best method of sterilization for septic wounds, provided that the technic can be carried out satisfactorily. There is, however, a difference of only 0.5 per cent. between the strength that possibly gives a harmful effect and that of an inert solution; and any so-called solutions of this kind that are stable are undesirable, because it is the instability of the solution and the rapid giving off of chlorine that make it desirable. In the military stress at the front, you cannot often get the technic demanded, and if you cannot, do not fuss with this method. Give it up and use a dressing made of plain yellow soap and water, which is practical and scientific, and is one of the best dressings for septic wounds that you can put on, if you cannot con-

\* Read before the Section on Orthopedic Surgery at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

trol the Carrel-Dakin technic. In the British hospitals, in P. S., where they could not control the Carrel-Dakin standard dressing, they used a solution of yellow soap on the wound. It did not dry, and harmful organisms cannot grow in a strongly alkaline solution. The mucus will be softened, and will come off easily; and such a dressing can be put on in the wild. Other solutions can be used in the same way. Another point: In the latter part of these infections, the sepsis is chronic; we used to call it chronic pyemia; and in the lists of our battle casualties for the last six months, almost all the seriously sick had chronic pyemia, which means that the temperature ran up within a day or two, and an abscess formed in some part of the body. When this condition declares itself, the abscess is inert and practically sterile. All that you need to do, then, is to put the knife in and drain it. You do not need to use the surgical solution of chlorinated soda. Those who are old enough to know about surgery in pre-antiseptic days will remember that the things we have seen in France are exactly the things that we saw in those days.

Dr. RICHARD H. SAYRE, New York: I have found that a combination pulley by which the patient can pull on a chain and raise himself, when immobilized and suspended in bed, is simpler and more useful than the ordinary compound pulley with a rope which has to be belayed. He can pull himself up and down, and by means of the sprocket which articulates with the chain, fix himself in any position desired.

Dr. WILLIS C. CAMPBELL, Memphis, Tenn.: I should like to ask Dr. Hawley whether he has had any experience with gonorrheal arthritis or other types of acute infectious arthritis treated by the mobilization method.

Dr. H. WINNETT ORR, Lincoln, Neb.: No discussion of this subject should be considered complete until a word of caution has been given regarding the danger of rendering apparatus ineffective by attempting to provide motional treatment. It works out in a great many cases that attempts to provide knee or elbow motion render the apparatus ineffective between the times when the motion is given. Apparatus for fixation and traction must be kept in position during the entire time of treatment, if results are to be obtained from its use.

Dr. JOSEPH BYRNE, New York: I have always admired the enthusiasm of the orthopedists in the problem of restoration of function, and for many years have collaborated in this neurosurgical-orthopedic work with Drs. Alfred S. Taylor and Samuel W. Boorstein. Secondary suture and early restoration bear an intimate and essential relation to the mechanism of degeneration and regeneration not only of nerve trunks, but also of the finer nerve branches supplying the injured parts. Integrated function of all kinds has a close dependence on the integrity of the neural arcs, both afferent and efferent, as well as on their related correlating and coordinating mechanisms. Hence, what takes place within the neural mechanisms during the stages of degeneration and regeneration after nerve injuries is of vital importance. After injury of a nerve the related neuron bodies in the dorsal root ganglions may undergo complete degeneration or merely exhibit axonal reaction phenomena. In the latter case, function is suspended temporarily in the related axons for a period of from fourteen to twenty-one days, and for a much longer period where infection complicates the injury. It is obvious, therefore, that where infection is present, as in war injuries it usually is, no benefit is to be gained by primary suture, as nerve regeneration cannot take place until after the tissues have become sterilized. Connective tissue, however, forms much more readily in the presence of a waning infection and offers an impenetrable barrier to the axon branches when these begin to sprout from the central segment. Where, however, a period is allowed to elapse after sterilization of the wound, the neuron bodies take on hypermetabolic activity, which is remarkably the outgrowth of the new axon branches after a secondary operation. Add to this the preparation already completed in the distal segments of the injured nerves by the formation of the tubulized protoplasmic bands for the reception of the outgrowing axon branches, and the conditions are ideal for rapid neural restoration after a secondary operation. Where very small nerve branches have been torn across, in

infected or sterile tissues, early movement of the parts aids greatly regeneration in the torn nerve by breaking up the connective tissue barriers, thereby throwing the connective tissue itself into an embryonal state which favors penetration by the axons.

Dr. GEORGE W. HAWLEY, Bridgeport, Conn.: I should like to emphasize a point brought out by Dr. Orr, that of the extreme care that must be exercised when using motion, early motion, in injuries of the extremities. It is really a new field, and we have a great deal to learn yet. It is a matter, largely, of combining effective fixation with motion. In answer to Dr. Campbell's question, unfortunately we had very little experience in the treatment of infected joints. For some reason we had comparatively few joint wounds; so I really can say very little, almost nothing, regarding the mobilization treatment as applied to the arthritis of the type that we see in civil practice. The next few years will present to us the problem of trying to adapt the best that war surgery has developed during the last four years, especially to the treatment of injuries of the extremities.

## RESULTS IN THE MODERN TREATMENT OF DIABETES\*

HENRY RAWLE GEYELIN, M.D.

NEW YORK

It seems appropriate at this time, after four years or more of trial, to review the therapeutic results that have been obtained with the Allen treatment for diabetes, which has received such universal adoption by the medical profession. With this in view I am going to discuss certain aspects of the treatment of diabetes, and with the help of charts illustrate some of the results obtained during the past four years, during which time we have treated patients according to the general principles laid down by Dr. Allen.

It is not necessary to go into a detailed description of the modern treatment, as it has received a great deal of attention in medical literature during the past four years and the reader, doubtless, is familiar with it. I have been much impressed, however, by the fact that, while many practitioners who have employed the fasting treatment have quite generally appreciated the use of the preliminary fasting period to abolish glycosuria and acidosis, they have not fully appreciated the great importance of the subsequent method of regulating the diet and the importance of keeping the patient free from sugar and ketone bodies. Probably the most important feature of the after fasting treatment is the proper regulation of the relative proportions in the amount of protein, carbohydrate and fat in the diet and the appropriate distribution of half days and fast days. Under the older methods of treatment it was the common practice to keep the carbohydrate intake very low and make up for its absence by feeding large amounts of protein and fat, particularly fat. The object was to keep up the patient's nutrition and body weight. How injurious to the diabetic process the high fat feeding can be has been well shown by Allen on dogs, and can be readily demonstrated in our diabetic patients.

The high fat feeding of former years has probably led to more fatal outcomes in diabetes than any other one factor. This has been so forcibly impressed on me in the past four years that I am inclined to say that

\* Read before the Section on Pharmacology and Therapeutics at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

coma may be averted in almost all our cases, even in the presence of infections, provided the fat of the food is kept at the proper level, or in extreme instances totally eliminated. One reason that it has taken so long to recognize the harmful effects of diets over-balanced in fat has been the fact that the effects are very insidious. For example, a patient may be put on a diet very high in fat and very low in carbohydrate and remain sugar and ketone free for a long period of

This table shows in the second column to the left the total number of diabetic patients treated in the Presbyterian Hospital during the years 1912 to 1918, inclusive. During 1912, 1913 and 1914 all the cases were treated by the old method of treatment. During 1915 most of the cases were treated by the old method, but some were treated by the modern treatment, as shown. From 1916 to 1919 all patients received the newer treatment.

Chart 1.—Course of diabetes in Case 1. In this and the following charts, the numbers on the extreme left border indicate the number of calories. The numbers on the extreme right border represent the grams of food. The numbers at the top of the charts indicate the months during which the patient has been under treatment. The three columns in each numbered space represent the average daily intakes of food; in grams reading from left to right they are: carbohydrate, protein and fat. In Charts 3, 4 and 6 the figures 1=3, 3=4 at the top represent three-month periods. The continuous and irregularly horizontal lines running across the charts represent the total caloric intake. The body weights are indicated by "Wt." The blood sugar values are indicated by "B. S." and are given in percentage amounts.

time; but without further change in the food, the time invariably comes, if the fat in the diet is high enough, when the blood sugar begins to rise and the blood carbonate begins to fall, then sugar and ketone bodies in steadily increasing amounts make their appearance in the urine. With this as a rule go all the subjective symptoms of mild acidosis. The danger of acidosis is not the only one, for there is also the difficulty of reestablishing the food tolerance and rid-

It will be noticed, first, that the number of patients treated by the modern method in three and one-half years is more than double that treated by the older method over a similar period of time, owing largely to the fact that it became known that the hospital was studying diabetes. In spite of the greatly increased number of patients, who were equally divided between the medical and the surgical wards, the mortality percentage (Column 4) has been notably diminished. It will also be noted that there are proportionately fewer deaths from coma during the past three and one-half years. This, I think, is due to the early withdrawal of fat from the diet on admission to the hospital, and the institution of fasting treatment.

Probably the most striking feature of this comparison is the great increase in the number of patients discharged free from sugar and ketone bodies. Except for the patients that died, there were only six patients out of ninety-five in 1918 discharged with sugar (and this was only in traces). These patients who were discharged sugar free derived more benefit from their hospital stay than did those in preceding years, because in addition to being sugar and acetone free and being on a properly balanced diet, all those intelligence permitted received instruction in calculation of their diets and the use of Benedict's solution in testing for the presence of sugar in the urine. They were thus able to control their condition in a much better manner.

Chart 2.—Course of diabetes in Case 2.

RESULTS OF OLD AND NEW METHODS OF TREATMENT

Year	Cases		Deaths		Deaths In Coma		Dish Sugar Free		Dish Keto-Tone Free	
	No.	%	No.	%	No.	%	No.	%	No.	%

ding the patient of his subjective symptoms, which in severe cases takes several months at a much lower caloric level.

In order to demonstrate in a general way the favorable results of the modern treatment (they are not all favorable) I have prepared the accompanying table, which offers a rather striking comparison between the results obtained with the new and old methods of treatment.

The comparison between the old and new methods of treatment is just as striking in the subsequent care of these patients outside the hospital. It used to be the aim in the dispensary to keep the glycosuria as low as possible; but always from 80 to 90 per cent. of the patients who returned for their dispensary visits showed traces of sugar or more, whereas under present day care less than 40 per cent. return for their regular visits showing sugar in the urine. It is not possible in this paper to take up a more detailed and statistical comparison of the old and new methods of treatment

as they apply to the dispensary care, but later on I shall show charts of patients originally treated in the hospital whose subsequent course has been carefully followed and controlled outside the hospital.

The table does not demonstrate one other advantage that has been very noticeable in the new method of

(fasting value) should be maintained at the normal or nearly normal level.

Half days or fast days, depending on the severity of the case, are given when sugar appears, and additional half days or fast days are given at regular intervals with the purpose of increasing further tolerance. If with this system of treatment we also obtain faithful cooperation of the patient in following his diet and testing the urine daily, together with timely observations of the blood sugar, improvement unquestionably occurs for periods of from one to three years at least, and possibly longer. This in a very general way sums up the treatment that has been carried out with the patients whose charts are given. All of these charts are from cases chosen, not because the patient showed an unusual type of diabetes, but because the case was rather typical of certain common forms of the disease and because they illustrate what treatment can or cannot accomplish in these groups.

Charts 1, 2 and 3 represent the course of diabetes in a certain group of young people. All of these patients have done well.

CASE 1.—A boy, aged 12, had shown sugar for one month previous to going under treatment. The onset had been sudden and the symptoms were severe. The day he appeared for treatment he was distinctly drowsy, the skin was very dry, and he was breathing deeply. It required four fast days to make him sugar free, and his average daily food intake for the first month was very low, a little over 300 calories. His food tolerance could not be raised above this level. For the next seven months his food was steadily increased until 1,700 calories were reached. This was obviously too much for him at this time, and the more frequent fast days and slightly lower regular diet that was instituted lowered his average daily calories for the eighth month, which was May, 1919. So far in June his diet has averaged 1,400 calories daily and I think will be maintained

treatment, namely, its effect on surgical conditions in association with diabetes. In cases of gangrene, carbuncles and other local infections, the results of combined medical and surgical treatment with its effect on the saving of life and preservation of limbs have been very much better than with the previous method of treatment; in fact, many operative procedures which were done hitherto have been rendered unnecessary.

As I indicated earlier in the paper, the most difficult part of the treatment for both the patient and the physician comes after the original fast, which we will assume has been effective in eliminating glycosuria and controlling acidosis.

The next step is gradually to increase the food until traces of sugar appear in the urine. A fast, or half day, is then given to eliminate glycosuria, and following this the patient is put on a slightly lower intake of carbohydrate, protein and fat, various ones of all these foods being gradually increased until a definite tolerance is determined. The manner of increasing the various foods, that is, carbohydrate, protein and fat, varies considerably with the type of case and also, to some extent, with the personal judgment of the physician. In a general way we aim to reach:

1. A much higher allowance of carbohydrate than was customary under the older methods of treatment. (It is astonishing at times to see how much more carbohydrate may be tolerated when we adopt the general policy of keeping the fats low.)
2. An allowance of fat ranging from 130 to 180 gm., depending on the patient's tolerance (it may be much lower).
3. A protein intake of about  $1\frac{1}{2}$  to 2 gm. per kilogram of body weight.

The urine must be kept free from sugar and ketone bodies, while the blood carbonates and blood sugar

Chart 3.—Course of diabetes in Case 3.

Chart 4.—Course of diabetes in Case 4.

at this point for from two to four weeks with the hope of gradual increase. He has not lost weight in this time but feels well, is quite active, perhaps too much so, and leads a normal life except as regards his diet.

CASE 2.—A girl, aged 11, had had diabetes for two months before coming under observation. Her history was essentially the same as the boy's and it took three fast days to rid her of sugar. She has had half days every two weeks and has shown sugar only twice in seven months. This child has shown a steady gain in tolerance, her present diet being

85 gm. of carbohydrate, 90 gm. of protein and 120 gm. of fat, and is one of five very favorable cases of children seen in the past four years. It is, of course, impossible to say what her prognosis is, but it would be more favorable than that of the preceding case.

CASE 3.—A man, aged 23, has been under treatment since September, 1917. Sugar was first discovered in a life insur-

continued diets too high in fat. How difficult it was, how long it took to develop a food tolerance, and how permanent this tolerance has been since 1916 is well shown in Chart 4. Unfortunately, the tolerance acquired by many similar patients is not so high as in the case of this man.

Chart 5.—Course of diabetes in Case 5.

ance examination. For two months previous to institution of treatment, he had followed a diet spasmodically. Glycosuria was eliminated in one fast day and the food was increased within six days to 60 gm. of carbohydrate, 90 gm. of protein and 70 gm. of fat, which produced glycosuria in considerable amounts. Chart 3 shows the subsequent course of events. This patient has been very faithful and has followed his diet religiously and very accurately, weighing all of his food for a long time; and when he became very proficient at this he began estimating the amounts of food, controlling this at intervals by periods of two to three weeks in which he weighed all the food. He has shown definite traces of sugar from time to time in daily tests, but has always been able to clear up the sugar by reducing his carbohydrate only. The patient has had almost no half days or fast days. He has been able to gain his normal weight and do a full day's work as electrical engineer. His blood sugar begins to rise as soon as he raises his carbohydrate intake above 250 gm, or if he stays on a daily intake of 250 gm. for more than one week.

Charts 4 and 5 are those of older patients who have done well. They have increased their food tolerance, and have gained in weight. Both were originally fairly severe cases, particularly Case 4.

CASE 4.—A man, aged 57, first came under treatment in April, 1915. He was showing much sugar and large amounts of diacetic acid in the urine. He was also suffering from very painful neuritis in both of his legs, which kept him awake at night. He had had diabetes for five years and had been on a very high fat diet with moderate restriction of carbohydrates but had never been sugar free. It took six fast days to render him sugar free, and for six weeks it was impossible to raise his tolerance above 900 calories, in spite of a very restricted intake of fat. He continued to have pains in the legs and show traces of diacetic acid in the urine. Fast days were liberally distributed throughout this entire period. It was not until his tolerance had been raised to about 1,600 or 1,800 calories that the pains and diacetic acid began to disappear.

This patient illustrates very aptly the fact previously referred to, namely, the bad effect produced by long

CASE 5.—A man, aged 47, had had diabetes for one year previous to his first visit. Sugar had always been present in large amounts and he had lost 80 pounds. He was so weak he could hardly walk and had been very drowsy and nauseated at times. He also had a very high fat intake; but his carbohydrate intake had been well over 100 gm., as the result of a generous allowance of gluten bread. It took three fast days to make him sugar free. The upward trend in this case has been somewhat interrupted twice, but he has gained in weight, is able to do a full day's work, and shows a normal amount of blood sugar.

I do not wish to give the impression that all cases of diabetes at this or at any other age show such favorable and

encouraging progress; but of those who follow treatment day in and day out with the care that these patients have, it is very unusual for them to do badly and show a progressive down hill course.

Among older people, that is, those over 30 years of age, I have seen very few patients with uncomplicated diabetes who have followed strict treatment go steadily down hill. This does not mean that many diabetics of this age have not shown downward progress, for many have; but with the exception of the few cases just mentioned, they have all flagrantly violated their dietary regimen. It has been considered almost axiomatic that diabetes in the young is fatal. That such may not

Chart 6.—Course of diabetes in Case 6.

always be the case is suggested by some of the results just cited. But for a certain group of diabetics, more often encountered in the young than in the old, there is no doubt that an inherent tendency to a downward course does exist and persists until death, in spite of any treatment. Such a case is Case 6.

CASE 6.—A woman, aged 23, had had diabetes for one year. It has never been difficult to clear up glycosuria by fast or half days, but this patient has always shown a tendency to

develop high blood sugar on even a very low food intake. Now after almost two years of faithful adherence to diet, with many changes in the relations between carbohydrate, protein and fat, she has gradually lost tolerance. There has been a loss of 28 pounds in weight, and there can be no doubt that she is slowly and steadily losing ground. Her present tolerance may be noted on chart.

There have been several other similar cases at this age; but only two of the patients have faithfully kept the diet. It would seem most advisable in this type of case to feed the patient, allow glycosuria in moderate amounts to continue, and make an attempt to build up the strength.

#### CONCLUSIONS

As the result of the experience of the past four years in dealing with many diabetic patients treated by the above described methods, and as the result of reviewing complete records of these patients who have been cared for under the modern treatment, there are certain inevitable conclusions to be drawn:

1. Diabetes in its severe and acute form is not limited to the first three decades of life, but may be found at any age, although rare in persons over 30. In my experience it is more common between 50 and 70 than between 30 and 50.

2. Absolute adherence to the diet is essential to a maximum degree of successful results in treatment. Without there is no hope unless the diabetes is very mild; and even in that case there is great risk of it becoming severe.

3. Fast days and half days are of great help in treatment of the majority of patients, but are not necessary as routine measures in all cases at all times.

4. It is wise for a patient under treatment to realize that he is not a normal person on a normal diet and to regulate his mental and physical activities, and, therefore, his caloric output, by his caloric intake.

5. Exercise should be advised only in exceptional cases and in proportion to the amount of energy afforded by the caloric intake. Rest rather than exercise should be urged.

6. Long continued diets overbalanced in fat (180 gm. and over) are harmful, and their harmful effect is insidious. Aside from their immediate effects in the production of acidosis and glycosuria, they have a depressing effect on tolerance. This effect is overcome only by long periods of low caloric intake.

7. We have no cure for diabetes; but we have a greatly improved method of treatment, particularly as regards prolongation of life and the avoidance of surgical complications, as many observers who have employed the general principles of treatment advanced by Allen will testify.

#### ABSTRACT OF DISCUSSION

DR. ALFRED STENDEL, Philadelphia: In the beginning of his paper Dr. Gevelin stated that while the modern treatment of diabetes is now quite generally understood, there is a question in the minds of many practitioners regarding the latter part of the treatment, and with many the after-treatment is the most difficult. This has been precisely my experience. Beginning with the same form of treatment in 1915 my results have been substantially the same as his, and the after-treatment of the disease has been that which has given me the most difficulty. I am quite certain that if I had all of my figures here they would show about the same proportion of cases in which the patient was rendered sugar free and ketone free in a relatively short time; but a very considerable number of these cases subsequently relapsed owing to imperfect methods of

treatment, failure to carry out instructions and various other causes. I want to point out particularly the difficulty of determining when and whether a case of diabetes is actually cured. One of my most instructive experiences was made in the case of a young man who had been sugar free and ketone free for nearly four years, and for three years had had a normal blood sugar figure despite the fact that he was on quite a substantial general diet. As a result of a mild attack of influenza his diabetic condition immediately relapsed, and he died in coma in seventy-two hours. Several other less striking cases have illustrated the unwisdom of asserting that a case of severe diabetes has been cured. The underlying conditions of the disease are apparently not cured, though the patient may have been got to a place where with some care in his mode of life the disease remains inactive. In milder diabetes there can be no doubt that a complete cure is much more frequent and can with greater propriety be assumed to have been attained. I do not wish to give the impression that even in severe cases a complete cure is an impossibility, but wish to insist on the importance of a distinction between rendering a patient temporarily sugar free, ketone free and with a normal blood sugar figure and absolute cure.

DR. JACOB ROSENBLUM, Pittsburgh: I think these figures are misleading, that there are few hospitals in this country which would allow such a large percentage of the older cases to go out with glycosuria. My difficulty in the adoption of this method in many cases has been that the patients are not intelligent, they will not stick to it, and in many cases they consider themselves too intelligent and tell you "we will not stand for such restrictions in our diets," and I think that the older methods of treatment have still a place. In cases which have to come to operation, in pregnancy and in children, I feel that the Allen treatment is certainly the best to use.

DR. PHILIP ROY, Washington, D. C.: This subject is very interesting. I was called to see a gentleman who had lost one leg by gangrene; the other leg was badly swollen; his urine contained 3 per cent. of sugar and it was also filled with casts and albumen. Under the Allen treatment the swollen leg has become better, and he is enjoying good health and attending daily to his business. I have not seen him for a year, but I know that he is perfectly well.

DR. H. O. MOSETHAL, New York: In regard to the after-treatment: The primary treatment is to render the patient sugar free, and whatever method we pursue makes little difference. The big difference of Dr. Allen's treatment from others is that we can render practically every person sugar free. The one problem we have to meet is when we cannot make the person sugar free, and have to restrict the diet in such a way that he cannot obtain enough nourishment to live. The form of diet that we have to give such a person is a mixture of art and routine. Formerly, we gave these people high fats and raised the calories in this way. But now the question of restriction of fats is the best course, and the best service which Allen has given us.

DR. E. P. JOSLIN, Boston: Dr. Gevelin's paper gives much encouragement. It is a striking fact that prior to 1915 one quarter of all diabetic patients entering the hospital died, and that since that date the mortality has been reduced to 10 per cent.; that prior to 1915 two thirds of the patients died in coma, and since that date a very small percentage die in coma, e. g., two out of forty. The statistics of the Massachusetts General Hospital showed that between 1893 and 1914 no improvement in diabetic treatment was obtained but since the Allen treatment was introduced marked improvement has taken place.

DR. L. F. KEELER, Washington, D. C.: I am gratified at the conservatism of Dr. Stengler relative to the curing of diabetes. Cases are reported free of sugar for a time and then relapse. I would like to ask Dr. Gevelin whether the increase from 19 to 95 represents a percentage increase of diabetic conditions or just an increase of cases that came to the hospitals, and if the latter, why did they come to the hospital? Since the enforcement of the food and drugs act we have done a great deal by restricting the statements

appearing on packages, and one disastrous result is that these people have transferred their statements to newspapers. We have a number of cases under consideration now where people are using the mails to treat diabetic cases by means of drugs.

DR. L. G. HEYN, Cincinnati: I had a patient who had been rendered sugar free for some time, and had applied for a life insurance examination. This particular company has a habit of giving all candidates from 100 to 150 gm. of glucose on an empty stomach. He remained sugar free. I think this was a very severe test.

DR. C. M. GRIGSBY, Dallas, Texas: I have never derived as much benefit from any therapeutic measure as I have from Dr. Allen's treatment for diabetes. In the statistics here, however, I wonder whether they are of full value, because in the last four years, we have had cases in the hospitals which were much more amenable to treatment than were those of the older days.

DR. H. RAWLE GEVELIN, New York: The time limit on all papers prevented my emphasizing and illustrating, by means of the charts, certain points concerning the treatment of diabetes. Whether the diabetes be mild or severe the patient should be made to realize that he must regulate his activities according to the amount of food he is able to take and remain sugar free. Mild cases of diabetes, cases that in all probability would always remain mild, may be rendered severe if diets, much overbalanced in fat, be administered over too long a period of time. As regards the glucose tolerance test, it should not be given often in the case of mild diabetes and certainly should not be used in cases of severe diabetes. I consider that the improvement in the treatment of diabetes made in the past five years has been quite remarkable and may yield the most favorable results in some cases. Whether or not diabetes is on the increase, or whether we are discovering it earlier, is a question which requires a thorough study of life insurance and other statistics of similar character before we can arrive at direct conclusions.

### THE INFLUENCE OF DESICCATION ON HUMAN NORMAL ISOHEMAGGLUTININS\*

HOWARD T. KARSNER, M.D.  
AND  
HERBERT L. KOECKERT, M.D.  
CLEVELAND

The practical importance of human normal isohemagglutinins in determining the suitability of prospective donors for the transfusion of blood has been emphasized many times. The quest for an accurate, rapid and convenient method of determining the compatibility of donor and recipient has led to the development of a large number of methods to supersede the older time-consuming methods described in the various textbooks.<sup>1</sup> The methods of Epstein and Ottenberg<sup>2</sup> and Fishbein,<sup>3</sup> designed to accomplish a large number of tests with a small amount of blood, were simplified first by Weil.<sup>4</sup> Rous and Turner<sup>5</sup> then added the advantage of further blood economy. The time-

saving method of Brem<sup>6</sup> was improved on by Moss,<sup>7</sup> but involved the use of washed corpuscles; this was obviated by Minot's modification,<sup>8</sup> which is quite similar to the method of Lee.<sup>9</sup> These were followed by the methods of Coca,<sup>10</sup> Vincent<sup>11</sup> and Abelman,<sup>12</sup> but the methods as employed by Karsner<sup>13</sup> and Lee<sup>9</sup> in military hospitals testify to their efficiency.

As a further means of saving time and affording greater convenience, Sanford<sup>14</sup> has recommended the use of dried serums. He allowed the serums to dry in air on cover-slips, after which they were wrapped in paper and kept in the icebox. For grouping an unknown blood, the dried drops of serums of Groups II and III were dissolved in one drop of the cell suspension and the grouping made according to the classification of Moss. He observed that the serums still possessed marked agglutinating properties after more than two months. Karsner<sup>15</sup> noticed that in France there seemed to be a deterioration and loss of specificity of the agglutinins a short time after they were dried. It was with this in mind that the following experiments were carried out:

#### EXPERIMENTS

Serums of Groups II and III were used, and dilutions of 1:2, 1:4, 1:8, 1:16, 1:32 and 1:64 were made with physiologic sodium chlorid solution. Small drops of undiluted serum and of each dilution were allowed to dry on glass slides in the air. The initial agglutinating titer was noted and tests were made at the end of each week for twelve weeks. One third of the slides (A)<sup>16</sup> were kept in the dark at room temperature, another third were kept in the refrigerator (B), and the remainder were kept in a vacuum desiccator over sulphuric acid (C). The corpuscles used were from individuals of Groups II and III, and the same individuals were used throughout the experiment. Further, in order to avoid variations in agglutination due to the quantity of cells used in the tests, a standard cell suspension was used throughout, namely, a suspension made by mixing in 1 c.c. of physiologic sodium chlorid solution the amount of blood which would fill the capillary tube of a white cell counting pipet, and which we have found to be the optimal concentration for isohemagglutination tests. Since the erythrocyte count of the individuals used remained practically constant, the resulting cell suspensions were also constant. The dried serum drops were dissolved in a loopful of cell suspension of each group. Since agglutination occurred more slowly in the higher dilutions, as has been observed by Ottenberg, and since, if agglutination occurred in any dilution, it did so within thirty minutes, that time was taken as a standard during which the mixtures were frequently observed microscopically. The slides were kept inverted in a moist chamber during this period, and for observation were placed in the same position on a slide the ends of which were raised by means of two small pieces of glass glued on with balsam, thus affording a very serviceable hanging drop preparation.

At the same time a series of small capillary tubes were drawn out and filled with the various dilutions of both

serums. These were kept in the refrigerator and used in the same way as the dried serums, paralleling each test exactly in technic (D). Each tube held a drop of moderate size sufficient for making one test. For use, the sealed ends were broken off and the contents expelled on the slide, a most convenient procedure and even more rapid and economical than using serum kept in ampules.

RESULTS

The results, as may be seen in the protocols, showed that deterioration began about the second or third week in the higher dilutions and gradually involved the lower dilutions; that complete deterioration never occurred in the undiluted serum; that after the third to the fifth week there appeared a loss of specificity, each serum agglutinating the corpuscles of both Groups II and III, the loss of specificity occurring first in the undiluted serums and gradually involving the higher

dilutions, until at the end of the tenth week, and often as early as the seventh, none of the dilutions were specific for the proper cells. Throughout the experiments the undiluted serums possessed marked agglutinating properties. Curiously enough, it will be observed from the protocols that approximately coincident with the gradual loss of specificity in the higher dilutions, the previously deteriorated dilutions gradually regained their agglutinating power up to the original titer, though without specificity. In no instance was any agglutination observed in dilutions higher than the original titer of the serums. The occurrence of these changes has not been constant as to time in the various series of experiments carried out, but the protocols will serve as a fair example of the results observed.

In the tubed serums, no deterioration or loss of specificity occurred at any time, even in the case of one

\* Figures in the dilution column represent dilutions of serum in physiologic sodium chloride solution, 1, 1:2, 1:4 and 1:8. No agglutination occurred with dilutions higher than 1:8. The agglutination of corpuscles of groups I and IV, which occurred in all dilutions of both Serums II and III in every series after prolonged drying, is not indicated. The sign + indicates agglutination; — indicates no agglutination; ± indicates tendency to agglutination.

series which remained at room temperature for more than three months.

In another series, phenol (0.5 per cent.) was used as a preservative, after which the drops were made and dried in air and kept in the refrigerator. The results observed by the usual weekly tests were the same as with the other dried serums (E).

#### EFFECT OF THOROUGH DRYING

The question of the thoroughness of the drying then presented itself. Shackell and Harris<sup>17</sup> have pointed out that deterioration of the virus of rabies in dried cord is due to imperfect methods of drying and the exposure to air, the atmospheric moisture of which is sufficient to dissolve the salts in a very concentrated form in a few hours and so destroy the virus.

Accordingly, the method of desiccation worked out by Shackell,<sup>18</sup> which he states "could be used for the absolute preservation of immune serums as well as the concentration of low potency toxins," and which has been employed by Achalmé and Phisalix<sup>19</sup> in the "preservation of vaccine virus in hot countries," and applied by Hitchens and Hansen<sup>20</sup> to the preservation of typhoid vaccine and by Hammer<sup>21</sup> to the preservation of various bacteria, was followed in another series of experiments, and careful attention was paid to the details of technic as suggested by Shackell. A well-made vacuum desiccator with smooth ground glass surfaces and tightly fitting stopcock was placed in a salt and ice freezing mixture. When the maximum cold was reached ( $-10\text{ C.}$ ) the slides were prepared, placed in the desiccator and frozen as rapidly as possible. The desiccator was exhausted by means of an ordinary water pump which was able to exhaust from 20 to 30 mm. of mercury, and the freezing, which occurred very quickly, maintained for twenty-four hours. The desiccator was exhausted and the sulphuric acid shaken up every day in an effort to assure as complete dryness as possible. These serums were used in exactly the same manner as the other dried specimens with apparently no difference in the results obtained, except a slight retardation of one or two weeks in the onset of deterioration and loss of specificity (F).

In another series the serums and various dilutions were dialyzed in parchment dialyzers for seventy-two hours before drying in order to eliminate the salts, the concentration of which might be the cause of the observed changes; the usual qualitative chlorid test, silver nitrate and potassium bichromate, was taken as an indication of salt content and found to be negative. The slides were then prepared, dried in air and kept in the refrigerator. The results obtained by the regular weekly tests were quite similar to those previously noted in the other dried serums (G).

Various serums which had dried in the flasks in which they were kept failed to show this loss of specificity. Why this was the case when a large amount of serum was allowed to dry as contrasted with the results obtained by drying small drops has not been determined; but this work is being carried on to determine, if possible, the factor or factors concerned.

including the influence of bulk; this, however, has usually been found to hasten rather than retard deterioration.<sup>22</sup>

A further interesting observation was made when suspension of corpuscles of Groups I and IV were used. Here again agglutination of those cells occurred in all dilutions. These tests were made after the eighth week, when the loss of specificity had been observed in all of the dilutions; but there is no doubt that agglutination of the normally unagglutinable corpuscles of Group IV would have been observed as soon as loss of specificity was noticed had the tests been made then. This agglutination of corpuscles of all the groups by each of several serums which belonged originally to Groups II and III emphasizes the agglutinative power of serum to be of vastly more importance in the process of agglutination than the agglutinability of the cells, and refutes the assumption of specific iso-agglutinophilic substances.

Hartman<sup>23</sup> has suggested, as a convenient method of grouping bloods, the use of serums dried on filter paper. This procedure was also carried out with serums of Groups II and III, the drying being done in air and the papers kept at room temperature. Proper agglutination occurred only with those papers which had been saturated with undiluted serum or the 1:2 dilution, and in these instances agglutination was never as marked as was seen regularly with the tubed serums or even with those dried on slides. Loss of specificity occurred occasionally, but it was often impossible to determine accurately whether or not such slight agglutination occurred because of the considerable amount of dirt and debris which constantly occurred and which, per se, frequently caused clumping of the corpuscles and greatly interfered with the accurate observation of such slight agglutination as frequently occurred. Regardless of the factors of deterioration and loss of specificity, this, together with the objections of loss of time in dissolving the serum and the inconvenience compared to the use of tubed serums, is sufficient reason to discard the method.

We also found it impossible, even with rapidly dried serum, to redissolve all the material by adding the amount of distilled water or physiologic sodium chlorid solution necessary to restore the original volume, and there was usually a reduction in the agglutinating titer of such redissolved serums. A Group III serum, which originally agglutinated in a 1:16 dilution, agglutinated only up to 1:2 when redissolved, and then only very weakly, whereas the original undried serum still maintained the original titer.

Any attempt to explain the deterioration and loss of specificity of iso-agglutinins at the present time could not be anything more than a speculation. The exact cause of the phenomenon of agglutination or adequate explanation of the specific character of iso-agglutinins for specific groups of cells has not been determined, and until the accurate conception of this phenomenon is advanced and accepted, it would be folly to attempt an interpretation of the changes that have been observed. The diminution in agglutinating power of iso-hemagglutinins in dried serum similar to that in heated agglutinating serum may find analogy in the deterioration of bacterial agglutinins that have been preserved at room temperature.

23. Hartman, F. W.: *New Methods for Blood Transfusion and I. Serum Therapy*, *J. A. M. A.* 71: 1658 (Nov. 16) 1918.

The explanation of the loss of specificity is baffling, for it is a phenomenon previously unobserved in antibodies. Doubtless, the answer lies within the field of colloidal chemistry, and its determination would seem to offer a considerable opportunity for investigation into the physicochemical changes occurring in dried serums due to various influences, including among others, age, alterations in hydrogen ion concentration, in electrical conductivity and in the dispersion of agglutinating substances, and the presence of otherwise feeble but non-specific "para-agglutinins." It has been considered sufficient at present to have established the facts and to present these observations concerning isohemagglutination.

#### CONCLUSIONS

1. Normal human iso-agglutinins exhibit deterioration within from two to three weeks and loss of group specificity within from three to five weeks after drying, regardless of the method of desiccation employed or the previous addition of a preservative or the elimination of salts by dialysis.

2. Complete loss of specificity with coincident acquisition of non-specific agglutinating power occurs within from seven to ten weeks after desiccation.

3. The agglutination of corpuscles of all groups by a serum that has lost its specificity for particular groups emphasizes the agglutinative power of serum to be far more important in the mechanism of agglutination than the agglutinability of the corpuscles, and refutes the assumption of specific iso-agglutinophilic substances.

4. There is a considerable reduction in the agglutinin titer by the redissolving of dried serum in enough distilled water or physiologic sodium chlorid solution to restore the original volume.

5. The use of undried serum, put up in small capillary tubes, is a most convenient, rapid and economical, as well as accurate, method for grouping blood.

### A NEWLY RECOGNIZED CAUSE OF PULMONARY DISEASE—ASCARIS LUMBRICOIDES\*

B. H. RANSOM

Chief, Zoological Division, United States Bureau of Animal Industry  
WASHINGTON, D. C.

It has long been known that the common roundworm of man (*Ascaris lumbricoides*) and the closely related and probably identical parasite of the pig (*Ascaris suum*) sometimes occur aberrantly in organs other than the small intestine, their usual location. Until the recent investigations of Stewart,<sup>1</sup> however, the fact that *Ascaris* is regularly parasitic in the lungs during an early stage of its development was not even suspected. Stewart's experiments have been repeated

by Yoshida<sup>2</sup> and by Foster and myself,<sup>3</sup> and Stewart's important discovery that the larvae of *Ascaris*, after hatching in the intestine of an animal that swallows the eggs, migrate to the lungs and then return to the intestine, has been fully confirmed. With reference to the rat and mouse theory, however, Foster and I have reached conclusions that are not in accord with Stewart's view that rats and mice may serve as intermediate hosts of *Ascaris*. Contrary to this view we have clearly shown that no intermediate host is necessary, and that infection of man or pig occurs as a result of swallowing the eggs of the parasite.

Briefly, the course of development is as follows: The eggs pass out of the intestine of an infested animal (man or pig) in the feces. The eggs are not infective until the contained embryos develop to a vermiform stage, which requires a period of two weeks or more, according to the temperature of the surrounding medium, oxygen supply, and moisture. Accidentally the embryos may hatch outside the body; but in this case they quickly perish. Within the highly impermeable egg shell, however, the fully developed embryo is very resistant to cold, dryness and other unfavorable conditions, and may remain alive for long periods of time, five years and possibly longer. If swallowed by some mammal, the eggs that contain fully developed embryos hatch in the small intestine. They will also hatch if artificially introduced beneath the skin.

Unless accidentally carried out of the body in the feces, the newly hatched larvae leave the lumen of the intestine and migrate to the liver, though some possibly go more directly to the heart, in both cases apparently aided by the circulation. From the liver, where they remain in most cases only a few days, they migrate to the lungs, evidently by way of the hepatic veins, inferior vena cava, heart and pulmonary arteries. They are stopped in the lungs by the capillaries, enter the air vesicles and bronchioles, pass up the bronchi and trachea, then into the esophagus, and finally reach the small intestine, where, if the animal infested is a suitable host, they establish themselves and continue their development to maturity. Occasionally some of the larvae appear to return to the heart from the lungs, as they may sometimes be found in the spleen, under the peritoneum of the abdominal cavity, and in other locations that they could scarcely reach except in the systemic circulation. In such locations they may attain the same stage of development that is reached by those in the lungs, but it seems unlikely that they can succeed in regaining the intestine or in continuing their development.

In rats, mice, guinea-pigs and rabbits, *Ascaris* larvae undergo the same migrations that they do in the pig and presumably in man, the only essential difference being that when they return to the alimentary tract after passing through the liver and lungs, they are unable to develop further and soon pass out of the body in the feces. The larvae thus eliminated in the feces are only slightly resistant to unfavorable conditions and die in a short time. The possibility of their being ingested by and continuing their development in a human being or pig after passing through a rat or mouse is of theoretical interest but seems to be of no

practical importance. As shown by Foster and myself, very young sheep and goats are better adapted as hosts for *Ascaris* than rats, mice, guinea-pigs or rabbits, since the larvae after their passage through the lungs may establish themselves in the intestine and develop to a stage approaching maturity, though they seem unable to reach their full growth as they do in man or pig.

In experimentally infected animals (rats, guinea-pigs, etc.), *Ascaris* larvae may be found in the liver as early as two days, in the lungs and trachea as early as three days, and in the intestine following their passage through the lungs, as early as six days after the eggs are swallowed. They are common in the lungs from seven to ten days after infection, becoming scarce in the liver as they become numerous in the lungs, and can be found passing down the esophagus in large numbers from eight to ten days after infection. During their migrations before returning to the intestine they increase in size from a length of about 0.25 mm. when newly hatched to a length of as much as 2.5 mm., commonly 1.5 mm. At the same time they undergo considerable change in structure, and molt at least twice. In the case of rats, mice, and other animals in whose intestines the parasites are unable to establish themselves, the larvae are all, or practically all, eliminated within a little over two weeks after infection. In closing this brief outline of the life history of *Ascaris* it may be of interest to note that if fully incubated eggs are injected beneath the skin of a guinea-pig they not only hatch as first shown by Martin,<sup>4</sup> who did not, however, follow the migrations of the larvae, but the larvae later appear in the lungs, just as they do when the eggs are swallowed.<sup>5</sup>

The fact that *Ascaris* in the course of its development regularly passes through the liver and lungs naturally raises the question as to the damage it may do during its migrations. Evidently it has capacities for harm not suspected so long as it was assumed, as formerly, that after hatching from the egg, the young worm simply settles down in the intestine and grows to maturity. Just how important it may be under natural conditions as a cause of disease of the liver, lungs or other organs that are invaded by the migrating larvae remains to be determined. Under experimental conditions, however, it has been found that the migrating larvae may seriously injure the lungs. As first observed by Stewart, experimentally infected rats and mice commonly die of pneumonia a week to ten days after infection, and the same is true of guinea-pigs and rabbits. Larger animals, such as young pigs, if heavily infested, may likewise succumb to pneumonia incident to the invasion of the lungs by the larvae; and even when a comparatively few eggs have been swallowed, more or less definite symptoms of pulmonary trouble, such as difficult and quickened respiration and fever, may commonly be noted about a week after infection. The symptoms of a disease known as "thumps," which is highly destructive to young pigs, are similar to those shown by pigs suffering from *Ascaris* pneumonia experimentally produced. Indeed, it is quite certain that in many of the cases of "thumps" *Ascaris* is an important etiologic factor, and evidence recently collected in field investigations shows very clearly that

*Ascaris* pneumonia is responsible for much of the loss of life and stunting of growth that occur among young pigs.

By analogy it is reasonable to suppose that *Ascaris* may occasionally if not frequently be involved in the production of pulmonary disease among human beings, especially young children. Young children are known to be more susceptible to infection with *Ascaris* than older persons, just as young pigs are more susceptible than older pigs; and it may be presumed that they resemble young pigs also in being more liable to suffer from *Ascaris* pneumonia than older persons.

As a matter of fact, certain observations are on record that are at least in harmony with the supposition that in human beings, as well as in various other animals in which the fact has been proved by experiment, *Ascaris* larvae may be a source of injury to the lungs. Over fifty years ago a German physician, Mosler,<sup>6</sup> fed *Ascaris* eggs in numbers as large as several dozen to healthy children of various ages. In no instance did the children afterward pass worms following anthelmintic treatment, and the experiment thus gave negative results so far as concerned the development of the worms from the eggs. In some cases, however, Mosler observed that the children a few days after the eggs were given to them suffered from fever and difficulty in breathing. He was inclined to doubt that these symptoms were caused by the experiment. In the light of our present knowledge, however, it is altogether likely that the symptoms in question were produced by an invasion of the lungs by *Ascaris* larvae.

Another experiment on man is recorded in the literature in which the ingestion of *Ascaris* eggs was followed by pulmonary symptoms. This experiment was carried out by Lutz<sup>7</sup> in South America, the subject being a grown person who volunteered for the experiment. Incidentally it may be remarked that Lutz's experiment stands in agreeable contrast to Mosler's, which, in the use of children as experiment animals, is quite indefensible from a moral standpoint.

Lutz's volunteer was 32 years old and was stated to have been absolutely free from *Ascaris* infestation for at least twenty years, living in circumstances and amid surroundings and with personal habits such that there was little likelihood of infection from sources outside the experiment. During the experiment, special care was taken to avoid conditions usually considered favorable to parasitic infection. A small number of *Ascaris* eggs were swallowed on a number of different days, namely, January 4, 5, 6, 7, 19, 23, 25 and 27, the average number of eggs per day being estimated at twelve, only about a third of which contained fully developed embryos. Altogether, therefore, about 100 viable eggs were swallowed, fifty in the early part of the month and fifty in the latter part of the month. Early in the experiment the subject suffered from acid dyspepsia, repeated vomiting, and a slight remittent fever, in addition to which an unusually severe bronchitis soon developed. These symptoms were gradually replaced by symptoms of an intestinal catarrh. The early symptoms were considered probably accidental by Lutz; but the persistent abdominal symptoms seemed to indicate a positive result from the experiment, and the patient accordingly was given an anthelmintic treatment, February 1. From the feces following this treatment, thirty-five immature ascarids from 5.5 to 13 mm. long were recovered.

Assuming that these worms came from the eggs fed in the early part of January, it is of interest to note

<sup>5</sup> Ransom, B. H., and Foster, W. D. (Footnote 3), second and third references).

<sup>6</sup> Mosler, quoted by Leuckart, Rudolph: Die menschlichen Parasiten und die von ihnen herrührenden Krankheiten. Ein Hand- und Lehrbuch für Naturforscher und Aerzte, Leipzig und Heidelberg, 2: 330, 1867.

<sup>7</sup> Lutz, Adolph: Zur Frage der Uebertragung des menschlichen Soma-wurms! Weitere Mittheilungen, Centralbl. f. Bakteriol. 3: 425-428, 1898.

that their size from twenty-five to twenty-eight days after infection corresponds closely to that of the worms found in the small intestine of a young goat twenty-seven days after it had been fed *Ascaris* eggs in an experiment carried out by Foster and myself, the length of the worms in the latter instance varying from 4.3 to 11.4 mm., averaging 7.9 mm. (twenty-nine worms measured out of several thousand present). There is thus practically complete agreement in the size to which the worms developed in the same length of time in the two experiments.

As to the significance of the early symptoms noted by Lutz as well as those observed by Mosler a few days after the ingestion of *Ascaris* eggs by human beings, it is quite possible that they were merely coincidental; but it seems much more likely that they were the result of the invasion of the lungs by the young parasites. Whether or not any importance is ascribed to the lung symptoms observed by Mosler and Lutz, the fact that *Ascaris* larvae can cause pneumonia in lower animals clearly indicates that they may do likewise in human beings. This possibility should receive serious consideration by those who have opportunity for its investigation, particularly in cases of pulmonary troubles among young children who are living amid surroundings favorable to gross infection with *Ascaris*.

#### SUMMARY

To recapitulate, some of the more important facts that have been established by recent investigations on *Ascaris lumbricoides* and conclusions to be drawn from them may be thus summarized:

Infection occurs as the result of swallowing eggs of the parasite containing fully developed embryos, no intermediate host being necessary.

After the young worms hatch in the intestine they do not immediately settle down, but migrate to the liver, lungs and other organs, meanwhile undergoing considerable growth and development.

Those that reach the lungs return to the intestine by way of the trachea and esophagus, then settle down and develop to maturity if in a suitable host (man, pig); otherwise they are soon eliminated in the feces (rat, mouse, guinea-pig, rabbit), or in some hosts (sheep, goat) may undergo an abortive development that falls short of fertile maturity.

Pneumonia commonly occurs in experimentally infected animals about a week to ten days after infection, at a time when the invasion of the lungs by the migrating larvae is at its height.

Mosler in 1867 and Lutz in 1888 recorded the occurrence of pulmonary symptoms in human beings following the experimental administration of *Ascaris* eggs. In the light of our present knowledge it is very probable that these symptoms were the result of invasion of the lungs by migrating *Ascaris* larvae.

The question of the occurrence of pulmonary troubles in human beings as a result of *Ascaris* infection should receive careful investigation, especially in the case of young children.

#### ABSTRACT OF DISCUSSION

DR. THEO ZBINDEN, Toledo, Ohio: I was recently interested in a case in which the diagnosis was made of foreign body in the lung. Dr. Hubbard made two bronchoscopic examinations and found nothing. The roentgen ray showed nothing. The patient's symptoms would last a few hours or a day or two, and then disappear. However, a few weeks after the last attack the child passed a full sized ascaris

worm. I would like to know whether the adult worm could have caused these symptoms by passing upward into the esophagus, and obstructing the larynx, or whether a number of larvae were passing out of the trachea. According to Dr. Ransom's description the larvae are very small and not likely to cause symptoms of obstruction.

DR. HENRY ALBERT, Iowa City, Iowa: Dr. Ransom referred to a condition in young pigs called "thumps." I would like to ask him if an investigation has been made regarding the relationship of worms to thumps. It is a common disease and it seems to me that the opportunity for making such an investigation should be easy to find. It is also a common observation among farmers that coughing is one of the usual symptoms of worms in hogs. I presume that there is a direct relationship between such and the irritation caused by the larval form of the ascaris in the lungs. I would like to ask Dr. Ransom if postmortem examinations of the animals have been made and if so what were the findings.

DR. C. C. BASS, New Orleans, La.: These observations have opened a future that we do not at the present fully estimate. When we recall the very widespread prevalence of this disease in man, especially in institutions, such as orphan homes, and among the poorer class of people, we can begin to appreciate the importance of this observation. Do the larvae which attack the lung damage it in the same way that the hookworm larvae do? If we infect animals experimentally with a small number of hookworm larvae, many small hemorrhages occur in the lung. Of course, if many worms are present, then massive hemorrhages occur and these may get large enough to kill the experimental animal in two or three hours.

DR. B. H. RANSOM, Washington, D. C.: As to Dr. Zbinden's question: I think in that case it was merely a matter of the aberrant wandering of a well developed or mature ascaris. Ascarids have the habit of crowding into narrow passages, into the bile ducts or pancreatic ducts, and cases are on record in which they have been found wandering in the esophagus, entestachian tubes, and in various other places outside of their normal location. As to the question of "thumps" in pigs, we have investigations under way, the results of which are not yet available. These investigations are being carried out in the Middle West and we hope to have some definite results from this season's work. Referring to Dr. Bass's question as to how the ascaris larvae injure the lungs, that matter is still under investigation, but they do very much as hookworm larvae do, produce minute hemorrhages. It is very characteristic in the case of experimental animals that have been infected with ascaris to find small petechiae scattered over the lungs and in some cases there are large hemorrhagic areas either as a result of a heavier infection or of other conditions that we do not exactly understand. The other question asked by Dr. Bass was in reference to age susceptibility. In the case of human beings, it is quite evident that children, because of their habits, are, perhaps, more exposed to infection than older persons, but I do not see how that explanation could be sufficient in the case of pigs, because as far as my observations have gone, adult pigs are likely to be just as much exposed to infection as younger pigs, and in fact their exposure is probably greater from the simple fact that they are older and have consequently had more opportunities to become infected. As a matter of fact the statistics we have gathered show that young pigs are more often and more heavily infected than older animals. I don't see any way of explaining the difference in the case of pigs except on the basis of the difference in age susceptibility.

**Treatment of Mental Disorders.**—The problem of mental disorders as now understood is no longer properly formulated by the phrase "the care of the insane." Mental disorders of many forms and in many stages are extremely prevalent. Those regarded as insane are simply the cases whose capacity for adjustment to the requirements of organized society has failed to such degree that they have become a burden or a menace.—W. L. Russell, *Canadian J. Mental Hygiene* 1:162 (July) 1919.

DESENSITIZATION OF PERSONS AGAINST  
IVY POISON

JAY FRANK SCHAMBERG, M.D.  
PHILADELPHIA

In an informal discussion<sup>1</sup> of a paper at the Detroit session in 1916, I announced that I had been able to protect persons susceptible to attacks of ivy poison by the internal administration of minute but increasing doses of the tincture of *Rhus toxicodendron*. Later my assistant, Dr. Strickler, made an alcoholic extract of the plant, which after aqueous dilution was injected subcutaneously and was found to be effective in preventing attacks.

During the past few years I have been employing this method in my private practice, with uniform success. I have treated almost a score of susceptible persons, and all have remained free of dermatitis during the ivy season, whereas prior to undergoing this treatment they rarely escaped.

I may briefly mention the case of a 12-year-old girl who for several years had spent a couple of months in bed each year from severe and repeated attacks of dermatitis venenata. She was so susceptible that she could not traverse a lane where ivy grew without being attacked. After taking the treatment she was rendered immune except for an extremely slight attack which developed as a result of her purposely handling the ivy plant to test her resistance.

The method of treatment which I have been carrying out is as follows: I prescribe:

B	Tincture of <i>rhus toxicodendron</i> .....	Cc. .
	Rectified spirit .....	5
	Syrup of orange, sufficient to make .....	100

The patient is instructed to take the mixture in half a glass of water after meals, as follows:

Breakfast, Drops	Lunch, Drops	Dinner, Drops
1	2	3
4	5	6
7	8	9
10	11	12
13	14	15
16	17	18
19	20	21

When this dosage has been reached, for purposes of convenience and simplicity, the patient takes a *teaspoonful* in half a glass of water merely *once a day*. This should be continued throughout the ivy season.

It has been my experience that the immunity (if one call it such) established after one month's administration will persist for about a month afterward. After this, susceptibility is prone to return.

TREATMENT OF AN ATTACK OF IVY POISON

The same mixture appears to exert a favorable influence on attacks of ivy poisoning in preventing an extension of the process, and in abbreviating the duration of the attack. In order to bring the patient more quickly under the influence of the drug, I administer it as follows:

Breakfast, Drops	Lunch, Drops	Dinner, Drops
2	4	6
8	10	12
14	16	18

Teaspoonful once a day, well diluted.

It is, of course, necessary to establish the fact that the ivy has been the cause of the dermatitis. *Rhus toxicodendron* tincture would probably be of no value in treating poison oak, primrose or other forms of

plant poisoning. I think it is more than likely, however, that desensitization against these poisonous plants could be accomplished by using extracts of *Rhus diversiloba*, *Primula obconica*, etc., in the same manner as detailed above.

The results obtained by this method in fortifying the resistance of persons against ivy poison suggest the possibility of achieving similar results against various pollen catarrhs—hay fever, rose cold, etc. If one can incriminate the particular pollen at fault, an extract taken by mouth might conceivably bring about a desensitization. This method is so much simpler than administration by hypodermic injection that it would appear to me to be worthy of trial.

1922 Spruce Street.

**Therapeutics**

A DEPARTMENT DEVOTED TO THE IMPROVEMENT OF THERAPY. A FORUM FOR THE DISCUSSION OF THE USE OF DRUGS AND OTHER REMEDIES IN THE TREATMENT OF DISEASE.

RESULTS IN THERAPEUTICS

Therapeutic truths not only deserve reiteration—they demand it. To determine what is the truth is most difficult, especially in therapeutics. Unfortunately, much of what passes as therapeutic knowledge is merely tradition or opinion; too much of our therapeutics is based on opinion. A fact is characterized by constancy, and constancy of results is what we need, above all, in therapeutics. Much of our treatment is not constantly successful because based on incomplete observation, on mere opinion. A definition for "constancy of results," as used here, might be called for. Of course, we cannot expect 100 per cent. results in therapeutics. The reason for this is the complexity and variability of the conditions to be met. The human body is not a test tube. We often cannot fathom all the factors at work. Hence it may easily occur that we employ our therapeutic reagents in conditions under which the desired result cannot happen. The more clearly and closely we draw the therapeutic indications, and the more accurately we adapt our technic to meet the requirements of the particular case at hand, the more nearly will our results approach the ideal of 100 per cent. However, to save ourselves disappointment, it is almost as important to know under what conditions our remedies must fail, as it is to know when they may be expected to succeed.

USE AND ABUSE OF CATHARTICS

The following is the first of a series of articles on pharmacology, physiology and practical application of the common laxatives and cathartics.

The physician who knows when to employ a cathartic has mastered an important lesson in therapeutics. In these days of revolution and reform, nothing is too well established to be questioned, too sacred for attack. The dictum, "Qui bene purgat, bene curat," shall give way to the maxim, "The less purging, the better."

CATHARSIS A CAUSE OF CONSTIPATION

That cathartics are a frequent cause of constipation may be gathered from such utterances as these:

In my opinion one of the most common sources of constipation in this country is the pernicious habit of resorting to

1. Schamberg, J. F., in Discussion on Eczema, J. A. M. A. 48: 87 (Jan. 13) 1917.

the use of drugs to secure a daily stool. . . . If we except England, there is no other country in which chronic consti-  
pension is so prevalent as it is here; and it is equally true that  
in no other land do people so frequently resort to the indis-  
criminate and senseless use of medicine in order to move the  
bowels. . . . It is a lamentable fact that not a few parents  
have the insane idea that, if they do not administer a cathar-  
tic frequently to their children, dire results will follow; and  
with their anxiety they eventually bring about or aggravate  
the very condition which they wish to avoid, namely consti-  
pation.<sup>1</sup>

A. C. Adams<sup>2</sup> would go so far as to prohibit the  
giving of cathartics to children, excepting under medi-  
cal supervision. He urges that the medical profes-  
sion attack the advertisements and display of aperients  
as inimical to the public health. With this we fully  
agree. The philosophy underlying the admission of  
cathartics into the advertising pages of newspapers  
and lay periodicals that discriminate against other  
forms of "patent medicines" displays the unfortunate  
lay notion that cathartics can do no harm. In point  
of fact, cathartics are not only habit-producing drugs;  
but, as in certain cases of intestinal obstruction, they  
may even kill.

However, while entering on such a campaign, let  
us be sure that our own hands are clean. A cathartic  
prescribed by a physician is no less liable to produce  
the cathartic habit—a habit that means increasing ill  
health—than one taken by the patient on his own  
initiative. Indeed, when the physician prescribes the  
remedy, the patient feels all the more certain that it  
is good for him, and he is likely to continue taking it.  
After all, the medical practice of the laity reflects the  
past practice of the medical profession.

Cathartics produce constipation in several ways:  
Excessive evacuation does not leave enough residue  
to excite bowel movement the next day. The patient,  
believing or instructed that he ought to have a daily  
bowel movement, repeats the dose; and he is well  
started on the way to a drug habit. For now fatigue  
of the musculature from overstimulation, or muscular  
spasm from abnormal irritability of the mucosa, due  
to excessive irritation, are likely to assert themselves,  
leading to the necessity of progressive increase in  
dosage and potency of the drug. Even the mildest  
and blandest laxatives, as well as enemas, must be  
charged with a tendency to get the bowel into slug-  
gish habits, for the very ease with which soft or  
liquid contents pass along the large bowel diminishes  
the necessity for muscular effort, and leads to atony  
and ultimate atrophy.

#### THE ACATHARTIC TREATMENT OF CONSTIPATION

In an extensive clinical study of constipation,  
Thayson<sup>3</sup> arrives at the conclusion that habitual  
constipation, as distinguished from secondary or symp-  
tomatic constipation, can be cured without the use of  
cathartics. This form of constipation usually begins  
before the age of 26 in women and 31 in men. The  
constipation beginning after these ages is generally  
secondary to some other disturbance. While he con-  
siders an atonic condition of the intestine, frequently  
hereditary, to be the predisposing cause in habitual

constipation, yet he believes that acathartic treatment  
should be resorted to in such cases, and that such  
treatment is generally successful. By going to stool  
at a regular time each day, regardless of whether  
there is a desire or not, and devoting fifteen minutes  
to an effort to have a passage, natural movements can  
usually be secured by the third or fourth day. Now,  
if this can be done in middle life at a time when the  
constipation has become a habit of many years' stand-  
ing, how much easier should it be to cultivate a correct  
habit in a little child, even though it had a hereditary  
tendency to constipation.

The psychotherapy of constipation, in which Paul  
Dubois<sup>4</sup> has been one of the most prominent pioneers,  
consists in implanting in the patient's mind the con-  
viction that constipation is merely a faulty habit that  
can be overcome by proper hygiene and diet and with-  
out recourse to evacuants or enemas, and in antag-  
onizing the fear that attempts at defecation will prove  
ineffectual. Frantic straining at stool may actually  
inhibit the process. Of course, before resorting to  
psychotherapy, we should first convince ourselves and  
what is quite as important, the patient, by means of  
physical, roentgenographic and sigmoidoscopic exami-  
nation that no organic disease of the bowel exists.

The psychic treatment is accompanied by correction  
of sins against hygiene. It is evident that those whose  
diet is at fault need diet and not drugs. The consti-  
pation of those with sedentary habits requires exer-  
cise—perhaps only calisthenics, walking, etc.—while  
those whose nervous system is below par from exces-  
sive work and worry need rest and recreation to  
enable the intestine to resume its proper function.

A word of warning should accompany even this  
treatment. The patient should be told that, if he does  
not succeed in obtaining a daily movement, it does not  
matter. We must not permit the patient to make of  
his bowel a fetish for daily and devoted worship.  
Says Samuel Jones Gee:<sup>5</sup>

Many of those who are continually complaining of con-  
stipation are suffering more from fear and hypochondria  
than from anything else. It is no law of nature that the  
bowels should be relieved punctually once in twenty-four  
hours. Some persons feel in better health when the bowels  
act once in two or three days; free evacuations are followed  
by a sense of weakness. Patience and contentment with  
nature's operations are not the worst remedies for constipa-  
tion.

While this may be true of the adult, it must be  
admitted that it is probably just as undesirable for an  
infant to go for several days without an evacuation  
as it is to get it started on the cathartic habit. If the  
bowel is permitted to retain fecal matter for a long  
time, the rectal reflex becomes chronically dull.<sup>6</sup>  
To prevent this, when the infant's bowels have not moved  
for more than twenty-four hours, a soap suppository  
or a simple glass rod suitably bent as suggested by  
Eggleston,<sup>7</sup> may be used. Of course, modifications  
of the diet, and giving an infant opportunity for exer-  
cise, are the chief measures to be employed in devel-  
oping regularity of bowel movement in infants.

## SPASTIC CONSTIPATION

In spastic constipation, cathartics, excepting the blandest of laxatives, such as oils, are contraindicated. When the patient suffers from colic—with or without meteorism—when he has a feeling as though the evacuations were unsatisfactory, when he presses a good deal at stool and evacuates long, thin, flattened fecal masses (though they may have other shapes) and when, on palpation of the abdomen, one can roll colonic segments under the hand like cords, and on rectal examination the bowel fits closely around the finger like the finger of a glove, cathartics not only are useless but they aggravate the disturbance. In these cases, antispasmodic treatment is indicated.

## PELVIRECTAL CONSTIPATION

In pelvirectal constipation (Hertz's<sup>8</sup> dyschezia), recognized by the fact that on roentgenologic exam-

ination the upper portions of the colon are emptied in the proper time, while the bismuth is retained for days in the sigmoid flexure and rectum, purgatives are likewise not only useless, but harmful, as they can act only when fluid stools are produced, which at one and the same time wastes nutriment and leads to intestinal atony. It is characteristic for this condition that enemas act much better in producing evacuation than do physics given by mouth, a fact of which some of these patients are well aware. Here the most important part of the treatment is to keep the rectum and pelvic colon empty, so that these may in time regain their normal tone and irritability. This can be accomplished by the regular use of enemas or of suppositories. Increasing the irritability of the rectal mucosa by the use of appropriate irritants is also likely to have a curative tendency.

## REMOVAL OF IMPACTED FECES

For the removal of impacted feces enemas rather than purgatives should be used. The latter merely add to the colic which is usually present and which indicates that the intestinal musculature is already contracting excessively.

**Passage of Human Infections.**—When the people generally and preachers, editorial writers and other teachers understand that human diseases are spread almost entirely from one human victim to another, it will be possible to focus attention on the main avenues of passage and control them. Until they do, we shall continue to be inefficient in controlling infectious diseases. In looking to all possible trails and ignoring the main ones, we are about as efficient as a young, untrained hunting dog which tries to divide his attention on a dozen tracks at the same time. Like him, we shall continue to run our legs off and finally lie down, confused and entirely satisfied that the thing "just can't be done."—*Milwaukee Health Bulletin* 281.

## New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

W. A. PUCKNER, SECRETARY.

**HIRATHIOL**—Ammonium Sulphoichthyolicum.—An aqueous solution of a synthetic product, the important medicinal constituents of which are ammonium compounds containing sulphur in the form of sulphonates, sulphones and sulphites.

*Actions and Uses.*—See sulphoichthyolate preparations (New and Nonofficial Remedies, 1919, p. 319). It is claimed that hirathiol is equivalent in every respect to the original ichthyol.

*Dosage.*—Since this article is claimed to be closely similar to ichthyol, its dosage is probably like that of the older preparation (see New and Nonofficial Remedies, 1918, p. 160).

Manufactured by Hirasawa Chemical Industrial Company, Tokyo, Japan (Takamine Laboratory, Inc., Clifton, N. J., U. S. selling agents). No U. S. patent. No U. S. trademark.

Hirathiol is a brownish-black syrupy liquid, having a characteristic empyreumatic odor.

It is soluble in water, glycerin and alcohol. It is miscible with fats. The aqueous solution of hirathiol (1:10) is faintly acid to blue litmus. The aqueous solution (1:20) yields a greenish-black, resin-like precipitate upon the addition of hydrochloric acid. This precipitate is soluble in ether; it is also soluble in water, but if dissolved in the latter solvent, it is again precipitated by the addition of hydrochloric acid or sodium chloride test solution.

Boil an aqueous solution of hirathiol (1:10) with potassium hydroxide test solution. Ammonia is evolved.

Hirathiol loses 46.5 per cent. of its weight when dried at 100 C. Weigh from 5 to 6 Gm. of hirathiol into a flask, and 25 Cc. of potassium hydroxide test solution and 100 Cc. of water. Distill the mixture until no more ammonia passes over, collect the distillate in 15 Cc. of normal sulphuric acid, to which 1 drop of methyl orange test solution has been added, and titrate the excess of acid with tenth-normal potassium hydroxide. The amount of normal sulphuric acid consumed corresponds to 3.18 per cent. of total ammonia (NH<sub>3</sub>).

Weigh from 5 to 6 Gm. of hirathiol into a beaker, add 50 Cc. of water and 10 Cc. of a 10 per cent. solution of albumen, followed by 5 portions of 5 Cc. each of diluted hydrochloric acid, shaking after each addition. Make up the mixture to a volume of 500 Cc. and filter through a dry filter. Heat 200 Cc. of the filtrate to boiling, add 10 Cc. of barium chloride test solution and allow the mixture to stand for twenty-four hours. Collect the precipitate of barium sulphate, heat and weigh. The weight of barium sulphate obtained corresponds to 6.16 per cent. of ammonium sulphate.

Weigh from 0.5 to 1 Gm. of hirathiol into a Kjeldahl flask, add 30 Cc. of water and 5 Gm. of potassium chlorate followed by 30 Cc. of nitric acid, and evaporate the mixture to about 5 Cc.; add 25 Cc. of hydrochloric acid and evaporate to 5 Cc.; again add 25 Cc. of hydrochloric acid and evaporate to 5 Cc. Then add 100 Cc. of water, heat to boiling and add 10 Cc. of barium chloride test solution, allow the mixture to stand for twenty-four hours, collect the precipitate of barium sulphate, heat and weigh. The weight of barium sulphate corresponds to 10.23 per cent. of total sulphur.

Calculate the ammonia obtained in the ammonium sulphate, as previously determined in hirathiol, and subtract the result from "total ammonia" as previously determined. Multiply the remainder by the factor 1.88. The result represents the sulphur present as "sulphonic sulphur." Calculate the sulphur contained in the ammonium sulphate as previously determined in hirathiol, and subtract the result from "total sulphur" as previously determined. The remainder (8.74 per cent.) represents the sulphur present in the organic, sulphonic acids contained in the substance. Subtract the "sulphonic sulphur" as previously calculated, from the sulphur in the organic acids, as previously calculated. The remainder corresponds to 5.73 per cent. of organic ("sulphide") sulphur. Hirathiol is incompatible with acids, saline solutions, and fixed alkalis.

**MEDICINAL FOODS** (see New and Nonofficial Remedies, 1919, p. 165).

**SOY BEAN GRUEL FLOUR.**—A flour prepared from the soy bean having approximately the following composition: protein, 44; fat, 20; sucrose, 10; ash, 4.3; fiber, 2; water, 4.6.

*Actions and Uses.*—Soy bean gruel flour may be used for preparing muffins. It is indicated in cases in which a diet relatively free from carbohydrates is desired, as in diabetes, amyloceous dyspepsia, etc. It has also been suggested for use in the diet in obesity. The nutritive value of 500 Gm. of this flour corresponds approximately to 2,027 calories, of which 902 calories are due to protein, 205 calories to carbohydrate, and 920 calories to fat.

Manufactured by the Cereco Company, Tappan, N. Y. No U. S. patent or trademark.

Soy bean gruel flour is made from soy bean with the removal of as much of the hull as is practicable.

Heat glass rod to serve as substitute for suppository treatment.

## THE LACTOSE CONTENT OF HUMAN MILK

Investigators of the alimentary disturbances of infants cannot succeed completely in interpreting their problems until they know something about the comparative composition of the intake of food and of the output of fecal residues in the cases with which they are concerned. Regarding cow's milk and the various feeding mixtures that have been concocted for pediatric practice, it is not difficult to secure dependable information. Such foods for the period of infancy have become standardized, so to speak, with the result that the physician who has occasion either to prescribe them or to judge of some result attributable to the ration used can gain a fairly accurate estimate of their food values in terms of the proximate principles.

The composition of human milk has heretofore not seemed to be equally certain. Enough analyses have been reported to show an unexpectedly large range of variation for fat and also some for protein. Although the average fat content of breast milk approximates from 3 to 4 per cent., maxima and minima of 9 per cent. and 1.5 per cent., respectively, have been recorded by dependable analysts. Talbot<sup>1</sup> reported that the percentage of fat depends more on how completely the breasts are drained and the amount of late milk which gets into the sample than on the stage of lactation. This illustrates the analytic difficulties involved in the study of the composition of human milk, and consequently the uncertainty as to the responsible factor to which digestive disturbances following the use of this food may be chargeable.

Until recently these uncertainties of composition have, perhaps, been greater in respect to the sugar in milk than for any other familiar component, owing to the unsatisfactory methods of analysis in vogue. At the Harvard Medical School and the Massachusetts General Hospital in Boston, Denis and Talbot<sup>2</sup> have secured enough dependable data to establish certain

fundamental facts as to lactose in human milk. The average amount of milk sugar in sixty samples was 7.2 per cent., with a general tendency for the content to increase throughout the period of lactation. It has long been known that the amount of lactose is low in colostrum; but the relative fixity of the higher figures in the later milk have not been so well realized. In the Boston samples, during the first ten weeks of lactation, two thirds of the specimens contained less than 7 per cent. lactose; whereas after the tenth week there were four times as many samples which contained between 7 and 8 per cent. as there were samples that contained less than 7 per cent., and many others which contained more than 8 per cent. of lactose. Since the weakest milk in these numerous samples, after the colostrum period, contained 5.5 per cent. of lactose, and the richest 8.35 per cent., the contrast between human milk and cow's milk in respect to their sugar content becomes emphasized once more. The sugar in cow's milk rarely exceeds 5 per cent.

## THE FACTORS INVOLVED IN CYANOSIS

Like several other signs of deviation from the normal, cyanosis has long been a familiar symptom meriting recognition from the physician, notably in diseases of the circulatory and respiratory systems. The bluish color of the skin and mucous membranes is by no means always manifest when respiration becomes impaired. Thus, in the coma of diabetes there may be asphyxial conditions without cyanosis. Strangely enough, despite the frequency with which this striking sign is observed in clinical experience, there has been no convincing and tenable explanation of precisely how cyanosis originates. Anatomic changes in the capillaries cannot be held to explain the characteristic changes in color. The production of blood pigments like methemoglobin having an unusual color has been postulated as a possible cause of cyanosis, particularly the so-called enterogenous cyanosis in which products of intestinal putrefaction have been held responsible for the alteration of the blood pigments.<sup>1</sup> Even if this doubtful reaction occurs it can at best account for relatively few cases in which the cyanotic symptoms are observed.

The most probable explanation of the blueness of the skin has seemed to lie in the amount of reduced hemoglobin present in the peripheral circulation. The precise factors implicated in cyanosis seem at length to have been definitely established by the careful researches of Lundsgaard<sup>2</sup> in the medical clinic of the University of Copenhagen. They demonstrate that abnormally high oxygen unsaturation of the blood in the peripheral capillaries is a cause of cyanosis.

<sup>2</sup> Denis, W., and Talbot, F. B.: A Study of the Lactose, Fat and Protein Content of Woman's Milk, *Am. J. Dis. Child.* **18**: 93 (Aug.) 1919.

<sup>1</sup> Wells, H. G.: Chemical Pathology, Philadelphia, 1918, p. 580.

<sup>2</sup> Lundsgaard, C.: Studies of Cyanosis, I, Primary Causes of Cyanosis, *J. Exper. Med.* **30**: 259 (Sept. 1) 1919; II, Secondary Causes of Cyanosis, *ibid.*, p. 271.

Despite this, however, no proportionality exists between the intensity of the blue and the amount of reduced hemoglobin. This, Lundsgaard says, may in small part be due to individual peculiarities of the skin and the subcutaneous tissue, which are known to influence in anemia the relation between paleness of the skin and the decrease in hemoglobin.

According to Lundsgaard's recent investigations, when the mean capillary oxygen unsaturation, which is calculated as the mean between venous and arterial unsaturation and is normally about 2 to 3 per cent. by volume, is increased to about 6 to 7 per cent., cyanosis appears. For this reason 6 or 7 per cent. may be called the threshold value of mean capillary oxygen unsaturation for the incidence of cyanosis. However, if the blood is completely saturated with oxygen in the lungs, the oxygen unsaturation of the venous blood may increase to 13 or 14 per cent. before cyanosis appears.

As might be expected, the change in the color of the venous blood due to oxygen unsaturation may arise in various regions of the body. In any event, the appearance of cyanosis will depend on the degree to which the venous blood happens to be oxygenated when it reaches the place at which unsaturation takes place and also on the vigor of the reduction proceeding therein. The increased oxygen unsaturation may, furthermore, be brought about either by an increased reduction of oxyhemoglobin to reduced hemoglobin in the peripheral capillaries or by an incomplete oxidation of the venous blood in the lungs. For example, abnormally great reduction during passage through the capillaries occurs during exercise, or when the blood flow is retarded, as in decompensated heart conditions. The other condition—incomplete oxidation in the lungs—may occur in certain maladies of the lungs and heart, and likewise when the alveolar oxygen tension is greatly decreased, as at high altitudes.

Obviously there must necessarily be a certain minimum of hemoglobin in the blood for cyanosis to result; for, as Lundsgaard points out, patients suffering from anemia in extreme degree cannot turn cyanotic. According to him cyanosis cannot be produced when the blood pigment is reduced to the point at which the oxygen capacity is below 6.5 per cent. by volume.

The bluish color arising under the conditions just discussed should be clearly distinguished with respect to its genesis from abnormal skin color associated with an increase above the normal number of red corpuscles in the circulation. Such a polycythemia or erythremia may be encountered at high altitudes and in certain forms of heart disease. The oxygen unsaturation in such cases does not exceed normal values. Usually the color of the skin is more reddish than blue, suggesting congestion or ruddiness rather than cyanosis; in fact, the oxygen content of the venous blood is likely to be greater even than that found in normal persons. Although the color of the skin in polycythe-

mic patients has been described as "cyanotic," it will be preferable, now that its underlying distinction from cyanosis is clearly understood, to follow Lundsgaard's suggestion<sup>3</sup> henceforth to designate the condition by the name erythrosis, or false cyanosis.

#### BACTERIA AND VITAMINS

The demonstration that the nutritive welfare of the higher animals is dependent on an adequate supply not only of the familiar foodstuffs but also of certain as yet unidentified "food accessories," the so-called vitamins, has been stimulating in various fields of biologic science. The hypothesis of the rôle of vitamins in nutrition has been transferred to the growth of plants by Bottomley<sup>4</sup> with results that speak strongly for an analogy between plants and animals with respect to the promoting factors. Subsequently the possible part that may be played by substances analogous in function to the vitamins of animal nutrition has been debated with respect to the multiplication of bacteria.

Bacteriologists have long recognized the difficulties attending the production of cultures of micro-organisms on synthetic mediums prepared from purified substances. Blood serum, tissue extracts and decoctions and other mixtures of largely unknown chemical make-up have been employed by preference as culture mediums for bacteria. For a long time the necessity of supplying such tissue products was assumed to be attributable to the fact that the lowest forms of life can attack only a limited group of fairly simple compounds. The native proteins, for example, are singularly resistant to direct disintegration by bacteria; whereas the cleavage products of proteins, the amino-acids, form an excellent nitrogenous pabulum for microbial nutrition. Lately, however, it has become apparent that mixtures of even such simple nutrient fragments as amino-acids, sugars and inorganic salts, in mixtures of suitable reaction are poor culture mediums. To earlier evidences of the need of something more in the successful cultivation of bacteria, particularly the more delicate pathogenic varieties,<sup>5</sup> further testimony has been added in the case of the diphtheria organism by Davis and Ferry<sup>6</sup> of Detroit. They found that it could not be cultivated in synthetic mediums composed of amino-acids and mineral salts adjusted to the optimal hydrogen-ion concentration. Addition of the extractives creatin and creatinin, and the purin bases xanthin and

hypoxanthum, was of no advantage. Typical luxuriant growth of *Bacterium diphtheriae* was obtained in a mixture of 99.5 per cent. of synthetic medium and only 0.5 per cent. of bouillon. Production of active toxin, however, required the presence of 10 per cent. bouillon. "Peptone" permitted only deficient growth and toxin formation. Davis and Ferry believe that such observations suggest a vitamin requirement, furnished in these cases by the beef infusion, not only for the luxuriant growth of the diphtheria bacillus but also particularly for strong toxin production. Incidentally, they believe that the results obtained favor the view that diphtheria toxin is not a synthetic product but rather "a catabolic substance elaborated by *Bacterium diphtheriae* only in the presence of certain amino-acids and accessory factors, the latter probably of a vitamin character."

Kligler<sup>7</sup> has recently noted, in studies made at the Rockefeller Institute for Medical Research, that the growth of a large number of pathogenic bacteria, including the streptococcus, pneumococcus and meningococcus, is favorably influenced by the addition of small amounts of tissue extracts. Beef heart, rabbit and cat tissues, and human nasal secretions contain substances favorable to the growth of the organisms tested. The mucosa of different organs, spleen, liver and kidney, are relatively rich in these substances, while muscle is relatively poor. The favorable effect of the extracts is manifested by an enhancement of growth and a reduction of lag. Neither the extracts alone nor the culture medium alone was capable of supporting bacterial growth suitably. Kligler interprets his results as evidence that the facilitating substances belong to the category of the vitamins; and since ether extracts are without the potency referred to, the conclusion is further offered that the vitamins favorable for bacterial development belong to the water-soluble rather than to the fat-soluble type.

#### "COLLOSOLS": AN UNCRITICAL ENGLISH ENDORSEMENT

Under the auspices of the British Association for the Advancement of Science, there has just appeared a report on the present status of colloid chemistry.<sup>8</sup> The work has been recognized as sufficiently important to receive the endorsement of the government Department of Scientific and Industrial Research. Of particular interest to physicians is the chapter on "Administration of Colloids in Disease" written by Alfred B. Searle, "consulting chemist, Sheffield." After a somewhat academic generalization of colloidal drugs, the "thesis" is devoted largely to the "Colloids"—proprietary preparations made by the Crookes Laboratories. The "scientific" evidence presented by Searle for col-

loids in medicine reads as if the advertising literature of the Crookes concern had been considered ample source of information. Thus: "Colloidal Manganese," besides having been "used with remarkable and surprising results in the treatment of cocceogenic skin diseases, . . . gives excellent results [in impetigo, chronic scorrhic eczema and acute folliculitis] when employed in conjunction with intramine"! The grave danger of the intramine therapy has been known for more than two years both here and abroad,<sup>9</sup> in fact, one author stated that in cases of intramine injections, "the pain is undiluted torture." In a style as bombastic and verbose as the usual house-organ write-up, the report recklessly details all sorts of conditions in which so-called colloids—and particularly the "Collosol" brand—have been recommended, but derogatory findings are conspicuous by their omission. Even Sir Malcolm Morris is quoted as lending his name (and title) to the endorsement of "Collosols."

In the United States the medical profession has created a means whereby physicians need not be misled by such "high" authorities as evidently has been the case with our English confrères. Once more the value of the Council on Pharmacy and Chemistry is strikingly manifested. What are the facts about "Collosols"? The Council has reported that a number of the "Collosol" preparations were not colloids at all, and "if . . . injected intravenously as directed, death might result, making the physician morally if not legally liable";<sup>10</sup> that in the cases in which the therapeutic claims were examined, the claims were found to be either exceedingly improbable or exaggerated; furthermore, that the A. M. A. Chemical Laboratory found "Collosol Cocaine," on analysis, to contain only 40 per cent. of the claimed amount of cocaine.<sup>11</sup>

Such are the findings which have been presented to the American physician. But the British physician is now being made the object of an intensive advertising campaign for "Collosols," based in part on an uncritical, pseudogovernmental endorsement. Just so long as the English profession will not protect itself by creating a competent board to examine and judge proprietary medicines and to control methods of exploitation, just so long will such extravagant and even cruelly misleading claims continue to impede scientific progress in therapeutics.

## Current Comment

### PATENTING THERAPEUTIC AGENTS

In the past, therapeutic agents and apparatus have been controlled by patents and trade-marks for profit. If there have been exceptions, they have been rare. The Principles of Medical Ethics of the American Medical Association contain this statement: "It is unprofessional to receive remuneration from patents for surgical instruments or medicines." This does not mean that the patenting is wrong in itself; there are occasions when it is wise, if not necessary, to obtain a patent in the interest of the public and, in the case of surgical instruments and medicines, of the medical profession. In certain instances it is absolutely necessary that the article produced shall maintain a definite standard of quality and purity—and, it may be added, shall be sold at a reasonable price. Enterprising pharmaceutical manufacturers have usually been ready to appropriate the results of scientific research by investigators or therapeutic measures suggested by practicing physicians. Not infrequently, in such instances, the desire for financial gain has caused the marketing of such products with extravagance, if not false, claims as to their value. Yet the patent laws may be used so as to protect and benefit the public and the medical profession. In research laboratories, work is being carried on resulting in the production of new therapeutic agents. It is important that these agents shall be so controlled that they may be made available without subordination to commercial interests. It has become practically necessary, therefore, for research workers to protect their products in the interest of the public welfare and scientific medicine. It has not been an easy matter to decide how best to bring about the desired results. This question has been before the Board of Trustees of the American Medical Association, and in 1914 the House of Delegates passed a resolution authorizing the board to accept at its discretion, patents for medical and surgical instruments and appliances, as trustees, for the benefit of the profession and the public, provided that neither the Association nor the patentee should receive remuneration from these patents. The Rockefeller Institute for Medical Research has solved the problem in a similar manner. In connection with the report of the discovery of several new arsenic compounds, Jacobs and Heidelberger,<sup>1</sup> working in the Rockefeller Institute, say:

It may be appropriate to mention here that this substance and related compounds, described in the present and following papers of the series, are covered by U. S. Patents Nos. 1,280,119-27. Patents have also been applied for in foreign countries. All discoveries made at the Rockefeller Institute are made freely available to the public, in accordance with the philanthropic purposes of the institution. In order to insure purity of product and protection against exploitation, it has been deemed necessary in certain instances to protect the discoveries by patents. It is the purpose of the institute to permit any drugs which may prove of practical thera-

peutic value to be manufactured under license by suitable chemical firms and under conditions of production which will insure the biological qualities of the drugs and their marketing at reasonable prices. Other than through the issuance of license, the Rockefeller Institute does not participate in any way in the commercial preparation or sale of the manufactured chemicals; and it receives no royalties or other pecuniary benefits from the licenses it issues.

Here we have medicine at its best. The altruism of pure science operating for the benefit of the general public; scientific therapeutics freed from commercial domination.

### VARIETY OF DIET IN THE ARMY

To many persons the dread of a monotonous, unvaried diet represents one of the supposed unpleasantnesses of army life. It is assumed by them that only a slightly varied routine of simple foods is the customary, if not the essential, feature of the dietary of troops. Monotony and limited range of food combinations are traditional accompaniments of institutional management which have all too often been the subject of criticism from "humanitarian" investigators. There have doubtless been times, as there still are places, in which consideration of the regimen of persons with restricted liberty has been unfortunately neglected. Today, ignorance can no longer serve as a valid excuse. In the light of present day knowledge of nutrition, disregard of the relation of diet to human welfare can only be ascribed to indifference. "How about the army?" it may be asked. "Are not the paramount needs of drill and equipment, of marches and battle, allowed to relegate dietary niceties to desuetude?" Once upon a time the answer might have been, "Yes"; but the statistics now published by the Section of Food and Nutrition in the Medical Department of the U. S. Army give a different reply with respect to our army camps in 1917-1918. According to dietary studies made by the Bureau of Markets in Washington in 1917, thirty-nine different articles enter into the weekly food inventory for the average family. A study of 390 army messes,<sup>2</sup> however, indicated that the average number of articles used per mess per week was about fifty-five. For organizations on the march, when difficulties of preparation and transportation of food demanded a simpler menu, the number of articles used per mess for a three-day period was sixteen. A popular treatise on nutrition<sup>2</sup> reminds us that the human being exhibits two psychologic tendencies in his diet—one, to stand by old favorites; the other, to demand variety from day to day. Hence the diet that suits best usually consists of staples along with variables. Variety was formerly acclaimed solely as a mode of escaping monotony of diet; today it is recognized as a factor of safety in avoiding the danger of a lack of some essential to nutritive well-being. The successful menu maker strives to recognize both the love and the possible need of variety, without catering to it alone.

## QUININ AND QUITENIN IN MALARIA

There still seems to be uncertainty among pharmacologists regarding the fate of quinin in the body. While one writer presents evidence that only one third to one fourth of quinin administered is slowly recovered in the excreta,<sup>1</sup> others assert that quinin usually begins to appear in the urine shortly after its administration, and that almost the entire amount may be excreted within two days.<sup>2</sup> Investigators at the Liverpool School of Tropical Medicine have noted the power of tissues removed from the body and of tissue extracts to destroy the alkaloid.<sup>3</sup> The active agent is thermolabile and exhibits the property of an enzyme. The liver, kidney, muscle, intestinal wall, and probably the pancreas have considerable power to destroy quinin postmortem, whereas little or no action has been observed with the blood, spleen, bone marrow and divers glands. It is an unsafe conclusion to assert on the basis of such findings that the body tissues also destroy quinin in vivo. However, certain facts bearing on the theory of quinin therapy in malaria have already developed from the Liverpool studies. One product of the action of liver tissue on quinin is now demonstrated to be quitenin, a long known oxidation derivative of quinin. This compound has been reported to appear in the urine after the use of quinin. To test the hypothesis that quitenin may represent the derivative of quinin directly responsible for the relief of malarial rigors, large doses were given to a suitable patient. The substance was entirely ineffective,<sup>4</sup> and seems to be broken up into inert compounds, since little if any could be recovered in the urine. The quitenin hypothesis may therefore be abandoned so long as no further indications of its rôle are forthcoming.

## ULTRAVIOLET RAYS AND VITAMINS

Although the effects of ultraviolet light on the organisms have as yet received all too little investigation, there is no doubt that these invisible light rays have more action on protoplasm than the visible light does. The familiar inflammation exhibited in sunburn (erythema solare) is an illustration of what ultraviolet light can bring about. This effect on the skin is not due to heat, but presumably to the products of some photochemical reaction set up in the arterioles. There is something almost subtle in the manifestations of the nonvisible rays. For example, diphtheria toxin is readily destroyed by them, although it is not so easy to render the antitoxin inert. Various enzymes have also been shown to become inert through the action of ultraviolet light. Recently the influence of this agent on certain types of products containing vitamins has been investigated by Zilva<sup>5</sup> at the Lister Institute for

Preventive Medicine in London. He found that butter exposed for eight hours to ultraviolet light undergoes a very noticeable change, the fat-soluble vitamin therein becoming inactivated. However, the antineuritic potency of yeast extracts and the antiscorbutic properties of lemon juice are not lost by such exposure. Zilva calls attention to the fact, noted by others, that the sterilization of milk by means of ultraviolet rays imparts to the milk a peculiar taste. He ascribes this to alterations in the butter fat brought about by the exposure. In view of the deterioration of the fat-soluble vitamin it seems likely that the action of ultraviolet light on milk may impair its nutritive value for infant feeding.

## Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

## ALABAMA

**Home Provided for Mental Inferiors.**—The legislature of Alabama at its recent session passed a bill providing for the establishment of a home at Tuscaloosa, for mental inferiors. The campaign which resulted in this bill was led by Drs. Thomas H. Haines and William D. Partlow.

**Sanitary Laws Enacted by Legislature.**—In a bill introduced in the legislature by Representative Cobbs, the promotion of public health by leveling, ditching and draining the swamp lands of the state, was provided. This bill was made a law, September 25.—A bill providing for strict regulation of hotels, cafés, restaurants and eating places was introduced by Representative McLeon in the house and has been enacted into law by the senate.—The house of representatives has increased the appropriation for public health from \$25,000 a year to \$250,000 for four years.

## ARKANSAS

**Typhoid Survey.**—Dr. R. Eugene Dyer, Little Rock, epidemiologist, U. S. P. H. S., has been sent to assist the state health officer in making a typhoid survey and other investigations of epidemic diseases.

**Held by Health Board.**—At present thirteen women are held in quarantine at the Sebastian County Hospital, Fort Smith, on account of venereal disease, while twenty-five others are under private medical treatment and under parole.

**Personal.**—Dr. John R. Dale, Texarkana, was run down and seriously injured by an autotruck, September 25.—Dr. John Thames, recently health officer of Little Rock, has taken over the U. S. P. H. S. work in that locality.—E. H. White, for eight years principal of the North Little Rock High School, has accepted the professorship of microscopy in the medical department of the University of Arkansas, Little Rock.

**State Venereal Clinic.**—At a meeting held in Little Rock, September 26, plans were discussed for a state clinic for the treatment of venereal disease. It was proposed that the Women's Reformatory and the Girl's Industrial School should each give \$2,500, and that the city should also contribute a share. Dr. Charles W. Garrison, state health officer, Little Rock, said that the state would pay \$1.50 per day toward the board and maintenance of each patient. It is expected that a building will be erected without delay.

## CALIFORNIA

**Tuberculosis Conference.**—A joint meeting of the Los Angeles County Medical Association with the Southwestern Tuberculosis Conference was held at Long Beach, October 1 to 3.

**Lane Medical Lectures.**—The Lane medical lectures will be delivered by Dr. Alonzo E. Taylor, professor of physiologic chemistry in the University of Pennsylvania, and will

1. Greer, C. W.: *Handbook of Pharmacology*, New York, 1914, p. 229.

2. Hatcher, R. A., and Wilbert, M. J.: *The Pharmacology of Useful Drugs*, Chicago, American Medical Association, 1915, p. 78.

3. Lipkin, I. I.: On the Distribution and Destruction of Quinine in Animal Tissues, *Ann. Trop. M. & Parasitol.*, **12**: 149 (July 31) 1919.

4. Lipkin, I. J. (Footnote 3), Stephens, Yorke, Blacklock, Macfie and O'Farrell: Studies in the Treatment of Malaria, XXVIII, Quitenin Hydrochloride in Simple Tertian Malaria, *Ann. Trop. M. & Parasitol.*, **12**: 117 (July 31) 1919.

5. Zilva, S. S.: The Action of Ultraviolet Rays on the Accessory Food Factors, *Biochem. J.*, **13**: 164 (July) 1919.

he on the topic, "Feeding of the Nations at War." The lectures will take place at Lane Hall, San Francisco, on the evenings of December 8 to 12, inclusive, under the auspices of the Leland Stanford Junior University School of Medicine.

**Emergency Physicians Needed.**—The secretary and executive officer of the California State Board of Health has issued a circular letter stating that the board would appreciate receiving the names of any physicians who, in the event of the return of the epidemic of influenza, would be willing to serve in emergencies in various parts of the state, at a salary of \$200 a month, with \$4 per day for subsistence and traveling expenses.

**Ungraded Rooms in City Schools.**—A bulletin has been published by the division of psychology of the Los Angeles city school district, and devoted to ungraded rooms. Part 2 describes the handling of feebleminded children in special schools, and Part 3 describes a plan of operation from which good results are said to be obtained in the advancing of mental ability as well as the borderline and backward cases. Mr. A. H. Sutherland, chief of the division, 419 South Olive Street, Los Angeles, will be glad to send to interested individuals copies of this bulletin, so long as they are available.

#### COLORADO

**Personal.**—Dr. Charles C. Reid, Denver, was elected first vice president at the meeting of the International Association of Lions Club, held in Chicago.—Dr. Rodney Wren, Trinidad, has been made chairman of the free clinic, which has recently been established in Trinidad.

**Denver County Physicians in Service.**—Out of a total membership of 378 during the war period, the Denver County Medical Society sent into the service ninety-six members, or 25.4 per cent. Of these, all but fifteen have returned, some of whom are on duty at U. S. General Hospital No. 21, Aurora. The only death in service was that of Lieut. Raymond E. Peblner, who died from pneumonia following influenza, October, 1918.

#### CONNECTICUT

**Personal.**—Dr. David R. Lyman, New Haven, superintendent of the Gaylord Farm Tuberculosis Sanatorium, has started for France, where he will attend the International Tuberculosis Conference as a representative of the National Association for the Study and Prevention of Tuberculosis.

**Anniversary of Sanatorium.**—In observance of the fiftieth birthday anniversary of the Gaylord Farm Sanatorium, the New Haven County Medical Association held its 135th semiannual meeting at the institution, October 1. Among the important papers presented were the presidential address by Dr. David R. Lyman, New Haven, who is superintendent of the Gaylord Farm Sanatorium, and addresses by Thomas R. Darlington, on "Industrial Medicine," and Dr. Edward R. Baldwin, Saranac Lake, N. Y., on "The Differential Diagnosis of Lung Conditions Usually Confounded with Tuberculosis."

#### DISTRICT OF COLUMBIA

**Building for Physicians.**—A modern office building is to be erected at Vermont and I. Streets, Washington, for the exclusive use of physicians. It will be known as the Ansherry Building, will be eleven stories in height, and will be thoroughly equipped with laboratories and other appliances necessary for the use of professional men.

**Personal.**—Dr. J. Breckinridge Bayne, who did such efficient work in the typhus epidemic in southern Roumania during the German occupation period of 1917-1918, and who was decorated by King Ferdinand, has again been decorated by being recipient of the Order of the Regina Maria, First Class. Dr. Bayne now has charge of three American Red Cross hospitals at Cojascu, Titu and Voineshti, Roumania.

#### FLORIDA

**Christmas Seal Campaign.**—The executive committee of the Florida Anti-Tuberculosis Association, at a meeting held recently in Jacksonville, arranged plans for the nation-wide campaign to be inaugurated in December. The quota for Florida is \$50,000. The state had been divided into zones, with Miami, Tampa, Jacksonville and Pensacola as headquarters of the respective districts. Dr. Louis A. Bize, Tampa, is zone chairman.

**Work of State Health Board.**—Dr. Ralph N. Greene, Chattahoochee, state health officer of Florida, has sent out

circular letters to physicians advising them of what has been accomplished by the board and inviting them to make free use of the machinery provided by the board for the benefit of the public health of the state. There are five diagnostic laboratories at Jacksonville, Tampa, Pensacola, Miami and Tallahassee, at which examinations are made, with the exception of serologic tests for syphilis and gonorrhea, which are made only at Jacksonville and Tampa. During 1918, 17,423 specimens were examined in the central laboratory, Jacksonville; 7,792 in the Tampa laboratory; 2,750 in the Pensacola laboratory, and 2,565 in the Miami laboratory. The report also describes the work of the orthopedic service, and of the sanitary engineering, vital statistics, and child welfare departments of the state board.

#### ILLINOIS

**Building for Physicians.**—A building for the exclusive use of physicians is to be erected in Rockford by J. Frank Deuel. It will cost about \$15,000 and will be equipped with a medical library, drug and medical supply rooms, and garage accommodations.

**Sanatorium for Livingston County.**—At a recent meeting of the board of supervisors of Livingston County, a tax levy of \$60,000 was voted to be used for the erection of a tuberculosis sanatorium. There is also available for this purpose \$20,000 previously collected. A site has been purchased south of Pontiac, and work will start early next spring. The institution will accommodate thirty patients.

#### Chicago

**Practical Nursing Class.**—The second class in practical and home nursing conducted by the Chicago Department of Health, which opened October 6, had an enrollment of 1,500 women.

**Personal.**—Dr. Rudolph J. E. Oden, who has recently returned from Cadillac, Mich., has been appointed attending surgeon to Augustana Hospital, and consulting surgeon to U. S. P. H. S. Hospital No. 2.—Dr. Roscoe C. Eaton has been discharged from the military service and has been appointed chief surgeon for Libby, McNeill and Libby.

**Northwestern University's Plans for Medical Education.**—Northwestern University has secured an option on 9 acres of land on the lake front at Chicago Avenue on which it is planned to erect within ten years buildings for its departments of medicine, dentistry, law and commerce, these buildings to cost approximately \$1,350,000. It is expected eventually that on the medical school alone \$2,500,000 will be expended. To carry out these plans the university has begun a campaign to raise \$25,000,000, half of which it is expected will be obtained by June, 1920.

**Faculty Changes.**—The Loyola University School of Medicine, Chicago, announces the following changes in its faculty: Dr. Louis D. Moorhead, Chicago, has been appointed acting dean; Dr. Sarned A. Matthews, Mobile, formerly professor and head of the department of physiology and pharmacology at the University of Alabama, has accepted a similar position at Loyola; Dr. Andrew C. Ivy of the University of Chicago has been appointed associate professor of physiology; Dr. Elmer S. Maxwell, formerly of Vanderbilt University, Nashville, Tenn., has been appointed assistant professor of bacteriology; Dr. Frank M. Phifer, Chicago, has been appointed professor and acting head of the department of genitourinary surgery, and Dr. Frank B. Lusk, Chicago, becomes supervisor of medical instruction in the dispensary.

#### MARYLAND

**Corps of Physicians Organized for Influenza Emergency.**—At the request of the United States Public Health Service, a corps of physicians for service in the event of a return of the influenza epidemic is being organized by Health Commissioner C. Hampton Jones. The corps will comprise 100 men who will be paid by the federal government. No serious outbreak is expected, but the Public Health Service wants to be prepared for any emergency.

**Personal.** Col. Henry Page and the staff at U. S. Army General Hospital No. 2, Fort McHenry, entertained the base hospital units of the Johns Hopkins Hospital and the University of Maryland, October 8. Luncheon was served and an inspection of the hospital was made.—Dr. Erik Waller of Landskoping, Sweden, is in Baltimore studying the methods employed at the Johns Hopkins Hospital and other local institutions.—Dr. Adolf Meyer, director of the Henry

Phipps Psychiatric Clinic, Johns Hopkins Hospital, who was recently injured in New York when a wagon ran over and crushed his foot, is able to deliver his lectures to the medical students.

**Influx of Patients at Fort McHenry.**—More than 500 patients have been admitted at U. S. Army General Hospital No. 2, Fort McHenry, in the past five days and Colonel Page states that this entails the heaviest surgical work the hospital has yet had. The majority of the men came from Colonia, N. J., and Williamsbridge, N. Y., where general hospitals have been abandoned, and from the base hospital at Hoboken, where many serious cases were taken on their return from France. Sixty of the patients were carried in on litters. Many will have to undergo operations. Nearly all of them are "long-time" ones and will remain at the fort for months. Some of the patients have already been in hospitals for a year and a half.

**Quarantine to Fort McHenry.**—As a result of a change of arrangements, the new quarantine boat, the *Neptune*, is now docked at a pier at Fort McHenry, and the quarantine inspector's office has been moved from the old Quarantine Building at Hawkins Point, opposite Fort Carroll, to a room in the Administration Building at Fort McHenry. The old quarantine station will not be used except for patients. Dr. Thomas L. Richardson, Baltimore, acting assistant surgeon of the U. S. Public Health Service, is in charge of the quarantine work. He has been connected with the quarantine service thirteen years, since it was taken over from the civic authorities and conducted by the federal authorities. He reports that the health conditions aboard vessels entering the port are very good.

#### NEW JERSEY

**Physicians Form Association.**—About fifty physician in the Clinton Hill section of Newark recently organized the Newark Physicians' Association to abolish contract and lodge practice. Dr. Bernhardt H. Woolf was elected president of the association.

**Personal.**—Clarence W. Way, Major, M. C., U. S. Army, Sea Isle City, who has been on duty in France since March, 1917, and is at present chief of the medical service at U. S. Army Camp Hospital No. 21, Autiel, Paris, has been ordered to Warsaw, Poland, to make a study of medical and sanitary problems of the Polish republic, and expects to remain in Poland for about six months.—Dr. Daniel Russell Hodgdon, head of the Newark College of Technology, has been elected president of the Hahnemann Medical College and Hospital, Chicago.

#### NEW YORK

**Cornell University Staff Changes.**—The Cornell University Medical College opened its twenty-second session, September 29. The annual address to the students was delivered by Dr. Graham Lusk, professor of physiology. The college announces the following appointments to the medical faculty in New York City: Drs. E. F. DuBois, assistant professor of medicine; Oscar M. Schloss, professor of clinical medicine, department of pediatrics; Henry H. M. Lyle, assistant professor of surgery; Jeremiah S. Ferguson, assistant professor of clinical medicine, department of pediatrics; Nellis B. Foster, assistant professor of medicine and associate attending physician to New York Hospital; John C. A. Gerster, assistant professor of clinical surgery; Charles V. Morrill and Robert Chambers, assistant professors of anatomy.

#### New York City

**Plan to Enlarge Hospital.**—Plans have been drawn up for the enlargement of the Kosher Hospital, Brooklyn, by an addition to the present hospital building which will give the institution 150 beds.

**Harvey Society Lectures.**—The second lecture of the Harvey Society series will be delivered by Dr. H. H. Dale of the Lister Institute of Preventive Medicine, on "Shock," at the New York Academy of Medicine, October 23, at 8:30 p. m.

**Society of Medical Jurisprudence Meets.**—This organization held the first meeting of the season at the New York Academy of Medicine, October 13. The paper of the evening was on "Selective Service and the Physician" by Dr. Victor C. Pedersen.

**Hospital Installs Group Practice.**—The Long Island College Hospital has installed a system of group practice whereby patients, by the payment of an ordinary fee, and in many cases without paying any fee, may have the benefit of

consultation with experts in various specialties of medicine and surgery. Dean Otto Huffman announces that the members of the dispensary staff will meet daily as a diagnostic board to receive cases referred to them by any alumnus of the hospital. For the present this service will be extended only to the alumni of the hospital.

**Personal.**—Dr. George E. Brewer has sailed for France, at the request of the Surgeon-General, as a representative of the United States at the interallied congress of surgeons shortly to convene in Paris. He will return to New York about the middle of November.—Dr. and Mrs. Charles Kohly of Cuba are spending a month in New York.—Dr. Caroline S. Finley, director of Unit No. 1 of the Women's Overseas Hospitals, has returned to this country.—Dr. Marie Louise Lafort, director of Unit No. 3 of the Women's Overseas Hospitals, has returned to France to take charge of the American Memorial Hospital, which the American Fund for French Wounded is establishing in Rheims.

#### PENNSYLVANIA

**Railroads to Aid Safety Fight.**—Following conferences between the state public service commission and officers of the Pennsylvania and Reading railroads, announcement was made, October 9, that danger signs, to warn automobilists and others of unprotected railroad crossings, are to be furnished free of charge by both railroads, to municipalities, counties and townships throughout the state in which such unprotected crossings exist. Other railroads are expected to make similar agreements. These conferences followed a recent investigation conducted by the public service commission to determine the number of deaths and accidents at railroad crossings. There are 11,738 grade crossings in Pennsylvania of which 9,773 are unprotected and 68 per cent. of all persons killed at crossings are killed at these unprotected ones.

#### Philadelphia

**Hospital Drive.**—The million dollar campaign for the University of Pennsylvania Hospital totaled \$370,164, October 11.

**Medical Club Meeting.**—The Medical Club of Philadelphia will hold a reception in honor of the Hon. William C. Sproul, governor of the state of Pennsylvania, Friday evening, October 17, at the Bellevue-Stratford. Just prior to the reception the regular meeting for nominations will be held.

**Personal.**—Dr. Charles J. Hatfield, executive director of the Phipps Institute and head of the Southeastern Pennsylvania chapter of the American Red Cross, sailed, October 9, to participate in a conference in London, October 16, 17 and 18, to arrange means to combat the spread of tuberculosis in the war ravished regions of Europe.

**Aid for Hospital.**—Residents in the neighborhood of the Frederick Douglass Memorial Hospital for Colored People planned to abstain from food one day in order to contribute to the hospital's campaign fund, October 11. Under the leadership of fourteen physicians, volunteer workers went into every section of the city to receive contributions for the hospital.

**Tuberculosis Conference.**—The North Atlantic Tuberculosis Conference was held, October 9 and 10, in the Bellevue-Stratford, and was one of the five like gatherings held throughout the United States to arouse the nation to the serious menace of disease. Three hundred and fifty delegates from the states of Pennsylvania, New Jersey, New York, Delaware, Maryland, Virginia, West Virginia and the District of Columbia, attended. This conference was held under the auspices of the National Tuberculosis Association and the Philadelphia Tuberculosis Committee.

#### WISCONSIN

**Hospital Notes.**—Health Commissioner George C. Ruhland announces that the South View Hospital, Milwaukee, is now available to physicians for diagnostic work, particularly in connection with diphtheria cases.—A tuberculosis sanatorium is to be established jointly by the counties of Menominee and Delta, in Menominee. A clinic for tuberculous patients has already been instituted.

**Personal.**—Dr. Harry Cohn, for four years acting superintendent of the Mirdale Sanatorium, Wauwatosa, and assistant medical director, has been given leave of absence for six months to organize and direct the new Milwaukee County Dispensary.—Dr. George R. Keay, LaCrosse, has resumed practice after twenty months' army service, of which

nine months were spent in France.—Dr. Frederick C. Rinker, for more than six years a member of the staff of the medical clinic of the University of Wisconsin, Madison, and chief of medical instruction of the University Extension Division, has resigned to enter private practice in Norfolk, Va.

**State Society Meets.**—The seventy-third (victory) meeting of the State Medical Society of Wisconsin was held in Milwaukee, October 1 to 3, under the presidency of Dr. Dennis J. Hayes, Milwaukee. This meeting was in honor of the 788 medical men of the state who entered the service during the world war, to welcome them home, to gain from their experiences, and to help them solve their problems. The following officers were elected: president, Dr. Charles R. Bardeen, Madison; vice presidents, Drs. Wilson Cunningham, Plattville; Henry W. K. Abraham, Appleton, and Philip F. Rogers, Milwaukee; delegate to the American Medical Association, Dr. Charles H. Lemou, Milwaukee, and alternate, Dr. Joseph F. Smith, Wausau.

#### CANADA

**Personal.**—Dr. Alexander D. Blackader, professor of pharmacology and therapeutics in McGill University, Montreal, delivered the annual address to the medical students on Founder's Day, his subject being, "Our Medical Faculty and the Value of Continued Medical Research."—Dr. Robert J. Kee, Toronto, has been acting for some months as expert to the pension board, Ottawa, in diseases of the eye, ear, nose and throat.—Major Harold Wilson, formerly of Kingston and Port Arthur, has been appointed medical advisor to the Canadian Pension Board in London, England. He served overseas with the C. A. M. C. four years.

**New Sanatoriums for Tuberculosis.**—The Canadian Association for the Prevention of Tuberculosis met in Ottawa, October 9 and 10. Dr. George D. Porter, the secretary, in presenting his annual report stated that a number of new sanatoriums had been opened in Canada during the past official year of the association. Among them was the new Laval Hospital at St. Foy, Quebec, at a cost of \$200,000; the Rosary Institute for Diseases of the Chest, at Vancouver, B. C., a large provincial institution in Alberta; a new hospital for curable patients in Montreal, and new babies' wards in the preventorium in Toronto and Saskatchewan. Dr. Porter further reported that the department of agriculture of Canada had taken important steps to guard milk from contamination and that important advances had been made by the department of soldiers' civil reestablishment in connection with the University of Toronto Research Department for the carrying out of serologic tests in both military and civilian cases.

**Dominion Health Council Summoned.**—October 7, the Hon. Newton W. Rowell summoned the new Council of Public Health for the Dominion of Canada. That board has fifteen members, composed of the chairman and chief executive officer of each provincial department or board of health in Canada, together with two women connected with women's activities, and a representative each of agriculture, academic, military and labor interests. To this National Council on Public Health the Dominion government set apart \$180,000—\$10,000 to be used for the combating of the venereal diseases—and \$1,000 to be expended by the federal department of health along the same lines. The balance of the original grant will be proportionally assigned to the provinces, to which will be added by the provincial governments similar, or equivalent, amounts. The discussions of the council took the following lines: measures against influenza; conservation of child life; industrial hygiene; rural hygiene; habit-forming drugs. On the last of these the council forwarded a recommendation to the minister of health which it is hoped will reduce the habit of drug taking to no inconsiderable degree. The new department will gather and distribute literature outlining progress made in public health matters in each province.

#### GENERAL

**To Eradicate Malaria.**—The American Anti-Malarial Association held a convention at Florence, Ala., October 15, under the chairmanship of Hon. O. W. Underwood, United States Senator from Alabama, with the purpose of launching a campaign to eradicate malaria from the southern states.

**Missouri Valley Society Election.**—At the meeting of the Missouri Valley Medical Association, in Des Moines, Iowa, September 18 and 19, the following officers were elected: Dr. Charles Ryan, Des Moines, Iowa, president; Dr. Paul

Gardner, New Hampton, Iowa, first vice president; Dr. Floyd Spencer, St. Joseph, Mo., second vice president; Dr. O. C. Gebhart, St. Joseph, Mo., treasurer, and Dr. Charles Wood Fassett, Kansas City, Mo., secretary.

**Occupational Therapy Meeting.**—The third annual meeting of the National Society for the Promotion of Occupational Therapy was held in Chicago, September 8 to 11, and the following officers were elected: president, Mrs. Eleanor Clarke Slagle of the Henry Favill School of Occupations, Chicago; vice president, Dr. Herbert J. Hall, Marblehead, Mass.; secretary, Mr. Louis J. Haas, Bloomingdale Hospital, White Plains, N. Y., and treasurer, Miss Marion R. Tabor, New York.

**Meeting of the Association of Medical Milk Commissions.**—The American Association of Medical Milk Commissions will meet in conjunction with the American Public Health Association at New Orleans, October 27 to 30. The program includes: the president's address, Dr. A. F. Furrer, Cleveland; "Production of a Safe Milk for Infants," Dr. W. H. Price; "Inspected Milk," Dr. L. R. DeBuis, New Orleans; "Human and Bovine Tuberculosis," Prof. M. P. Ravenel, Columbia, Mo.; "Dry Sterilization of Dairy Utensils," Dr. H. Moak, Brooklyn; "Changing Standards in the Production of Certified Milk," Prof. F. W. Howe, Boston, and "Present Status of Municipal Milk Control in This Country," Mr. G. B. Taylor of the U. S. Department of Agriculture. Following the scientific session will be a meeting devoted to the business of the organization.

**Prize for Research on Carcinoma of the Cervix.**—At the opening meeting of the Chicago Pathological Society, October 13, the president, Dr. Emil Ries, in lieu of a presidential address offered the following prize:

In 1896 in the first radical operation for carcinoma of the cervix by Ries certain lymph-nodes were removed on examination of which gland-like structures hitherto undescribed were discovered by him. These findings have since been confirmed and pictured by other authors. Robert Meyer claims that these structures are due to irritation of the endothelium of the lymph sinuses by infectious material absorbed from the ulcerated carcinoma.

It is desired that this claim be further investigated and the following points are tentatively suggested for examination:

1. Do all infected carcinomas produce such gland-like formations in the regional lymph-nodes? (for instance: ulcerated carcinomas of stomach, rectum, lips, breast).
2. Are closed, noninfected carcinomas ever accompanied by similar formations? (for instance: closed carcinomas of breast).
3. Do infected lymph-nodes not associated with carcinoma, as for instance with primary sclerosis, soft chancre, infected wounds of the extremities, present similar structures?
4. Can the structures be produced experimentally?

For the most satisfactory solution of this problem a prize of \$100 has been deposited with and will be paid by the treasurer of the Chicago Pathological Society on the decision of the prize committee. Prof. L. Hektoen, R. Zeit and E. R. LeCount have consented to act as a committee. The competing essays must be in the hands of the secretary, Dr. George H. Weaver, 629 South Wood Street, Chicago, by Sept. 1, 1920, bearing some number for identification. A sealed envelope bearing the same number and containing the name and address of the essayist is to be inclosed. The winning essayist will be invited to present personally the result of his investigations at the first meeting of the Pathological Society in October, 1920. If no essay is offered in competing for this prize at the expiration of the above term, the amount shall be returned to the donor.

#### FOREIGN

**Centennial of Laennec's Auscultation.**—The town of Quimper in France celebrated recently the hundredth anniversary of the publication of Laennec's first work on auscultation, the "Traité de l'auscultation médiate," by placing a wreath of palms at the foot of his statue in the public square and commemorative tablets on the house where he was born and on his tomb.

**Guide to Medical Paris.**—The Paris Medical Faculty has recently published a practical guide to medical Paris and especially to its own courses, clinics and laboratories. The *Presses Médicales* is giving away copies of this pamphlet to its subscribers on demand. It is requested that those wishing copies address *Presses Médicales*, 120 boulevard Saint-Germain, Paris. Enclose 5 cents for postage.

**Memorial to Pontoppidan.**—A memorial tablet and bust in bas relief was recently unveiled at Copenhagen at the Kommunehospital in honor of Prof. Knud Pontoppidan, whose work as a teacher, clinician and hospital administrator was

extolled. He occupied the chair of forensic medicine at the University of Copenhagen for many years, and published numerous works on nervous and mental disease and treatment. He died in 1916.

**Deaths in the Profession Abroad.**—Dr. C. E. Socin, professor of pathologic anatomy since 1917 and director of the pathologic institute of the University of Lausanne, Switzerland, died from perforation of the stomach while on a mountain climbing trip, aged 32.—Dr. J. Pfister of Lucerne, Switzerland, a well known ophthalmologist, research worker and writer on his specialty and on general subjects, aged 61.—Dr. F. Fulci of the medical faculty of the University of Catania.

**Foundation of Italian Archives of Biologic Sciences.**—The *Riforma Medica* announces that a new medical review is soon to appear, to be entitled the *Archivio di Scienze Biologiche*. Prof. F. Bottazzi of Naples is to be the editor-in-chief, assisted by ten Italian professors, including Albertoni, Galeotti, Herlitzka and Sabbatani. The *Archivio* is to be published as material accumulates, in numbers of 100 or 150 pages, and will embrace in its scope animal and plant physiology, physiologic chemistry, physical chemistry applied to biology, and experimental pharmacology and pathology.

**International Conference of Neurologists.**—The Société de Neurologie de Paris has recently decided to inaugurate an international exchange of views on neurologic questions by inviting neurologists and psychiatrists from other countries to attend a special meeting to be held annually at Paris in July. It is planned to have two days of work with two sessions each day, and some one subject is to be appointed for discussion. The first meeting it is announced will be organized in July, 1921, and the subject appointed for discussion at that time is the clinical forms and the treatment of syphilis of the nervous system. Prof. J. A. Sicard has been appointed to open the discussion.

#### LATIN AMERICA

**Sanitary Funds in Chile.**—The congress of Chile has voted an appropriation of 300,000 pesos which the president can use to eradicate infectious diseases in any part of the country.

**Railroad Sanitation in Brazil.**—There has been established in Brazil a railroad sanitation service charged with caring for all matters connected with the health and welfare of railway employees. This service will include medical and surgical treatment of the employees, and preventive measures against the diseases that prevail in the zones crossed by the railroad.

**Railroad Sanitation in Chile.**—There has been established a railroad hospital at Santiago de Chile, which will be utilized to treat the victims of railroad accidents and also railroad employees taken sick while on duty.—There has also been established a sanitary service for railroads in the form of hospital cars for the transportation of sick people.

**Banquet Tendered Austregesilo.**—The *Brazil Medico* reproduces the addresses at the banquet recently tendered to Prof. Antonio Austregesilo at the Derby Club, Rio de Janeiro, by his friends and pupils. He has long been the incumbent of the chair of nervous diseases at the University of Rio, and is a director of the *Archivos Brasileiros de Medicina* and of the *Archivos de Neurologia*.

**Malaria in Cuba.**—In connection with the annual recurrence of malaria in the provinces of Camaguey and Oriente, Cuba, Dr. Juan Guiteras, the director of sanitation, has emphasized the need of additional funds in order to carry out antimalarial measures during the next winter and spring, as the appropriations previously available for this purpose have been exhausted. This year there were more cases of the disease, this being attributed to the immigrants from Jamaica who spread the disease in Cuba.

**Typhoid Fever in Lima, Peru.**—Dr. M. Pagador B. has just published some notes on the prevalence of typhoid fever in Lima. His study shows that the disease is most prevalent during the first four months of the year, and that the majority of cases, contrary to the experience elsewhere, occur between the ages of 1 to 5 years. The mortality showed an increase until the year 1901 when it began to show a slight decrease until this year, when it has again shown an alarming increase. The native Indians show the highest mortality rate, next in order the half breeds, and then the whites. The colored people seem to possess a relative immunity, but the yellow race shows a high mortality rate which has increased especially during the last few years.

## Government Services

### Personnel of the Medical Corps of the Army

For the week ending October 10 there were in the Medical Corps 4,428 officers, a decrease from the previous week of 409. The Medical Reserve Corps listed 3,589 officers. Since the beginning of the war there have been discharged 29,219 officers.

### General Ireland Discusses Army Reorganization

At a meeting of the House military committee, October 3, Surgeon-General M. W. Ireland explained his objections to the pending bill for Army reorganization. According to the Army and Navy Register, General Ireland said in regard to the general staff:

#### THE GENERAL STAFF

"Under the Overman act the general staff has departed from supervising and coordinating the different branches of the Army, and has become an administrative bureau to a considerable extent. The administration of the medical department has suffered very seriously on this account, particularly in the handling of supplies, finances and of its personnel.

"Under the present organization of the purchase, storage and traffic, all of our splendid organization has been destroyed and an organization substituted which is not built upon sound principles, is most difficult to operate, is dreadfully expensive in overhead personnel and is thoroughly inefficient. The interference with the medical department supply system began about March, 1918, and the records are filled with instances of delays caused by the interbureau procurement system. Striking instances can be given:

#### PURCHASE OF MEDICAL SUPPLIES

"1. Gauze is one of the articles most frequently used by the surgeon in his operations. In fact, surgical processes cannot be carried on without an ample supply of sterilized gauze. Under the interference of the interbureau procurement system an attempt was made to substitute for the gauze we required a type of gauze wholly unfitted for surgical use.

"2. Before the interbureau procurement system was started my office had made arrangements to purchase from a reliable firm 20,000,000 meters of gauze at 65 cents a pound. When this came to the attention of the new system, the procurement of this material was taken over by it. At once the price went up to 95 cents a pound, and the purchase was eventually made at approximately 75 cents a pound, plus any increase in operating expense—a loss to the government, due to this interference, of \$200,000.

"3. One of the crying needs in France was convalescent suits for patients in hospitals. Request for these suits was made from France in December, 1917. The Council of National Defense attempted to secure the material for these suits, but failed. Requisition for them (about 400,000 suits) was placed with the quartermaster department, under the interbureau procurement system, about May, 1918. Not a single suit was delivered before the armistice was signed.

"Let it be distinctly understood that the purchase, storage and traffic division did not take over the supplies of the medical department entirely until Nov. 15, 1918, several days after the fighting had ceased. In other words, the admirable record for furnishing the troops at home and abroad with medical supplies was due entirely to the supply system built up by the medical department at the beginning of the war. Since Nov. 15, 1918, the history of the handling of medical supplies has been a continuous one of failure and inefficiency. We have on file records of dozens of instances where great delay in filling requisitions has hampered the administration of our hospitals where the overseas sick have been treated. One of the glaring instances which came to the attention of the medical department within the last week was the failure to fill a requisition from General Hospital No. 21, Denver, dated July 1, for urgently needed mess equipment until September 27."

#### MEDICAL PERSONNEL INTERFERENCE

General Ireland further said:

"In the handling of personnel the medical department has suffered a great deal from the organization of the personnel division of the general staff. The assignment of the personnel of the medical department is one of the very important duties in the Surgeon-General's Office. In the medical department this can only be done by a medical officer. Yet the personnel branch of the general staff has taken upon itself to interfere with our work in many ways. On Aug.

14, 1918, a memorandum was issued at the direction of the general staff stopping all appointments of officers from civil life. This memorandum was issued without consulting the Surgeon-General's Office, and did not take into consideration the fact that the medical department obtained practically all of its officers from civil life, and not through training camps. Of course, this memorandum had to be modified for certain staff corps. Later regulations were issued, without consultation with the Surgeon-General, that all applications placed in Class 1 by the local draft board would be inducted into the service as enlisted men before being commissioned. The absurdity of such regulations was apparent to any one familiar with the problems of the medical department and the sources from which medical officers were obtained.

"When the order stopping all appointments was first issued it was published in the public press and caused a tremendous amount of uncertainty in the minds of medical men who had applied for service with the medical department. It gave an idea that a sufficient number of medical officers had been obtained to meet the expected needs. Medical men thereupon gave up the idea of entering the Army and resumed their civilian activities. It took a long time to explain to the medical profession of the country that the medical department needs were unsatisfied. These obstructions to the process of obtaining medical officers came at a time when the medical department was exerting all its energy to secure enough medical officers to meet the demands of the Army, and simply added another burden for the department to carry when the office was already strained to its utmost to accomplish the work in hand.

"In October, 1918, the personnel division of the general staff issued an order assuming entire responsibility for the appointment of officers for all branches of the military service. By these regulations all personal touch between the department requiring the applicant's services and the applicant himself was removed. Thereafter staff corps were to obtain their officers by requisition on the general staff, in the same manner as soap or harness oil is obtained from a depot.

#### DISCHARGE OF OFFICERS

"Upon the signing of the armistice orders governing the discharge of officers were issued, without consultation with the Surgeon-General's Office, and without any apparent comprehension or consideration of the problem confronting the medical department. Department and camp commanders were authorized to discharge officers, including medical officers. At this time practically all the sick and wounded resulting from active operations of the American Army overseas were still in France, and the medical department was confronted with the necessity of opening additional general hospitals in this country in anticipation of the return of these sick and wounded to the United States. The only source of supply of medical officers to run these hospitals was the officers and enlisted men of the medical department at camps in the United States rendered surplus by the signing of the armistice. This source of supply was jeopardized immediately by the issue of Circular 75. The Surgeon-General asked to have this order modified, so far as it related to medical officers, but this was refused by the general staff. The situation, however, was eased a good deal by the publication of a circular on December 7. But in spite of the fact that the general staff stated that 'the needs of the medical department, both past and future, are appreciated,' on March 24 a circular telegram was sent to all department and camp commanders directing them to make changes in assignment of officers without reference to higher authority, and stating that any Class 1 or 2 officers who could be spared may be discharged without securing the approval of chiefs of staff corps; and added that no officer in Class 1 or 2 would be thereafter available for reassignment when surplus. It took the medical department several days to obtain a modification of these instructions, and, in the mean time, a number of valuable officers of the medical department who were needed for the proper care of the sick and wounded were discharged without reference to the Surgeon-General.

"In the demobilization of medical officers the general staff has insisted that all medical officers for discharge shall be reported to Room 330, War Department, instead of the Surgeon-General. As these reports all had to come to the Surgeon-General for his recommendation, the resulting delay has cost the government thousands upon thousands of dollars, without any benefit to the service. The reading of the circular 'Operations and Plans of Personnel Branch, Operation Division, General Staff,' published over the signa-

ture of the chief of the personnel division, shows how extensively the general staff proposes to go into the actual control of the personnel of the different staff corps and departments, altogether outside of the recognized duties of the general staff to supervise and coordinate the different activities of the Army."

#### LACK OF REPRESENTATION ON STAFF

Questions were asked by Mr. Sanford as to the representation of the medical department on the general staff. While officers had been detailed to the staff it was not fair, remarked General Ireland, to assume that his department was actually "represented." A month ago Colonel Miller was assigned to duty with the general staff, and, on reporting there, was instructed to return to the Surgeon-General's Office, and was informed that he would be called upon whenever it was necessary to use his services. The result was that he had performed no duty with the general staff and was performing no duty in the Surgeon-General's Office.

General Ireland called attention to the effect of the bill on the admission of officers to the corps; it evidently repealed existing law that had been in satisfactory operation since 1834, and which had been a protection against favoritism. General Ireland was also desirous that the bill provide for medical corps personnel on a percentage basis, instead of by numerical strength. As to this and other defects in the bill, Mr. McKenzie took occasion to remark that "there was no danger of the pending bill being reported out of committee, and the Surgeon-General could be assured that Congress would take care of the medical department." It was also pointed out to the committee that the bill repealed the present excellent promotion system pertaining to the medical department. General Ireland being "strongly opposed to any process of selection." The method of elimination in his corps was eminently satisfactory, and it was essential to retain it. He was even in favor of extending this to grades senior to those now affected. General Ireland recommended that the period of service as first lieutenant be reduced from five to three years. This would make the service more acceptable to candidates, which it was now exceedingly difficult to obtain.

As for the reservists who had served in the war and who desired to enter the regular corps, General Ireland suggested that it be arranged so that they would receive credit for the service, as it was during the war, when first lieutenants were promoted after one year's service. This, under existing circumstances, would practically place these emergency officers in the grade of major. He would not increase in these cases the age limit of 40 years, but he would waive the minimum age limit of 32 years now applying to other candidates. Mr. Sanford referred to the American medical reservists who had served with the British forces, and who had not been promoted, giving the instance of a friend who had been through the worst of the battles in France, many times under fire, and, at the end of the war, was demobilized as a first lieutenant. This was on account of an order that prohibited the promotion of these officers, and, understanding that the chief of staff issued this order, Mr. Sanford did not hesitate to say that it was "the most cruel and stupid order he had ever heard of." General Ireland agreed as to the injustice with which these officers had been treated.

#### ELIMINATION AND PROMOTION

General Ireland suggested that the present law be changed so that it would be possible to get rid of an officer who was disabled through his own misconduct without being obliged to wait a year for his reexamination, as in the case of other officers disqualified by service. These officers, he said, should be separated from the service without any such delay. This could be accomplished by leaving the question of whether an officer should be retired or wholly retired to the discretion of the President. General Ireland also opposed the provision in the bill for second lieutenants in the dental corps. It was hardly to be expected that qualified dentists would be attracted to the service by this "handicap." He suggested the abolition of the grade of second lieutenant in the veterinary corps for the same reason.

Mr. McKenzie endeavored to obtain from General Ireland some general views on the merits of the pending bill, but that officer considered it was more of his affair to go fully into a discussion of the measure, preferring to confine himself to a presentation of the needs of the medical department. He felt, however, that there was little required in the way of amendment of the national defense act to meet the situation adequately. This would, for example, provide a "surgeon general" as the head of the medical department, instead of a "major general" at the head of the medical

corps only, as is provided in the War Department bill. General Ireland spoke earnestly of the difficulty in obtaining medical officers and of the desire of officers to resign. He also reminded the committee that if universal training were adopted it would be necessary to have fully a thousand doctors at the camps, for it must be remembered that the boys would be afflicted with the diseases of childhood, and there must be every action taken against sickness. He felt that for this purpose the members of the profession in civil life would offer their services as they had done so generously during the war without resort to conscription.

## BELGIAN LETTER

LIFE, Sept. 17, 1919.

## Medical Progress During the Period of the German Occupation

The evacuation of Belgian territory by the Germans has afforded the physicians who remained in the country during the occupation a welcome opportunity of publishing the results of their experience. On reading the publication of their records, it would seem that new diseases or at least new phases of old diseases have arisen and have been added to certain chapters of medicine. What we who took part in the war outside of Belgium know of the medical aspects of the war has nothing in common with what our colleagues had the misfortune to witness during the course of five long years. The bad quantitative and qualitative food conditions, together with the privations of every kind imaginable, have, it would seem, created very peculiar pathologic conditions, which, in turn, are reflected in all branches of medicine.

## The Psychophysical Condition of Belgian Women During the War

M. Keiffer in the *Scalpel* contributes an article on the psychophysical condition of Belgian women during the war. The untold privations and the unheard of difficulties of human existence beginning with 1915, produced among the population of Belgium, many affections due to faulty nutrition, such as marked loss of weight, cervical adenitis and rachitic symptoms, which in many cases terminated fatally. Tuberculosis caused great ravages, especially among girls from 14 to 20 years of age. One phenomenon observed very frequently among married women at an age long before the menopause normally sets in was amenorrhea. This affection increased from 1915 on, and diminished in frequency and in tenacity along toward the time of the signing of the armistice. In certain women this condition lasted from two months to a year or more. It affected young unmarried women and also married women, and the question as to whether their fiancés or husbands, as the case might be, were present in the neighborhood or were absent seems to have played little part in the matter. This interruption of function in the ovarian gland cannot, then, be attributed to the absence of the men. Whether we regard this phenomenon as a state of torpor or as a momentary dormant state, it remains true that it was always possible with the organo-therapeutic means at command to restore the physiologic rhythmic function of the gland. In endeavoring to discover the causes for this phenomenon one cannot put forward loss of weight, for, under other circumstances, this has proved rather favorable to menstruation; nor can we postulate chlorosis, nor mental depression, nor lack of exercise, nor lack of pleasurable excitement—social gatherings and participation in sports so necessary to the young. The etiology can be explained by an examination of the food-supply curve and more particularly by an inspection of the relative nutritive value of the materials entering into the flour and the bread used at various periods during the fifty-two months of war. The curve representing the fat content of the foods used could likewise be utilized in the research. Indeed, from the time when an improvement in the food conditions was brought about, the number of cases of amenorrhea decreased in an almost parallel manner. We are concerned, then, with a deficiency disease, although unable to specify just what elements were lacking entirely or existed in insufficient or in superabundant quantities in the food consumed; just what circumstances the presence or absence of which is necessary for the functional activity of the ovarian gland to proceed in its normal course. Keiffer calls to mind the great mental suffering that the Belgian women had to endure during the five years of the German occupation. He pays homage

to their ardent and tenacious patriotism which made it possible for them to withstand "with serenity the Machiavellian inventions of the Germans calculated to break down their resistance and annihilate their hopes."

#### Edema Among the Deported

At a meeting of the Académie de médecine de Belgique, M. Vandervelde and M. Cantineau introduced a suggestive communication on the deportation of Flemish civilians in 1916. Two hundred patients treated by them in the Saint Pierre Hospital at Brussels gave them the opportunity of making interesting observations from a medical point of view. Most of those deported suffered from a marked edema of the lower limbs, which was frequently associated with grave phlegmons. The general condition was brought about by lack of food and by the deplorable hygienic conditions under which they were compelled to live. The cardiovascular apparatus was attacked, and a profound anemia was added to their weakness, while the slightest effort occasioned an intense dyspnea. It would seem that this syndrome must be attributed to general intoxication due to renal insufficiency. With the clinical picture outlined above, oliguria was also constantly associated. The authors of the paper endeavored to make a special study of the urinary changes among the deported, for they all showed more or less serious symptoms manifested at times by oliguria and at times by genuine Bright's disease.

The therapeutic measures employed were exclusively of a dietetic nature. All that was needed by these poor, oppressed people, who had received no medical attention whatever, was rest and sufficient food, in order to soon be rid of all the symptoms mentioned.

Rest and proper food were all that was needed to do away with the blocking of the kidney and to cause the diuretic curve to mount suddenly, while, at the same time, the edema of the lower limbs disappeared. That is to say, it was not a question of a definite nosologic entity, and the cause of the condition lay entirely in the bad treatment and cruelty they had suffered at the hands of the Germans.

This indifference, on the part of the invaders, to health was, furthermore, quite the regular thing. Those deported were forced to do hard labor and were recruited without any medical examination. A military commission, without the aid of any medical authorities, had enrolled by force all the inhabitants of a given region whether they were afflicted with serious diseases or not. Definite examples of these cruel and inexcusable abuses are given. Forty-two per cent. of those deported were found to be suffering from tuberculosis in some form.

#### The Physical Development of Children

The investigations carried on by M. Demoor, professor in the Brussels School of Medicine, with reference to the height and weight of the public school children of Brussels during the war, led to conclusions analogous to the foregoing. In spite of all the societies for the protection of children, in spite of all the efforts to preserve their health, the growth of all the pupils has been retarded. Demoor found that (1) the average weight of children (boys and girls classed together) of all ages has diminished. At the end of four years the observed deficit is greater than the value of the normal development of two thirds of a year. The average height of children of all ages has decreased to the extent of one third of the usual annual development; (2) the average total decrease from 1914 to 1918 in the age-group comprising the ages from 7 to 14 is approximately equal—in both boys and girls—to the development of one year for weight, and to the development of one-half year for the boys and one-seventh year for the girls as regards height.

The truth of these observations was particularly evident among the population of the poorer quarters. This retarded physical development of children, which affects especially the children from 10 to 14 years old, may have a bad influence even on their future development. These children are at present much inferior to what they should be. Will this period of privation cause them to have a lessened resistance for the future? Will this physical impairment that they have suffered continue to exert a baneful influence on their future development? The author of the communication bases his conclusions on the curves of morbidity and mortality at different ages of childhood as plotted by Key in Sweden and by Porter in America. He believes that a relation exists between the age, the weight and the height, on the one hand, and the resistance to disease and death, on the other hand. The differences that he himself has observed thus far do not, however, justify him in forming a positive

and exact opinion, he thinks, with reference to the resistance of the human organism to disease as shown by Belgian children. Nevertheless, in addition to these statements in regard to height and weight, the fact that in children affected by the period of occupation there was an increased number of cases of cervical adenitis, chronic affections of the nasopharynx, rachitic symptoms and pernicious anemia would indicate that the mortality was increased. It must be admitted that in the case of a great number of children the war produced organic affections more or less lasting and serious, although it is true that no definite statements can be made as yet in regard to the possibility of complete recuperation.

#### Cutaneous Affections

The manifold privations, the difficulties of human existence and the neglect of all hygienic rules of living had the same repercussive effect on cutaneous affections. In the *Paris médical*, Dr. Bayet gives the results of his personal experience on the subject. Three classes of affections were observed: (1) affections dependent on some disease of the nervous system; (2) affections that have their origin in insufficient or in unwholesome food, and (3) affections that are directly attributable to uncleanness.

Among the affections associated with some disease of the nervous system he observed especially cases of lichenoid and of eczematous neurodermatitis, prurigo and alopecia areata. These affections were often resistant to treatment and subject to frequent recurrence. The author noted a pemphigus as the result of an emotional shock, and another time a generalized scleroderma.

The affections due to malnutrition were especially numerous among people of moderate means. The increase and the aggravation of tuberculosis afforded the opportunity of observing a greater number of cases of lupus tuberculosus, often associated with swelling of the lymph nodes. This special aspect of the affection and its frequency gave rise to a new term among the people, namely, "collier de la guerre" (war necklace).

Hard edemas, edemas of inanition so-called, generalized furunculosis and anthrax became much more common, not only among the poorer classes but also among the well-to-do.

A form of alopecia resembling that which very commonly results from infectious diseases was very prevalent, even among people in good circumstances, with negative family histories.

Affections due to uncleanness were particularly numerous, the two principal reasons for which were the almost absolute lack of soap and the high price of coal. The latter factor was very important. Linen and underclothing being no longer boiled when laundered made possible the transmission on a grand scale of all kinds of contagious skin diseases: scabies, trichophytosis, etc. This hit not only the poorer classes but also the rich, for stopping at even first-class hotels was associated with a veritable danger from the standpoint of contagion.

The aforementioned studies on diseases observed during the German occupation of Belgium are the first to be published since the evacuation of the territory by the Germans. No doubt others will follow and will shed more light on these special pathologic conditions which one is tempted to call the "pathology of misery." A Holland journal recently called attention to the peculiar circumstance of the increase of cerebral hemorrhage and softening of the brain during the period of rationing that the Netherlands was obliged to submit to toward the end of the war. All this would seem to suggest that there may be some connection between deficiency diseases, among which beriberi may be mentioned, and certain aspects of war edemas.

## Marriages

GEORGE YELLOTT MASSENBURG, Macon, Ga., to Miss Dorothy Shedd, of Columbus, O., in New York City, September 10.

JOHN HENRY COSTELLO, to Miss Frances Alice N. Hagerty, both of Dorchester, Boston, September 28.

JAMES HARRY FEYTER, Chicago, to Miss Gertrude Chase Colwell, of Rutherford, N. J., September 22.

HOWARD LYONS, Winchester, Ky., to Miss Dixie Belle Helm, of Morgantown, Ky., October 2.

ARTHER CLYDE TAYLOR, to Miss Adele G. Williams, both of Wilmette, Ill., September 30.

## Deaths

**Robert Montgomery Thornburgh** \* Colonel, M. C., U. S. Army; Dartmouth Medical School, Hanover, N. H., 1897; aged 47; commander of Letterman General Hospital, Presidio of San Francisco; was killed, October 9, in a collision between automobiles. Colonel Thornburgh entered the military service as a Contract Surgeon in 1900, and was commissioned First Lieutenant and Assistant Surgeon U. S. Army a year later; was made Captain five years later, Major in 1910, Lieutenant Colonel, Medical Corps, and Colonel, M. C., National Army, in 1917. He was chief of the surgical service in Letterman General Hospital, Presidio of San Francisco, from 1910 to 1913; chief of the surgical service and commanding officer of the Department Hospital, Manila, P. I., from 1914 to 1916, and on his return to the United States was made camp surgeon of Camp Pike, Ark., prior to his reassignment to duty at the Presidio of San Francisco.

**George Dallas Hersey**, Charleston, S. C., formerly of Providence, R. I.; New York University, New York City, 1874; aged 72; a Fellow of the American Academy of Medicine, secretary of the Rhode Island Medical Society from 1880 to 1885; librarian since 1879 to 1912, and president in 1899 and 1900; editor of the *Providence Medical Journal* from 1899 to 1912; and editor of the *Annual Transactions of the Rhode Island Medical Society* for thirty-one years; from 1888 to 1908, visiting surgeon to the Rhode Island Hospital, and consulting surgeon to the institution thereafter; died at Somerville, N. C., September 28, from cerebral hemorrhage.

**David Bernard Van Slyck**, Pasadena, Calif.; University of Buffalo, N. Y., 1852; aged 90; surgeon of the 101st New York Volunteer Infantry, and of the Twenty-Second New York Cavalry, surgeon in chief of the Second Brigade, Third Division Cavalry Corps; medical inspector and medical director of the Army of Shenandoah, during the Civil War, thereafter a practitioner of Burlington, N. J., and Brookline, Mass., until 1885 when he moved to California; for several years president of the Pasadena Medical Society and once president of the Southern California Medical Society; died at his home, September 30.

**William A. DeLong**, Brooklyn, N. Y.; New York University, New York City, 1863; aged 79; a member of the Medical Society of the State of New York; a veteran of the Civil War, in which he served as assistant surgeon of the Seventy-Seventh Regiment, New York State Volunteers, from 1863 to 1865; inspector of the Brooklyn Board of Health from 1869 to 1876; and surgeon to the Brooklyn Fire Department for twenty-five years; died at his home, October 3.

**Oscar Orlando Meredith**, Breckenridge, Mo.; American Medical College, St. Louis, 1903; aged 39; a specialist in pediatrics; a member of the Missouri State Medical Association; who served during the war as Lieutenant, M. R. C., U. S. Army, and was honorably discharged, December 27, 1918; was crushed by the engine of the airplane, of which he was a passenger, when it fell at Cameron, Mo., September 27.

**Emanuel S. Gans**, Philadelphia; Jefferson Medical College, 1886; University of Pennsylvania, Philadelphia, 1894; aged 63; a member of the Medical Society of the State of Pennsylvania; for many years lecturer in the Medico-Chirurgical College of Philadelphia, dermatologist to the Medico-Chirurgical, Philadelphia General, and Mt. Sinai hospitals, Philadelphia; died at his home, September 30, from pneumonia.

**James Jackson Shuler** \* Raton, N. M.; University of Virginia, Charlottesville, 1879; New York University, New York City, 1880; aged 61; for many years chief surgeon for the Santa Fe System at Raton; died in the Atchison, Topeka and Santa Fe Railway Hospital, Topeka, Kan., September 28, after an operation for appendicitis.

**Grace M. Clarke** \* Detroit; University of Michigan, Ann Arbor, 1902; aged 41; president of the Detroit Free Dispensary for Women and Children; a member of the Women's Hospital and Infants' Home and a member of the Faculty of the Detroit College of Medicine; died at her home, September 28, from pneumonia.

**William Sunderland Mott**, Salem, Ore.; Eclectic Medical Institute, Cincinnati, 1885; aged 64; at one time president and later secretary of the Oregon State Board of Medical Examiners; died at his home, October 3, from heart disease.

**Marshall F. Price**, Los Angeles, Calif.; Northwestern University, Medical School, Chicago, 1875; aged 85; surgeon of the First Pennsylvania Light Artillery during the Civil War, with the rank of major; first president of the Southern California Medical Society; died at his home, September 25.

**James Bernard Dinnan**, Meriden, Conn.; Yale University, New Haven, 1904; aged 38; a member of the Connecticut State Medical Society; president of the Meriden Medical Society in 1914-15; superintendent of the State Tuberculosis Sanatorium, Meriden; died October 3, from typhoid fever.

**John Alexander Hearst** \* Philadelphia; University of Pennsylvania, Philadelphia, 1893; aged 48; for several years a member of the staff of the Polyclinic Hospital; a specialist on diseases of the ear, nose and throat; died at his home, in Germantown, October 4, from heart disease.

**William Gaynor States** \* New York City; New York University, New York City, 1881; aged 58; adjunct professor of rectal surgery in the New York Polyclinic Medical School for more than twenty years; a Fellow of the New York Academy of Medicine; died at his home, October 6.

**George Washington Parker**, Philadelphia; Hahnemann Medical College, Philadelphia, 1870; aged 80; a veteran of the Civil War, and for one term surgeon of the Department of Pennsylvania, G. A. R.; died at his home, October 4, from cerebral hemorrhage.

**George M. Bower**, Lenexa, Kan.; Bellevue Hospital Medical College, 1862; aged 82; a practitioner until 1906, when he organized the State Bank of Hillsdale, Kan., of which he became president; also state senator in 1872-73, died at his home, recently.

**Evan Pickerell**, Benson Mines, N. Y.; University of Pennsylvania, Philadelphia, 1890; died in the City Hospital, Watertown, N. Y., October 3, from fracture of the skull caused by the overturning of his automobile near Watertown.

**Robert I. Fletcher**, Arma, Kan.; College of Physicians and Surgeons, Keokuk, Iowa, 1857; aged 87; surgeon of U. S. Volunteers throughout the Civil War; died at the home of his son in Arma, September 26, from cerebral hemorrhage.

**Leshar K. Francis**, Royertown, Pa.; University of Pennsylvania, Philadelphia, 1871; aged 73; for four years a druggist of Philadelphia; died at the home of his son in Pottstown, Pa., September 22, from cerebral hemorrhage.

**George Arneke Kretsinger**, Oakland, Calif.; University of California, San Francisco, 1915; aged 31; a member of the Medical Society of the State of California; died at his home, September 8, from pneumonia following influenza.

**Snyder John Henry Louthar** \* Somerset, Pa.; American Medical College, St. Louis, 1893; aged 51; who was honorably discharged as Captain, M. C., U. S. Army, January 8, 1919; died at his home, September 24.

**George Orf**, Indiana Harbor, Ind.; Central College of Physicians and Surgeons, Indianapolis, 1905; aged 44; a member of the Indiana State Medical Association; died at his home, July 12, from cerebral hemorrhage.

**Peter George Woods**, Versailles, Mo.; Washington University, 1867; aged 75; a member of the Missouri State Medical Society; died in Kansas City, Mo., September 11, from valvular heart disease.

**Green Leslie Robertson**, Leander, Texas; University of Louisville, Ky., 1890; aged 53; a member of the State Medical Association of Texas; died in the City Hospital, Austin, Texas, September 22.

**Louis Drechsler** \* St. Louis; Washington University, St. Louis, 1896; aged 53; a specialist in diseases of the ear and throat; died at his home, June 23, from malignant disease of the face.

**Washington Foster**, Amherst, Ohio; Michigan College of Medicine and Surgery, Detroit, 1892; aged 66; for many years health officer of Amherst; died at his home, September 27.

**George M. Tate**, Botkins, Ohio; Cincinnati College of Medicine and Surgery, 1868; aged 81; died at the home of his son in Botkins, September 27, from carcinoma of the stomach.

**Charles Belt**, Batavia, Ohio; Medical College of Ohio, Cincinnati, 1878; aged 62; died at his home, September 17, from acute nephritis.

**William W. Peek**, Louvale, Ga.; Louisville (Ky.) Medical College, 1873; aged 67; died at his home, September 17, from heart disease.

**William T. Blythe**, Glazen, Ind. (license, Indiana, 1897); aged 69; died at his home, July 4, from arteriosclerosis.

\* Indicates "Fellow" of the American Medical Association.

## The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE JOURNAL'S BUREAU OF INVESTIGATION, OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE FRAUD ON THE PUBLIC AND ON THE PROFESSION

### THE WILLIAM A. WEBSTER CO. AND THE DIRECT PHARMACEUTICAL CO.

The following letter from a Detroit physician was received a few days ago.

To the Editor.—I have just received a letter from the Direct Pharmaceutical Co. of St. Louis, Mo., quoting prices on drugs which are not more than one half what the leading manufacturers are quoting on the same drugs. I have received previous literature from this company but have not done business with them. I would be unwilling to prescribe their drugs unless I were satisfied that they are what is claimed for them. I would be glad to receive any information regarding this firm that may be available.

THE JOURNAL has also received some letters from physicians regarding the William A. Webster Co. of Memphis, Tenn., relative to a letter the concern was sending physicians in the form of a testimonial (reproduced in miniature on this page) and alleged to be from Dr. F. W. P. Butler of Columbia, S. C. Typical letters on the Webster advertising follow:

To the Editor.—Is there not some way through which the dignity of the medical profession can be protected from the circulation of such adiotic drivel as the enclosures display?

To the Editor.—I am sending you an example of the sort of "evidence" which some so-called ethical pharmaceutical houses expect physicians to take for scientific proof. It is pathetic that there are some in our profession who "fall for" such trash. I trust you will continue your campaign for honest and intelligent medicine.

The "evidence" to which one of the correspondents refers and which another characterizes as "idiotic drivel" is reproduced on this page in miniature. It is a testimonial for William A. Webster Company's "Ferritonic-Woods."

Our readers may wonder why we are discussing in one article the William A. Webster Company of Memphis, Tenn., and the Direct Pharmaceutical Co. of St. Louis. The reason is that the Direct Pharmaceutical Co. of St. Louis is apparently merely a sales agency for the William A. Webster Company of Memphis. It appears that orders sent in to the Direct Pharmaceutical Co. go to Memphis to be filled.

The following information regarding some of the products that have in the past been put out by the William A. Webster Company should be of interest to the profession. In government bulletins issued by the Department of Agriculture in October, 1913, there were reported some cases of adulteration and misbranding on the part of the William A. Webster Co. of Memphis, Tenn. A "Pure Concentrated Extract of Lemon" shipped by this concern was found by the federal chemists to be colored with a coal-tar dye "whereby its inferiority was concealed," and while purporting to be a

concentrated lemon extract, "in fact, it was not a concentrated lemon extract." Some "Pure Concentrated Extract of Banana" was found to have mixed with it an imitation banana flavor and an artificial color so as to "injuriously affect its quality and strength" and so that "its inferiority was concealed." "Pure Concentrated Extract of Pineapple" was found to have had mixed with it "an imitation extract of pineapple artificially colored." "Pure Concentrated Extract of Strawberry" had been mixed with "an imitation strawberry extract artificially colored." The same bulletins described the case of the government against a shipment of "Syrup Iron Iodide" made by the Webster concern in which the amount of iron iodide was less than half that claimed on the label. In each of the cases just described, the company pleaded guilty and was fined.

In a similar bulletin issued August, 1914, there were recorded several more cases of adulteration and misbranding charged against the William A. Webster Company. Some "Wine Coca Leaves" was held adulterated in that the amount of alcohol present was wrongly declared on the label; it was held misbranded in that while it contained cocaine, the label failed to bear any statement regarding the quantity or proportion of this drug. Tablets of "Acetanilid and Sodium Bromid Compound" were found deficient in strength. "Anti-Vomit Tablets," "Aspirin Tablets," "Bismuth and Calomel Tablets," "Quinin Laxative Tablets," "Salol Tablets," "Sodium Salicylate Tablets," "Neuralgic Tablets," "Diarrhea Calomel Pills" and "Morphin Sulphate Hypodermic Tablets" were also misbranded in that the amount of certain ingredients found in them failed to tally with the amount declared on the label. In all of these cases also the William A. Webster Company pleaded guilty and was fined.

In a government bulletin issued in June, 1917, the same company was charged with adulterating and misbranding a quantity of Aspirin tablets which, instead of containing 5 grains as labeled, contained only a fraction over 1 grain. In this case, too, the company pleaded guilty and was fined. The table that follows summarizes some of the cases just referred to:

COLUMBIA S C

Sept 19th, 1919.

The Wm. A. Webster Company,  
Memphis, Tenn.

Gentlemen!

It is useless to treat malaria unless the system is fertilized or put in a receptive condition for the effect of the antidote for malaria so prevalent in this country. The human system is a good deal like land to be cultivated. If the land is not put in a proper condition the seed will not germinate effectively.

In your product you have an ingredient to agitate the proper flow of bile, and cause the liver, the great sugar and disinfectant mill of the human system to functionate normally. Therefore, giving quinine from any other condition is like pouring water on a duck's back.

I have begun the use of your Ferritonic-Foods! and only wish it was in my power to make every doctor in North and South Carolina do likewise.

Yours truly,  
*F. W. P. Butler*

Reproduction (reduced) of a testimonial letter sent to physicians by William A. Webster Company of Memphis, Tenn. Those who operate this concern also have a sales agency in St. Louis, Mo., known as the Direct Pharmaceutical Co.

## ANASARCIN ADVERTISING

To the Editor.—As an old Fellow of the A. M. A. I beg to present the following facts to you, and to ask if anything can be done by you to expose the methods of these people: A concern calling itself "The Anasarcin Chem. Co." of Winchester, Tenn., has caused to be sent to physicians a chart on the subject of "Diagnostics of Renal Diseases." This chart contains eighteen plates, which were all taken without knowledge or permission of either myself or my publishers, Wm. Wood & Co., from the third edition of my book on "Urinary Analysis and Diagnosis." The plates are partly composite plates, but mostly portions of plates, exactly reproduced from my book. I at once caused my publishers to write to the Anasarcin Company and a few days ago received a letter from a Dr. H. Elliott Bates of 118 East Twenty-Eighth Street, New York, whose letter-head says, "Medical Advertising." In this letter the writer says that it was he who suggested the sending of such a chart, and admits that all the plates were taken from my book. In this letter he offers to have a letter sent to every physician of the country "in which it is explicitly stated that the cuts on the chart were taken from your book, and that complete information regarding the matters treated on the chart can be found in your book." In other words he offers to advertise my book free of cost to me, so that I should take no further steps in the matter. I consider this entire matter an outrage, and thought it best to write to you for advice, since my publishers seem to think that in spite of the violation of the copyright nothing can be done.

Besides the cuts, some of the text on the chart is bodily taken from my book, while some of the other text, not taken from my book, but apparently compiled from different articles, is in part entirely wrong, so much so that I must be ashamed of its being associated with any of my own work.

By giving this letter your early consideration, and advising me what you think it best for me to do, you would greatly oblige

LOUIS HEITZMAN, M.D., New York.

[COMMENT.—Readers of THE JOURNAL are, of course, familiar with the articles<sup>1</sup> that have been published on "Anasarcin," the "dropsy cure!" Knowing the standard of ethics that the Anasarcin concern adopts in the exploitation of its ridiculous squill mixture, our readers will not be surprised at the standard of commercial ethics which would justify the appropriation of copyrighted scientific material for nostrum advertising purposes. The statement of Dr. Heitzman's publishers that "in spite of a violation of copyright nothing can be done" is, of course, incorrect. Something can be done by those who hold the copyright.—Ed.]

1. THE JOURNAL, Jan. 26, 1906; May 4 and 11, 1907, and Dec. 8, 1917.

**The Cattail: A New Food.**—Among the many products which the Indians have taught us to use are such common and now indispensable foods as corn and potatoes. There are, however, many products which the Indians used and relished that have received little or no attention from the white man. The common cattail (*Typha*) is one of these products. The vast areas of cattail have been little utilized. Here is a plant with prolific growth, rich in starch and other products of food value, growing in situations now regarded as waste lands. The rhizome is the part used. Cattail flour is not much different in composition from other flours and could probably well be used. The practicability of obtaining the flour from the field is a question which deserves further attention and experimentation. Likewise, the question of cultivation would require careful investigation. The fact, however, remains that there are thousands of acres of cattails containing considerably over 2 tons of flour per acre which at present finds no use. It is not so difficult to get the flour in small quantities. Half an hour at digging and "peeling" has yielded three or four cupfuls of flour. The digging is not so different from digging potatoes and the peeling is about equally facile. This flour has been used in this investigation in several ways, first as part substitute for cornstarch in puddings.—P. W. Claassen, *Scientific Monthly* 9:179 (August) 1919.

## Correspondence

## NEED OF FURTHER RESEARCH ON THE TRANSMISSIBILITY OF MEASLES AND VARICELLA

To the Editor.—I have just read the abstract in THE JOURNAL (Oct. 4, 1919, p. 1086) of Sellards' article on "The Insusceptibility of Man to Inoculation with Blood from Measles Patients" (*Bull. Johns Hopkins Hosp.* 30:257 [Sept.] 1919).

It is remarkable that Sellards was unable to produce this highly infectious disease by means of the blood or the nasal secretion of infected individuals. Not long ago, however, I had a similar experience with varicella (*Am. J. Dis. Child.* 16:34 [July] 1918). Thus we are confronted with two diseases—the two most infectious of the endemic diseases in this part of the world—which we are unable to transmit artificially from man to man. The result was most surprising in regard to chickenpox, and if the same rule holds good for measles it would seem as if a basic principle must be involved. Evidently in our experiments we do not, as we believe, pursue nature's mode of transmission; either we fail to carry over the virus, or the path of infection is quite different from what it is commonly thought to be.

I am writing this note because this question has been in my mind for some time and has been stirred up again by this recent work on measles. It appears to be a phenomenon that might well be called to the attention of readers of THE JOURNAL; perhaps an experimental study of the question might be undertaken by those who have the opportunity and are not engaged in other fields of work.

ALFRED F. HESS, M.D., New York.

## "FORMULAS FOR USE IN STANDARDIZING AUTOGENOUS VACCINES"

To the Editor.—In THE JOURNAL, October 4, under Clinical Notes, Suggestions and New Instruments, Sergeant Leo R. Tehon presented formulas for use in the standardization of bacterial vaccines. While serving as laboratory director of Evacuation Hospital No. 10, A. E. F., I had frequent requests for autogenous vaccines. At first we used Wright's method unmodified; but finding it rather cumbersome, we decided to try to modify it in some way that would make it more simple and take less time. After several trials we adopted the following method; it is very simple and can be done in a very short time: First, we used the blood of a soldier who gave a count of 6,000,000. We made a small puncture in the finger or ear, as in a cell count, and drew up the blood to point 0.5 in a white cell diluting pipet. Then a standard sodium citrate solution was drawn up in the pipet to point 1. This was drawn up in the bulb of the pipet, and the bacterial suspension was drawn up quickly to point 1, and this and the citrate blood were mixed as in an ordinary cell count. We had in this a blood with 3,000,000 red cells, and if we found two bacteria for each blood cell we had 6,000,000 per cubic millimeter, or 600,000,000 per cubic centimeter. We always worked with concentrated bacterial suspensions, as it was a very simple matter to dilute to any desired concentration of a lower count. The whole operation takes no more time than a simple blood count, and no other equipment except the sodium citrate solution.

J. S. WILSON, M.D., Lake Village, Ark.

## REPORTS ON LOCAL ANESTHETICS IN LARYNGOLOGY

To the Editor.—At the suggestion of the Council on Pharmacy and Chemistry of the American Medical Association at its last meeting, the Section on Laryngology, Otology and Rhinology appointed a special committee to study and report on the "Special advantages and disadvantages of the various local anesthetics in nose and throat work."

The committee is very desirous of learning from members of the profession of any toxic effects, not necessarily fatal,

occurring in their practice, and will be greatly pleased to receive communications regarding any ill effects noted by them following the use of any local anesthetics.

All such communications will be regarded as strictly confidential, and may be sent to the chairman of the committee.

EMIL MAYER, M.D., Chairman,  
40 E. 41st St., New York.  
ROSS HALL SKILLERN, M.D., Philadelphia.  
ROBERT SONNENSCHNEIN, M.D., Chicago.

### Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

#### THE DETERMINATION OF LEAD IN THE URINE

To the Editor.—Please furnish me with details of tests for detection of lead in urine, referred to in the article of Dr. Louis I. Harris, THE JOURNAL, Sept. 20, 1919, p. 880. Kindly omit my name in answering.  
A. A. P.

ANSWER.—Dr. Harris does not give the method used by him for the determination of lead. In qualitative work the following method is commonly employed:

A liter (quart) of urine, acidified with acetic acid, is evaporated to dryness and the residue fused in a crucible with a little potassium nitrate until the melt becomes white. The crucible is cooled, hot dilute hydrochloric acid added, the extract filtered, the filtrate treated with ammonia to alkaline reaction, and ammonium sulphid added. The precipitate, which contains the lead as sulphid, is washed three times by decantation with hot water; then water acidified with hydrochloric acid is added and the whole allowed to stand over night. The mixture is filtered through a small filter and the residue washed. A few drops of nitric acid are then added, drop by drop, to dissolve the lead sulphid on the filter. This filtrate is collected in a watch-glass, evaporated to dryness, and the final test made by adding a drop of water and a small crystal of potassium iodid. A yellow precipitate denotes lead.

If quantitative results are wanted, the filter containing the lead sulphid, as obtained above, is digested on the water bath with dilute nitric acid containing a little hydrochloric acid, the mixture filtered and the filter washed with a large excess of hot water. The filtrate and washings are evaporated to a small volume, a few cubic centimeters of dilute sulphuric acid are added, the solution is evaporated on the hot plate until white fumes appear, 25 cc. of 50 per cent. alcohol are added, the mixture is allowed to stand twenty-four hours, and the precipitated lead sulphate is collected in a weighed Gooch crucible, dried and weighed.

Electrolytic methods for the determination of the lead are known also, and these are to be preferred if the amount is small. They are usually carried out in the solution obtained from the solution of the lead sulphid in nitric acid, the lead being deposited as lead peroxid and weighed as such, after drying at 180 C.

#### THE PRESCRIBING OF PAREGORIC

To the Editor.—Please inform me if it is necessary for a physician who prescribes paregoric in a mixture to keep that prescription on file and keep a narcotic record as prescribed in the Harrison law for narcotics.

A. I. LAWRENCE, M.D., Cabinet, Mich.

ANSWER.—Paregoric is exempt under the provisions of the Harrison law. The U. S. circuit court in the case of the *United States v. Oliver* held that paregoric is exempt only when legitimately used as a medicine, and that prescribing or dispensing it to satisfy the cravings of a drug addict is a violation of the law. It is, therefore, wise for physicians to prescribe paregoric only in cases in which they will be able to justify its use if called on to do so. A physician is not required to keep a record of such prescriptions, but the druggist filling them must do so.

## Medical Education, Registration and Hospital Service

### COMING EXAMINATIONS

ARKANSAS: Little Rock, Nov. 11-12. Sec. Regular Board, Dr. T. J. Stout, Brinkley Sec. Electic Board, Dr. Claude E. Laws, 803 1/2 Garrison Ave., Fort Smith.

CALIFORNIA: Sacramento, Oct. 20-23. Sec. Dr. Chas. B. Pinkham, Butler Bldg., San Francisco.

CONNECTICUT: New Haven, Nov. 11-12. Sec. Regular Board, Dr. Charles A. Tuttle, 196 York St., New Haven. Sec. Homeopathic Board, Dr. Edwin C. M. Hall, 82 Grand Ave., New Haven. Sec. Electic Board, Dr. James E. Hair, 730 State St., Bridgeport.

FLORIDA: Tampa, Dec. 1-2. Sec., Regular Board, Dr. Wm. M. Rowlett, Citizens' Bank Building, Tampa.

ILLINOIS: Chicago, Dec. 1-3. Mr. F. C. Dolds, Supt. of Registration, Springfield.

KENTUCKY: Louisville, Dec. 2. Sec., Dr. A. F. McCormack, 532 W. Main St., Louisville.

LOUISIANA: New Orleans, Dec. 1-3. Sec., Regular Board, Dr. E. W. Mahler, 141 Elk Place, New Orleans.

LOUISIANA: New Orleans, Nov. 4. Sec. Homeopathic Board, Dr. F. H. Hardenstein, 702 Machesa Bldg., New Orleans.

MAINE: Portland, Nov. 11-12. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

MASSACHUSETTS: Boston, Nov. 11-13. Sec., Dr. Walter P. Bowers, Room 501, No. 1 Beacon St., Boston.

NEBRASKA: Lincoln, Nov. 12-14. Sec., Dr. H. J. Lehnhoff, 514 First Nat'l Bank Bldg., Lincoln.

NEVADA: Carson City, Nov. 3. Sec., Dr. S. L. Lee, Carson City.

NEW JERSEY: Trenton, Oct. 21-22. Sec. Dr. Alexander MacAlister, State House, Trenton.

SOUTH CAROLINA: Columbia, Nov. 10. Sec., Dr. A. Earle Boozer, 1806 Hampton St., Columbia.

TEXAS: Galveston, Nov. 18-20. Sec., Dr. M. F. Bettencourt, Mart.

#### Rhode Island July Examination

Dr. Byron O. Richards, secretary of the Rhode Island State Board of Health, reports the written and practical examination held at Providence, July 10-11, 1919. The examination covered 7 subjects and included 70 questions. An average of 80 per cent. was required to pass. Four candidates were examined, all of whom passed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
University of Maryland	.....	(1917)	85.0
Tufts College Medical School	.....	(1917)	82.0
University and Bellevue Hospital Med. Coll.	.....	(1918)	93.6
College of Physicians and Surgeons, Memphis	.....	(1911)	84.7

#### Arizona July Examination

Dr. Allen H. Williams, secretary of the Arizona State Board of Medical Examiners, reports the oral and written examination held at Phoenix, July 1-2, 1919. The examination covered 10 subjects, and included 100 questions. An average of 75 per cent. was required to pass. Of the 6 candidates examined, 5 passed and 1 failed. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Georgetown University	.....	(1864)	77.5
National Medical University, Chicago	.....	(1908)	79.1
Northwestern Medical College	.....	(1894)	83.0
Memphis Hospital Medical College	.....	(1894)	79.2
Trinity Medical College	.....	(1886)	84.5
FAILED			
Southwestern Homeo. Med. College and Hospital	.....	(1903)	45

#### North Dakota July Examination

Dr. George M. Williamson, secretary of the North Dakota State Board of Medical Examiners, reports the oral, written and practical examination held at Grand Forks, July 1-4, 1919. The examination covered 13 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 6 candidates examined, 4 passed and 2 failed. Eight candidates were licensed by reciprocity. One candidate, a graduate of Jefferson Medical College in 1917, was licensed on presentation of a certificate from the National Board of Medical Examiners. The following colleges were represented:

College	PASSED	Year Grad.	Per Cent.
Chicago College of Medicine and Surgery	.....	(1916)	76
Northwestern University	.....	(1918)	79

College	Year	Reciprocity
University of Tennessee	(1917)	73.2
Marquette University	(1919)	84
FAILED		
Kentucky School of Medicine	(1906)	65
University of Louisville	(1905)	67.5
LICENSED THROUGH RECIPROcity		
College	Year	Reciprocity
Northwestern University	(1912)	Illinois
St. Louis Medical College	(1913)	Illinois
South University of Iowa College of Medicine	(1905)	Iowa
Indiana Medical College	(1913)	Kansas
Harvard University	(1912)	Illinois
Univ. of Mich. Homeopathic Medical School	(1913)	Michigan
Hamline University	(1907)	Minnesota
University of Minnesota Medical School	(1914)	Minnesota

**South Dakota July Examination**

Dr. Park B. Jenkins, secretary of the South Dakota State Board of Health and Medical Examiners, reports the written and practical examination held at Deadwood, July 8-10, 1919. The examination covered 13 subjects and included 105 questions. An average of 75 per cent. was required to pass. Seventeen candidates were examined, all of whom passed. The following colleges were represented:

College	Year	Per Cent.
George Washington University	(1911)	87.6
Chicago College of Medicine and Surgery	(1918)	81.8
College of Phys. and Surgs., Chicago	(1896) 87.6, (1897) 82.3	87.1
Northwestern University	(1908) 79, (1918)	87.1
Royal Medical College	(1902) 86.1, 87.3, (1919) 86.6, 89.6,	
Saginaw Valley Medical College	(1902)	86.1
Washington University	(1903)	84.1
Chicago Medical College	(1908)	83.5
University of Pennsylvania	(1909)	85.4
Catanooaga Medical College	(1898)	88.4
Trinity Medical College	(1904)	82.8

**West Virginia July Examination**

Dr. S. L. Jepson, health commissioner of the West Virginia Public Health Council, reports the oral, written and practical examination held at Huntington, July 8-10, 1919. The examination covered 9 subjects, and included 90 questions. An average of 80 per cent. was required to pass. Of the 38 candidates examined, 29, including 2 osteopaths, passed, and 9, including 3 nongraduates, failed. Two candidates were granted osteopathic reciprocity certificates. The following colleges were represented:

College	Year	Per Cent.
George Washington University	(1910)	91.7
Loyola University, Chicago	(1919) 80.1, 90.4	
University of Illinois	(1915)	85.7
Johns Hopkins University	(1919)	85.3
University of Maryland	(1917) 83.7, (1919) 83.6,	87.4
Harvard University	(1918) 88, 89, (1919)	82.5
University of Michigan Home. Medical School	(1901)	87.4
Columbia University	(1918)	87.4
University of Cincinnati	(1919)	85.7
Jefferson Medical College	(1916) 85.2, (1918) 86, (1919) 85.1, 88.6	
Temple University	(1918)	83.3
Meharry Medical College (1915) 80.1, (1919) 80.7, 81, 82.1, 83.5, 88.3		88.3
Medical College of Virginia	(1918) 87.4, 91.7	

College	Year	Per Cent.
University of Louisville	(1910)	45.1
Eclectic Medical College	(1918)	76.6
Meharry Medical College	(1916) 65.6, (1918) 77, (1919)	76.8
Memphis Hospital Medical College	(1912)	73.6

Dr. Jepson also reports that twenty-nine candidates were licensed by reciprocity since November, 1918. The following colleges were represented:

College	Year	Reciprocity
George Washington University	(1910), (1912)	Dist. Colum.
Atlanta College of Physicians and Surgeons	(1913)	Georgia
Atlanta Medical College	(1914)	Georgia
Chicago Coll. of Med. and Surg.	(1914)	Illinois, (1917) Nebraska
College of Physicians and Surgeons, Keokuk	(1897)	Iowa
University of Louisville	(1892), (1911)	Kentucky
Atlantic Medical College	(1908)	Virginia
Palmire Medical College	(1896)	Virginia
Johns Hopkins University	(1917)	Maryland
National University of Arts and Sciences	(1915)	Missouri
University Medical College of Kansas City	(1904)	Missouri
Leonard Medical School	(1906)	Virginia
American Eclectic Medical College	(1894)	Kentucky
Eclectic Medical Institute	(1902)	Ohio
Medical College of Ohio	(1897), (1907)	Ohio
Western Reserve University	(1917)	Ohio
M.-d., Coll. of the State of So. Carolina	(1906), (1917)	S. Carolina
Vanderbilt University	(1893)	Colorado
Medical College of Virginia	(1910), (1913), (1916)	Virginia
University College of Medicine, Richmond	(1909)	Virginia
University of Virginia	(1907), 2	Virginia

**Book Notices**

**MEMBERS OF THE MALMED.** The Anatomical and Physiological Principles Underlying the Treatment of Injuries to Muscles, Nerves, Bones, and Joints. By Arthur Keith, M.D., F.R.C.S., LL.D. Cloth. Price, \$6.50. Pp. 335. New York: Oxford University Press, 1919

In presenting the growth of orthopedic surgery as a specialty, with a view to defining its present status, the author has used an interesting method, tracing the growth of the specialty through significant achievements by certain personalities. Each chapter concerns the life and work of some great physician who initiated an advance. Beginning with the orthopedic principles of John Hunter, chapters are devoted to Hilton, Thomas, Duhamel, Sayre and many others, including in each chapter pictures and biographic notes of the orthopedic surgeons whose work is discussed. The method is thus defined:

I have sought to guide the reader to the hospital wards, the physiological laboratories, the dissecting rooms, and private workrooms in which the great advances of orthopedic surgery were made, and to introduce to them the "Members of the Maimed" as they were in the heyday of life. In only this way, I conceive, can Medical History be written profitably.

The unique method of presentation, the beautiful literary style, and the authoritative character of the book make it one of significance not only to the orthopedic surgeon, but to all who are interested in the advance of medical science.

**PULMONARY TUBERCULOSIS.** By Maurice Fishberg, M.D., Clinical Professor of Medicine, New York University and Bellevue Hospital Medical College. Second Edition. Cloth. Price, \$6.50. Pp. 744, with 125 illustrations. Philadelphia: Lea & Febiger, 1919.

The great responsibility in treating tuberculosis, the author believes, rests on the general practitioner: that many cases are not hopeless, even though advanced, that institutional treatment is not the only effective method, and that careful home treatment is productive of practically the same improvement and ultimate results as institutional treatment. In discussing the clinical aspects, Fishberg emphasizes the constitutional symptoms. He gives attention both to bacteriology and to serology, as well as to the roentgen ray as aids to diagnosis; but the main reliance is placed on physical findings.

The treatment which he recommends is based on his own practice, and since it is in this particular phase of the subject that most men are interested, it may be well to recapitulate some of the views advanced. He lays considerable stress on air, food and psychic influences. A chapter is devoted to the open air treatment, in which, with diagrams and numerous illustrations, the author shows how this may be applied in the home. Climate is given a chapter, and another is devoted to institutional treatment. Under medicinal treatment it is pointed out that there is no specific for this disease, nor do we have any agent that will enhance the resistance of the tissues against the ravages of the tubercle bacilli. We do, however, have a distinct use for drugs in controlling symptomatology. The patient has no confidence in a physician who has no remedy for his ailment. As the author states, "If his medical adviser will not prescribe for him, he will seek remedies from another who is more obliging in this respect, or from an advertising quack." As has been pointed out several times, this is more particularly true of the intelligent patient than of the ignorant, for the latter distrusts his own knowledge and is more likely to place great reliance on the command of the physician.

The author discusses, under separate headings, the use of creosote, ichthyol, arsenic, iodine, mercury, the phosphites and cod liver oil. In a chapter on specific treatment he reviews the evidence thus far available on the use of tuberculin, pointing out its uses and dangers. The former he believes to be rather slight, stating that:

Tuberculin treatment is only efficacious in intelligent patients who are under the impression that they have mastered the theoretical aspects of infection and immunity and of specific therapy from reading popular books and articles on tuberculosis. In fact, in my experience, untreated patients hardly ever improve under tuberculin treatment because they cannot understand the benefit of fever, malaise, pain in the joints,

rausea, debility, etc. On the other hand, intelligent patients look forward to the reaction as an indication that the tuberculin is "working in their system" and they often improve, provided infinitesimally small doses have been given.

Finally, he says, "The general practitioner should not use tuberculin at all. He can obtain the same results by the judicious use of drugs without incurring any risk."

The book is well illustrated, and an exceedingly practical work. It contains some material with which the scientist who has devoted all of his attention to tuberculosis may disagree; but, on the whole, the advice may be considered practical and reliable.

## Social Medicine, Medical Economics and Miscellany

### THE PHYSICIANS' STRIKE

The suggestion of a physicians' strike has usually been a facetious one. There are times, however, when even the ever patient physician becomes irritated. The *Medical Press*, London, contains the following comment relative to a recent labor agitation in Yorkshire:

Correspondence in the local journals shows that the outpatient staff of the General Infirmary at Leeds are refusing treatment to the miners on strike. When two miners attended at the outpatient department, the medical officer on duty informed them that he was on strike too. Subsequently he offered to prescribe for them, but this offer they refused, on the grounds that they had been insulted. The miners, of course, have stated their grievances in the local press, and the correspondence has grown, partly in sympathy with the miners' complaints, partly alleging that retaliation must be expected in view of the hardships the miners have brought upon the public. Meanwhile the aggrieved miners, having asked for an inquiry into the conduct of the medical staff, the secretary of the infirmary has intimated that the committee will concede the request. The incident in question is an exceptional one, and we may believe without precedent. But the miners have only themselves to blame for its occurrence. Their unlicensed attitude in regard to their work having called forth general public indignation, accompanied by hardships from which they themselves are free, it is natural that resentment against them should take an active form, just to remind them that the game they play can also be played by others. A medical man with no coal in his house because the miners have refused to work, can hardly be expected to regard with any degree of effusive complacency, miners on strike who gratuitously seek his aid at a hospital. Medical men are not exclusively humane; they are also human like other people.

### PATHOMETRY OF THE INFLUENZA EPIDEMIC

At the last annual meeting of the American Public Health Association, a committee on the statistical investigation of influenza was appointed. A meeting of the subcommittee on pathometry was held at Columbia University, September 19. This committee includes a number of authorities on statistics, and hygienists representing various universities, the government services, and some insurance companies.

The committee first took up the question as to whether any mathematical function can rationally express the epidemic process. This question was answered in the negative, since it is clear that the epidemic process is by no means as simple as the controlled procedures of the physical and chemical laboratories. As it is impossible to stipulate which of the many factors in the epidemic process are supremely important, there is no definite basis from which to begin in order to produce an analytic expression for the "law" of an epidemic which will be valuable.

The second question discussed was: "Shall the pandemic explosion of 1918 be studied in relation to the course of acute respiratory disease since the preceding world-wide extension of the disease known as "influenza"? This resolved itself into a discussion as to whether the pandemic of 1918-1919 was to be considered as an isolated explosive

phenomenon, or as a part of a chain of events leading back thirty years or more. Dependent on the answer to this question by epidemiologists and clinicians, the committee may take up the charting of respiratory disease for the thirty-year period since 1889.

In considering the causal relationships in influenza, the subcommittee wishes to caution all research students in the use of statistical devices ordinarily employed to assist in arriving at conclusions of a causal relation between one phenomenon and another. It is pointed out that in any phenomenon of infectious disease, there are three physical elements: (1) the invading organism or group of organisms; (2) the host or population receiving the attack, and (3) the external environment of both invader and host. These factors may be subdivided as follows:

1. The Invader:
  - (a) The size of the dose of infection.
  - (b) The frequency with which the dose or doses are brought in contact with the host.
  - (c) Tendency of the invader to specific localization.
  - (d) Infectivity of the organism or organisms (power to produce sickness).
  - (e) Virulence (power to produce death).
  - (f) Activity of invader in the presence of existing bacterial flora.
2. The Host:
  - (a) Opportunity for receiving dose of infective material; Density of population; transport systems; public assembly; other channels of communication between the infected and the uninfected.
  - (b) Natural and acquired immunity to invasion and multiplication of organism or organisms, and to poisons produced by the invader.
  - (c) Resistance factors:
    - Nutrition; general physical condition; fatigue status; hygiene of environment; existence of definite bodily and mental states (injuries, effects of other diseases, intoxications, etc.); personal habits; medical and nursing care of those infected.

### 3. External Environment:

Temperature and humidity, separately and when acting together, and changes in these, may be expected to have some influence on infectious disease and especially on respiratory and influenza disease. By the ordinary methods of graphically associating weather and influenza-pneumonia data no very clear idea can be formed of the relation between these two elements. Students of this phase of the causal relation problem are urged to employ proper methods of measuring the combined effects of temperature and humidity, and of variations in them. It is possible also that only accumulations of excess or deficiency of temperature and humidity from an "optimum" or "norm" will show correlation with influenza. Some of the points to bear in mind in these correlation studies of weather and influenza data are, it seems to the subcommittee:

- (a) Explosiveness or "epidemicity" of the epidemic.
- (b) Time distribution.
- (c) Aggregate of epidemic damage regardless of explosiveness or time distribution.
- (d) Infectivity of the organism at various stages of the epidemic wave.
- (e) Virulence of the organism at various stages of the epidemic wave.

As to the effect of weather conditions on the case fatality of the disease, the committee recommended that, wherever possible, mention be made on case records of prevailing weather conditions, and that such case records be studied in relation to the various weather elements and variations in them.

**Care of the Eyes.** Glasses ordered for astigmatism or any compound refractive error require particularly accurate adjustment, and should be mounted preferably in spectacle frames. Children under 16 years of age should always wear these frames.—W. M. Carhart, *Pub. Health*, Michigan, September, 1919.

### Not Liable for Malpractice of Substitute Physician

(*Moore v. Lee (Texas)*, 211 S. W. R. 214)

The Supreme Court of Texas reverses a judgment of the court of civil appeals, which reversed one of the district court that was in favor of the defendant, and affirms the judgment of the district court, in this suit brought by plaintiff Lee to recover damages for an alleged breach of contract by defendant Moore to attend and treat the wife of the plaintiff during and after childbirth, and for alleged malpractice on the wife, during her confinement, by another physician for whose acts and negligence it was charged that the defendant was liable. The supreme court says that the plaintiff and the defendant had entered into an agreement whereby the wife of the former was to have the services of the latter, as a physician, for an agreed fee, during the approaching confinement of the wife. The defendant visited and examined her between 1 and 2 o'clock one morning, and promised to return when needed. Before 9 o'clock, the plaintiff notified him it was time to come to Mrs. Lee, when the defendant replied that, because of important business, he would be unable to come, but would send another physician, to which the plaintiff responded with a request to send him in a hurry. The defendant then telephoned to a physician whose general reputation as a physician was good, saying that he had a case to which he wanted to send him, that it was a partnership case, of which he expected to take care, and requested him to go out and look after the plaintiff's wife, and to notify him if he needed help or anything went wrong, whereupon he would either come himself or send assistance. The substitute physician reached the plaintiff's home at about 10 o'clock and attended to the delivery of the child, and there was evidence to raise the issue of injury to Mrs. Lee through his acts or negligence. However, the plaintiff expressed no dissatisfaction to him, at the time the child was delivered, and paid him on his second or third visit the full fee, which he testified he had agreed to pay the defendant, and paid nothing to the defendant. A jury trial resulted in a verdict and judgment for the defendant, which was reversed by the court of civil appeals, and Section B of the Commission of Appeals recommended that the judgment of the court of civil appeals be affirmed; but it is reversed by the supreme court, and the judgment for the defendant affirmed, as stated above.

It was immaterial on the matter of the defendant's liability for the substitute physician's negligence or lack of skill, under the issues joined, whether the defendant represented him to be his partner at the time he proposed sending him, no pleading was filed by the plaintiff alleging that he was held out as the defendant's partner, nor seeking to hold the defendant liable as a partner with the substitute physician, nor seeking any damages for any misrepresentation of his status as a partner. So the question was simply, What was the defendant's duty, under the law, when the plaintiff asked him to dispatch speedily another physician to treat Mrs. Lee? In the opinion of the supreme court, this question admitted of no answer save that the duty of the defendant was to exercise ordinary care in the selection of the physician to be sent. The opinion in *Texas Central Railroad Co. v. Zumwalt*, 103 Texas 607, 132 S. W. 113, declared that when a railroad company furnished an employee with a physician, the railroad company would not be held liable for the physician's negligence, unless, in treating the employee, he was the agent of the railroad company. No more could the defendant physician be held liable for the other physician's negligence or lack of skill, in the absence of facts to establish that such other physician was acting as his agent while he was treating the plaintiff's wife. From the very nature of the employment, the physician who takes the place of another must, while he alone is treating the patient, exercise his own judgment and his own skill; and he is truly an independent contractor. In the light of the long-established custom among the physicians in that community for one unable to treat all his patients to send another physician to those he was not able to attend, the defendant's state-

ments should be construed to mean that he expected to resume charge of the case when his other engagements would permit, and expected the physician sent to be compensated for the services he would render, while he himself would be compensated for the services he would render.

### Sufficient Evidence That Child Was Born Alive

(*Taylor v. Catwood et al. (Mo.)*, 211 S. W. R. 47)

The Supreme Court of Missouri, Division 1, says that the question at issue in this case was whether or not the child of the wife of the plaintiff was born dead or alive. If it was born dead, then the mother's heirs inherited certain real estate; but, if the child was born alive, then the plaintiff inherited the real estate from the child. The physician to whose maternity hospital Mrs. Taylor was taken in a very low condition, six or seven days prior to the full expected period of her pregnancy, after she had the day before been seized with uræmic convulsions, finding that her nervous condition was such as to prevent an examination without an anesthetic, made arrangements for an instrumental delivery; but Mrs. Taylor died after she had taken only a few inhalations of the ether. The physician then undertook, with all possible speed, to deliver the child, without an operation, and was successful, the child being delivered in two or three minutes. He testified that he used the methods which are known for respiration, blowing in the face, sprinkling cold water, and slapping the baby, and it breathed a few times or gurgled loud enough so that the other physicians could hear it, and the heart beat for a minute or two. That was one evidence of life. This was done while the cord was attached, in the hopes that a little circulation might start in the body; that if the mother was alive it would get a little supply of blood from her. The cord was left attached a minute or two; but, as no further evidence of life was observed, the cord was cut, and a nurse was told to take the baby upstairs where there was a plentiful supply of hot water and go through the other modes of respiration. All the physicians and nurses present at the time of the confinement testified that they either saw or heard unmistakable evidences of life in the child after the death of the mother, except that one physician said he heard a sound from the child, but did not know what caused it. The court thinks not only that a prima facie case was made by the plaintiff, but also that it was supported by substantial evidence. An attempt was made to impeach the physicians first mentioned by introducing in evidence a certified copy of the certificate of the death of the child, made by him shortly after the death occurred, to the central bureau of vital statistics, in which he stated that the cause of death was "premature birth—stillborn." In explanation, he said that he did not know very much about the death certificate, that the death certificates and birth reports were made in such a way that the physician did not give them much attention; that the death certificates were made out at the undertaker's, and once in a while, with these little fellows, they called up and asked if they could sign it; he did not remember about this one, but thought he signed it; that his office girl made out the birth reports, and errors might creep into them very easily. The trial court evidently took into consideration the testimony given as to the birth and death of the child, the certificate of death, and the explanation given, as well as all the other facts and circumstances in evidence, and on the whole decided in favor of the contention of the plaintiff that the child was born alive. Nor was much probative force to be attached to the fact that the brain, heart, lungs, kidneys, etc., of the child were not examined at the time of death. In fact, had it been done under the circumstances shown to have existed in this case, it would, to say the least, have called forth unfavorable comment. Besides, in the absence of the existence of some special reason therefor, the physicians, in such a case, would never have thought of examining those organs, which would have required the holding of a necropsy for the purpose of showing whether the child was born dead or alive. In fact, had they undertaken such a thing, under the circumstances, they certainly would have encountered a sharp rebuff at the hands of all its relations.

Southern Surgical Association, New Orleans, Dec. 16-18.  
Western Surgical Association, Kansas City, Dec. 15-16.

### INDIANA STATE MEDICAL ASSOCIATION

Annual Meeting, held in Indianapolis, Sept. 26-27, 1919

#### INFLUENZA SYMPOSIUM

##### Influenza in Children

DR. NETTIE B. POWELL, Marion: In uncomplicated influenza in infants and children, the tendency is toward a leukopenia rather than a leukocytosis, although there is a slight leukocytosis in cases of complicating pneumonia, and in general the prognosis is better in the latter cases. There is nothing sufficiently constant in the differential count to be of aid either in diagnosis or in prognosis. The general condition of these patients needs first attention. They are anemic and flabby, as though suffering from anhydremia; hence special attention must be given to the quality of the food and the quantity of water ingested.

##### Clinical Manifestations and Sequels in Influenza

DR. CHARLES P. EMERSON, Indianapolis: It behooves us to maintain the general health of those who come under our observation by recommending that they avoid assemblages of people, eat good food, and get plenty of sleep and lots of fresh air. Now is the time to attack the tonsils, look out for the nasal sinuses, drain the infected gallbladder and treat the chronic prostatitis.

##### Correlation of Bacteriologic and Pathologic Findings in Influenza

DR. E. N. KIME, Indianapolis: The influenza lesions are widespread and severe, but the lung lesions, while most spectacular, form a relatively small part of the entire picture. The morbid anatomy and bacteriologic findings vary with the stage of the disease, and depend largely on the nature of the endemic flora. Early diffuse toxic or hemorrhagic lesions are manifest in the skin, mucous membranes of the respiratory tract, serous membranes of the chest and head, and the parenchymatous tissues of the entire body.

#### DISCUSSION

DR. F. B. WYNN, Indianapolis: I want to emphasize especially the importance of preparing patients who had the severe type of influenza for the possibilities which may arise during the coming winter. Counsel them to look out for bad tonsils or any other infection, for that is a weak spot.

DR. VIRGIL H. MOON, Indianapolis: The failure of the lung to return to normal is one of the salient pathologic features in this so-called influenza. This was demonstrated at the necropsy. In the case of persons who had lived through an acute attack and afterward died from some foreign cause, the lungs did not return to their normal condition. We found areas which macroscopically and microscopically showed the same characteristics as those of persons who died during the acute attack.

DR. CHARLES H. GOOD, Huntington: The etiology is still unknown; but with rest in bed, not too much fresh air, and a building-up treatment, the prognosis in my experience is good.

DR. CARROLL C. COTTON, Elwood: I wish to emphasize that encephalitis occurs frequently. It generally occurs in children who had pleuritis. The pleural cavity should be drained early by incision.

DR. G. W. McCASKEY, Fort Wayne: Fresh air is the most important factor.

DR. GEORGE W. SPOHN, Elkhart: I do not know anything that is better than vaccine as a protective measure, if it is given properly. Study the vaccines; study the method of giving them; use a vaccine from a reliable house, and a large majority of cases of ear and throat trouble will subside.

DR. CHARLES E. REED, Culver: Our greatest effort should be prevention, not treatment. We should discourage public assemblies and urge people to keep themselves in good general health and avoid exposure. The elimination of diseased tonsils is also important. We used the Rosenow vaccine; I believe it was a large factor in preventing pneumonia and other complications, and possibly it modified the influenzal process, although it did not prevent the disease itself.

DR. A. C. KIMBERLIN, Indianapolis: In nearly all these cases on physical examination of the lungs you found two things: First, there is found rather frequently, if listened for carefully, a degree of moisture plainly recognizable and scattered throughout the pulmonary tissue. And there would also be a very marked diminution of the vascular volume. Percussion in most of these cases was of no value, but the diminished vascular volume was important.

#### CHILD WELFARE SYMPOSIUM

##### Relation of Ophthalmology to Child Hygiene

DR. JOHN RAY NEWCOMB, Indianapolis: The rôle of the ophthalmologist, the family physician, the family and the school is one and the same. Early and thorough examination of the eyes should be made by a competent ophthalmologist, and obedience to directions he may give in regard to the hygiene of the eyes and the use of corrective or remedial measures is essential. Nothing is more important to the child than normal visual function, and this means the best professional advice obtainable. The statement that a child's general health may be affected seriously, and even endangered by errors of refraction, may be questioned by some; but a study of case reports will convince one of the intimate relationship of ophthalmology to the general physical welfare of children.

##### Child Hygiene and the Doctor

DR. ADA E. SCHWETZER, Indianapolis: That valuable work in child hygiene has already been done in Indiana is shown by a fairly regular lowering of our infant mortality rate for the last ten years, the lowest point (80 deaths under 1 year in each 1,000 deaths) being reached in 1915. The highest mortality was 144, in 1909. For 1916, 1917 and 1918 the rates are 85.5, 83 and 88, respectively, the increase in 1918 being largely due to the influenza epidemic together with the increased cost of living.

##### Relation of Otolaryngology to Child Hygiene

DR. DANIEL W. LAYMAN, Indianapolis: The past decade has shown the laryngologist active in tonsillar surgery, because the internist and pediatrician, backed by the scientific work of the pathologist and bacteriologist, have advocated the removal of tonsils which are troublesome. Today, the progressive laryngologist does not wait until the tonsils have caused a diseased condition, because he knows diseased tissue is a menace to health, rendering the child much more susceptible to respiratory and gastro-intestinal disturbances of all kinds, as well as to the infectious diseases. Reports from contagious disease hospitals over the country show that in from 80 to 100 per cent of contagious disease cases diseased tonsils are present, and that they are nearly always present in the cases that develop complications.

#### DISCUSSION

DR. O. C. BREITENBACH, Columbus: Two important factors in bettering the condition of the children of the United States are: first, our standardized methods of grading children, and second, school inspection. School inspection must be more than mere inspection; it must include a follow-up system that will carry the life-saving principles of modern medicine into the homes.

Dr. W. A. HOLLIS, Hartford City: Not all that is written about child hygiene is written by physicians, and not all that is read on the subject is read by physicians; nor is all the good advice on the management and rearing of children to be obtained from physicians. I am frequently surprised at the amount of information intelligent women and mothers have collected, and I am always glad to learn from them.

Mr. J. L. MILLER (Office of Food and Drug Commissioner), Indianapolis: In regard to labeling poison alkalis, I do not believe that we have done our duty to our children until we have secured legislation that will secure the proper control of the distribution of these poisons, and I believe the physicians are the best people to bring about a sentiment in favor of enacting the proper law.

Dr. GEORGE W. SPOHN, Elkhart: I do not believe in the universal removal of tonsils. So many mistakes are made that we should be extremely careful in our differential diagnosis. Tonsils should be removed only when it is really necessary.

Dr. CHARLES STOLTZ, South Bend: One great trouble lies in our school inspection. This should consist of more than looking into a child's throat and finding out if it has myopia. School inspection should ascertain the conditions in the child's home, and the attitude of the community toward industrial problems.

Dr. H. O. PANTZER, Indianapolis: More care must be taken with medical records. In 99 per cent. of records only the most perfunctory reference is made to this subject, simply saying, "Has had ordinary diseases of childhood." We must do better in this respect in the future.

(To be continued)

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

*Third Second Annual Meeting, held at Cincinnati, Sept. 15-17, 1919*

The President, DR. JOHN F. ERDMANN, New York,  
in the Chair

### SYMPOSIUM ON VENEREAL DISEASE

#### Work of the Detention Home for Women in the Management of Venereal Disease

Dr. PALMER FINDLEY, Omaha: In June, 1918, at Fort Omaha, measures were taken to protect the soldiers from venereal disease. After the detention home was established, that infected girls and women could be treated properly, the percentage of venereal disease among the soldiers was greatly reduced.

#### Pioneering in Venereal Disease Control

Dr. A. J. McLAUGHLIN, Sioux City, Iowa: Educational methods, such as authentic literature and lectures, are useful in bringing about a demand in different communities for suppression of these diseases; but the carriers are not reached by this form of control. Law enforcement is the only method through which they can be reached; and if the law enforcement is strict enough, venereal disease can be eradicated.

#### Value of Detention as a Reconstruction Measure

Dr. C. C. PIERCE, Washington, D. C.: The war has given us volumes of data proving conclusively that the prostitute or sex-offender requires individual, correctional care to overcome the handicaps of mental inferiority, physical defects, educational neglect, and hereditary and environmental influences. The detention home has a definite place in the reconstruction program, but it must be a detention home only in the sense that individuals are detained until such time as they can be returned to society equipped to take their places as respectable and respected citizens. Merely to use a detention home for the cure and treatment of venereal diseases is to promote a vicious cycle. Unless the detained individual is given a vocational training whereby a decent economic status can be maintained, the detention home contributes to delinquency rather than corrects it.

The war-time detention house was designed primarily to meet an emergency, to protect the fighting men from venereal infections. The peace-time detention house for such an institution must be carried over with the peace-time program; it must be designed to protect the working forces—posterity—from venereal infections. The peace-time detention home must provide correctional facilities as well as medical facilities.

#### Detention and Treatment of Infected Women as a Measure of Control of Venereal Diseases in Extracantonment Zone

Dr. W. F. DRAPER, Richmond, Va.: The detention hospitals were a potent factor in controlling the spread of venereal diseases in extracantonment zones: (1) by making it possible to remove a large number of infected immoral women from the community and holding them absolutely apart from the general population for a number of months; (2) by making the chances of isolation for a considerable period of time so great as to discourage immoral women from operating in these areas; (3) by giving a practical demonstration to the community of the high prevalence of venereal diseases among immoral women, and the time and effort necessary in the treatment of these diseases, and (4) by actually removing foci of infection by medical treatment. The actual treatment of the women is believed to have been of far less importance in controlling venereal diseases in the extracantonment zones than the other factors mentioned. A period of treatment lasting only a few months is of doubtful efficacy, and serves only to embitter the patient without in any way detracting from her intention of again resorting to prostitution immediately on her release from the hospital. It is believed that the period of detention and treatment should be extended for a period lasting from one to four years, thus allowing time for more definite results as to treatment, and affording an opportunity for rehabilitation. In cases in which the mentality is so low as to preclude the possibility of a life other than one of prostitution, it would be an economy and a humanitarian act to commit such individuals to institutional care for life. The cost of the detention hospital is the most serious obstacle in the path of its development. Few communities are willing, if, indeed, they are able, to maintain such an institution. It is freely admitted, therefore, that federal aid in the establishment and maintenance of detention hospitals for women will be necessary for a considerable time to come.

### SYMPOSIUM ON ADMINISTRATION OF ANESTHESIA IN OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY

#### Safety Factors in the Team-Work of Operator and Anesthetist

Dr. JOHN J. BUETTNER, Syracuse, N. Y.: The duty of the anesthetist is not merely to administer the anesthetic agent, but also to help prepare the patient for the operation. When possible, the anesthetist should begin his work when the surgeon has decided that an operation is needed. It is advisable to have the patient in the hospital at least forty-eight hours before the operation. A full physical examination of the patient is advisable. A thorough examination of the urine should be made, and, when possible, a functional test. The examination for acetone is too often neglected. It should be made a routine practice. A full blood examination, including the clotting time of the blood, is another safeguard. It is especially in genito-urinary surgery that this preoperative care and preparation of the patient is valuable. Patients who formerly were doomed to die are now made fit subjects for surgery that affords not only relief, but oftentimes cures.

#### Some Adjuncts Which Promote Efficiency in the Use of Local Anesthesia

Dr. ROBERT EMMET FARR, Minneapolis: Elements which have influenced me in the adoption of local anesthesia are the facts that liberal amounts of procain can be used if safeguarded properly; the development of an improved armamentarium; the development of a morale on the part of my assistants and the hospital attachés which, together with the gradual education of my clientele, greatly influenced the

mental attitude of prospective patients, and an improvement in the method of handling the tissues. My experience leads me to believe that postoperative ileus and gas pains are, in the absence of infection, directly proportionate to the amount of trauma employed during the operation. Nausea, thirst, vomiting and pain are largely eliminated. When operations are performed on children under local anesthesia, restraint is necessary while the anesthetic is being introduced. My experience has been that the restraint necessary is probably less than one-tenth that required during the administration of a general anesthetic.

#### Surgical Barrage

DRS. CHARLES W. MOOTS and ELMER I. MCKESSON, Toledo, Ohio: A surgical barrage may be defined as the process of surrounding the surgical patient with all the skill and refinement known to specialists in the various departments of medicine and surgery during the preoperative, operative and postoperative periods. Surrounded with such a barrage, the patient may reasonably anticipate the lowest possible mortality rate, with the shortest and least uncomfortable morbidity period. The question of the advisability of nurses administering anesthetics has recently been brought up. While many nurses may be taught to administer the safer agents in uncomplicated cases in a manner highly satisfactory to the operator, yet the principle is fundamentally wrong. The administration of a general anesthetic is the giving of the most powerful and dangerous drug at the most perilous time of the patient's life. During any major operation the anesthetist may be called on to make one or several new diagnoses and prognoses, and this certainly constitutes the practice of medicine and demands unusual skill. The war has corroborated our previous observations that when nitrous oxid-oxygen was available in skilled hands, this form of narcosis is one of the best shock prophylactics. It is not remarkable that nitrous oxid-oxygen should be safer in shock and in preventing shock than other anesthetics when one recalls the fact that muscles cannot be paralyzed with it.

#### Postoperative Analgesia

DR. BERTHA VAN HOESEN, Chicago: Postoperative analgesia means a painless convalescence for surgical patients. The factors in postoperative analgesia technic may be thus enumerated in the order of their importance: scopolamin-morphin anesthesia; large enemata (from 4 to 5 quarts) given in one-half hour following operation and retained; frequent minute doses of scopolamin-morphin at regular intervals after operation and continued for the first twenty-four or thirty-six hours; the use of sharp instruments during the operation, avoiding blunt dissection; sponging gently and infrequently; a comfortable posture for the patient, with an effort to secure relaxation or support as may be required for the traumatized part of the body.

#### Care of Bowels During Puerperal Period

DR. ROSS MCPHERSON, New York: Nine hundred women were given routine catharsis, and 911 were not. Among the 900 who had catharsis, eighty-four at some time during their convalescence developed a temperature of 100.4 F. Among the 911 to whom no catharsis was administered, fifty-three developed the same degree of temperature. While I am far from believing that there is never any necessity for administering a cathartic in the puerperium, I wish to emphasize the danger and uselessness of routine drugging, and assigning certain effects to conditions which have not been shown to be the cause of the symptoms exhibited.

#### Method of Placing Sutures in Immediate Repair of Perineum

DR. WILLIAM D. PORTER, Cincinnati: In simple longitudinal tears the usual method is to place the sutures transversely. I place the sutures longitudinally. The torn surfaces being well separated, the needle is carried through the mucous membrane half an inch to the left of the apex of the torn surface; then carried longitudinally under the torn surface, keeping half an inch to the left of the gutter of the tear, the needle is brought out through the skin half an inch to the left of the deepest point in the skin tear. The needle is next

removed and placed on the other end of the suture, which is then carried down in a similar manner half an inch to the right of the gutter. The next stitch is placed parallel to the first, and half an inch to the outside. In a complete tear, the first stitch is carried through the skin near the mucocutaneous junction in such a manner as to transfix the end of the torn and retracted sphincter muscle; then under the torn surface parallel with, and near to, the edge of the torn rectal mucous membrane up to the apex of the tear in the septum, and transversely through the septum and down on the other side until the other end of the torn circular muscle is transfixed, and the needle brought out to correspond to the point of entrance. Succeeding sutures are placed parallel to the first.

## Current Medical Literature

### AMERICAN

Titles marked with an asterisk (\*) are abstracted below. Single case reports and trials of new drugs are usually omitted.

#### American Journal of Diseases of Children, Chicago

October, 1919, 18, No. 4

- \*Caloric Requirements of Normal Infants and Children from Birth to Puberty. F. B. Talbot, Boston.—p. 229.
- \*Influenzal Croup. H. L. Lynch, New York.—p. 238.
- Health Study of a Boy's School. E. M. Smith, Boston.—p. 248.
- \*Certain Nutritional Disorders of Children Associated with a Putrefactive Intestinal Flora. L. Porter, G. B. Morris and K. F. Meyer, San Francisco.—p. 254.
- Study of the Stools in Children's Institutions showing the Incidence of Intestinal Parasitic Infections. L. R. DeBoys, New Orleans, and H. L. Dwyer, Kansas City, Mo.—p. 269.

**Caloric Requirements of Normal Infants and Children.**—In a series of studies made at the Nutrition Laboratory of the Carnegie Institution of Washington, D. C., on the energy metabolism of normal infants and children from birth to puberty, 108 boys and seventy girls, were investigated. The majority of the younger subjects were normal breast fed infants. These were studied at the Boston Directory for Wet Nurses. The older subjects were selected from the New England Home for Little Wanderers, all possible efforts being directed toward individuals who represented normality. The findings are presented in a series of six charts.

**Influenzal Croup.**—Seven cases of influenzal croup are reported in detail by Lynch. Apparently, there are four distinct types of respiratory involvement according to the location of the lesion: (a) laryngeal; (b) tracheobronchial; (c) bronchopulmonary or asthmatic, and (d) pneumonic.

**Nutritional Disorders and Intestinal Flora.**—From their observations the authors have been able to show (1) that children whose diet is well balanced and whose nutrition is normal have an intestinal flora consisting of fermentative and putrefactive types without preponderance of either; (2) that children fed on large quantities of cow's milk have a more complex flora made up of various types, most of which are facultative putrefactors; (3) that in children who suffer from certain of the types of alimentary intoxication with malnutrition, the intestinal flora departs in a uniform manner from the normal, and that this departure is always characterized by the establishment of bacterial type predominantly putrefactive; (4) that the return of these children to normal health is coincident with a regression of the intestinal flora toward predominantly fermentative types and a later swing to balance between the two types; (5) that such changes in the intestinal flora can be brought about in the intestine of the human infant by withdrawing animal protein and persistently feeding large amounts of lactose (from 2 to 4 ounces daily), and other carbohydrates, that the period which may be necessary to produce this variation is from ten to forty days. While feeding acidophilus cultures has in a few cases aided a more rapid establishment of aciduric flora in the baby's intestine, this influence was not very great; (6) that the progressive cessation of the symptoms of intoxication and a return of toxic patient to

nutritional health coincides with the recognizable dominance of a fermentative flora; (7) that lactose and dextrins are the carbohydrates most effective in encouraging the rapid establishment of a fermentative flora in the intestine of infants and children. Following these investigations a system of treatment was devised and in nine cases during the last two years there has been but one fatality. The patient who died came late in the course of the intoxication. The plan calls for lavage of the stomach with a 2 per cent. sodium bicarbonate solution, and the washing out of the bowel with from 2 to 6 quarts of a 5 per cent. solution of the same salt, two to three times a day. All food is withdrawn, except that the patient is given large quantities of an iced, 7 per cent. solution of lactose with 2 per cent. of the sodium bicarbonate solution by mouth, and this is continued in spite of the vomiting. The patients suffer less if they are supplied with large quantities of fluid, and the vomiting ceases more promptly especially if the ingested fluid is kept cold. The intravenous injection of isotonic solution of glucose has been made a routine, even in those cases in which some sugar appears in the urine. If the respiratory signs of acidosis become alarming, Fischer's solution is injected into a vein in a quantity appropriate to the age and weight of the patient. The improvement in each case began at a time when it was possible to show that the intestinal flora had altered in type from putrefactive to fermentative.

 Study of Hysteria, Based Mainly on Clinical Material Observed in U. S. Army Hospital for War Neuroses at Plattsburg Barracks, N. Y. A. J. Rosanoff, Kings Park, N. Y.—p. 419.

**Therapeutic Meningeal Irritation in Neurosyphilis.**—Experiments were undertaken by Mehlertens and MacArthur to find out if the normal penetration of arsenic into the spinal fluid could be increased by an irritation of the meninges such as must occur in all of the intradural treatments. They found that irritation of the meninges by intradural injection of the patient's own serum caused a cellular reaction ranging from 100 to 2,300 cells per cubic millimeter of spinal fluid. Simple intravenous injection of 0.6 gm. arsphenamin resulted in a positive test for arsenic in the spinal fluid in 43 per cent. of the cases examined. Complete drainage of the spinal fluid did not increase the number of arsenic penetrations. Intravenous injection of arsphenamin, six hours after meningeal irritation, gave 92 per cent. penetrations, and compared with the controls gave three times as strong an average concentration of arsenic.

**Locomotor Disturbances in Disease of Cerebellum.**—Meyers describes the apparatus he used for studying the movements of the upper and lower limbs and details the findings in a number of cases studied. In a previous publication he advanced the theory that the essential function of the cerebellum is to inhibit, to regulate the activity of the motor cortex and of the tonus centers, probably located in the medulla. This theory seems to be supported by the graphic records here reported.

**Action of Certain Drugs on Brain Circulation in Man.**—On the basis of plethysmographic observation on the brain circulation in man under normal, in vivo, condition Raphael and Stanton claim that amyl nitrite causes a marked dilation of the brain vessels; epinephrin induces a primary constriction of these vessels, which is followed by a marked dilation; caffeine produces no demonstrable change in the dosage employed, and pituitary extract is followed by a dilation of the brain vessels, accompanied by a distinct "leukoreaction."

**Invalid Reaction.**—Richards gives a summary of sixty cases and reports six of these cases in detail to illustrate some of the psychobiologic twists for which invalidism may be a substitute. The author urges that a more careful and searching examination be made in these cases, in which only psychopathic treatment will lead to favorable results.

 Bed-side Roentgenography with a New Portable Roentgen Ray Apparatus. The Army Bed-side Roentgen Ray Unit Adapted As a Portable Apparatus For Civilian Practice. W. K. Coffin, Boston.—p. 431.

**Energy Content of Extra Foods.**—This paper deals with a group of materials very frequently eaten as extras, as incidental light meals, as ingredients of lunches, at picnics, spreads and on automobile tours, such as olives and olive products, sardines, nuts, potato chips, doughnuts, confectionery (such as caramels, nougats, chocolate almonds, peppermints, etc.). In view of their extensive consumption by children, the Benedicts have also determined and report here the caloric content of a large number of candies popularly sold under the name of "peppy goods," that is, sold in portions costing one cent each. They likewise include partial reports on cream cheeses, popcorn and crackers, including pretzels, and, finally, they report the average helpings of granulated sugar as measured by seventeen members of the laboratory staff, as well as weights and sizes of various lump sugars. The calories of olives range from 1.147 to 1.553 per gram. The caloric values per gram of the so-called ripe olives, range about 2.4 calories per gram, due to the extra fat. A can of imported sardines will yield not far from 500 calories, and a can of American sardines will yield from 221 to 533 calories. The high fat content of nuts accounts for their high caloric value, which runs in all cases not far from 7 calories per gram. Owing to the fat content of potato chips, their caloric value is, on the average, 5.9 calories per gram. The caloric value per gram of doughnuts varies with

the fat content, ranging from 4.4 to 5.1 calories, averaging not far from 200 calories per doughnut. The caloric value of crackers and pretzels per gram is not far from the caloric value of starch, i. e., 4.2 calories. The caloric value of caramels is somewhat over 4 calories per gram. The caloric value of chocolate coated candies for the most part runs above 4 calories per gram. Not far from 50 to 60 calories are commonly secured in penny candies for one cent. Popcorn candy has a caloric value of 4030 calories per gram; Philadelphia cream cheese, 3,654 calories per gram; Neufchâtel cheese, 2,056 calories per gram. The average teaspoonful of sugar furnishes from 29 to 35 calories.

**Medical Supervision of Framingham Schools.**—Of the 2,449 children examined in the Framingham schools, 408 were found to be anemic; 1,113 had enlarged cervical lymph nodes; 1,167 had hypertrophied tonsils of varying degrees; 29% had defective nasal breathing due to nasal obstruction from hypertrophied turbinates, adenoids or injury to the nose; 133 children had eyes testing <sup>20/40</sup> or worse; 146 had heart murmurs; 39 had functional irregularities of rhythm; 11 cases of pulmonary tuberculosis were found; 64 other children had a history and abnormal physical signs in the chest which suggested possible tubercle; 172 had bronchitis and 6 cases of pleurisy were diagnosed. Of the skin diseases, impetigo contagiosa held first place with 29 cases, with pustular dermatitis, eczema, acne, scabies, ringworm, ichthyosis, following in the order named. One case of ichthyosis congenita, a rare skin affection, was diagnosed. One thousand six hundred and eighty-one children had teeth needing urgent attention.

Röntgen Diagnosis in Its Broader Application. L. W. Cunningham, Jacksonville.—p. 62.

Atypical Syphiloderms. J. L. Kirby-Smith, Jacksonville.—p. 63.

**Study of Gastric Mucus in Diagnosis of Anorexia Nervosa.**—The point in diagnosis referred to by Smith is that the microscopic study of the mucus taken from the stomach of these patients usually shows many incorporated epithelial cells if the condition is purely a nervous affection, whereas their absence suggests an organic state. In the treatment of this condition it is Smith's plan to select a well ventilated, quiet room—up stairs, if possible—leading out on an open porch; remove unnecessary wall decorations, drapery, flowers, etc.; give the stomach twenty-four hours rest from all kinds of food and medication; directing the nurse to administer one tablespoonful of very hot distilled water to the patient every hour during the day or until pain and nausea seem to be diminished; require all food kept out of sight and caution the nurse not to even use the words "pain," "food," "medicine," "nausea" or "vomiting" at any time in the presence of the patient. To safeguard against toxic symptoms and to insure the patient of a fair night's rest and sleep Smith gives first a colonic irrigation of warm distilled water and then administers from 30 to 40 grains of sodium bromid in 16 ounces of distilled water or else he introduces a rectal suppository containing from 15 to 20 drops of deodorized tincture of opium using precautions not to have a habit formed. Early the following morning the patient is made to swallow the weighted end of a modified duodenal tube, requiring him to spend some time on the right side after the tube has reached the pylorus. In about thirty or forty minutes the tube will be 1 or 2 feet in the jejunum. Smith's modification of the original duodenal tube is its great increase in length, and the end of the tube has long, fenestrated openings in it to prevent choking as the food escapes. The fact that the end of this tube is 2 or 3 feet below the stomach Smith has found to be of great value in preventing the tube from being forced back into the stomach and also the food from

regurgitating should reversed peristalsis occur. Another great advantage in depositing this nourishment considerably down in the small bowel is that the stomach is given prolonged and continued rest, the presence of the tube usually not giving any sensation whatever. If the patient tolerates the tube well, it is left in place all day; on the other hand, if it annoys the patient it is removed for about four hours during the middle of the day. The extent to which artificial digestion is resorted to before introducing the various foods depends entirely on the result of analysis of the gastric contents. If all enzymes are absent, as they usually are in neurotic cases, the liquid nourishment, such as purées, animal broth, toasted or untoasted cereal gruels, is subjected to thirty minutes' digestion on a hot water bath, or other device, at about 37 C., using diluted hydrochloric acid, malt extract and pepsin. If these feedings are given about every two or three hours regularly, the patient soon regains sufficient strength to have this process discontinued and begin gastric feeding by mouth, at which time normal hunger and appetite return.

**Antimeningococcal Action of Certain Dyes.**—A study by Binger of the action of safranin on suspensions of meningococci showed inhibition of their growth at dilutions between 1:1,000 and 1:10,000. This led to an investigation of the behavior of certain other common dyes both on meningococci and other pathogenic organisms, and a comparison of their inhibitory action with that of a few of the common anti-septics. Of the dyes studied, guttan violet, crystal violet, brilliant green, bismarck brown, safranin, methylene blue were found to inhibit the growth of meningococci. Basic fuchsin, vital red, fluorescein and eosin had no inhibitory action. The study of the comparative action of methylene blue on various types of meningococci and other pathogenic organisms showed that the growth of meningococci was inhibited at dilutions which failed to inhibit the growth of the other organisms with one exception. The inhibitory action of methylene blue on the meningococcus and the gonococcus, biologically related organisms, was the same. No fixed point of dilution has been established at which methylene blue inhibits the growth of different suspensions of meningococci. This varies with the number of viable organisms present in the suspensions. For a given suspension, however, the inhibitory point is constant. A study of the comparative action of methylene blue, formaldehyd, mercuric chlorid and phenol showed mercuric chlorid to exert the most powerful action, phenol the least, while methylene blue and formaldehyd exerted an equal influence intermediate between the other two. The presence of native protein of inflammatory cerebrospinal fluid did not interfere with the inhibitory action of methylene blue on the meningococci. The hope of finding a chemical therapeutic agent for the meningococcal group of infections is what prompted Binger to make this study. He suggests that methylene blue may possibly fit the requirements. It inhibits the growth of meningococci at fairly high dilutions. It is relatively non-toxic, it is readily diffusible through the choroid plexus and to have a special affinity for nerve tissue.

**Destruction of Typhoid Bacilli in Rabbits.**—The observations made by Stone suggest the mechanism of bacteriolysis in the body of the immune animal, namely: Typhoid bacilli disappear more quickly from the organs of immune animals than from normal animals. Macerated organs taken from immune animals, cut sections, or their extracts are not bactericidal even on the addition of fresh immune serum. Typhoid immune serum is nonbactericidal for typhoid bacilli in vitro. Fresh normal serum is highly bactericidal for typhoid bacilli in vitro. Fresh immune serum in vivo, has apparently a high bactericidal power. Fresh normal serum in vivo has no protective power. This would seem to indicate that the destruction of typhoid bacilli in the immune animal is due either to some interaction between the tissue cells and plasma in vivo, or to some other factor which has thus far been overlooked.

**Experimental Streptococci Tonsillitis.**—During investigations of 155 human volunteers to study the epidemiology of influenza, sixteen different individuals developed tonsillitis apparently due to hemolytic streptococci. All cases of tonsillitis occurred in men receiving crude nasopharyngeal washings and bronchial secretions from early, acute, typical, uncomplicated influenza patients—with exception of six cases in which the common donor had acute tonsillitis; no cases of tonsillitis occurred in those into whose nares were instilled filtered nasopharyngeal washings and bronchial secretions from influenza donors. The causative organisms of the tonsillitis were very similar to the hemolytic streptococci isolated from the nasopharyngeal washings and bronchial secretions of the donors of the respective groups. Three of the cases of tonsillitis developed in persons who had received, one month previously, a vaccine containing, in addition to other organisms, three presumably adequate doses of hemolytic streptococci.

**Effect of Feeding Yeast on Antibody Production.**—According to Wolf and Lewis the feeding of yeast has no stimulating effect on the production of antibodies to sheep blood in rabbits. The production of antibodies was even less than in controls. There is no evidence of any effect of yeast on the gastro-intestinal tract of rabbits.

**Biologic Classification of Streptococci.**—By means of agglutination tests Havens establishes three distinct groups of the hemolytic streptococci, constituting 93 per cent. of a series of 292 strains. The first group is much the largest (47 per cent.), the second group contains 19 per cent., and the third group, 27 per cent. The remaining twenty-two strains, or 7 per cent. of the series, evidently constitute a heterogeneous group, possessing different biologic characteristics. Diagnostic serums can be produced for each group. A protective serum for mice against each of these three groups has been demonstrated. Each serum is specific for its own group, furnishing no protection against other groups.

**Positive Wassermann Reaction in Hyperthyroidism.**—Biggs calls attention to the large percentage of hyperthyroid cases in State Hospital No. 1, Fulton, Mo., giving a positive Wassermann in which it was impossible either from clinical history, physical examination or inquiry into the family records, to establish any syphilitic infection or taint. The patients were insane, with two exceptions, and their cases had been diagnosed under the head of "thyrotoxic psychosis." Those individuals all became unmanageable to a greater or less degree at their respective homes, necessitating their confinement in an institution for the insane. The psychosis of each, in the main, was characterized by wild delusions, irritability which sometimes developed into acute excitement, slow speech and deliberate mentation, absence of suicidal or homicidal tendencies, lassitude and indifference to surroundings and apparent feeble-mindedness in some. There was in these cases a total lack of the symptoms which are manifested in a psychosis which results from syphilis infection, either acquired or inherited. The physical signs were such as one would find in the average case of this type. In most of the cases an exophthalmic state was found to exist with marked tachycardia and other symptoms which accompany conditions of this kind. In some of the cases the enlargement of the thyroid was more lateral and varied in size to a great extent. The changes in the skin, teeth, blood, and temperature of the body, are typical of this class of cases. The prevailing mental tone associated with the disease was fear and apprehension, frequently associated with hallucinations of hearing and vision; voices were heard saying disagreeable things and with these hallucinations occurred anxious and agitated states. A brief case history of twelve patients is given.

**Extra-arterial Factors in Angina Pectoris.**—Three cases are reported by Bohan as evidence of causes of angina out-

side the cardiovascular system. The first case, one of severe angina, indicates that heart strain and reflex disturbance from irritation of the fifth nerve was either the sole cause or an important contributing factor. Irritation of the fifth nerve as a possible factor in angina, is illustrated by the second case. The third case indicates that infected tonsils, apical abscesses, neuritis in the left shoulder and gallstones were possible factors.

**Oak Pollen Anaphylaxis.**—Annually for the last nine years, within a few days of the first of April, Kerr's patient became ill with symptoms of hay-fever, irritation and injection of the conjunctiva with excessive lachrimation, sneezing, etc. After the first week, a papular eruption appeared on the anterior surface of the neck, elbows, groin and popliteal spaces. In about a week the papules coalesced, forming a weeping eczematous condition, which persisted very obstinately for about four weeks. During this time a considerable bronchitis and some very slight symptoms of asthma appeared, and he was incapacitated for school work. Superimposed on all this there was a bacterial infection which was followed by a furunculosis which manifested a predilection for the region of the groin and buttocks. It was evidently an anaphylactic condition. A positive reaction was obtained from oak pollen. The condition cleared up quickly when the patient got away from the oak trees among which he lived.

**Neutrophilic Index in Diagnosis of Tuberculosis.**—Polymorphonuclear neutrophil leukocytes with two or more separate lobules, absolutely apart and not connected by an isthmus band, are more "matured" and are endowed with a better phagocytic and a greater antibody action than the polymorphonuclear neutrophil leukocytes with one lobule. In

cases of tuberculosis where tuberculin is administered, Durel recalls there is always an increase of polymorphonuclear neutrophil leukocytes with one lobule after the injection of a "tonic" dose of tuberculin. This is generally followed in a few days by a corresponding increase of polymorphonuclear neutrophil leukocytes with two or more distinct and separate lobules. Cases where tuberculin reactions are frequently repeated always show a persistently high neutrophilic index, i. e., a high percentage of polymorphonuclear neutrophil leukocytes with one solid lobule. These cases also always show an increase of moisture over the tuberculous lesions. This increase of moisture is accounted for by the overcrowding of polymorphonuclear neutrophil leukocytes about the tuberculous foci, the pressure of the cells against each other producing a pneumonic serum exudate. Durel emphasizes again that the predominance of one lobule polymorphonuclear neutrophil leukocytes, associated with an increase of moisture (moist rales) over the tuberculous lesions, and following a reaction to tuberculin or severe exertion, clears up a doubtful condition often seen, but for which no tangible reason could be given nor accountable cause assigned.

**Normal Human Serum Treatment of Pneumonia.**—Cannon reports a case of pneumonia in which he injected 30 c.c. of serum obtained from a donor who had not had pneumonia or influenza. After obtaining a negative Wassermann and finding the blood of the donor and the recipient compatible, about 75 c.c. of blood was drawn into a sodium citrate solution, and after allowing it to settle overnight in the refrigerator, the serum was pipetted off and 30 c.c. were given to the patient by the gravity method. In about an hour he had a rather severe chill, rise of temperature to 104 F., associated with a severe coughing spell; he became very nervous and cyanotic (probably from the exertion of coughing) and the pulse became very rapid. This was followed in an hour by a drenching sweat and an improvement in all symptoms. Within five and one-half hours after the injection the temperature had reached normal, pulse 102, and respirations 24. In the case cited the fact that the patient had had influenza and still had the cough he developed with that disease Cannon suggests that it is possible at least that it may have been associated with the Type IV infection which he had, although clinically the case was one of pure lobar pneumonia.

**Fate of Bone Graft.**—Campbell is of the opinion that in adolescents and young adults, grafts are more vigorous and apparently act as a living, integral part, showing no disintegration, but a gradual increase in size and thickness. Spinal grafts in young children, and probably in adults, are absorbed. The graft may be inert or very feebly osteogenic but mechanically perform the function for which it was employed, as in the neck of the femur (dense into spongy bone).

**Treatment of Hour-Glass Stomach.**—It is Walton's custom to excise the ulcer, to occlude the pylorus and to perform a posterior gastro-entostomy. With these methods, which have been carried out in over eighty cases, much more satisfactory results have followed. Hour-glass constriction may be met with in all stages. Sometimes the ulceration is the chief factor, the stenosis is slight, and there are no symptoms of mechanical obstruction. In such instances, the treatment is that of a simple ulcer on the lesser curvature. Ten case histories are presented.

**Metastatic Carcinoma of Spine.**—Pfahler claims that deep roentgenotherapy will bring about a healing process in deep seated carcinoma. Metastatic carcinoma of the spine is not a superficial disease. It is not Pfahler's intention to recommend roentgenotherapy in the treatment of such advanced carcinoma. Pfahler also encourages the use of the roentgen rays in the early treatment of carcinoma, claiming that a favorable and curative effect can be produced on carcinomatous tissue, even in an advanced stage. In all of the cases of metastatic carcinoma of the spine, which Pfahler reports, the disease was of the breast. Pfahler says that one cannot expect the patient to make a complete, permanent recovery, for ultimately the disease is apt to show metastasis, particularly in the areas not treated. However, with the clinical and microscopic proof of the destructive action on malignant tissue followed by a healing process, and with the experimental proof of a decrease in the malignancy of cancer tissue which has been exposed to the roentgen rays and a decrease in its capability of inoculation, Pfahler recommends most strongly the use of deep roentgenotherapy both as ant-operative treatment to be followed immediately by operation and then post-operative treatment, given after the proper interval, which should be four weeks after the ant-operative treatment.

**Radium Treatment of Uterine Cancer.**—The cases reported by Janeway in which radium therapy was used, are, briefly, as follows: Carcinoma of the cervix, seventeen cases, twelve clinically cured to date, from three and one-half years to six months after treatment; recurrent carcinoma of cervix, four cases; two clinically cured, sixteen and twenty-five months after treatment, one improved; carcinoma of fundus, four cases; two improved for periods of two years, two clinically cured, fourteen and twenty-one months after treatment; carcinoma of external genitals, five cases; three clinically cured to date, from twenty-one to sixteen months after treatment was begun; one improved, one unimproved.

**Secondary Melano-Epithelioma of Bladder.**—Richard's patient had pigmented moles irregularly distributed over the entire body. For the past five or six years, he had noticed that a rather large mole situated on the right side of the abdomen near the umbilicus had a core of granular debris which could be expressed, and two months previously it had begun to enlarge and had a tendency to bleed. Because of the bleeding the patient consulted his physician who excised the growth. Histologic examination revealed melano-epithelioma. Further surgical advice was sought, and the examination was negative, except for slight enlargement of the inguinal lymph nodes. The urinary findings were negative. A gland removed from the groin was found to be malignant in character, and therefore all the lymph glands

in both groins and Scarpa's triangle were removed; the external saphenous vein was ligated. While the patient was convalescing from the operation radium treatment was begun, and was continued at frequent intervals. Eight months later another small gland in the inguinal region was discovered, which proved to be of the nature of those previously removed. Ten months later increased frequency of urination and diminution in the size of the stream, and nocturia were noticed. The urine contained a number of erythrocytes and pus cells. On cystoscopic examination multiple areas of black rounded tumors, varying in size from 2 to 5 cm. were found on the right base of the bladder anterior to the right meatus. On the left wall two of the tumors had pedicles; the others were sessile. As soon as the bladder condition was discovered, intravesical radium treatment was instituted. To the present time 400 mg. hours have been given. At the last cystoscopic examination no material change was noticeable, except, perhaps, a slight increase in the size of one or two of the tumors.

**Sacral Suspension of Uterus.**—Young's conception of the indicated surgery in uterine displacement cases is as follows: In nullipara, for physiologic retroversion, round ligament shortening; for pathologic mechanical retroversion and descensus, sacral suspension and, if needed, round ligament shortening; when there is a conical long cervix, the tracheloplastic operation of Sturmdorf. In multipara, the restoration of all birth trauma; dilatation and curettage if indicated; for the hypertrophied infected lacerated cervix, the tracheloplastic operation for cystocele, the restoration of the vesicovaginal endopelvic fascia by the method of Rawls; for rectocele, the restoration of the retrovaginal endopelvic fascia, and the muscular interposition perineorrhaphy. He describes his uterosacral ligament shortening operation in detail.

**Omental Grafts in Intestinal Surgery.**—Finton and Peet find the use of detached omental grafts preferable to fixed grafts, except in the presence of general infection. They may be used on any abdominal organ. The indications are to replace lost portions of peritoneum; to straighten suture lines; to prevent adhesions; to check hemorrhages; to occlude the pylorus; to cover the stump of the cystic duct or fallopian tube and to reinforce the peritoneum in threatened perforations. The technic is simple and may be performed with little trauma and in a minimum period of time. In the absence of infection the thin graft survives at least six months practically unchanged.

**Futility of Bridging Nerve Defects with Nerve Flaps.**—In Stookey's opinion the repair of nerve defects by means of nerve flaps has not been definitely supported clinically, as evidenced by a critical study of the reported cases. Experimentally, it has been shown that nerve flaps do not serve as conducting paths for the down growing neuraxes. Nerve flaps whether central or peripheral are merely degenerated partial nerve segments. Continuity and union of neuraxes does not take place at the point of suture. By the formation of nerve flaps from the central stump a portion of the nerve from which neuraxes must grow is removed. Distal as well as central flaps may sever muscular branches. By reversing the flaps they are taken out of their field. Thus the down-growing neuraxes are prevented from reaching the muscles through these muscular branches even were regeneration to take place. For these reasons the nerve flap method to bridge nerve defects should be discarded in peripheral nerve surgery.

**New Sign of Fecal Impaction.**—The sign described by Finocchio is the auditory translation of the Gersuny sign. It is elicited as follows: Over the chosen area the funnel shaped end of a French stethoscope is applied. Over the shell end is applied the observer's ear, holding the instrument lightly with the fingers. The abdominal wall is depressed a few (from 10 to 40) millimeters with the stethoscope, and then the pressure is suddenly released. During the withdrawal of the stethoscope is heard a large moist rale if the sign is positive. Sometimes this is heard not only during the release of pressure, but also during its appli-

caution. Sometimes it is necessary to change frequently the place of the funnel in looking for this sign before it is found. Finocchio has found the sign positive in every patient with fecal impaction.

**Foreign Body in Urinary Bladder.**—In order to remove a paraffin pencil from the bladder without operation, Caples injected into the bladder 125 c.c. of a solution of 33.33 per cent. gasoline in paraffin oil at 110 F. Six subsequent injections, each of 125 c.c. at 110 F., were given. These were retained for intervals varying from two to five hours. The entire treatment covered a period of three days, and the total time of exposure to the solvent was seventeen hours. The urine and solvent were collected after each injection and by chilling them the paraffin was precipitated in decreasing amounts down to the fifth specimen. As the sixth and seventh gave no precipitate, the injections were discontinued. In the meantime, the patient's symptoms abated rapidly, and two days after his last injection his condition was normal. One week later on cystoscopic examination the bladder was normal and no trace of paraffin could be found.

**Tracheotomy Without Loss of Blood.**—Guthrie makes an incision in the midline of the neck from  $1\frac{1}{2}$  to  $1\frac{3}{4}$  inches long. The incision must end one-half inch above the sternal notch to avoid the arcus of the anterior jugular veins. The skin and the superficial fascia are incised and the wound held open by a pair of catspaw retractors which should not be more than 1 inch in breadth. The parallel branches of the anterior jugular veins escape injury if the incision is made in the midline of the neck because they lie to either side of it. The sternohyoid and sternothyroid muscles are separated by blunt dissection. If care can be exercised during this step of the operation, the muscles can usually be separated without injury to the thyroid ima beneath. The retractors are reset. The left blade holds aside the skin, the fascia and the two muscles; the right blade holds the skin, fascia, the muscles and the thyroid ima vein. This exposes the trachea. It is incised, the head is straightened, and the tracheotomy tube inserted. This method has been employed successfully fourteen times in all types of cases.

**Etiology and Treatment of Cystocele.**—Neel draws down the cervix and makes a deep transverse incision just below the bladder wall, through the vaginal mucosa and the underlying fascia. The proximal flap is caught by forceps, care being taken to include the fascia; the dissection is carried between the muscle wall of the bladder and the fascia to the urethra; a median incision is then made, the bladder is dissected free of the cervix and the fascia and displaced upward to its normal position. This section is carried out by a small piece of gauze over the finger, the pressure being applied chiefly over the fascia and edge of bladder. The fascial and mucosal edges are then caught separately by clamps and the separation begun by sharp dissection, care being taken to locate the proper layer in order to preserve the entire fascia; by blunt dissection the separation is carried well up to the pubic bones on either side. The remaining steps of the operation are the same as those employed in the treatment of hernia.

**Sterilizing Catgut Sutures.**—The only logical way in Watson's opinion in which sterility of suture can be obtained and maintained throughout the process of preparation is to sterilize the sutures in their ultimate storing fluid after sealing the tubes. The perfection of such a method constituted the problem studied by him. Representative sizes of catgut sutures corresponding to those usually employed in surgical practice were heavily infected with three different species of sporulating bacilli, this producing a more massive and resistant bacterial infection of the gut than would occur even under the most unfavorable conditions. With toluol as a tubing or storing medium the sutures were subjected to a temperature of 165 C. for five hours after the tubes had been sealed. The sutures were removed from the tubes and tested for the presence of living bacilli by appropriate bacteriologic methods. The fact that none of the sutures, after having undergone this sterilizing process showed the presence of any viable organisms would seem to prove the complete efficiency of this method of sterilization.

- \*Primary Carcinoma of Ovary at Age of 11. C. A. S. Ridout.—p. 380.

**Treatment of Liver Abscess.**—In Talbot's opinion the majority of these cases can be treated successfully by aspiration with an ordinary 20 c.c. glass serum syringe. It does not appear to be necessary even to withdraw all the pus. Once the tension in the abscess cavity is relieved, the emetin carrying plasma can pass through the walls of the abscess cavity and exert its lethal effect on the amebas present there. After aspiration every patient was given a course of hypodermic injections of emetin hydrochlorid, 1 grain daily for one week and then on alternate days until 12 or 14 grains had been given. Whenever possible each patient was given 1 grain of emetin a few hours before operation, so that the first serum to flush the walls of the abscess should be carrying emetin. In addition to the fifteen cases of proved liver abscess Talbot saw seven or eight cases of hepatitis following dysentery, some of which were probably in an early suppurative stage and which cleared up rapidly with emetin.

**Primary Sarcoma of Liver.**—The symptoms in the case reported by Morrow and McKinstry were as follows: A man, aged 42, was admitted to the hospital in a condition of advanced emaciation. He stated that his health had been good until a year previous, when he began to feel pain in the stomach about half an hour after taking food, and he had a constant sense of discomfort during the intervals between meals. Flatulence was a prominent feature, but there had never been any vomiting. There was no noteworthy constipation. There had been a steady progressive loss of weight. The abdomen was distended by a large smooth solid tumor, extending from the costal margin to the brim of the pelvis; at its lower edge a distinct fissure could be felt in the middle line. There was some bronchial catarrh, with a persistent irritating cough. The urine was normal. A blood count showed only a slight secondary anemia (red cells, 4,000,000; hemoglobin, 70 per cent.), total white cells, 10,000 and differential white count normal. A Wassermann test was negative. The patient gradually sank, and died on the fourth day after admission. On opening the abdomen the liver was seen to have a mottled appearance and to be enlarged greatly, extending on both sides as low down as the iliac crests. The surface of the liver presented a large number of grayish white areas of new growth some of which were about the size of a pea, while others were larger, umbilicated, and slightly raised above the surface. The general "mottling" appeared to be due to the coalescence of these nodules, forming large grayish patches which were little, if at all, raised above the surface. In the gastro-hepatic omentum and in the mesentery slightly enlarged lymph glands could be felt, and those about the head of the pancreas were particularly large and matted together. The lungs showed numerous small whitish patches scattered over the surface. On microscopic examination the growths from the liver, lungs and lymph glands were found to present the same histologic features, those of an alveolar sarcoma. In view of the facts, first, that no evidence of a growth could be found in any of the other abdominal organs, and, second, of the enormous size of the growth in the liver, it was inferred that the tumor was a primary growth in the liver.

**Primary Carcinoma of Ovary at Age of Eleven.**—The tumor in Ridout's case weighed 2 pounds 14 ounces, and was about 8 inches in its long diameter. The pathologic report showed the presence of carcinoma cells in a scanty stroma.

 Tropical Hypertension. C. McNeil, p. 180.  
 Leishman. T. A. Ross, p. 175.

**Wound Shock and Its Treatment.**—McCartney summarized his observation as follows: Injury to muscle tissue causing a traumatic toxemia is one of the main features causing secondary shock. Other probable secondary factors are hemorrhage, cold, fatigue, pain and lack of food. The result of shock is to cause a marked lowering of blood pressure, and the consequent anemia affects especially the nerve centers. In resuscitation work the treatment of three phenomena has alone yielded successful results, namely: (a) Lowering of body temperature; (b) lowering of blood pressure; (c) diminution of blood volume. The author emphasizes that it is the cases of hemorrhage combined with little shock which form the successes in resuscitation work, and that the treatment of acidosis by intravenous injection of sodium bicarbonate has little or no practical value in cases of shock.

- \*Resistance of Ascaris Eggs. Yoshida and Hotta.  
 Prevention of Abortion, Especially the Customary Abortion. Taniguchi.  
 \*Efficacy of Epinephrin in the Treatment of Night-Sweats. Takaki.

**Resistance of Ascaris Eggs.**—One of the most interesting things discovered by Yoshida and Hotta was the fact that the eggs of ascaris do not develop in urine. If they are left standing for a considerable time in urine, they all die. Urine kept in a warm room kills the eggs more rapidly. They think that the killing of the eggs greatly depends on the penetrability of the liquid in which the eggs are kept. Their experiments proved that liquor formaldehydi and sulphuric acid do not affect the exterior coating of albumin, but they coagulate the egg white that surrounds the embryo, and, therefore, they do not penetrate deep enough to reach the embryo. When the eggs are kept in a solution of glacial acetic acid and nitric acid for a long time, the albuminous membrane decays and the chitinous wall is exposed, but the embryos within the eggs develop, for these drugs will not penetrate through the chitinous membrane. Hydrochloric acid also brings about a similar result. Phenol, on the contrary, seems to kill the eggs in a shorter time.

**Efficacy of Epinephrin in Treatment of Night Sweats.**—According to Takaki epinephrin has an absolute value in the prevention of night sweats in tuberculous cases. Its efficacy lasts for three days. Individual hypersensitiveness may be prevented by administering it in 10 c.c. of physiologic sodium chloride solution. If after the first injection no improvement should occur the same quantity may be given for the second time after an interval of one day. By the third injection and in increased doses, the ultimate result is often obtained. The author gave 0.7 c.c. but thinks much larger doses may be given. Diabetes, myocarditis and pulmonary hemorrhage are contraindications.

- \*Experimental Investigation of Mixed Immunization. Anagishi.  
 \*Influence of Sugar in Infection of Pathogenic Microorganisms. Takekura.  
 Microscopic Findings on Nerve Endings in Eye after Injection of Araphenol. S. Suganuma.

**Experimental Investigation on Mixed Immunization.**—Anagishi carried out an experimental investigation on immunization with the trivaccine consisting of *Bacillus typhosus* and *B. paratyphosus* A and B. Injection of either the nonmixed or the mixed vaccine produced equal result, as has been reported by other investigators. There seemed hardly any difference between the quantity of the antigen and the strength of its reaction test.

**Influence of Sugar in Infection of Pathogenic Microorganisms.**—Considering the fact that the diabetic is liable to tuberculous affection, Takemura carried out experiments on animals. He made rabbits suffer from experimental diabetes and then they were inoculated with tubercle bacilli. By injecting the bovine type of the tubercle bacilli into the vein of the experimental diabetic rabbits, tuberculous infection developed more easily than in the controls. Tuberculous affection of the thoracic cavity developed more easily in the experimental diabetic rabbit than in the normal rabbit, when the bovine type of tubercle bacilli was injected into the thoracic cavity. Tubercle bacilli injected either into a vein or into the thoracic cavity, found their way into the lungs more easily in the experimental diabetic rabbit than in the normal. The phagocytic power of the leukocytes in the serum fluid of the thoracic cavity was found remarkably lower in the experimental diabetes animals than in the normal. The same lowering of the phagocytic power of the leukocytes in the serum fluid of the abdominal cavity of the experimental diabetic rabbit has been proved. Sugar in the culture medium proved noninfluential against tubercle bacilli. It neither hindered nor accelerated their growth.

 Case of Stenosis of Aorta. G. R. West, p. 195.

**Influenza and Public Health Administration.**—Levers claims that the recent pandemic of influenza is practically the first in history which has challenged the powers of a fairly universally established public health administration. He says that we should not be afraid as a profession to recognize and to confess that some of our most cherished hopes and beliefs in public health administration have been very badly shaken by this pandemic influenza, and we should not in any spirit of injured pride or stiff necked obstinacy attempt to bolster up or perpetuate official measures of control which have been proved all over the world to be futile. We ought not to shirk the fact that different infections demand methods of official supervision and that it is impossible to handle epidemic influenza in the same way as epidemic smallpox.

**Heart and Interstitial Pneumonia.**—Gullett is convinced that one of the after-effects of influenza will be some weakness of the heart. What the effect on the lungs will be in those patients who have recovered from the pneumonic type, remains to be seen.

**Archives Mens. d'Obstétrique et de Gynécologie, Paris**  
April, 1919, 8, No. 3

- \*Interstital Pregnancy, R. Vaudesal.—p. 177.
- \*Abdominal Cesarean Section, E. Essen-Møller—p. 2, 1.
- \*The Stillborn during the War, V. Chambrelent.—p. 230.

**Interstitial Pregnancy.**—Vaudesal reports a case in which the interstitial pregnancy had continued for more than four months without serious accidents from rupture. The fetus had become encysted while the placenta remained in the primitive cavity of the implantation of the ovum, and it had continued its development. In this and in a second case the uterus was removed, but in a third case merely a wedge-shaped resection was made at an emergency laparotomy done for hemorrhage. These cases show that an interstitial pregnancy develops like any extra-uterine pregnancy up to and including the rupture. The possibility of this anomaly should be suggested by the Ruge-Simon sign, asymmetry of the adnexa, and the lateral insertion of the round ligament in relation to the tumor. If the tumor pivots more towards the Douglas pouch, the probabilities are more in favor of a tubal pregnancy. With the tumor farther forward, the course of the case will decide between the interstitial or the angle site. With the latter the pregnancy becomes a uterine pregnancy but the other proceeds to rupture. Nothing was found in all this research to indicate formation of decidua at any point. The forty-three page article concludes with considerable bibliography.

**Cesarean Section.**—Essen-Møller presents 106 cases of cesarean section at the Lund maternity as a basis on which he discusses certain obstetric problems, especially the question when he should save the child in this way even when we know that the risk for the mother will be enhanced thereby. He is confident that the improvement in the results of cesarean section in recent years has been so great that we need not hesitate to resort to it at need. In the 10 cases of cesarean section done for eclampsia, three of the women died, but in these fatal cases he had temporized so long that the intoxication was intense. His experience in these eclampsia cases has converted him to the view that vaginal cesarean section is preferable in these cases unless the narrowness of the vagina forbids. In 7 sections for placenta prævia one of the women died, probably from embolism. Fetal embolism has been known even after version alone, in these cases. He does not approve of cesarean section for placenta prævia except when hemorrhage is profuse, the cervix is not dilated enough for version and the mother is certainly not infected. In one case he did cesarean section knowing that the child was dead. There was very little hemorrhage during the operation, certainly much less than if he had waited for spontaneous dilatation of the cervix.

He makes a point of removing the uterus after the child has been extracted when the operation is done for malignant final conclusion is that abdominal cesarean section should be preferred to version or perforation when certain

that the woman is free from infection. With the slightest suspicion of infection, he attempts version or forceps extraction to avoid perforation of the living child. If conditions preclude a living child later or if there are absolute indications for it, he does cesarean section by the Porro technic. All the women recovered in his eight cases of this kind. The important point is to estimate when to operate. He does not approve of prophylactic interventions nor of waiting until the woman is in danger of infection. In all discussions of cesarean section he says that the outcome for the children should be recorded as well as for the women. Only one child's life was sacrificed, and this, from hemorrhage of the umbilicus, might have been avoided. All of the other 109 infants were safely delivered except the seven that were dead before hand and one that succumbed to the effect of malformations. The mortality was 5.6 per cent. among the 106 women.

**Stillbirths in France.**—Chambrelent's statistics show that there was no increase in the average of stillbirths in France during the war.

- The Minor Signs of So Called Latent Foreign Bodies in the Esophagus, Gusez.—p. 196.
- Cephalopod's Malformation of the Teeth, P. Fargouyol.—p. 200.

**The Ocular Manifestations of Polymorphous Erythema.**—Terson remarks in concluding this study of polymorphous erythema, that almost all affections of the eyes have a number of factors, even in the specific cases. General causes and occasional causes cooperate to induce the morbid condition. In certain cases of iritis and choroiditis no treatment seems effectual until the teeth are put in order, or the liver is treated, or the diseased urethra or uterus. Some times a vigorous purge will be followed by the complete subsidence of a conjunctivitis that has been showing but slight improvement under local measures. Dianoix has reported the powerful adjuvant effect, actually curative, of acetylsalicylic acid in a typical syphilitic iritis. He cites Manly's case of a woman of 51 who had eleven attacks of nodose erythema and in two of them, about the fourth day, siliceous glaucoma developed, requiring an emergency iridectomy and cured by this. Terson regards acute glaucoma as an identical process with acute edema of the lung. It induces hypertony because the means for excretion and exosmosis are so scanty. General pathology thus explains and identifies glaucoma. Le Comte has reported a case in which glaucoma alternated with arthritis, and once there was an attack of acute edema of the lung.

**The Fourth Symptom with the Hutchinson Triad.**—Cantonnet regards chronic hydrarthrosis of the large joints, especially of the knees, as so common with Hutchinson's triad, keratitis and deafness in inherited syphilis that it deserves to be included with them in the characteristic triad. The joint and corneal lesions all yield to mercury as a rule.

- Perforating Traumatic Fracture of the Skull, H. Roper.—p. 423.
- Esophageal Anastomosis for Operating on the Stomach, A. Goussier.—p. 424.

**Tuberculosis of the Skull.** Roper remarks that recent publications show that vertebrae toward the base of the skull are not so rare as generally assumed. 13 cases have been published by five French writers since Pott's time.

plation of 206 cases in 1910. About 75 per cent of the cases develop before the age of 20, and there are almost invariably other tuberculous lesions elsewhere. The lesion causes few symptoms, merely a dull ache caused by pressure and not worse at night. In the case illustrated, the opening in the frontal bone was a necropsy surprise. If the condition otherwise permits, extensive resection into sound tissue is the most certain means to ward off recurrence.

- \*Early Treatment of Acute Osteomyelitis. P. Vignard.—p. 501.
- \*Comparison of Expansion of the Two Sides of the Chest. L. Binet.—p. 502.
- \*Cultivation and Isolation of Anaerobes. M. Rhein.—p. 504.

**Early Treatment of Acute Osteomyelitis.**—Vignard expatiates on the difficulty of diagnosing and locating osteomyelitis in certain cases. He says that he has had several cases which proved fatal within two days although the general condition had not warned of profound intoxication. Wavering between the fear of aggravating conditions by an early operation and the fear of the process spreading and inducing septicemia or locating in an undesirable region, he finally compromised by making a fixation abscess, and he here reports seven cases in which a prompt cure followed the production of a turpentine aseptic abscess. In one case he temporized too long and the fixation abscess came too late. In less than a month later he had another almost identical case, the upper end of the femur swollen, painful and red, and the general condition so bad that an operation seemed inadvisable. Even after the fixation abscess 3 cm. in diameter had been induced, the fever kept high for two days but then conditions promptly righted themselves and the cure was soon complete. In another case the boy of 14 had fever and delirium after complaining of pains in his legs. The temperature had kept at 40 C. for three days. Then puncture of the hip joint released 3 or 4 c.c. of a turbid fluid, but the fever kept high and persisted for a day or two after the turpentine abscess had been induced, but then the temperature began to go down and the cure was soon complete. He now induces a turpentine abscess as a routine measure in all cases of osteomyelitis.

**Measuring Expansion of Each Side of the Chest.**—Binet gives an illustration of a device for photographically recording the expansion of each side of the chest separately.

**Cultivation and Isolation of Anaerobes.**—Rhein's method is merely cultivating, along with the anaerobes, *Bacterium faecale-alecaligenes*. On account of the absence of ferments in the cultures of the latter, the saccharolytic and proteolytic power of the anaerobes shows up very distinctly, and their characteristic odor is unmistakable. As the former is not toxic for animals, test inoculation with the combined cultures is practicable and instructive. To obtain pure cultures of the anaerobes, all that is necessary is to heat the combined culture for ten minutes at 56 C. This kills off the faecale. The latter can be used in the same way as a symbiote with the botulism. The anaerobes seem to proliferate as perfectly in combination with the symbiote as alone. Rhein generally uses pancreatic peptonated bouillon, and it does not have to be boiled before inoculating it with the germs. He gives a number of minor points, and a modification of Marino's method for isolating anaerobes, and he emphasizes the facility and reliability of this symbiotic culture technique which does not require any special apparatus and can be applied to almost all anaerobes.

- \*Etiology Transformation of Chronic Bursitis. J. P. Tourneux and A. Ginesty.—p. 311.
- \*Tuberculosis in Children. L. Rihadeau-Dumas.—p. 312.
- \*Spa Treatment of Bone Disease. L. D'Arlois de Jubainville and P. Mathieu.—p. 317.

**Fibrous Transformation of Hygroma.**—In the three cases described the tumor had been first noticed two or three months before, and it was readily shelled out. There seemed to be two factors involved, liquefaction of the adipose elements and hyperplasia of the connective tissue.

**Pulmonary Tuberculosis in Children.**—Rihadeau-Dumas has never been able to learn much that was conclusive from physical examination of infants and young children suspected of tuberculosis, but roentgen examination clears up the diagnosis. Tubercle bacilli are also significant, but they may be difficult to discover. Phlyctenae on the conjunctiva are instructive, and tubercle bacilli are often found in minute cutaneous or subcutaneous abscesses which seem an ordinary pyodermitis. He says that the best hope in treatment seems to be with tuberculin, especially with extremely minute doses given by the intradermal technique.

- \*Spa Treatment of Disease of Upper Air Passages. P. Bourgeois.—p. 325.
- \*Ether in Treatment of Pertussis. Audrain.—p. 329.

**Psychomotor Instability in Schoolchildren.**—Paul-Boncour explains psychomotor instability in children as the continuation of what Simon calls cerebral irritability and Comby calls cerebral excitation. It may be traceable to some slight brain lesion. The child constantly changes his ideas and attitude. Nothing really interests him, and nothing can hold his attention for more than a brief period. The tendency can and often does disappear in time under vigorous treatment, hydrotherapy, special gymnastic exercises, rest between classes, and sedatives; sometimes specific treatment may be required. On account of the motor weakness, training for a trade is difficult unless muscles and hands are given special training to strengthen them. Puberty generally comes late in these children. If the medical inspector recognizes early this psychomotor instability, much can be done for the children.

**Ether Treatment of Whooping Cough.**—Audrain asserts that whooping cough can be rapidly cured by three or four intramuscular injections of ether at 66 degrees, given every second day. The dose is 1 c.c. up to the age of 10 months, and then 2 c.c. The series of four injections is rarely necessary, two or at most three usually suffice.

- \*The Sponge in Gynecologic Surgery. C. Pellanda.—p. 217.

**Influenza in the Pregnant.**—Andréodias states that in 37.9 per cent of his 29 cases of influenza in pregnant women the pregnancy was interrupted. This is almost exactly the proportion noted in the records of the 1889-1892 epidemic of influenza. The abortion or premature delivery did not mitigate the disease; labor even seemed to whip it up. No tendency to hemorrhage was observed, and 61 per cent of the children were viable. The death rate among the 29 women was 34 per cent.

**The Sea Sponge in Gynecologic Surgery.**—Pellanda emphasizes the advantages of the sponge which becomes distended as it soaks up fluids; gauze loses its elasticity under the same circumstances. He regards it as almost indispensable for arresting profuse venous or capillary hemorrhage such as sometimes occurs after a difficult Wertheim operation. It is useful further in draining after colpotomy for pus in the pelvis. Used in hundreds of cases in Pollosson's service for these indications, there have never been any by-effects from it, and he lauds the absolute harmlessness and efficacy of the sea sponge for these conditions.

- Erethistic Oligophrenia. P. Sarasin.—p. 324. Cont'n.
- \*Schizophrenia and the Choroid Plexus. C. v. Monakow and S. Kitabayashi.—p. 363.

**Localization of Stereognosis.**—Bing and Schwartz affirm that the diagnosis of a cortical lesion is justified whenever the subject is unable to recognize objects by the touch, his sensory and perceptive powers otherwise unimpaired. The cortical lesion may be diffuse in which case there is loss of secondary tactile identification, but usually it is a symptom from a focal lesion. They have generally found this focal lesion at the middle third of the parietal ascending convolution and the parietal lobe on the opposite side from the astereognostic hand. In a case described with illustrations, the astereognosis of the left hand was so pronounced that, with the eyes closed, the man was unable to tell a coin from a pencil, a watch from a box of matches. Other symptoms also suggested a tumor in the brain; they had come on suddenly and by the tenth day left hemiparesis developed. The consent to the proposed operation was deferred and the young man died the seventeenth day after the initial symptoms. Necropsy confirmed the diagnosis, an abscess being found at the point specified above while the parietal lobe was nearly and the supramarginal gyri completely intact to all intents and purposes. The findings confirmed Head's statements based on study of war wounds of the cortex. Forty-three articles on various aspects of touch paralysis are listed in conclusion.

**Biology and Psychiatry.**—Von Monakow's extensive article is an attempt to bring psychiatry out of its place apart—according to the general acceptance of psychiatry at present—and have it take its proper place among the other departments of medicine. He seeks to demonstrate the logical physiologic connection between the brain and the psychic and nervous symptoms. This would simplify medical thinking, and if it can be corroborated by physiologic facts—which he thinks is fairly well established to a certain extent even now—the physician will be protected against many erroneous and lay interpretations of so-called nervous conditions, and the way will be smoothed for the diagnosis and rational treatment. He declares that under the influence of toxic action not only the mechanical innervation but the emotions and instincts can be completely transformed. The toxins responsible for this may come from without or may be generated in the body. Morphologic changes, alone or combined with disturbance in the internal secretions, may entail an embryologic retrogression, a retrograde generation of psychic functions which may lead to actual loss of functional continuity between the various centers or neurons of the cerebral mechanism. He reiterates that along with the biophysical Ablauf of function we must recognize a biochemical Ablauf. This latter may be irregular and migratory. The effect is a retrograde generation, a dropping back into earlier phases of psychic development, even back to infancy. But this dropping back does not affect all the elements of the mind in the same measure, and this results in great incongruities. The dropping back may be only temporary or it may be permanent. The reaction, he asserts, is always a defensive reaction. The psychosis in all its forms is merely this defensive reaction, plus possibly compensatory effects. It always represents the self-defense of the individual against the injurious influences acting on the central nervous system. These primary and secondary reaction conditions thus all conform to biologic-psychologic laws. He claims that these views provide for the first time a foundation on which can be built a bridge between the brain, the organ of the psychic and the symptoms of mental impairment. This biologic-physiologic mode of thought, keeping in constant touch with physiology and anatomy, will open new fields for research, especially on the choroid plexus, cerebrospinal fluid and biochemistry in general as factors in psychoses. He has been

impressed with the frequency of severe structural disturbance of the choroid plexus at necropsy of the insane.

**The Plantar Reflex.**—Bersot's title is "Variabilité et corrélations organiques. Nouvelle étude du reflex plantaire." The different reflex reactions seem to follow the variations in the total capacity for reflex action. The toe and the contralateral reflexes are peculiar in that, while following these variations, they amplify them. Bersot insists that the plantar reflex in itself has not much significance, but it becomes really and objectively important when we record its frequency and the variations of this frequency.

**Schizophrenia and the Choroid Plexus.**—As mentioned in the abstract above, von Monakow has been impressed with the frequency of severe structural changes in the choroid plexus in the insane. In twelve cases of severe chronic schizophrenia, of different types, the choroid plexus was never found even approximating normal. In some of these cases the choroid plexus showed actual necrosis. It was most pronounced in the case of a physician with paranoid hallucinations but not much mental derangement, who committed suicide. Photomicrographs from this case show the amyloid degeneration of the connective tissue, scattered degeneration of the fringelike structure, accumulation of colloidal masses, and interpapillary exudation. Merely senile changes in the choroid plexus differ entirely from those found with schizophrenia.

- Alleged Endemic Occurrence of Yellow Fever on Peruvian Coast. J. Arce.—p. 219. Cont'n. See abstract, page 945.

**Nervous Complications of Typhus.**—Odriozola reviews recent literature on this subject, and describes a case in which during convalescence hemiplegia became installed, with certain spastic phenomena and aphasia. The paralysis subsided somewhat, but a tendency to atelectosis and the persistence of the aphasia denote actual degeneration. The urea content of the blood was high—1.80 gm.—but there were no appreciable disturbances from this. It seems as if urea in the blood does not have an unfavorable prognosis outside of chronic nephritis, according to his experience.

**Mycosis in Rat.**—Escemel gives an illustrated description of a mycosis affecting the head and inducing extensive destructive lesions in rats. In his two specimens there did not seem to be much toxic action as the animals were agile and not emaciated, although the eyes and scalp had been destroyed. The special fungus involved was the malassezia of the hyphomycetes group.

**Acute Fatal Dilatation of the Stomach.**—Quesada reports the case of a man of 40 convalescing from dysentery at a health resort, who complained of sudden, intense pain in the stomach. It was not relieved much by household measures, and he was taken to the hospital but died on the way, only a few hours after the first symptoms. Necropsy revealed extreme dilatation of the stomach with the duodenum occluded by pressure from the mesenteric vessels, plus the mechanical and toxic action of the liquor which the man had been drinking. Quesada remarks that the action of some

vacuum always opens the scene in these cases, but that the dilatation is promoted by the unconscious swallowing of air. Even with extreme dilatation of the stomach, no immediate harm results until the duodenum gets compressed by mesenteric vessels stretched taut by the abnormal conditions. Although the outlet of the stomach and duodenum thus becomes closed, there is no hindrance to the swallowing of air. There is even suction of air into the esophagus by a kind of valve action from the diaphragm excursions which are amplified by the nervous stress. The case described confirmed all these assumptions.

### Anales de la Facultad de Medicina, Montevideo

- \* *Respiration in Babies*. J. Maria Estapé, p. 391.
- \* *Serotherapy in Agitans for Transfusion of Blood*. J. D. Parietti, p. 413.

**Blasomycosis in America.** Escome! relates that cases of blasomycosis in man have been published in Argentina, Brazil, Peru and Bolivia and that probably some cases classed as leishmaniasis probably belong in this category. When the fungus has once invaded the mucosa, it is liable to persist throughout life. There is no contagion from it in places where it is not endemic, as it seems to require the intermediation of some biting insect. There has been no effective treatment until recently, but tartar emetic by the vein and mouth, plus heliotherapy, seem to have awakened hopes of conquering the disease in the near future. He describes its geographical distribution, always to date in tropical forest regions, the characteristic salivation, and the crossed ridges on the palate. In three cases described the benefit from the above treatment amply confirmed the diagnosis.

**Ligation of Hypogastric Artery.**—Pou Orfila has ligated the hypogastric artery in three cases which he describes with illustrations, and commends the technic he followed. The ligation was done for an arteriovenous aneurysm of the hypogastric artery and vein in one woman of 32 and to arrest hemorrhage after colpotomy in a younger woman with grave postabortus infection and recurring hemorrhages. A pus pocket in the pelvis had required the colpotomy. In the third case the intraperitoneal ligation of the hypogastric artery had been done for secondary hemorrhages from spontaneous obstetric rupture of the uterus and bladder. This route is preferable for the obese. By taking advantage of the cleavage, it is easy to reach the hypogastric artery through an incision in the flank. This technic is particularly useful when there are infectious processes in the pelvic cellular tissue. For the intraperitoneal route, a transverse incision above the symphysis is advisable. Ligation of this artery should be always considered in treatment of rupture of the uterus with threatening hemorrhage. Unilateral enlargement of the buttocks and pudenda is an important sign of aneurysm of the hypogastric artery. Thrill in the vaginal culdesac may be due to other local causes. He advises ligating with catgut in case of hemorrhage, and with silk for an aneurysm.

**Law of Specific Energy.**—Estapé refers to the law of the specific energy of sensory nerves which Müller enounced in 1840. Estapé argues that this law applies to all living matter, in all its manifestations, biologic, sociologic and psychologic. Muller's law aids us to define sensation as the transmission to the consciousness of a quality or state of the sensory nerve determined by some external cause in the different sensory nerves.

**Transfusion of Blood.**—The method of transfusion to which Parietti calls attention is done by means of a single tube which aspirates the blood from the donor and passes it on and into the vein of the recipient. The blood thus flows in an almost continuous stream, protected from the air, directly from one vein into the other. The suction is done by a small standard with two adjustable rollers between which passes the tube. By adjusting the rollers tight and pushing the frame back on the tube, which the rollers squeeze flat, a

vacuum is induced which aspirates the blood from the vein. A tube from a jar of 4 per cent. solution of sodium citrate enters the tube near the recipient's end, and the blood is thus citrated as it passes into the second needle. The article is illustrated.

### Annaes Paulistas de Med. e Cir., S. Paulo

May, 1919, 10, No. 5

- \* *Tuberculosis in Children in S. Paulo*. C. Ferreira, p. 97.
- \* *Serotherapy of Toxemia of Pregnancy*. A. Vieira Marcondes, p. 101.
- \* *Silent Gastric Ulcer*. Z. do Amaral, p. 105.
- \* *Friedreich's Disease*. A. de Almeida Prado, p. 108.

**Tuberculosis in Children in S. Paulo.**—Ferreira relates that tuberculosis has never been particularly prevalent at S. Paulo, and of late has been reduced still more, until recently it has been only 1.2 and 1.1 per thousand of the general mortality. Most of the cases are in the old part of town. In fourteen years up to 1916 there had been 186 deaths recorded from pulmonary, and eighty-three from abdominal tuberculosis in children under 10, and forty-three of tuberculous meningitis, a total of 350 deaths from tuberculosis, but it is probable that tuberculosis contributed to the death rate from pneumonia, measles, etc. During the last few years a vigorous campaign has been waged against tuberculosis, especially in children, and welfare work of different kinds is bearing good fruit, S. Paulo ranking high in defensive hygiene, public and private.

**Serotherapy of Toxemia of Pregnancy.**—Vieira has been experimenting with a liver-suprarenal extract in treatment of toxemia of pregnancy but found this unsatisfactory as it was blind work, not knowing which glands were at fault. More recently he has been using the serum from gravid goats. This induced urticaria in some cases, and actual serum sickness in one woman, consequently this method of serotherapy was modified. The proteins were extracted from this goat serum, but the other elements were left unmolested, and the serum was evaporated to one fifth, so that a single dose represented only 1 c.c. Clinical experiences with this perfected technic showed that the therapeutic effects were the same as with the whole serum, while it had none of the by-effects of the latter. With one or two injections, uncontrollable vomiting and eclampsia subsided promptly in some cases reported, and the effect was favorable also in pregnancy sciatica, neuralgia, jaundice, headache, and gastro-intestinal disturbances. With the aid of this *soro hormo gravidica*, as he calls it, there is no need to interrupt the pregnancy. It is made under Vital Brazil's direction at the Instituto Soro-therapico Butantan, the state institute for serotherapy.

**Perforation of Silent Gastric Ulcer.**—Do Amaral reports the sudden perforation of an unsuspected gastric ulcer in a young man. The intense pain was located in the appendix region, and the rigidity of the abdominal wall was most pronounced here. There was no history of stomach or duodenal symptoms, and the incision the eleventh hour was made for the supposed appendicitis. A gush of fluid escaped, but the appendix was exonerated. Then a supra-umbilical median incision revealed the perforation in the stomach. In two other more recent cases, twenty-four hours had elapsed before the operation and both of the patients died.

**Exceptionally Severe Case of Paralysis Agitans.**—In Fernández' case the woman of 79 presented continuous and intense tremor of the entire body, including the jaw and tongue. The tremor of the tongue had irritated it until it had

swollen and hung pendent from the mouth, incessantly shaken by the intense tremor. The tremor was complicated by absolute rigidity of the whole body, as if it were one solid piece, and extreme difficulty in breathing and in swallowing completed the clinical picture. Tracheotomy is being considered.

- \*Arsenical Treatment of Inherited Syphilis in Infants. Diaz Villarejo.—p. 54.
- Spinal Anesthesia in Surgery. C. Calderón.—p. 57.

**The Functional Capacity of the Heart.**—García applied different tests to twenty persons to determine the functional capacity of the heart, including Lian's method, Mendelsohn's and Mackenzie's, with Vaguez' differential pressure, the difference between the maximal and minimal tension, and the oculocardiac reflex. By comparing the findings with several of these tests we can generally obtain good oversight of conditions in the heart as a whole. His findings harmonized with the course of the cases, while the findings were unreliable with the Abrahams, Hertz and Gräupner tests.

**Treatment of Early Inherited Syphilis.**—Díaz has found mercury alone too slow in its action to depend on for young infants with severe manifestations of inherited syphilis. Combined with arsenic, as for adults, it will prove effectual in the majority of cases, but with involvement of the stomach or bowel, etc., mercury should not be given at all. These children are liable to have large numbers of the spirochetes in their viscera, and if the arsenic is given by the vein or muscle in too large doses at first, the massive destruction of the germs liberates such quantities of endotoxins that the child may succumb to this shock. Injection of neo-arsphenamin into the subcutaneous cellular tissue allows gradual and perfect assimilation of the drug, and its very slow elimination. He injects 1 cg. dissolved in 5 c.c. of serum per kilogram of body weight, making the injection in the shoulder, and waits two weeks during which the syphilitic lesions show improvement and the weight increases. The injection is then repeated twice at fifteen day intervals, possibly increasing by 1 cg. the last time. Then mercurial inunctions are begun and alternated with neo-arsphenamin. When the infant shows only mild manifestations of the syphilis, he begins with mercurial inunctions, and then adds the neo-arsphenamin in the same way.

**Chronic Abdominal Disease from Tardy Inherited Syphilis.** The main points of these articles were summarized recently on page 1169. Fourteen large roentgenograms accompany the case histories in these instalments.

**Painful Attacks from Sclerosis of the Pancreas.**—Bonorino and Carulla report a case in which paroxysms of agonizing pain, connected with the meals at first but later continuous and persisting, were the only appreciable symptoms, except for gastric achylia. There was no glycosuria and no tender points could be found. Functional tests of the pancreas failed to reveal insufficiency, but there was progressive weakness. No relief was obtained from any measures, including treatment as for syphilis. An exploratory laparotomy showed the stomach and duodenum normal. There were no pathologic antecedents except an obliterating arteritis with gangrene nine years before, compelling low amputation of the leg. The man died five days after the laparotomy, and

necropsy revealed sclerosis of the head of the pancreas although the rest of the organ seemed normal. The pains must have been the result of compression of some portion of the solar plexus, actual celiac crises.

- Subacute Nephritis with Retention of Chlorids. Id.—p. 54.

**Endless Dilatation of Stenosis of Esophagus.**—Pini and Becco give an illustrated description of their case of cicatricial stenosis of the esophagus in a young man, from taking by mistake a tablespoonful of sulphuric acid kept for cleansing his hands. He took olive oil and tepid water at once and vomited several times, and also took a dose of calcined magnesia. There was repeated hematemesis, and the stenosis of the esophagus compelled an operation the third day as only fluid could be swallowed. With esophagoscopy, a sound was worked down into the stomach and drawn out through a gastrostomy opening and a stout silk thread attached to it. Rubber tubing fastened on the endless thread was found the most convenient means for enlarging the contracted lumen. The sharp edges of the tubes were smoothed off and the tube once in the stenosis was left in it for twenty-five or fifty minutes. The length of the piece of tubing is not specified, but the picture shows it as long as the distance from eyebrow to chin, and also shows how it was introduced at the corner of the mouth, the head thrown back. Other means of treating cicatricial stenosis are discussed, with considerable bibliography.

**Diathermy for Gonorrhoeal Orchi-Epididymitis.**—Niseggi and Astraldi expatiate on the advantages of this treatment which they regard as the most rapid, most energetic, harmless and painless method of treating this frequent complication of gonorrhoea. They report ten cases from their experience with twenty-three. This technic is now the routine treatment at the Hospital Nacional de Clínicas.

- \*Tachycardia. A. Castro.—p. 32.
- Gastrocnemiotomy. L. Restrepo I.—p. 40; II R. Villegas Arango.—p. 45.

**Exophthalmic Goiter in Colombia.**—Montoya comments on the rarity of this disease in his province, Antioquia, and reports in detail a case in a man and one in a young woman. The latter has improved considerably without any special medication, the pulse now being 100 instead of 130, and the patient is able to attend to household duties, but there is still emotional instability. Only one case has been published before in the province, and Montoya knows of only eleven cases in sixteen years. Seven were in well-to-do young women and two died. The result was mediocre in the few operative cases, as a rule, but in one woman of 44 thyroidectomy was promptly followed by subsidence of all the symptoms except the exophthalmos which has been only slightly improved.

**Tachycardia.** Castro's patient is a man of 26 whose extreme tachycardia is not influenced by change of position, time of day or exercise. Only the tachycardia of exophthalmic goiter presents these features, and the man seems excitable and loquacious but otherwise presents no symptoms.

**Prognosis and Treatment of Diabetes.**—Carro insists that minute and continued study of the case is necessary before it is possible to institute proper treatment and draw the prognosis. The latter depends mostly on the multiple complications to which the diabetic is liable. It is important to discover whether there is other coexisting disease that may modify the course of the diabetes. When all this has been ascertained, Lahlé's test diet should be enforced for three days and then the third day the whole of the twenty-four hours' urine should be collected and tested for sugar, uric acid, chlorids, phosphates, purin bases, total nitrogen, urea and the azuric coefficient. The urine may be apparently normal except for retention of chlorids, and although the sugar may have disappeared yet the case may present an unfavorable prognosis on this account. When there is an arthritic diathesis or tendency to eczema, dyspepsia or nephritis, the dietetic treatment has to be materially different in each, as he describes in detail. By watching over the course of the case we can detect aggravation of certain symptoms or the appearance of new, and by modifying the diet to correspond may steer the patient past the danger point. On the whole he regards the pancreatic type as the gravest of the four forms of diabetes. The prognosis is also bad in the nervous or lypophysic type, generally of endocrine origin. A cure is usually realized in the type connected with acute infections, but less frequently with chronic infection or alcoholism. Diabetes in pregnancy generally subsides afterward.

**Parallel Between Intubation and Tracheotomy.**—Martínez cites authorities from the first century of our era who described diphtheria, but then and for long after it was regarded as a purely local affection. The first to describe it completely as a general intoxication from a local affection were Spanish writers of the sixteenth century. No symptom has been added since to their complete description "De morbo puerum." Tracheotomy is as old as diphtheria itself, even Hippocrates referring to both. Martínez continues, "Intubation was suggested in antiquity, and Bouchut of Paris in 1858 presented a tube for the purpose, but it was criticized so severely that intubation was not adopted until O'Dwyer of North America took it up—the fate of many initiatives in the Latin races, their initiative coming to flower and fruition in other countries which get the credit for the whole." Sota of Seville was the first to use the new method in Europe. All became enthusiastic over it when diphtheria antitoxin was discovered, but even now Martínez prefers tracheotomy when the child cannot be kept under constant surveillance with skilled hands to replace the tube if it is

coughed out. He always goes prepared for both intubation and tracheotomy. In three cases he found coexistent thymitis which rendered intubation impossible. In one case a retro-pharyngeal abscess had the same effect, and in some others edema of the larynx. The edema of the larynx in one case had closed the opening of the tube in the throat and grasped the tube so firmly that the tube could not be removed. The emergency tracheotomy and artificial respiration resuscitated the apparently moribund infant. The tube was thus in the larynx and the cannula in the tracheotomy opening for four days, but no harm resulted. Tracheotomy is indicated further when there is excessive production of tough membranes, and when there is preexisting subglottic laryngitis or bronchitis. In one case with pneumonia, forty hours after the tracheotomy the child had apparently fatal suffocation, but Martínez dilated the trachea and with forceps he extracted plugs of mucosa. Then he introduced into the trachea and bronchi a lubricated soft rubber tube, drawing it up and down, and thus extracting large quantities of mucus, starting up the respiration anew, and the moribund child was brought back to life. He has applied this technic in a number of other cases, and reported in 1900 his success with this sweeping out the tracheobronchial passages. He deems this useful for combating accumulation of mucus, and paralysis of the bronchi, and for inciting to cough and respiratory movements, whether there is diphtheria present or not. In nine cases the tracheotomy was done in extremis. Even when the opening had been made, no air entered the lungs as the thorax was in a paralyzed condition, but he pounded twice on the abdomen, inserted the cannula, and started artificial respiration, with stimulating injections of caffein, camphorated oil and ether, and in a few minutes the child was resuscitated.

- \***Pathogenesis of Primary Hypertension.** D. Klinkert, p. 554.

**Pathogenesis of Primary Hypertension.**—Klinkert tabulates the arterial pressure findings, with the urea content of the blood serum, and the Ambard coefficient as recorded in twenty-five persons with an arterial pressure above normal. They had all applied for treatment on account of incipient angina pectoris, shortness of breath, or other symptoms from abnormally high blood pressure, but they did not present any symptoms calling attention to the kidneys which were presumably sound. But the urosecretory coefficient determined by Ambard's formula told an entirely different story. The Ambard index was much above normal in all but two of the twenty-five, the figure ranging from 0.101 to 0.300, in comparison to the normal figure of 0.06 or 0.08. Fourteen of the twenty-five also had a urea content of 500 mg. He lists and discusses the various theories in vogue as to the kidney being responsible for the high blood pressure or vice versa, pointing to the tabulated findings in his cases as apparently settling the question.

- \***Ileus in the Pregnant and in the Parturient.** P. V. Tuxen, p. 921.

**Ileus in the Pregnant and in Parturients.**—Tuxen has been able to find on record only 106 cases of ileus in pregnant and parturient women, but he has encountered three cases himself. In one, torsion of an ovarian tumor had compressed the bowel, inducing mechanical ileus. In his second case, four and a half hours after the woman of 41 had been safely delivered of her fourteenth child, she suddenly developed symptoms of ileus, and a ruptured dermoid cyst was found. The contents of the small cyst had set up irritation, with dynamic ileus as the result. In the third case the bowel had become incarcerated from pressure of the gravid uterus at the sixth month. Diligent search failed to reveal any other cause for the ileus. The uterus expelled its contents a few days later.

## THE RANGE OF THE GENERAL PRACTITIONER IN PSYCHIATRIC DIAGNOSIS\*

E. E. SOUTHARD, M.D.

BOSTON

One cannot help marveling at the progress made by psychiatry in the American medical scene. But the standing of psychiatrists and the prominence of psychiatric topics among medical men at large is more than paralleled perhaps by the vogue of psychiatrists and psychiatry in the broader circles of mental hygiene. It has been my privilege, as delegate from the Commonwealth of Massachusetts, to attend in the last few years many meetings of nonmedical workers, such as meetings of social workers, psychologists, general scientific workers, and even of teachers of philosophy; and I can report that this associate medical world (if we may call it so) is ready to go more than half way in meeting physicians on a mental hygiene platform. Too eager to enter on unsuitable tasks are these non-medical workers, some advocates of a Little Medicine might aver. But the Greater Medicine should open its arms to what Weir Mitchell called the "assistive" arts and sciences and, in matters touching the community, give over all that savors of a closed shop for M.D.'s only.

Though the face which psychiatry presents to the "assistive" nonmedical branches of mental hygiene is most respectable (the osmotic interchange perfect, one might say), the interior relations of psychiatry to the rest of medicine form something of a problem. One difficulty, which I do not here more than mention, is the proper adjustment of the planes of contact between clinical neurology and psychiatry. The research basis of these two divisions of practical medicine forms a continuous unit, having structural and functional aspects, to be sure, but nevertheless growing steadily together.

Leaving the interrelations of neurology and psychiatry to themselves for the moment, I come to my chosen topic. I consider that, all in all, the appreciation of psychiatry by the general practitioner has not kept pace with the increasing appreciation of it now being shown by neurologists and with the even greater advance in the esteem in which psychiatry is held by social workers, psychologists, philosophical and ethical teachers, and other practical and scientific types of nonmedical mental hygienists. In short, the general

practitioner ought to enter consciously and confidently the field of mental hygiene, some of the tasks of which lie very near his hand.

But why is neuropsychiatry caviar to the general practitioner of medicine? It is also, we must admit, caviar to the general theorist, in American medicine at least. A determined effort to overcome the step-motherliness of practitioners and theorists toward the general topics of this section of the American Medical Association must soon be made, if we are not to be quite outstripped by other nations even on the barest practical lines. I do not assign our unpopularity to inborn deficiencies of American practitioners. I am not even sure that our medical theorists are altogether responsible for averting their eyes. I am a little more inclined to fix the blame on the pedagogic group in our medical schools. Not that appropriate curriculums fail to be arranged, and not that clinical opportunities fail to be thrown open to medical students. But there is on the part of teachers in other branches than the neuropsychiatric an almost constant avowal of their lack of interest in nervous and mental diseases. This avowed apathy can hardly miss exerting its effect on the weary medical student, looking (as is his duty) for things not to learn. But what is the cause of the pedagogic look askance at nervous and mental diseases? Some of our own specialistic colleagues, who talk glibly of everything as a defense reaction, intimate darkly that neuropsychiatry is a sore subject with most medical teachers because they are so ignorant thereof. Be that as it may, I feel that not all the blame attaches to our nonpsychiatric colleagues, and that our own obscurantism has blocked progress.

How much can be done with a frontal attack is doubtful. But correspondence following a paper presented to this section last year on a similar topic led me to think that a flank attack on medical teachers and research controllers might not be necessary to secure greater interest in mental hygiene on the part of the general practitioner. In the first place, the psychiatrist is, in a different way, almost as general in his approach as the general practitioner. The map quality and representativeness in the nervous system of virtually all other systems in the body insures a consideration of many things by the psychiatrist after the precise manner in which a general practitioner faces the same situation. This generality of view (e. g. that a psychiatrist, like a general practitioner, has to be something of an endocrinologist, a good deal of a syphilographer, etc.) is just as advantageous and just as dangerous as the generality of view which it is the duty of the general practitioner to have. Again, the psychiatrist, far more than any other spe-

\* Read before the Section on Nervous and Mental Diseases at the Seventeenth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

cialist (unless perhaps the obstetrician), has to take his patient as a total person, as a global individual—and this is precisely the duty of the general practitioner, and precisely the difficulty of the office consultant specialist as we usually see him. In passing, it may be noted that one of the reasons for the augmenting vogue of group practice by associated specialists is the demand for a more global and comprehensive view of each patient. Nevertheless, it must be conceded that even group practice often leaves the patient a *dividual* (as old scholastics said) rather than an *individual*, and that the studies made are apt to remain on an analytic basis rather than aspire to the higher terrace of synthetic work. Otherwise put, the *dividual* is considered to have flat foot for the orthopedist, astigmatism for the ophthalmologist, gastropnoxis for the surgeon, and so on: the *dividual* patient remains a congeries rather than a collection of symptoms. This is a quarrel which the general practitioner and the psychiatrist lunge in common against specialized medicine.

Perhaps no more need here be said of the community of views and tasks between general practitioners of medicine and specialistic practitioners of psychiatry. A presupposition of my argument is that the general practitioner, if he is to live up to the designation "general," ought to grasp and use relatively as much in any one specialty (e. g. dermatology, ophthalmology, psychiatry) as in any other specialty. But, as the general practitioner is ready to agree, he certainly does not know as much about psychiatry as about many other specialties. How shall he proceed?

In the first place, there is often a bit of an obsession to rationalize. The general practitioner feels his education in psychiatry deficient and any postgraduate instruction practically impossible. He develops a general *psychopathophobia*. Moreover, if in his presence some psychiatrist inadvertently uses a term like *psychopathophobia*, it becomes easy for the old outcry about terminology to be raised. As a matter of fact, the terms of dermatology or of the chemistry of metabolism are just as difficult as those of psychiatry, often more so. What we are dealing with (to continue with this naive terminological joking) is another phobia, *onomatophobia*. One must, of course, acknowledge that terms for exact and complex things can hardly ever become much less precise, and much more simple than the facts, without destroying the facts. But there are signs that terminology is solidifying and getting less and less equivocal in psychiatry. In any event, the immediate duties of the general practitioner do not carry him into actual mares' nests of terminology.

Suppose the *psychopathophobia* and *onomatophobia* to be sufficiently rationalized. There is another comment on the relation of the general practitioner to psychiatry which has an optimistic tinge. Judging him by the standard of his range in other specialties than psychiatry, the general practitioner is found to be comparatively well up in major aspects of psychiatry.

I will not repeat in detail the arguments before presented concerning the general practitioner's reasonably sufficient equipment for handling the syphilitic, feeble-minded, epileptic, alcoholic, focal brain (that is, these disorders in their major aspects), somatic ("symptomatic"), senile, and even perhaps the psychoneurotic disorders. Inadequate practice, at any rate grossly inadequate practice, is not often found among these

disorders, if we judge the practitioner by his achievements in other specialties.

In order to learn something of the status of the general practitioner with respect to psychiatry, I have looked over 500 brief descriptions of mental patients going to the psychopathic hospital in cases of the group we call the "temporary care group." That group is composed of patients who have never passed through the probate court or any judicial procedures. They are cases which physicians, or in some instances the chiefs of police and heads of boards of health, have thought suitable for observation at the psychopathic hospital. There is nothing mandatory about the hospital's receiving these patients for observation. The law says that the hospital may receive these cases for observation. Accordingly the admitting officers must make some preliminary observations of their own before the patients are admitted for observation. It must be carefully noted that these patients are *admitted*, not committed, to the hospital. A similar law to that for temporary care in Massachusetts is also in force in the municipality of New York. The law forms, as is well known, the acme of procedures in the interest of the mental hygiene of a community, as the modern psychopathic hospital acts as a magnet to bring psychopathic and all sorts of acute, curable, incipient or dubious cases to the state's observation and care.

For my present purpose, however, the point I wish to bring out is that this clinical material is very similar to and almost identical with material which, in most parts of the country, remains for many weeks or months under the control of general practitioners without recourse to the courts. Something like 1,200 or 1,500 patients of this order are under observation at the psychopathic hospital in Boston during a period of a year. They pass rather rapidly through a hospital of 110 beds, operating at from ninety to ninety-five beds, and are then passed back into the community or forward into receptacles for more chronic cases. Something like one third of all the patients are turned back into the community under proper supervision or, if possible, without supervision. This material, then, is exactly what the general practitioner has to deal with, though in most states he has no recourse to a modern institution like a psychopathic hospital. Accordingly the remarks about these patients made by the general practitioners will probably indicate what the status of psychiatry is in the mind of the general practitioner in Massachusetts.

Of course, among these "temporary care cases" there will be a number which have passed through the hands of specializing neurologists or psychiatrists.

A report made by such a specializing neurologist may run as follows: "Emotional deterioration, apparent impairment of memory. Hallucinated, aural. Depressed. Delusions, somatic type. No initiative. Listless, apathetic. Poor cooperation. No capacity for work." Such a report is informative, suggests the diagnosis dementia praecox, and is a fair sample of the routine report of a neurologist. The idea "emotional deterioration" is in our experience almost beyond the range of the general practitioner, nor have the words any very profound meaning for many excellent internists. Yet it would be comparatively easy in a brief period of observation in almost any hospital for the insane (not necessarily a psychopathic hospital) for a general practitioner or an internist who wished

to brush up this specialty to learn the special meaning of a phrase like emotional deterioration.

Another neurologist's report speaks of an army case as "showing marked motor acceleration, flight of ideas, and press of activity." These are phrases due to the effect of the Kraepelinian psychiatry on our American institutions. I am not at all sure that I believe the general practitioner of medicine in America should learn all the slang of the psychiatric clinics; but the general ideas underlying the differential diagnosis between dementia praecox and manic depressive psychosis ought certainly to be understood by every general practitioner.

We also receive many cases referred from general hospitals, some of which are of the highest standard. The only instance in which catatonia was specified in any of these reports came from such a high grade general hospital. The fact that an assistant physician in a general hospital should know of the existence of catatonia and be able to specify it in a report on a case ought not to be a remarkable fact. Still it is an isolated fact in the series of 500 cases whose temporary care data I looked over. We, I believe, did not determine that the catatonia in question really was a catatonia, but that is not the point I make. How many general practitioners are advised of the existence of catatonia and really envisage catatonia as they might sundry conditions in specialties like dermatology?

From a very good general hospital we received a statement something as follows: "Onset sudden with acute retention of paralysis (flaccid) of legs ten days ago. Severe pain in lumbar region preceding above. Temperature of 103 to 104. Remains high. Mentally deranged for about twelve hours." Mental derangement! This is a phrase like several others—"mental failure," "irrationality," "mind unbalanced," "cerebral degeneration," "nervousness," "patient erratic"—which phrases all seem to dodge the specific issue and to argue an utter lack of specification in the mind of the practitioner as to different forms of mental diseases and symptoms. There will be found in these reports excellent detailed accounts of the radiation of pain, the situation of tenderness, the Wassermann reaction, the phthalcin test with digitalis, the appearance and disappearance of edema of the ankles, and the like; but there is no corresponding objectivity in the account of mental symptoms.

To our astonishment, we one day received from a high-grade general hospital the following: "Patient has been moderately depressed. Yesterday and last night patient became confused, showed fleeting hallucinations and ideas of a somatopsychic character, somewhat nihilistic. Unreasonable. At times disoriented. Difficulty in keeping the patient in bed or on the ward." We afterward discovered that this report had been made by one of our own former psychopathic hospital interns who had become connected with the staff of the general hospital in question. Here was a very informative report, but one apparently quite beyond the range of most hospital practitioners.

Let us now come to the general practitioners themselves. There is a group of reports in which absolutely nothing is said of value. For example: "A violent and dangerous maniac" seems to say a good deal about a patient, who, however, turns out to be neither maniacal, dangerous, nor violent. Another statement, "This man has been acting queerly for the

last six months and seems to be all run down," is of little value, as also the report, "Has been gradually becoming mentally weak and physically weak." With all due allowance for the carelessness of some practitioners and the fact that many things may be said in conversation that cannot be put on official slips, it is clear that there is a good deal of dodging the issue, and what in the military service was so universally known as "passing the buck," in the field of general practice as it touches psychiatry.

On the other hand, there are numerous perfectly objective reports which, though they indicate absolute ignorance on the practitioner's part concerning psychiatry, nevertheless are very informative, for example, "Crying and laughing. Breaking furniture. No sleep for three nights. Very destructive. Burned \$150 in bills. Threw watch and chain away. Burned up new shoes and clothes." There is a report which tells something, though from other evidence we are aware that the physician in question has no claim to psychiatric knowledge.

Here is another objective report: "Patient does not sleep, is depressed, is afraid she is going insane, and has expressed a desire to die, but has never spoken of an attempt at suicide. The patient says she is worried about something in the past which she can never tell any one. Patient has an irregular heart, possibly on an arteriosclerotic basis."

Or take another objective report: "This man sits and broods, avoiding the company of other people always. He will not enter a street car if others are present. If empty, he will probably go in and sit down. He says other people have no use for him. He imitates actions of others in minute detail. He says he can't go on living this way."

These objective reports indicate clearly that we have in many practitioners a great deal to build on in our propaganda for the extension of psychiatric knowledge among general practitioners.

I have collected a number of instances of the grossly inaccurate use of phrases. Sometimes the users of these phrases are otherwise objective enough. Their inaccuracy merely points to their inadequate medical education. They are perhaps good observers, but poor reporters.

For instance, the statement that a girl has "hallucinations that a fellow has moved into the same house with her" means in modern technical phrase not "hallucinations" at all but "delusions." This confusion of hallucinations and delusions is the most common error in these reports. You may regard it as a venial error, seeing that as a rule the context will tell the psychiatric examiner whether the reporter meant delusions or hallucinations. That is of course true. But my point is that this confusion argues elementary ignorance on the part of the general practitioner, since practically the first thing which a medical student learns concerning psychiatry is this distinction between hallucination and delusion.

A more gross error in phrasing is the following: "Dementia resembling circular insanity developed." The fact that circular insanity, even if the phrase were now in common use, is a nondementing psychosis and does not resemble a dementia ought to be common knowledge among practitioners.

Such ignorance as this can readily be repaired by postgraduate work, and it is clear that a propaganda to this end will meet general approval.

It will be more difficult to eradicate odd ideas concerning etiology. In answer to the question, "What is the cause of the patient's mental derangement?" facts from the anamnesis are almost at random picked for exposition. Thus, "Patient gave her wrong age in securing a position and said that she had two brothers in the army. She feared she would be found out in these lies and arrested." Another, to the question, "What is the cause of the patient's mental derangement?" is "in love?" Another, "Overstudy." Another, "Has worked very hard for the past six months."

These facts on examination seem to be merely items in general situations. No one nowadays denies the psychogenic origin of a certain portion of mental disease or the psychogenic factor in every mental disease, but we must certainly do something about our statistical blanks if we are not to perpetuate fantastic etiology in the common run of cases. A patient, who is described as having "fallen forty years ago and injured his back, excited, destructive, depressed," has as the cause of his derangement "high blood pressure." This patient turned out to be a case of hemorrhagic encephalitis. Another sample: "Patient comes in after an argument over something. In this case it was over the proper way to fix the bent stern of a submarine chaser which he was working on, and he being a house carpenter undertook to make the ship carpenter do it his way, hence the attack."

I need make no further comment on these etiologic statements. An extension of our propaganda to the demonstration of a few samples of the major groups of mental disease in clinics for general practitioners given at the various hospitals for the insane nearest the centers in which general practitioners might congregate would no doubt serve to erase most of the etiologic rubbish here hinted at. But the propaganda would also wipe out some of the grossly inaccurate use of phrases above mentioned.

Meantime the internists and general hospital physicians would have to brush up their psychiatry and undergo a reeducative or an educative process. All of which would minister to the mental hygiene of the community.

#### SUMMARY

Psychiatry has become almost more popular with nonmedical mental hygienists than the medical profession. Of course, the relations that are ultimately to stand between clinical neurology and psychiatry are not entirely clear. But the relations between psychiatry and the general practice of medicine are disturbed by special difficulties, e. g., phobias on the part of the general practitioner concerning nomenclature and concerning his own supposed ignorance of psychiatry.

A frontal attack is proposed on the general practitioner, in addition to the flank attacks considered desirable in the past, for his proper postgraduate education.

Psychiatry is more a synthetic art than is clinical neurology, now predominantly analytic. But, being synthetic, psychiatry has much in common with general medicine. General medicine, psychiatry, and (to a certain point) obstetrics treat the patient as an *individual*, whereas the majority of the specialties treat the patient (in scholastic phrase) as a *dividual*.

The body of the text contains material illustrative of some inadequacies of the general practitioner re psychiatry. Many of these are easily reparable.

#### ABSTRACT OF DISCUSSION

DR. E. STANLEY ARBOT, Belmont, Mass.: Dr. Southard has advocated a frontal attack on the general practitioner. I think we should also make an attack on the medical student. After all psychiatry deals much more with abstract than with concrete symptoms. Not many men are interested in abstract things, but the psychiatrist has to be. We want to get hold in the schools of those medical students who can be interested in abstract topics of conduct, action and so on. In order to do that we must begin earlier than the subject of psychiatry is usually taken up in the medical schools. There has been difficulty in interesting medical students in psychology, partly because of the lack of development of the science itself. Until very recently it has not dealt with the every day matters of conduct and behavior, and yet that is what the psychiatrist is constantly running up against. Psychology as taught seems to have had no relation to psychiatry. What we need, therefore, is the introduction into the curriculum of the medical schools of a psychology that deals with the mental activities involved in the normal adjustments of everyday life and their application to the behavior disorders that are the subject matter of psychiatry. A few years ago I looked up the number of medical schools teaching psychology and there were only twelve or thirteen that had any place for it in the curriculum. I think that is one of the reasons why the general practitioner has so little knowledge of psychiatry when he goes into practice. Psychology seems to the average man an abstruse and mysterious subject with which he is incompetent to deal. That attitude must be broken down by avoiding the language and terminology that is so mystifying to him. By presenting a psychology of every day life as a preparation for psychiatry more men will be interested in it and go out as general practitioners without the defects of special knowledge which Dr. Southard deplors.

#### THE PHARMACOLOGY OF THE LOCAL ANESTHETICS\*

CARY EGGLESTON, M.D.

AND

ROBERT A. HATCHER, M.D.

NEW YORK

Acute intoxication in man from the use of the local anesthetics is far more common than is indicated by the number of recorded cases. We undertook to investigate the causes of such intoxication, and sought to find means of avoiding it, or combating it when it arises. This investigation has included a study of the literature of the more important cases of human intoxication, and the performance of over 300 experiments on cats. The details of this work are published elsewhere,<sup>1</sup> the present communication being limited to a short discussion of the more important facts brought to light, especially with reference to their bearing on the clinical problem.

Nine of the local anesthetics were studied, and the maximum toxicity of each was determined by rapid intravenous injection into cats. The drugs used, the fatal dose of each, the concentrations of the solutions employed, and the relative toxicities of the drugs are shown in the accompanying chart. From the chart it is seen that cocaine is about intermediate in the group with reference to its maximal toxicity for the cat.

\* From the Department of Pharmacology, Cornell University Medical College.

<sup>1</sup> Read before the Section on Pharmacology and Therapeutics at the Seventeenth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

<sup>2</sup> Part of the expense of this research has been defrayed by a grant from the Committee on Therapeutic Research of the Council on Pharmacy and Chemistry of the American Medical Association.

J. J. Pharmacol. & Exper. Therap. 12, 1919.

These relative toxicities, however, apply only for single doses injected rapidly into the blood stream. When large fractions of the minimal fatal doses are injected intravenously at intervals of from fifteen to twenty minutes, or when relatively dilute solutions of the drugs are injected slowly and nearly continuously, the several drugs can be divided into two groups based on the difference in their rates of elimination. Group 1 includes alypin, apothecin, beta-eucain, nirvanin, procain (novocain), stovain and tropacocain, all of which are rapidly eliminated, so that several times the minimal fatal dose of any of these can be injected in the ways just mentioned in periods of one or two hours without causing death of the animal. Group 2 includes cocain and holocain, which are much less rapidly eliminated, and which therefore cause death in much smaller total doses when given as described.

When injected subcutaneously into cats, the local anesthetics can again be divided into the same two groups, depending on their rates of elimination. All are apparently absorbed rapidly, but those of Group 2 are much more toxic by subcutaneous injection than those of Group 1 because their elimination is not rapid enough to keep pace with their absorption. Five or more times the minimal fatal vein dose of any of the members of Group 1 can be injected subcutaneously without causing death, while less than four times the fatal vein doses of those of Group 2 prove fatal.

When absorption from the subcutaneous tissues is delayed by the simultaneous injection of epinephrin, the difference between the two groups is emphasized, and the toxicity of the members of the first group is reduced far more than that of the members of Group 2. The elimination of members of Group 1 proceeds at the rate of at least one fatal vein dose every twenty minutes, while not all of a subcutaneous dose of cocain, one and one-third times that fatal by vein, may be eliminated in twenty-four hours or more.

The elimination of all of the local anesthetics is accomplished almost entirely by their destruction in the liver, as can be demonstrated by perfusion of the excised, surviving organ with diluted blood containing large quantities of the drugs in solution, and subsequent determination of the amount remaining in the perfused fluid.

Various efforts were made to influence the toxicity of the local anesthetics, including the administration of atropin or caffeine prior to the intravenous injection of the anesthetics; the addition of sodium bicarbonate to the solution of the anesthetic just before intravenous injection, to liberate the base; the production of nervous exhaustion in the cat; severe acute hemorrhage by removal of one fourth of the cat's total blood; and the production of narcosis by the administration of hydrated chloral. None of these measures had any influence on the cat's susceptibility to the intravenous injection of any of the anesthetics except acute hemorrhage and narcosis by chloral. Both of these caused some increase in the cat's susceptibility, as

shown by the fact that often it succumbed to doses smaller than the average fatal dose. This increased susceptibility is accounted for by the fact that both these measures interfere with the destruction of the anesthetics in the liver by reduction in the blood pressure and impairment of the circulation. The resistance of both the heart and the respiratory center is also probably reduced by the impaired circulation.

The symptoms produced in cats by toxic doses of the various local anesthetics are essentially alike, and they are also essentially the same as those observed in man. All of these drugs kill by simultaneous paralysis of the heart and the respiratory center. We therefore tried artificial respiration in cats as a resuscitative measure, with and without cardiac massage, but it proved ineffective, even when combined with massage of the heart.

The employment of artificial respiration in combination with stimulation of the heart by the immediate intravenous injection of epinephrin, however, enabled us to resuscitate the majority of cats after the rapid intravenous injection of doses of the local anesthetics up to twice the average fatal dose. Since the heart had stopped in most of the cats, it was necessary to practice massage of the heart in order to bring the epinephrin into contact with it. The success of this method of resuscitation depends on the rapid destruction

of the local anesthetics, whereby the excess administered is promptly eliminated if the circulation can be maintained for only a few minutes by the stimulation of the heart with epinephrin. But even with such stimulation, and when it is evidently recovering, the animal will die of respiratory paralysis unless the center is supported for a few minutes by artificial respiration.

The success of the preceding measures, in which the brief stimulation of the heart played the most important part, led us to try the effects of previous stimulation of the heart by the administration of a dose of ouabain (so-called crystalline strophanthin). We then administered doses of the local anesthetics up to twice the average fatal dose, and employed artificial respiration to tide over the period of respiratory paralysis. By these measures, cats usually survived doses of the anesthetics up to one and three quarter times the average fatal dose.

It is evident, therefore, that if the circulation and respiration can be maintained for even a few minutes, the rapid destruction of the local anesthetics by the liver will care for amounts considerably in excess of those which are usually fatal. The close analogies between the behavior of man and cats to toxic doses of the local anesthetics, and the fact that man also recovers rapidly from the effects of nonfatal doses, suggest that he also accomplishes their elimination or destruction in his liver, and it seems highly probable that the use of epinephrin and artificial respiration will prove effective as resuscitative measures in many cases of acute poisoning in man. It is, however, to be remembered that serious intoxication has been seen in man following extremely small doses of the local anesthet-

Relative toxicity and range of concentration of solutions for the several local anesthetics; fatal doses in milligrams per kilogram.

ies, suggesting the occasional existence of a marked degree of hypersusceptibility; and in such cases doses which are relatively small, as compared with the average commonly employed, may actually be several times the minimum which would be fatal in the particular individual, so that even the most effective resuscitative measures may well fail under such circumstances.

While cardiac massage cannot be carried out so efficiently in man as in the cat, it can be performed sufficiently to cause the greater part of an intravenous injection of epinephrin to reach the heart; and several satisfactory methods are available for carrying on artificial respiration in man. These measures, also, are all such as can be applied without loss of time under most conditions, and they certainly seem to be the most effective means at our disposal for saving life after the development of symptoms of acute intoxication by the local anesthetics. Since acute poisoning in man occurs when least expected, those who frequently employ these local anesthetics should always be prepared to apply the three resuscitative measures of intravenous infusion of epinephrin, artificial respiration, and cardiac massage. All three should be used in combination, since no one alone is effective, except in rare instances.

Finally, in order to diminish the likelihood of intoxication from the subcutaneous injection of the local anesthetics—especially those of Group 1—in man, epinephrin should be added to their solutions as a routine, because by delaying their absorption it renders it more probable that the destruction by the liver can keep the amount present in the circulation at any one time at a point below that sufficient to cause intoxication. The use of epinephrin also has the further advantages of prolonging the anesthetic action of a given quantity of the drug and of reducing the amount required for anesthesia by permitting a larger proportion of the dose injected to remain in contact with the tissues to be anesthetized, and by maintaining the contact for a longer period of time than when the drug is injected alone.

414 East Twenty-Sixth Street.

#### ABSTRACT OF DISCUSSION

Dr. DAVID I. MACHT, Baltimore: I wish to say a word concerning the toxicity of the recently discovered new local anesthetic, phenethylol or benzyl alcohol. If you inject into the saphenous vein of an unanesthetized normal dog (as can easily be done), a 1 per cent. solution of benzyl alcohol in doses of 20 c.c. per kilogram weight of the animal, the animal will get up and play as normal as ever. This is not the fatal dose of the drug. The fatal dose is at least forty times less than that of cocaine. As far as I know, this toxicity is less than that of all the commonly known local anesthetics. The low toxicity is due to the fact that the drug is not an alkaloid or a narcotic, but a simple compound, which is easily and rapidly metabolized and detoxified by the body and is excreted for the most part as hippuric acid.

**Mother's Milk and Cow's Milk.**—Many are familiar with the chemical difference of the two milks, but we wonder how many really appreciate the total difference in physical and chemical properties. The fats of the two milks contain different proportions of palmitic, stearic and oleic acids, have different melting points, and the fat globules are of different size, all producing a difference in digestibility and absorbability. The proteins contain different proportions of casein and globulin and a different amount of lecithin and chemically combined phosphorus that are very important in bone formation and brain development.—Julius Levy, M.D.

## HYSTERICAL HEMIPLEGIA

REPORT OF CASE RESULTING FROM A SHRAPNEL WOUND OF THE SCALP AND PRESENTING INTERESTING CLINICAL FEATURES \*

HARRY H. DRYSDALE, M.D.

AND

J. S. S. GARDNER, M.D.

Assistant Surgeon, United States Public Health Service  
CLEVELAND

While the history and clinical picture we are privileged to report may not be considered especially unusual by those medical officers who, during the great war, encountered all manner of functional nervous manifestations, the condition nevertheless does possess features of interest to the general practitioner and presents several points worthy of discussion by the neurologist.

#### REPORT OF CASE

*History.*—W. P. W., a married man, aged 29, American, marine diver, enjoyed good health during youth and obtained a common school education.

So far as we could determine, the family history presented nothing noteworthy. His mother and father were dead; the former died from a complication of diseases at the age of 62; the father succumbed to pneumonia a few weeks before. The patient had two brothers and two sisters. One brother died from wounds, in France, during the past year. The remaining brother and two sisters were alive and well.

April 22, 1902, he enlisted in the United States Navy; he contracted malaria during July, 1903, and was discharged for this disability, May 10, 1904. Shortly thereafter he was awarded a monthly pension of \$12, which is still in force.

After this country declared war against Germany, this man applied for enlistment in the military service of the United States, but was rejected at Detroit and Cleveland as "medically unfit," for what reason we are unable to ascertain; but it is presumed that the examining officers took into consideration the fact that he had been discharged from the Navy as physically disabled. May 1, 1917, he was accepted by the authorities at Windsor, Ontario, and went overseas with the Canadian Expeditionary Forces, June 27, 1917.

His service at the front was uneventful until on or about Aug. 1, 1917, when he claims to have volunteered to accompany a rescue party, at night, in search of their captain, who was reported lost in No Man's Land.

The officer was found severely wounded and in need of prompt surgical attention. In the face of a heavy German bombardment this soldier started back to safety, carrying the wounded officer. As he approached the communicating trenches, shells were exploding thick and fast; but he succeeded in delivering his charge to the stretcher bearers. At that moment he felt a sharp sting on the left side of the head and believes he fell forward into the trench. He was treated at the clearing station during the subsequent twenty-four hours and then removed to British General Hospital No. 8, where it was found he was paralyzed on the entire left side of the body, including the face. The period of unconsciousness, he stated, was brief. He was confined to bed for a period of one month. Since then he had been able to get about with the aid of crutches or a cane.

Oct. 28, 1917, he was transferred to England and received treatment and observation in several special military hospitals. During the many examinations he heard his condition discussed as a "hemiplegia" resulting from a shrapnel wound of the left scalp. He intimated that the examiners used the term contrecoup. The weakness of face, he avers, gradually disappeared in a few weeks.

\* Read before the Section on Nervous and Mental Diseases at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

June 7, 1918, he was invalided to Canada and further observed. The disability, however, remained practically unchanged and he was discharged at Toronto, Jan. 2, 1919, as "medically unfit." A monthly pension of \$50 was granted him.

From the medical history of this soldier as recorded in the final report of the Canadian Medical Board, dated Toronto, Ont., Dec. 12, 1918, a copy of which was kindly furnished by Major E. E. Fletcher, I quote the following:

"History: Wound of left side of head by piece of H. E. shell and struck on head by piece of timber. This was followed by hemiplegia on same side as wound. Hemiplegia may be due to contrecoup or more likely to some intracerebral vascular disturbance. X-ray of skull negative. Operation considered inadvisable.

"Present Condition (Objective): Power of left arm poor throughout, about one-third normal. Loss of all power for fine movements of left hand. Partial loss of power of left leg. Coarse tremor of left arm and sometimes of left leg. Sustained left ankle clonus. Plantar reflexes give Babinski response on left side. Left foot held in position of partial equinovarus. Can walk (using a stick) with marked limp on left leg. Sensation normal; no astereognosis. Small depressed area on left side of skull about 2 inches above left ear. Is somewhat emotional and at times hysterical. There is slight mental deterioration.

"Present Disability: (1) Partial loss of function of nervous system. (2) Defective eye sight.

"Final Conclusions of Board: Wassermann on spinal fluid and blood negative several times in England. Disability of soldier now 100 per cent. The report also states that this soldier told one of the medical officers there was a weakness of left side of body, following his attack of malaria in 1903; but he now denies having made this assertion."

*Examination.*—Our first examination, Jan. 20, 1919, disclosed a man of large frame and excellent development. He was exceedingly tremulous, anxious and depressed. He walked with crutches, carried the left arm close to the body, and dragged the left leg in a somewhat flexed position. The fingers of the left hand were firmly contracted but not of the Babinski and Froment type of reflex contracture. A partial left hemianesthesia prevailed; reflexes of the left side were quite sharp; a fairly well sustained clonus of the left ankle and left patella were detected, and as typical and complete a Babinski response of the left foot as we have ever encountered was elicited. The Oppenheim and Gordon signs, however, were absent. The left leg was paretic and slightly atrophied without appreciable change in the electric reactions. No vasomotor or thermic abnormalities existed.

A healed depressed scar, about three-fourth inch in length, adherent to the skull, was found on the left scalp at a point about 2 inches above the left ear. This wound is said to have been infected. The small toe of the right foot was amputated some years ago following a crushing injury.

The heart, lungs, blood vessels and abdominal viscera were normal. The pulse rate was 110, regular and of fair volume. The blood pressure measured 115 mm. systolic and 98 diastolic.

The patient's record, as personally related, plus the physical findings, was strongly suggestive of an organic palsy, and not until his history was further scrutinized and a more careful study made of the symptoms did it appear that we were probably dealing with a functional derangement.

He went on to say that he had returned to Cleveland a cripple, and he became quite emotional as he told of his wife's unfaithfulness during his absence in France and how he had lost his American citizenship by enlisting in the Canadian army. He stated that he had applied at the U. S. Marine Hospital, this city, in the hope that the trouble in his brain might be located and possibly corrected by surgical means. If his condition was incurable he wanted to know it at once, as suicide was preferable to a life of invalidism.

Complete roentgenograms of the skull were made by Dr. T. J. Taylor at Lakeside Hospital, and not a single suspicion of fracture was detected.

Dr. Leo Wolfenstein made a painstaking investigation of the eyes, and reported that the patient claimed defective vision of the left eye, apparently about 20/100; but when he placed a plus 600 sph. in front of the right eye, the vision of the left eye was found to be at least 20/30. In the right eye, the patient claimed vision of about 20/70, but with a little strategy the vision of the right eye proved to be normal. During his observation of the case the vision seemed to vary from time to time. The eye grounds were entirely healthy, and no error of refraction was detected. The fields also varied considerably from day to day. There was no nystagmus.

The spinal fluid was obtained by Drs. Richard Dexter and C. L. Cummer, and their findings were: Pressure, not increased; globulin, not increased; cell count, none.

The Wassermann reaction read: 0.1 c.c., negative; 0.3 c.c., negative; 0.5 c.c., negative; 1.0 c.c., negative.

*Treatment and Result.*—Arrangements were then made to subject the patient to a systematic plan of therapy. He was candidly informed that his brain had not been organically damaged, and was assured that if he would cooperate with us a recovery might consistently be expected. It was explained to him that he undoubtedly had been severely shocked and his nervous system undermined thereby; but the trouble, fortunately, was functional.

Sedatives were used to allay the extreme emotionalism and to overcome a persistent insomnia. Saline baths each night, galvanism every other day, and regulated exercises were prescribed.

From the very beginning, a decided change for the better was noted. His nervousness gradually abated, and he became enthusiastic and hopeful. In less than two weeks his gait was very much more stable, and to our surprise the alleged Babinski phenomenon and clonus of the left ankle and knee disappeared. Crutches were discarded for a cane, and within a month he was able to go about unassisted. He complained, however, of difficulty in crossing congested streets. Crowds excited him, and he sometimes feared he might lose his control and be injured by some passing vehicle.

During the first six weeks the left hand remained more or less contracted. He told us, however, that sometimes when alone he was able to walk and use the left arm almost as well as before he was wounded; but the moment he came in contact with people the paralysis would recur. With the use of electricity we seldom failed to relax fully the contracted left fingers, but the result was temporary. As an additional suggestive measure, alcohol was injected into each left finger with the same psychic effect. On one occasion he remarked that the alcoholic injections seemed to release something in the left side of the head.

Time after time this soldier would report for treatment remarkably improved and highly encouraged. At other times he was tremulous, fearful and deeply depressed. Trouble of some sort continued to cross his path. Always impressionable, the slightest annoyance invariably aggravated the disability and increased his nervousness. A chance meeting with his alleged unfaithful wife, a death in the hospital and the notification of his father's demise were some of the numerous perturbations which retarded his progress. As our observations proceeded, we finally were convinced that the Canadian medical officers made a proper interpretation of his mental state. He was not only poorly equipped to withstand ordinary strains and stress but wholly incapable of adapting himself to his environment. Many of his statements proved to be base prevarications, and he made claims that were extravagant and oftentimes sensational. His chief ambition was to pose as a wounded hero, and he habitually feasted on pity and sympathy. One day I saw him marching in a military parade, leaning heavily on a cane and carrying the left arm in an unnecessarily awkward position for the evident purpose of attracting attention. His expression of sadness and dejection was pronounced.

For a while the condition, though greatly improved, remained somewhat stationary, and we decided to take a firm stand with him. Instead of remaining at the hospital to follow instructions, he was wandering about the streets mak-

ing acquaintances of a questionable character. The odor of liquor had been detected on his breath; but this he stoutly denied. He did, however, admit that persons had stopped him on the street and urged him to forsake medicine and seek relief at the hands of various cults whose cures, they declared, were more permanent.

We openly accused him of loafing on the job, and he was told that it looked very much as if he was not especially anxious to regain his health so long as he enjoyed monthly pensions in the amount of \$62. This seemed to jar him, so to speak, and he instantly retorted that if he could be convinced that the paralysis would never recur, a full recovery would probably follow. He also admitted that his general sense of well-being was greatly improved; that the paralysis was ever so much less; that the nervousness and insomnia had practically subsided, but that he was constantly haunted by the fear that a piece of shrapnel had penetrated his brain, as the examining officers so often declared. Another interesting assertion was the confession that more than once he felt as if his health had been restored, but some excitement would arise to blast his hopes.

At the final examination, May 15, 1919, the patient looked well and was adequately nourished. He had gained 10 pounds in weight. He walked alertly with a slight limp, favoring the left leg. He was able to stand erect with the heels and toes together, and could stand on either foot unassisted. No clonus or Babinski toe response prevailed. He carried the left arm in an almost normal position, but there remained a moderate contraction of the thumb and first finger of the left hand which interfered with the fine movements of the left hand. The grasp of the left hand and the strength of the left arm and left leg were vigorous. The heart action was normal. The pulse rate was 88. The blood pressure measured 130 mm. systolic and 93 diastolic. The depressed flesh wound of the left scalp remained unchanged. The patient was able voluntarily to extend the great toe of each foot while the remaining toes retained their normal position. The tendon of each extensor hallucis longus was still prominent.

Mentally he was quiet and self composed. He had lost much of his emotionalism and apprehension, but was still morbidly impressionable. He was optimistic as to his recovery, which he believed was not far distant. He stated that during the excitement incident to the recent socialist uprising in the Cleveland streets, May 1, he almost forgot that he was a cripple.

#### COMMENT

The case is of interest in consequence of the confusing nature of the neurologic symptoms. Our initial examination disclosed a contracted left hand, a decided weakness and limp of the left leg, plus an apparently complete Babinski phenomenon of the left foot with a more or less pronounced clonus of the left ankle and patella. These clinical observations were also detected and recorded by the Canadian medical officers, and unquestionably influenced their opinion that the affliction was an organic hemiplegia and therefore a total disability.

At first we readily would have agreed with this classification; but the facts that the soldier sustained a slight flesh wound of the left scalp followed by paralysis of the same side of the body, including the face, and that subsequent roentgenograms of the skull and Wassermann tests of the blood and spinal fluid were reported by competent observers to be negative aroused sufficient doubt in our minds to warrant delay in forming a definite conclusion.

After one month's observation and treatment we became convinced that the disability was none other than the expression of a hysterical disturbance. The early subsidence of the suspicious nerve signs and the marked general improvement by suggestive measures

only, the abnormal impressionability of the individual, his inability to withstand the ordinary pin pricks of life, the pronounced emotionalism, and the eye manifestations did much to shape our diagnosis.

Little significance was placed on the clonus of the left ankle and patella, as this symptom frequently occurs in functional disorders and is therefore worthless as a pathognomonic sign.

The possibility of an admixture of hysteria and an organic lesion was carefully considered and eventually excluded. Nor did we overlook the importance of the reported observations of experienced neurologists that hysteria has never developed on the battlefield or when the soldier is still in danger, but only when he finds himself in relative safety. This patient is unable to give any reliable data as to when the paralysis first appeared. During the first twenty-four hours he was dazed and confused, but he entertains a vague impression that the condition developed while en route to the hospital in a military train.

The question now arises as to whether or not the alleged Babinski response of the left foot was genuine and therefore pathologic. We are inclined to doubt it and prefer to interpret the phenomenon as a psychogenic movement of resistance. On the other hand, when the sole of the left foot was gently stimulated there was a prompt, though slow, dorsal excursion of the large toe, and a simultaneous plantar flexion of the four external toes, symptomatic of the Babinski reaction. Perhaps the undue prominence of the tendon of the extensor hallucis longus as well as the patient's ability to cause voluntarily a full dorsal movement of both large toes, while the other toes retained their normal position, may have influenced the behavior of this symptom.

In medicolegal work, instances are on record in which litigants have ingeniously succeeded, after some practice, in producing a full upward movement of one or both large toes, in much the same manner as certain persons have learned to wriggle an ear or wrinkle half of the forehead; but this patient emphatically denies that anything of the sort ever entered his mind.

The man has been under systematic treatment for a period of four months; and, while he is still partially disabled, a full recovery, we believe, may reasonably be anticipated.

Unfortunately, he has been subjected to innumerable examinations and tests; has listened repeatedly to discussions and controversies concerning his condition; and during his long residence in various special military hospitals, has come in intimate contact with all sorts of nervous invalids. All of this has undoubtedly tended to impress on his susceptible mentality the conviction that he is an incurable paralytic. It is also important to note that as a result of his extensive medical experience he has acquired a knowledge of "traumatic hemiplegia," which is interesting if not instructive. Then, again, if his disability has earned for him monthly pensions sufficient to satisfy his ordinary needs, without exertion on his part, there is little incentive to call into action his higher control. On the contrary, it is apt to operate, consciously or unconsciously, as a deterrent to his recovery.

Finally, it may be added that this clinical report serves the additional purpose of pointing out with what degree of perfection hysteria may simulate organic disease, and also emphasizes the difficulties one experiences in avoiding errors in diagnosis.

## ABSTRACT OF DISCUSSION

DR. ALFRED GORDON, Philadelphia: The Babinski sign has been reported to have been found in cases of hysteria, but a careful examination will always reveal some error in the procedure or the method of bringing out the reflex. One has to stroke very gently the sole of the foot in order to bring out a genuine Babinski without dorsoflexion of the entire foot. With reference to the knee jerks in hysteria one must equally be careful in interpreting the reflex. A brusque, abrupt, sudden elevation of the leg is more in favor of a diagnosis of functional disease than of organic disease. Here again the case reports do not give a detailed account of the procedure employed or a detailed description of the phenomenon. With regard to the compensation question in functional nervous disease, there is a tendency at present to regard hysteria as malingering on the part of the patient. At the meetings of French neurologists the question was raised especially and for a special detailed discussion by the most eminent men. At first there was an inclination to decline compensation for cases of functional nervous disorders, hysteria included, and only one man, Pitres, of Bordeaux, raised his voice against such a decision, discussing at length the injustice rendered the individuals in this class. Another meeting was held for the same purpose and finally the entire association came around to Pitres' views, and 20 per cent. disability was considered as a standard for hysterical paralysis or other functional manifestations.

DR. TOM A. WILLIAMS, Washington, D. C.: Two fallacies in such cases must be guarded against. One is mistaking for the extensor reflex the true Babinski, the defense reaction. Another is the simulation of the Babinski on the part of the patient. The defense reaction can readily be differentiated from the true Babinski phenomenon, if one knows the behavior of each. With reference to ankle clonus, it is not difficult for a patient to simulate this. The experienced neurologist, however, can make the differentiation, and if not an experienced neurologist, by a kymographic tracing. There is another interpretation in some of these cases, namely, that the patient has had a lesion capable of producing disorder of the pyramidal tract which will produce that sign and which rapidly disappears, such as meningeal irritation. The patient grafts the hysteria on the organic condition, and when he is examined one discovers only the hysteria and wrongly imagines the former reactions are due to the hysteria. The criterion of the case is the fact that the phenomenon can be induced and removed by persuasion and suggestion, in which case it cannot be an organic phenomenon.

DR. ALBERT E. STERNE, Indianapolis: We have practically all had similar experiences, or will have like experiences at this time of returned soldiers, for reexamination is often requested by the war risk department and a number of cases will present similar complexities which we are somewhat at a loss to interpret. We are laboring between two emotions, ourselves, in making our reports on these cases; namely, that we want to do justice to all the boys coming back who have been injured, but at the same time protect the government and ourselves from fraud. Whether organically injured or functionally disabled makes little difference, because a man functionally disabled is almost as badly off and sometimes worse off than one with a palpable bodily injury. The government compensations will amount in time to terrific figures and we are all anxious, naturally, to see that compensation is not awarded where it is not due. The suggestions grafted on these men in their prolonged convalescence in various camps must not be overlooked. I am convinced that the great majority of these boys do not desire to remain invalids; they are not in the malingering class, but they exaggerate. There is a tremendous proclivity in the average normal individual to exaggerate symptoms, either through self-pity or the desire to excite sympathy. We must not be too sure about the revelations the reflexes present. Where the reflexes are seemingly positive, if tested and retested often enough they may be found changed. They are not always consistent. You should make the patient feel that you are with him, as much as possible, but are not going to encourage any unfit-

ness on his part that can be cured, or encourage him in functional invalidism.

DR. LEWIS J. POLLOCK, Chicago: The important fact as to compensation for the war neuroses is not that the patients are not going to be compensated enough for their disability or that the government is going to be cheated out of money wrongly applied. The important thing is to get the boys well. If you hold out the promise of a compensation to a hysteria patient you will afford him an opportunity for continuing the functional condition. If it is decided that there is to be no compensation for functional disease that disease will disappear much more rapidly. The best compensation for a neurosis is its cure, and any other form of compensation is a sad commentary on our therapeutic efforts.

DR. HUGH T. PATRICK, Chicago: I understood Dr. Williams to say that if this were hysteria it would immediately disappear under persuasion or suggestion. If he would modify that to "immediately disappear under effective persuasion" I would agree with him. But the fact remains that some do not disappear under persuasion or suggestion. Hysteria in soldiers is more easily treated than hysteria of civil life and yet the records show that they have been subjected to persuasion and suggestion for many months at a time and have not been cured until they reached the man who made the suggestion which appealed to the patient and then they got well. I think it should not go abroad as the sense of this section that hysteria will at once disappear under suggestion or persuasion. I would like also to support what Dr. Pollock said about these functional cases. They also can be compared to the same thing in civil life. If a man or woman has traumatic hysteria and sues for \$20,000 it is well known that in the vast majority of cases after litigation is ended the hysteria disappears. A few days after the signing of the armistice the vast majority of the war neuroses had disappeared. Consequently, the giving of compensation to a purely hysterical disability is a great mistake. In the prewar period any one who had the opportunity to see the thousands of cases of traumatic hysteria in Germany and found practically none in France because the laws of the two countries were so different, would come to the same conclusion.

DR. W. S. LINDSAY, Topeka, Kan.: I understood Dr. Williams to say that he did not consider that this case was organic. I have known of a case of cerebral tumor attended by convulsions where it was possible for the attendant to avert the convulsive seizures by engaging the attention of the patient. We cannot exclude cerebral disease because we must take into consideration the fact of cerebral inhibition.

DR. FOSTER KENNEDY, New York: The question of compensation of discharged soldiers suffering from hysteria is a matter of most potent interest at present and we should get our minds clear on this question. The British government pensioned about 25,000 soldiers for what was called shell shock up to May, 1918. This involved a very large sum of money and a large number of men. These cases furnished the medical view of what shell shock is. The doctors were wrong and the soldiers were right. The soldiers knew it was a neurosis associated with the desire to preserve life, also a breakdown of the man's adaptation to environment. It was not the result of petechial hemorrhages in the brain. The medical men advised the government and the result was this method of compensation. I understand the French take the position that they will not compensate for a functional condition. That seems to be a serious thing for the individual and in these days of the civilian army the individual should be given a certain amount of consideration. It is not true that you will cure your hysteria patients if you do not compensate them. You will have to decide what is hysteria and what is organic disease first. If you can be sure of your diagnosis then you can decide accurately. As a matter of fact, most people when they get an injury of the arm in war go through a period of defense immobilization. If they are told that the arm is paralyzed then the seed of hysterical paralysis is sown. You must make it a rule to be very sure of your diagnosis, or you must have a very strong compensation board to decide what is hysteria in some cases and

what is organic in others because the chief error that is being made all the time is a question of diagnosis.

DR. EDWARD F. MAYER, Pittsburgh. I do not believe it wise to assume the same attitude toward war hysteria now as was done before the armistice. I agree with Dr. Patrick and Dr. Pollock that the feature of noncompensation was advisable during the war and that it would have been better had all the armies practiced it from the beginning. But there is a different angle to the problem now. Though the fear of the battlefield has been removed and the instinct of self-preservation is no longer disturbed, nevertheless continued disability not only implies a fixation of symptoms but a protective mechanism which needs removal and which is in most cases due to other factors than the war situations and experiences. They are unable to care for themselves and must be given hospital facilities, vocational work and competent neurologic oversight until recovered and after-care help so that no economic worry affects them after discharge. The War Risk Insurance Bureau, I know, realizes this problem but it is complicated I find by the fact that many of the war neuroses have been discharged and must themselves take up with the War Risk Board their problems instead of its having been done by army neurologists in advance of discharge. Let us, therefore, separate the compensation problems of the war and the compensation problems of after-war. In the latter case, compensation is deserved and necessary and we neurologists must above all recognize it.

DR. JULIUS GRINKER, Chicago. At the meeting of another section I heard some one remark that the diagnosis of hysteria is only a sign of the examiner's perplexity. I did not think I would hear a similar expression voiced in this section. Many people mean different kinds of disease when they speak of hysteria. In hysteria there is simulation, but it is of the unconscious kind. This we know to be only one of the many symptoms of hysteria. I think the speakers who preceded me had in mind conscious as much as unconscious simulation when they spoke of war hysteria. After everything has been said on hysteria one thing is certain, namely, that it exists and is a functional disease and must be treated as such. Not all cases of traumatic hysteria which have been awarded compensation in industrial life have thereby been cured because the disease is not synonymous with simulation. No one remedy will cure all forms of hysteria. Whatever name you give the disease, it exists, and as medical men we are justified in recommending compensation to those who become genuinely hysterical as the result of trauma whether in peace or war.

DR. HARRY H. DRYSDALE, Cleveland. Dr. Williams is inclined to regard the curability of hysteria a rather easy matter, but it has not always been so with us, especially in the cases of long duration. The case I have brought to your attention was complicated by the award of a liberal pension which consciously or unconsciously has served to deter recovery. The differentiation between simulation and true hysteria should not be difficult if the investigation is carefully conducted. When necessary, suitable observation will clear up any doubtful points. I am heartily in accord with the remarks of Dr. Pollock and Dr. Patrick.

**Industrial Tuberculosis Experience in 1918.**—The industrial department of the Metropolitan Life Insurance Company has recently published a report of the department's tuberculosis mortality experience for the year 1918. The death rate from tuberculosis (all forms) has decreased every year for the Metropolitan since 1911, when the rate was 224.6 per hundred thousand. In 1918 the death rate had fallen to 187.4, which is, however, only slightly lower than the rate for 1917—188.9. With this experience rate of the Metropolitan company may be compared the general mortality rate for 1917 throughout the death registration area in continental United States, which was 146.4. It would be interesting to study the causes as to why the death rate of those insured by the company should have been 42.5 higher in 1917 than the general rate for the whole United States. In view of the fact that those insured averaged doubtless younger one would naturally expect the rate lower.

## UROBILIN AND UROBILINOGEN OF STOOL AND URINE IN PERNICIOUS ANEMIA

THEIR VALUE IN DIAGNOSIS AND PROGNOSIS\*

G. H. HANSMANN, M.D.

AND

C. P. HOWARD, M.D.

IOWA CITY

The material for this study consisted of twenty-seven cases of pernicious anemia, and as pathologic controls nine miscellaneous conditions which included one case each of chlorosis, carcinoma ventriculi, purpura, familial hemolytic icterus, Banti's disease, lymphosarcoma, acute cholecystitis, hemochromatosis, and tabes dorsalis.

The method was a modification of Wilbur and Addis's<sup>1</sup> spectroscopic method. The modification was instrumental and has been described recently by J. D. Boyd,<sup>2</sup> working in our laboratory under the direction of Dr. Louis Baumann. The instrument "was constructed from a Hellige colorimeter and a hand spectroscope and consisted essentially of a hollow glass wedge which can be moved vertically before a fixed spectroscope" (8 cm.). The sample is prepared in the usual manner. "The cell, which holds about 10 c.c., is filled with the solution, and the point is found when the spectrum just disappears with moderate light<sup>3</sup> but reappears when the light is diminished by changing the light screen of the spectroscope." It is essential to obtain a uniform sample of the stool mixture. The results were reduced to terms of 1 cm. of liquid.

Calculations for the stool are made from the formula:

$$\frac{2,000}{5} \times \frac{100}{2} \times 8 \times \frac{1}{2}$$

The 2,000 = dilution of stool; the 5 = Wilbur and Addis' concentration unit; 100 = instrumental reading; 8 = previous dilution;  $\frac{1}{2}$  = results reduced to 1 cm. divided by the size of the top of the wedge.

For the urine the formula is slightly modified, thus:

$$\frac{24 \text{ hour volume}}{5} \times \frac{100}{R} \times 2 \times \frac{1}{2}$$

All attempts to separate accurately the stools for a given period with carmin, charcoal, barium sulphate and bismuth subcarbonate, though a constipating diet was used, yielded no constant results. This uncertainty was due first to the occasional administration of purgatives to the patient by the medical staff without the knowledge of the laboratory; secondly, to the individual constipation so often present in bed patients which necessitated, with laboratory approval, the administration of a cathartic and consequently the evacuation of a soft stool in which demarcation was impossible; and thirdly, to the occasional presence of a diarrhea.

Further, even if a correctly demarcated stool was obtained, the length of time necessary for the collection of the stools is so great that the true amount of urobilin and urobilinogen may be reduced by oxidation, either in the intestinal tract or in the laboratory container. These difficulties seem insurmountable from a clinical standpoint. An attempt was made to overcome

\* From the Medical Clinic of the University Hospital of the State University of Iowa.

2. Boyd, J. D., Jr.: *J. Lab. & Clin. Med.* 4: 495, 1919.

3. We found full light better.

them partially by collecting stools as they occurred over a period of seventy-two hours, determining in each stool the urobilin and urobilinogen content, and then dividing the total dilutions by the number of the twenty-four hour periods studied, namely, three. Lastly, the occasional condensation of Ehrlich's reagent by the putrefaction derivatives in the urine and stool interferes with the distinctness of the absorption band of the urobilin. This was overcome by the determination of the urobilin before the addition of Ehrlich's reagent, then of the urobilinogen after the addition of the reagent, and adding the results together.

The urobilin and urobilinogen estimation of the duodenal contents, so enthusiastically recommended by Schneider,<sup>4</sup> and subsequently by Giffin, Stanford and Szlapka,<sup>5</sup> was determined in five cases. Four showed definite, and one questionable qualitative increase in bile pigment. Three showed the abnormal presence of urobilinogen, which amounted to 6,800, 2,400 and 1,520 dilutions, respectively; the other two cases which were negative were undoubtedly cases of pernicious anemia, and there was a well defined increase of the urobilinogen in the stools. We have therefore placed less confidence in the duodenal determination than in that of the urine and stools, contrary to our expectation entertained after reading Schneider's and Giffin's articles. It is, of course, possible that more experience in this method might overcome our present prejudice.

No attempt has been made to review the literature, but we cannot refrain from referring to one or two papers. H. Scholz<sup>6</sup> quotes Salomon and Charrias as asserting that in pernicious anemia the urobilinogen content of the stools is two or three times the normal amount, while in chronic gastritis and in cancer of the bowel or stomach it is only a third or a half of the normal. Scholz himself, using Authenriet's colorimeter and a standard sodium phenolphthalein solution, found that in eleven of thirteen cases of carcinoma ventriculi the urobilinogen content of the stools was materially reduced but that in the two other cases the findings were conflicting. Further, his findings in pernicious anemia, both in the urine and in the stools, were not constant. He concludes that while the urobilinogen content of the stool has only slight differential value, a marked urobilin content can determine the extent of the hemolysis and whether the case is suitable for splenectomy or not.

On the other hand, O. H. Robertson<sup>7</sup> found an increased quantity of urobilin in the stools in eleven cases of pernicious anemia, and observed that "those patients in whom the evidence of blood destruction was most marked gave the highest urobilin estimations." He concludes "first, that the quantity of urobilin in the stool may be taken as an approximate measure of the degree of hemolysis occurring in the body, and second, that such estimation is of very definite clinical value in the diagnosis of conditions questionably hemolytic in character, particularly in anemias of uncertain type."

Robertson<sup>8</sup> in a later paper states that "the variation in the urobilin output may be taken as an index of

corresponding changes in the course of that disease." McCrudden<sup>9</sup> more recently came to very similar conclusions.

## RESULTS

We have divided over twenty-seven cases of pernicious anemia into four groups according to the degree of the anemia as determined by the total red cell count. In the tables representing each group, in addition to the figures of the urobilin-urobilinogen content, we have indicated in one column the other evidences of the hemolytic process, namely, the high color index and the presence in the stained smears of poikilocytes, anisocytes, erythroblasts and polychromatophilic cells. For each of these abnormalities we have given a value of 1, so that when the table shows a figure 3, it means that three of the five above enumerated abnormalities are present, and so forth.

We thought it would also be of interest to tabulate the evidence of the disease process in the nervous system as indicated by the presence of paresthesia, diminution of objective sensibility (particularly the vibration and the two point discrimination senses), and disturbances of coordination and alteration in the cutaneous and tendon reflexes. If these various tests are applied as a routine, it is surprising how frequently some evidence of a subacute degeneration of the spinal cord can be demonstrated in cases of pernicious anemia. In fact, one cannot emphasize too much the diagnostic value of a careful examination of the nervous system in all cases suspected of pernicious anemia.

TABLE 1.—FINDINGS IN GROUP 1

Case No.	Blood Count	Blood Sugar	Cord Lesion	Urobilin and Urobilinogen		
				Urine	Stool	Total
4	4,700,000	0	+	2,910	24,000	26,910
9	4,000,000	2+	+	13,120	60,000	73,120
8	4,000,000	3+	+	2,466	42,156	44,622
10	4,000,000	4-	+	.....	21,000	21,000
5	4,000,000	2+	?	300	50,000	50,300

Group 1 included five cases with a red cell count varying between four and five millions. All five cases showed, in spite of a very slight anemia, a well defined increase in the urobilin and urobilinogen content of the urine and stools, ranging from 21,000 to 73,122 dilutions, or an average of 40,400 dilutions. Further, in all but one case (Case 10) and possibly in another (Case 35) the urobilin and urobilinogen were definitely increased in the urine, which is, of course, pathologic. It is of interest to note that four of the five cases showed other evidence of disturbed blood formation either in the shape, size or staining reaction of the individual red cell, in the presence of nucleated red cells, or in the high color index. Lastly, the existence of a long standing disease process was evidenced by well defined signs of a subacute sclerosis of the cord in at least four cases.

Group 2 comprised nine cases with counts varying from three to four million. This group did not reveal so striking an increase in the urobilin and urobilinogen content of the urine and stools, varying from 4,800 to 30,600 dilutions, or an average of only 12,400 dilutions. All but one case (Case 30), and that a clinically doubtful case, showed other evidence of disturbed red cell reaction. Further, six of them had definite objective signs of a cord lesion, while the three others

showed at least subjective sensations suggestive of an early process in the sensory tracts.

We believe that the relationship of relatively high blood count and low urobilin and urobilinogen content in this group may be explained by the development of a period of improvement, so frequent in the course of the disease.

TABLE 2.—FINDINGS IN GROUP 2

Case No.	Blood Count	Blood smear	Cord Lesion	Urobilin and Urobilinogen		
				Urine	Stool	Total
26	3,800,000	3+	—	...	9,300	9,300
27	3,800,000	3+	—	3,000	27,400	30,400
28	3,800,000	4	+	560	0,000	20,500
29	3,800,000	3+	—	...	8,000	8,000
30	2,600,000	0	—	200	4,000	4,800
13	3,700,000	3+	—	...	7,000	7,000
10	3,250,000	2	—	...	14,613	15,893
14	3,250,000	2	—	931	8,975	9,106
20	3,250,000	3	—	80	8,700	9,000

Group 3 comprised five cases with blood counts ranging between two and three million red cells. As in Group 1, all showed a very marked increase in the urobilin-urobilinogen content of urine and stools, varying between 44,640 and 130,285 dilutions, or an average for the series of 98,565 dilutions. The evidence of disturbed hematopoiesis was more marked in this group than in any, not excepting Group 4. Lastly, signs of cord involvement were present in four cases and were questionable in the fifth.

TABLE 3.—FINDINGS IN GROUP 3

Case No.	Blood Count	Blood smear	Cord Lesion	Urobilin and Urobilinogen		
				Urine	Stool	Total
11	2,600,000	4+	—	2	2	121,000
1	2,100,000	5	—	15,000	112,600	130,600
15	2,000,000	5+	—	30	50,100	50,700
16	2,000,000	3+	—	1,740	12,540	41,400
19	2,000,000	5	?	300	95,500	96,000

Group 4 comprised seven cases with a red cell count ranging between one and two million. The total urobilin and urobilinogen content in this group varied between 21,350 and 136,000, or an average of 62,950 dilutions. On the other hand, the evidence of disturbance of the red cells was most marked, even more so than in Group 3. The cord lesion was definite in five cases, doubtful in one, and absent in one case.

TABLE 4.—FINDINGS IN GROUP 4

Case No.	Blood Count	Blood smear	Cord Lesion	Urobilin and Urobilinogen		
				Urine	Stool	Total
7	1,700,000	5	—	750	30,570	21,250
31	1,700,000	2+	—	1,200	135,160	136,200
17	1,260,000	4+	—	...	40,000	40,600
18	1,000,000	5+	—	3,120	49,000	43,150
18	1,000,000	5+	0	460	30,200	20,600
17	1,000,000	5+	?	1,848	18,000	49,848
6	1,000,000	5+	—	2,000	117,000	119,000

## CONCLUSIONS

1. The evidence of abnormal hemolysis occurs first in the stools, second in the duodenal contents, and lastly in the urine.

2. An increase of the urobilin and urobilinogen in the urine and stools above 12,000 dilutions is a constant finding in pernicious anemia during the period of remission.

3. The presence of even small amounts of urobilinogen in the urine is evidence of a probable pernicious anemia in the absence of signs of biliary or hepatic disease.

4. A low red cell count with a low urobilin and urobilinogen count indicates an arrest of the activity of the disease process, and a period of improvement may be anticipated.

5. On the other hand, a high red cell count with a high urobilin-urobilinogen content indicates a marked hemolysis and often precedes a steadily falling blood count, as was also demonstrated by Robertson and McCrudden.

## THYROIDECTOMY IN TOXIC GOITER

## A BASIC FAULT IN THE SCHEME OF OPERATION

H. M. RICHTER, M.D.

CHICAGO

The reaction following partial thyroidectomy in very toxic cases of hyperthyroidism is well known. The use of various surgical and nonsurgical methods of reducing thyroid activity as a preliminary to thyroidectomy is universal. Various methods of preventing the psychic and operative traumatism inflicted by the operation itself are also in use.

It has seemed to me that the excessive reaction sometimes observed is due not merely to faulty technic but to a basic fault in the scheme of operation, and that the primary mortality can be radically lowered and the ultimate result materially improved by the operative method suggested.

The reaction is essentially an excessive, acute hyperthyroidism. Were it permissible to make a complete extirpation of the gland, the only reaction possible would be due to the manipulation of the gland during its removal, which would be analogous to the administration of so much toxin hypodermically; that is, with the action of the given dose, the effect would cease, whereas, as a matter of fact, the reaction is often persistent and progressive. This reaction is due not merely to the technical error of inflicting traumatism on the gland during its manipulation, though this undoubtedly plays a material part. It is rather that we initiate an excessive degree of activity in the portion of the gland that we leave behind; and that we leave behind so much thyroid tissue that it is capable of responding to the traumatism by producing a profound degree of intoxication.

The basic fault in the scheme of operation is to leave behind an amount of thyroid altogether unnecessary and capable of such excessive action. The term "subtotal," as used by Bartlett of St. Louis, serves well to describe the extent of the operation. The removal of all or nearly all of the thyroid is, of course, not a new procedure. The early history of the development of the modern surgery of the thyroid includes the story of complete removal with operative myxedema following. Yet so little thyroid tissue was found to be necessary that apparently very complete removal of the gland often caused no harm. The general practice today is to leave altogether too much thyroid tissue behind. The amount of thyroid necessary to the patient is very small: the danger of removing too much—that is, of leaving too little—is not great. The normal thyroid weighs from 35 to 50 gm. Here, as in other organs, the gland is in enormous excess of the requirements of the organism, and may be operatively reduced to but a fraction of this weight. A few grams of thyroid tissue suffice to carry on its function.

It is not rare for a lobectomy in very incomplete thyroidectomy to be carried out in the more toxic patients for the purpose of reducing the hyperthyroidism. But, it is just here that it is unusually dangerous to leave behind a large amount of hyperfunctionating thyroid. It is to the toxic cases that a very radical thyroidectomy offers the patient the best means of escaping the danger of immediate overwhelming intoxication. We leave behind a large mass of hyperfunctionating thyroid tissue, throwing it into excessive activity as we do so. Instead, we should leave behind nothing more than a safe minimum. The removal of "two-thirds" to "three-fourths" of the thyroid will not do. Irrespective of the size of the goiter, we should leave only a few grams of the gland. It is possible that even less hyperplastic than normal thyroid need be left behind.

I have carried out the radical operation here suggested in a fair series of cases. The operation was not so radical in the earlier cases, and the records are faulty in determining just how many of the series were subjected to the complete operation. But in a consecutive series of more than 100 cases, dating back over a period of five years, at Wesley Memorial Hospital, including the less radical operations, there has been only one death. This patient became delirious on the table while the operation was in progress under local anesthesia, and died within twelve hours of an intense exacerbation of all of his symptoms. One patient died while in the hospital awaiting operation. No patient who consented to operation was refused operation or told to come back later for operation; that is, no opportunity was taken to avoid extreme risks. A few preliminary ligations were made before I felt safe in carrying out the radical operation in severely toxic cases, and undoubtedly a preliminary ligation will always be preferable in a very limited number of the more critical cases. In my experience this has been well under 10 per cent. of the toxic cases.

In the same period in my service at Cook County Hospital, the total number of cases was rather small. Here, too, the radical operation was almost universally carried out, no ligation being made in the series. Here, too, no operation was deferred when the consent of the patient could be obtained. One death occurred in the entire series. The operation in this case was carried through without incident. The patient apparently was in good condition. She died suddenly on the table before removal from the room. No necropsy was obtained. In this case the table was elevated to the semisitting position during the operation. Thus, in the two cases that terminated fatally, a deviation from the usual method was made that probably had no important part in the result; but I believe that neither local anesthesia nor the semisitting position is desirable in operations for goiter.

In several of the cases it was found that, after the removal of the goiter, more thyroid tissue was left behind than was intended. In these cases the greater part of this remaining thyroid tissue was strangulated by sewing through and through with moderately heavy catgut. While faulty in that it left a mass of tissue behind to undergo necrosis, no bad results were clinically noticeable, and it served to reduce the operating time below what would have been necessary to carry out a further excision.

## PROSTHETIC APPLIANCES IN SURGICAL TREATMENT OF WOUNDS OF THE FACE AND JAWS\*

V. H. KAZANJIAN, C.M.G., D.M.D.

Professor of Military Oral Surgery, Harvard University Dental School,  
BOSTON

In general, maxillary splints are anchored in the teeth and the alveolar ridges. The amount of retention depends on the security and the method of attachment used, while the position and existence of teeth relative to the fracture determine the type of splint to be employed in a given case. When an injury includes the partial or total loss of teeth, or renders the existing teeth unavailable as a means of anchorage, fixation of the fragments is gained (1) by the adaptation of the splints entirely to the alveolar ridges, (2) by external appliances which acquire their support from the cranial bones, or (3) by sutures through the maxillary bones, either alone or in combination with certain appliances.

It may be necessary in the treatment of a case to use any one or all of the foregoing methods to effect the immobilization of the maxillary fragments.

In the event of extensive destruction of the maxilla or the mandible, with consequent gaps in the continuity, perhaps no bony union may be anticipated; yet it is necessary to provide that such portions as remain shall be capable of some degree of function in order that oral restorations may subsequently be successfully accommodated. Unless the remaining stumps of the mandible are conserved and favored through the use of adequate appliances, then ultimate uselessness ensues through displacement, deformity and lack of habitual mobility.

The teeth serve as the basis for immobilization, and at the same time as the accurate guide to the former occlusion and position of the jaws in their normal relation one to the other. If the splint is so constructed that the former occlusion of the teeth is restored, then the relocation of the body of the mandible in an automatic position is a near certainty.

The assertion that fracture of the mandible by a foreign body is invariably accompanied by a loss of tissue may be true so far as the teeth and alveolar ridges are concerned; but in the majority of cases, even when there is extensive comminution, the destruction is insufficient to cause a lack of continuity at the points of injury. In other words, severe comminution does not necessarily imply a practical nonapproximation of the fragments of the mandible.

In view of these facts, it is a safer standard to restore the segments by the splinting to a natural occlusion, leaving modifications for application in very rare and peculiar cases. This principle is especially true in the accomplishment of early fixation, because experience has shown that in many cases of grave comminution, in which there were apparently gaps in the continuity of the mandible and a loss of substance, bony union ultimately formed. In the early days of treatment, it is not possible to foretell the regenerative powers which the tissues will manifest under careful methods.

\* Read before the Section on Stomatology at the Seventy-sixth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

APPLICATION OF MECHANICAL FORCES TO  
THE SOFT TISSUES

Any comprehensive scheme of treatment for the repair of bone is tempered by the condition of the soft tissues, and the construction of a splint for the immobilization of a maxillary fracture is influenced by the

Fig. 1.—Hand and wire splint with a perpendicular wire or T. A vulcanite piece with grooves corresponding to the wire is made of sufficient bulk to prevent tissue contraction, and at a later stage it acts as a support in connection with plastic operations.

nature of the wound of the face. The surgeon's aim is to restore all tissues as nearly as possible to a normal state, in other words, to repair the injured bones without loss of function, and to close the wounds with the least possible distortion, scar formation or adhesion. If no appreciable loss of soft and hard tissues has occurred, then these objects are easier of attainment; but if, on the contrary, a distinct loss has taken place, it becomes necessary to resort to plastic operations for the correction of soft tissue deformity, and to utilize artificial devices as functional and cosmetic substitutes for bony tissue.

In a strict sense, the splint deals with the repair of bone. But in nearly all cases of gunshot wound of the face and the jaw, the involvement of the soft tissues is appreciable, a circumstance which likewise can be met by the construction and adaptation of an appliance. Such an appliance may be in reality an integral part of the splint or an adjunct to it, or it may be entirely separate from it.

Fig. 2.—A hand and arch splint maintains the correct relation of the posterior segments to the mandible, while the anterior segments are brought in alignment by means of wire sutures through the bone.

Experience has shown that the treatment of the fracture cannot be carried out as a thing apart from the wound of the face; and in bringing about the repair of both hard and soft tissues, due regard must be given to each in the construction of mechanical devices. As a case under treatment progresses from day to day, slight or even radical changes are frequently indicated in the splints or appliances, and often surgical assis-

tance is necessary or may tend to hasten the patient's recovery or forestall a certain deformity. Just as the care of the wound and the fracture should not be reduced to two distinct, separate procedures, so the mechanical and surgical technics are inseparable; for perhaps a proposed operation would fail without the help of a suitable mechanical device, and perhaps a certain device would serve no purpose unless adapted and applied by surgical assistance.

The mechanical devices used on the soft tissues are intended primarily to direct the course of recovery and not to correct a deformity. Their greatest usefulness is to be obtained by their application at an early period in the treatment of a patient, when undesired conditions can be anticipated and the occurrence of disfigurement prevented.

Appliances may be used immediately after injury to support the soft tissues, for at this time the parts are soft and still flexible, though inflamed. Gentle pressure applied to the facial tissues during the early course of healing is a satisfactory means of averting undue contraction.

Appliances are also used intra-orally to keep the tissues in a state which prevents undue adhesions to the alveolar ridges, and therefore maintains a more suitable field for the reception of later artificial restora-

Fig. 3.—The hand and arch splint maintains the correct relation of the posterior segments, while the vulcanite appliance supports the soft tissues during the process of healing.

tions. If this aspect of the treatment is neglected, then the ultimate ideals will not be attainable. In orthopedic surgery, the operative technic is modified as far as circumstances permit to facilitate the adaptation of artificial limbs; and the same practice is advisable, and even obligatory, in the treatment of injuries of the face and jaws. The remaining tissues must be prepared for the artificial restorations which will constitute the last phase of the treatment.

As a rule, appliances of a semipermanent nature are indispensable to the success of a plastic operation on the soft tissues. During the work they serve to hold the contour of the face, lips or nose from within, and in general to act as a support for the soft tissues, as did the natural bony structure of the parts involved prior to the injury.

## CLASSIFICATION OF FRACTURES

As stated heretofore, in order to utilize the mechanical appliances intelligently, it is necessary to have a comprehensive knowledge of the principles governing the application of splints, and for this reason a practical classification of fractures is of service. Many such classifications are offered. The one which I presented in 1915 was based on the location of the fractures in relation to the mechanical forces governing the construction of splints, and was faithfully used in the

oral surgery department of the Harvard unit until the termination of our services with the British army.

FRACTURES OF THE MANDIBLE

1. *Fractures Anterior to the Last Existing Tooth.*—

In this type, the sound teeth on both sides of the fracture serve as a basis of anchorage for the splint which reduces the displacement. The splints are modified only to accommodate the variations of extent of injury between these existing teeth.

Figure 1 shows a very common type of injury of the mandible, in the treatment of which metal caps or bands are fitted to the teeth and connected by a strong arch wire. If the area of fracture is extensive, the arch is naturally longer, and carries at about its middle a short, perpendicular wire, the purpose of which is to form the source of attachment for a removable appliance of vulcanite rubber for the support of the soft tissues. This combination of splint and appliance

Fig. 4.—Immobilization of segments of fractured mandible when there are no teeth available on one side.

illustrates the use of mechanical devices both for the repair of the bone and of the soft tissue; the metal splint holds the parts of the fractured mandible in the

In some of the more extensive injuries, there exist available teeth on both sides of the fracture, but there is also a severe laceration of the soft parts, and the fragments of bone in the area of fracture are grossly displaced. In this condition it is necessary to raise the fragments to alignment by means of wire sutures from

Fig. 5.—Splint and appliance designed to obtain a gradual correction of the position of the edentulous side of the mandible.

the arch wire of the splint (Fig. 2). An external appliance is utilized to aid the support of the part involved.

If the injury includes a substantial loss of bone, the same method of splinting is employed to maintain the remaining parts of the mandible in an anatomic position; but the vulcanite appliance becomes more extensive in design, and is practically intended to replace the portion of the jaw which has been destroyed (Fig. 3).

It sometimes happens that the band and wire splint, when constructed, is difficult to adjust and cement to the teeth. In this event, it is made in two parts, in such a manner that they may be applied separately. The arch wires of the sides pass each other and are ligated tightly together.

2. *Fractures Posterior to the Last Existing Tooth.*—

In this type of injury, a different method of fixation is necessary, because teeth (or a tooth) are available on one side of the fracture only for the attachment of a maxillary splint. As a rule, the teeth of the upper jaw serve as the anchorage for the appliance which immobilizes the fragments of the lower jaw.

A simple illustration of this type would be a case in which the dentition was good and there existed a fracture of the mandible at the angle. Immobilization of the parts of the mandible is effected by upper and lower metal cap splints cemented to the teeth, with small hooks on them for intermaxillary ligation.

In some instances the comminution includes a considerable portion of the mandible, a condition in which,

Fig. 6.—Intermaxillary vulcanite splint made in sections to facilitate introduction and adjustment in the mouth.

as previously described, no teeth are left on one side of the injury. In this case, the remaining part of the jaw, with teeth intact, is immobilized by means of splints attached to both upper and lower teeth, and, in addition, an arch wire is extended from the lower splint over the injured area. This arch wire serves the same purposes as were described in the previous type of fracture (in which teeth existed on both sides of the

desired position, and the vulcanite serves to prevent collapse and contraction, with subsequent adhesion, of the muscular tissue.

fracture), for the attachment of vulcanite appliances and for the suspension of smaller fragments of the mandible by means of wire sutures (Fig. 4).

In this type of fracture, great inconvenience is experienced because of the fact that the portion of the

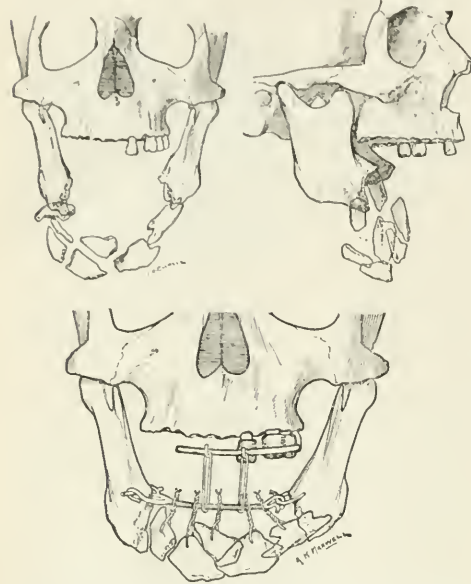

Fig. 7.—Immobilization and alignment of greatly displaced segments of a fractured mandible when no teeth are available for the attachment of splints. When the arch and wire sutures lose their efficacy, they are replaced by a vulcanite intermaxillary splint. Additional support is also procured by means of an external chin piece, as in Figure 13.

mandible which is devoid of teeth has a pronounced tendency to be displaced upward, outward and forward, thus lessening the natural intermaxillary space at this region. In order to overcome this fact, a small intermaxillary splint of vulcanite is constructed for the edentulous side of the jaw, having its bearing on the upper occlusal surfaces of the teeth and the lower alveolar tissue. This appliance is held in place by its accurate fit to the tissues, and by attachment to the wire arch which passes over the injured area (Fig. 5).

3. *Condition in Which There Are No Teeth Adjacent to the Fracture.*—If the fractured lower jaw is edentulous, the process of immobilization is rendered more difficult, and the control of the fragments is not effected as securely.

If the fracture is not severely comminuted and the displacement of the parts of the mandible is not pronounced, then satisfactory fixation is gained by the adjustment of the ordinary intermaxillary splint, which fits the remaining alveolar ridges and the upper ridges and teeth. The intermaxillary splint may be constructed in sections to facilitate introduction into the mouth (Fig. 6).

If the comminution and displacement are severe, and there exist fragments of the bone which can be saved, then the following means of immobilization is resorted to: A heavy arch wire is attached to the posterior segments of the mandible and passes over the injured area. To this the fragments are suspended and drawn

forward and upward by means of wire sutures; and the assembled lower jaw, as a whole, is immobilized by means of intermaxillary ligatures which pass from the lower arch wire to a metal splint applied to the teeth of the uninjured upper jaw (Fig. 7). After a few weeks, when the fragments have become consolidated and the light sutures have lost their efficacy, the lower splinting is removed, and an intermaxillary splint of vulcanite replaces it.

In cases in which the lower jaw presents no teeth, and there is a large gap in the continuity in which there are no fragments worth conserving, a splint is used to keep the posterior fragments in as good condition as possible. This comprises small intermaxillary splints for both sides—accurately fitted between the mandibular stumps and the posterior teeth of the upper jaw—which are joined either by a heavy wire, or by a piece of heavy plate metal which allows a certain amount of flexibility (Fig. 8).

It is important to emphasize the necessity of caring for almost any portion of the lower jaw which remains. Even though there is left only a short stump of the mandible at the angle, it should be favored and, by the application of an appliance, kept active, free from adhesions and in good anatomic position, with a view to its service later as a means of support for oral restorations.

#### FRACTURES OF THE UPPER JAW

In some respects, the maxilla is in extreme contrast to the mandible: It is sufficiently rigid to prevent complete fracture from its attachment; but, at the same time, it offers greater resistance to a penetrating foreign body, thus transmitting fractures to the nasal bones and other structures which are in anatomic proximity. The structural delicacy of its parts con-

Fig. 8.—Intermaxillary vulcanite splint used when there is less extensive loss of mandible posteriorly. The vulcanite fits the mandibular stumps, and adhesions, displacement and inactivity are averted.

Fig. 9.—The model shows destruction of the maxilla anteriorly and a fracture of the right malar region. The fracture is immobilized by a band and wire splint cemented to the teeth. The vulcanite base plate fulness and contour to prevent undesirable adhesions and contractions of the soft tissues. It also serves later as a supporting appliance in connection with plastic operations.

duces to extensive comminution. In cases of partial or complete fracture of the upper jaw, the resultant displacement is lateral if the comminution is slight; but if it is great, the displacement is downward.

1. *Fracture of the Alveolar Process.*—The simplest type of fracture of the upper jaw is that in which the piece of metal causes comminution of the alveolar

This immobilization is effected by the use of a tightly fitting jacket splint or by a band and arch wire cemented to the teeth. If the latter method is adopted, a jacket splint or a removable vulcanite piece should be used in conjunction with it, if the wound of the soft tissues is of appreciable size, to support the face about the affected area. The same procedure is indicated when the injury is confined to the palate.

3. *Complete Fracture of the Maxilla.*—Comminution and laceration of the entire maxilla is not rare. It is evident that in the event of this condition there is no basis of anchorage for immobilization available within the mouth, as in the types of cases previously described, and that extra-oral means of support must be used. Before proceeding further with the description of the splints needed, it is advisable to show the construction of a headgear which meets the requirements of the condition.

Gutta-percha, 4 mm. thick (as used in orthopedic surgery), is cut to fit the forehead and temporal regions, softened in hot water and then bandaged over these parts until it has regained its natural hardness. The headgear is completed by the addition of webbing straps which form a sort of cap over the head. From

Fig. 10.—Gutta-percha is fitted to the forehead and temporal regions and is retained by a headgear of webbing. The wire arch which passes in front of the face rotates in the holes in front of the ears to allow a wider range of adjustment. In this illustration, the ends of the arch are threaded and pass through small metal tubes (which have short spurs soldered at right angles to permit introduction to the holes in the gutta-percha) with nuts to control the length. In other instances, the ends of the facial arch may be bent at right angles to allow direct insertion in the holes. The median wire controls the height of the arch. Any part of the appliance serves as an anchorage for intra-oral splints, and for nasal and facial supports.

process. In some instances this is accompanied by lines of fracture which radiate to other parts of the bone. The treatment of such cases is primarily surgical, since no definite repair of the bony tissue is possible, and consists of the removal of loose and useless spicules and fragments, followed by the approximation of the borders of the lacerated mucous membrane, provided the inflammation is not severe.

It is highly desirable to construct a vulcanite base plate which fits the entire mucous surfaces of the injured maxilla, and which has an accurate occlusal contact with the lower teeth. The purpose of this appliance is to mold the palate and alveolar ridge as the healing goes on, in order that no objectionable muscular adhesions which would render the retention of a denture difficult at a later date shall be allowed to form.

2. *Partial Fracture of the Maxilla.*—In addition to an injury to the alveolar process, there may occur the fracture of a part of the maxilla, with attendant displacement and mobility of a portion. The fixation of the loose segment is accomplished by using the solid part of the maxilla as a point of anchorage (Fig. 9).

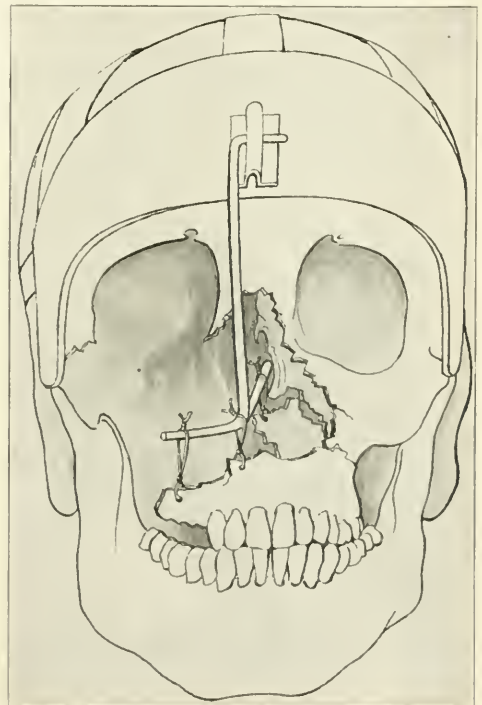

Fig. 11.—Immobilization of the maxilla following complete fracture. Owing to the free exposure of the superior aspect of the maxilla, the method of direct wiring, from the nose to an extension from the headgear, is in some cases very efficient, and also easily done.

the lower ends of the gutta-percha, at about the level of the tragus of the ear, a heavy arch wire is attached, which passes just in front of the mouth. A stiff but lighter wire also passes vertically over the nose from

the median line of the arch to the median line of the gutta-percha (Fig. 10). After the headgear has been fitted, the occipital region of the head may be shaved and adhesive tape used to secure the webbing which covers that part to the skin. Thus, either the gutta-

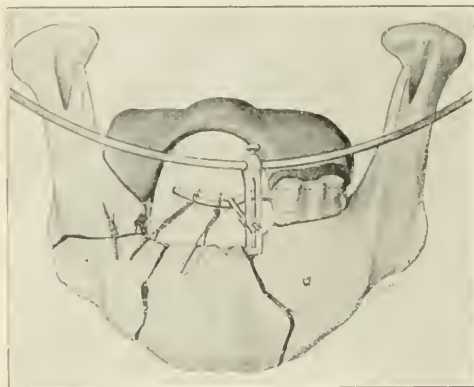

Fig. 12.—Adjustment of the splints to the arch wire; compare Figure 10.

percha or the arch is available as a firm anchorage for nasal, facial, intra-oral or extra-oral attachments; and the appliance may be modified in many ways to meet the requirements of an individual condition.

A simple case of fracture of the entire maxilla, with no displacement, may be effectively treated by strong bandaging of the head and jaws with the teeth set in natural occlusion. This condition, however, is more usually encountered in accidental fractures.

The upper jaw, as the result of gunshot injury, may be reduced to a number of small fragments, with some attendant loss of tissue. When this is the case, it is necessary first to assemble the parts in good relation, and then to effect immobilization by means of extra-oral appliances. The well known Kingsley splint, anchored to the arch wire of the headgear, is admirably suited to complete the fixation.

Large, open wounds of the nose and zygomatic region often have intimate connection with the maxilla, permitting the fixation of the upper jaw by means of a wire suture passed directly through its upper aspect, which suspends it from the headgear directly. Supplementary support may be given to the jaw by a chin piece so adapted as to press the lower jaw continuously in occlusion with the upper teeth (Fig. 11).

If the foregoing methods do not meet the situation in certain instances, the following method may be utilized: The teeth of the sound lower jaw are covered with a cap splint which carries a small attachment—hook, tube, etc.—at its median line. Elastic force is used from this attachment to the headgear to pull the lower jaw against the upper, thus producing a fixation with good relation of the teeth after consolidation.

In applying splints to the upper jaw, there are certain facts which should be observed. The fragments tend to become firm sooner after injury than in the case of fracture of the lower jaw, and the consequent displacement is very hard to correct. Early fixation, even if it be but temporary, is indicated.

In the case of comminution of the upper jaw, provided there are sufficient teeth remaining to reconstruct a useful dentition, the occlusion of these teeth naturally serves as the best guide for the position of fixation. But if that method of splinting is used which brings the teeth into operation, the point at which the teeth come into occlusion is the point for immobilization, and not the point at which the maxilla meets resistance from pressure by the splinting against associated structures. In other words, the comminuted maxilla is so mobile that it can be pushed upward or inward a considerable distance beyond its former anatomic position.

If the Kingsley splint is used, it should be so constructed that the occlusal surfaces of the teeth are visible, and in actual contact with the lower teeth without the intervening thickness of vulcanite or metal.

#### FRACTURES OF BOTH THE MANDIBLE AND MAXILLA

Fractures of both the mandible and maxilla are quite common. The general principles and methods used in the immobilization of the parts are a combination of those already outlined. If there exists partial fracture of the maxilla, then the parts are assembled first, next, the lower jaw is repaired, and, if necessary and available, support is provided for the mandible from the splint applied to the maxilla, if the remaining firm portion of the latter is capable of withstanding the strain put on it without injury. If a solid portion of the upper jaw cannot be utilized, or if the patient is

Fig. 13.—Chin piece used when upward and forward pressure on the tissues is required. The rods of the chin piece pass upward through metal tubes. The tube carries an irregular shaped wire, the lower end of which is bent at a right angle to allow rotation in a second tube attached to the headgear, and the upper end of which passes to the temporal region. The lower elastic causes upward pressure, while the elastic at the temporal region gives the forward pressure.

edentulous, then, in case of necessity, the headgear may be used to supply the desired basis of anchorage (Fig. 12).

If both jaws are edentulous, then the intermaxillary vulcanite splint, preferably made in two sections to facilitate introduction in the mouth, is used, and aided in its adaptation, if necessary, by attachment to the headgear, or by pressure beneath from a chin piece (Fig. 13).

### UNITED FRACTURES OF THE MANDIBLE TREATED BY BONE GRAFT

PRELIMINARY REPORT \*

F. J. TAINTER, M.D.  
Major, M. C., U. S. Army  
ST. CHARLES, MO.

The severe injuries of the jaw, incurred in the past war, necessitated some formulating and standardizing of treatment. The chronology is rather interesting because economic questions entered somewhat into the manner they were handled, especially in the beginning

from the rib, tibia and ilium, and osteoperiosteal grafts had their percentage of successes.

Free bone grafts embedded in vascular tissue were conscientiously and deliberately attempted by Imbert and Real to remedy bony defects in the mandible.

Fig. 1.—Cole's pedicled graft: incision made so that graft can be taken from opposite side of mandible, if necessary; intratracheal anesthesia.

of the war, when men were scarce and it was necessary to get many back to the front in the shortest possible time.

My observations were made while serving with the British at various hospitals in London, and during a personal experience in the clinic of Messrs. Cole and Bubb, at King George Hospital.

At Croydon, one of the largest jaw hospitals in England, Mr. Colyer shortened the period of convalescence and got most marvelous results by approximating the broken fragments at the expense of occlusion, depending on extractions and artificial dentures to give what I saw to be nearly if not perfect functional results.

Summaries of the results of autogenous bone grafts for defects of the lower jaw, from various operators in the different countries, including 237 of the enemy, reported by Lindemann at Düsseldorf, justified its general use.

The technic was slowly improved, and the percentage of "takes" rose proportionately. Grafts were taken

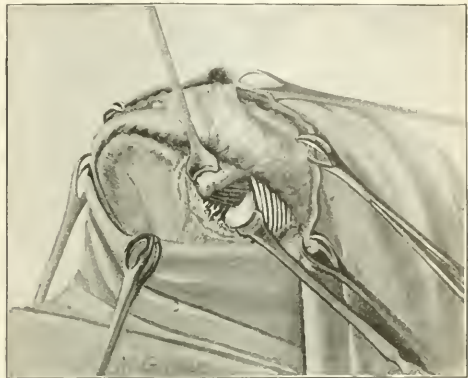

Fig. 2.—Defect in mandible due to loss of bone; fragments immobilized by intra-oral splints (open bite).

Such attempts were made with the idea that the graft would be more likely to succeed after its nutrition had been definitely determined by the establishment of fresh vascular connections. They found that if the graft was embedded more than from three to four weeks it so softened that effective fixation could not be attained. In all cases the results as regards bony union were a complete failure.

Mr. Cole, a highly trained and skilled surgeon, chief of the maxillofacial department of King George Hospital, maintained from the beginning that the ideal treatment should be applied to the jaw, as well as to

Fig. 3.—Cutting graft from lower border of mandible with electric saw, leaving its vascular muscular attachment as pedicle.

other parts of the body, where there was loss of bone. In his extensive experience in the treatment of ununited fractures of the mandible, he developed what is generally known in England and this country as Cole's pedicled bone graft. He has reported<sup>1</sup> thirty-

\* Read before the Section on Stomatology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

five cases, in nearly all of which I had the pleasure to assist. I had the opportunity, while in his service at the King George Hospital, to do seventeen additional bone grafts and three at U. S. Army General Hospital No. 40.

Fig. 4.—Drilling anterior and posterior fragment preparatory to wiring.

With the exception of a few cases, in which operation was performed just before I left England, the success in practically all was assured. The exact statistics, however, will be published in a later paper, which will include many cases which are awaiting bone graft in my service in General Hospital No. 40.

I have carried out the technic as worked by Mr. Cole, not finding it necessary to vary in the least, and the

Fig. 5.—Wires through fragments and graft; graft held by Cole's forceps.

accompanying illustrations are made after that technic. The nontouch or "knife and fork" surgery, as it has been called, is most scrupulously carried out. A piece of the mandible about a quarter of an inch wide is removed with the electric saw, leaving attached muscle

and fascial tissue, which includes the platysma myoides and usually most or all of one or two of the anterior bellies of the digastric muscle. This graft is shifted across the gap and wired firmly to the anterior and posterior fragments.

The graft is very viable and bleeds readily; in one case there was present a spurting vessel from the cut surface of the graft. In exposing the fragments, should the mucous lining of the mouth be opened, it is better to abandon the operation and wait until it closes. However, in one case of mine a salivary fistula resulted which showed that I had opened into the mouth; but it closed in a few days and the graft gave perfect union in the usual length of time.

There was perhaps no other clinic, especially in the beginning of the war, that better appreciated the valuable coordination of dentist and surgeon. Mr. Bubb, a very keen, skilful and resourceful dentist, had charge of the dental maxillofacial department of the clinic. The mechanically perfect, though complicated orthodontic splints which have grown out of the valuable teachings of Claud Martin were not adapted to war

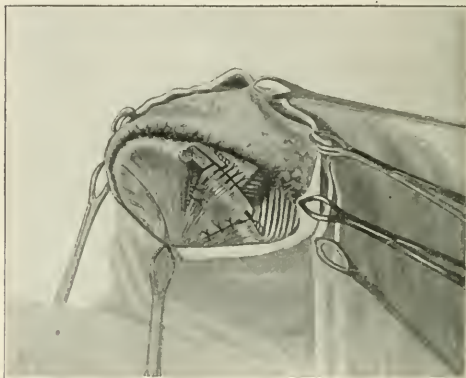

Fig. 6.—Graft in place; wires twisted tight and a few catgut sutures placed to obliterate dead space under pedicle.

purposes, when hundreds of jaw cases are treated and time and lack of mechanics are a factor. The standardized splint was termed by Mr. Bubb a "modified detachable Gunning." The open bite splint was used universally, and the fractures treated in terms of the upper jaw. Impressions were taken in sections, if need be, and assembled on a proper articulator. The posterior fragment was always most carefully controlled and put in proper relation to the anterior fragment and the upper jaw.

The distinct advantage of the open bite which is appreciated by the surgeon has other things to commend it. Trismus was unknown in patients treated in our clinic.

Plastic operations of the mouth should always be done in the open bite. Extension appliances with intra-oral pads which were always used before any extensive plastic operation, were made detachable, and of wire, so that they could be quickly adjusted with the pliers, a great advantage or improvement over the complicated jackscrews with bolts and nuts to adjust. All plastic reparation was invariably done first, before a bone graft was attempted, a reasonable length of time being

allowed to pass for the tissues to clear up from a possible latent infection in the tissues. In some cases the time was materially reduced, as we found that liberties could be taken with the pedicled graft which would not be tolerated with the free graft.

When it was deemed necessary to thicken the walls so as to make a proper bed for the graft, decalcified bone was introduced beneath the skin, after it had been undermined. This worked most admirably. The process of absorption developed a good fibrous wall which could be used in from four to six weeks. We were struck with the tolerance the tissues had for this foreign body, even after it was put into a septic bed. This was a substitute for the fat graft, and it was soon used exclusively for filling spaces after depressed scars were raised.

In edentulous cases a circumferential wire was used around the body or ramus of the mandible and fastened to the splint. This maintained the proper position of the fragments until the contraction of the muscles was no longer a great factor in misplacements. The wire could usually be removed in several weeks, after which a saddle or gutter appliance attached to the Gunning splint well controlled the fragments.

Intratracheal anesthesia was invariably the choice, in which we were fortunate to have the expert services of Mr. Francis Shipway.

While the roentgen ray was deceptive in some cases in the determination of the progress of osteogenesis, the marked and uniform difference between a free and pedicled graft proved that the pedicled graft is superior, because it remains a live graft throughout the process of repair and does not absorb, as we have noted the free grafts do, both in many of our own cases and in those done in France and Switzerland.

**Safety Zone for Babies.**—According to a report on infant mortality in Saginaw, Mich., given out by the Children's Bureau of the U. S. Department of Labor, it is more than six times as dangerous for a baby to be born in one section of the town as in another. The investigations of the bureau have shown that the essentials of a safety zone for babies are that a majority of the fathers in it must earn a living wage, the mothers must not be employed during the year before or the year following the baby's birth, the mothers must receive proper care when their babies are born, both fathers and mothers must be able to read and write, and the babies must be housed properly. In the ward in Saginaw where the least favorable conditions prevailed, one baby out of every six died before it was 1 year old, as compared with one death in every thirty-four babies in the best residential wards. In the ward having the highest infant mortality, a majority of the fathers had very small wages. The infant mortality rate for the babies of working mothers was 132.7 as compared with 78.3 for those whose mothers were not gainfully employed. In Saginaw the deaths of two thirds of the babies were due primarily to prenatal causes. Thus the baby's environment and economic condition at birth determines to a great extent whether or not it shall survive.

## INFECTED FRACTURES OF THE MAXILLAE\*

E. P. DAMERON, D.D.S.  
Captain, D. C., U. S. Army  
ST. LOUIS

In the brief period of time allotted for this discussion of infected fractures of the maxillae, I will not enter into a detailed description of them, but will confine the paper to a few observations made in connection with work done at one of our hospitals, at which such cases were received for treatment.

These fractures range from simple fractures to those associated with great loss of bony substance and the enveloping flesh. The treatment of simple fractures requires only approximation of the parts and fixation of the jaws by various means already understood, accompanied by proper care and cleanliness. This is the type of fracture usually dealt with in civil practice, and infection rarely occurs.

Fractures due to gunshot injuries in the war are accompanied with and complicated by projection of bone and tooth fragments into the surrounding soft tissues, loss of bone substance, extreme laceration of the flesh, and the presence of foreign bodies and pus-forming organisms, all open wounds being infected by these organisms.

The early treatment of these cases has been fully outlined previously, such as the work done at dressing stations, and at field, evacuation and base hospitals. Those that came under observation and treatment at General Hospital No. 11 had all received

some previous treatment but still presented ununited fractures, union having been delayed by infection.

Many of the patients wore excellent dental splints, so that fixation was accomplished. In some, the loss of bone was so great that union was not to be expected (though the amount of bone that forms in some of these cases is surprising), and bone grafting was necessary. Bone grafting too early after healing of the wound is to be avoided, experience here, as elsewhere, having shown that latent infection in closed wounds is exceedingly likely to be violently aroused, and the graft lost. A large percentage of the cases presented sinuses, external and internal, and required frequent dressing and irrigation with either physiologic sodium chloride solution or surgical solution of chlorinated soda (Dakin's solution).

In this connection, the following appears in a recent number of *Review of War Surgery and Medicine*:

It is stated by Groves that the probability of latent infection, and the length of the duration in any given case, are

Fig. 7.—Wound closed with fine horsehair; often a drain is left for twenty-four hours in lower angle of wound.

\* Read before the Section on Stomatology at the Seventieth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

in proportion to the extent of the primary wound and its degree of infection; the amount of scar tissue deposited between the tissues; the length of time during which manifest infection is known to have been present, and the extent of bone involvement.

Taylor and Davis, however, say that latent infection is due to the persistence of bacteria for a long period within the dense structure and the canaliculi. There they are protected from the body fluids and phagocytic cells. They fur-

is particularly essential that no loose bone fragments be removed from the site of the fracture if there is the slightest attachment to the tissues. Bone fragments apparently hopelessly injured will often recover their vitality and serve as a valuable matrix for new bone formation, even should some of these fragments be thrown off later, it having been found that bone fills in more rapidly than when extreme curettement has

Fig. 1 (Case 2).—Two sinuses from infection by teeth in line of fracture; five months after injury.

Fig. 2 (Case 2).—Five teeth in fracture area.

Fig. 3 (Case 2).—Teeth removed; union occurring, sinuses healed; after twenty days.

ther state that the presence of organisms within the dead bone (whether in sequestra or in portions still attached to living bone) rather than in the soft tissue, is probably the cause of the sinus and the occurrence of the acute recrudescences of infection or flare after secondary procedure.

By the gradual erosion of the sequestrum at the bottom of the sinus, as well as the outgrowth of bacteria from this nidus of infection, continued reinfection of the sinus tract may occur.

#### SEARCH FOR THE CAUSE OF INFECTION

The problem, then, was to discover and remove the cause of continued irritation and infection in these

been done. Piersol states that on the inner surface of the inferior maxilla one may trace the mylohyoid ridge running upward and backward from the sublingual fossa past the molars. Above this line the bone is covered by the mucous membrane of the mouth. Diseases of this portion find expression in the oral cavity. Those of the lower portion of the bone are likely to involve the soft parts and the glands of the neck.

Aided, then, by roentgenograms, clinical evidence and anatomic relations, careful search was made to find the cause of the nonunion of these old fractures.

Fig. 4 (Case 4).—Sinus from injury below mylohyoid ridge; four months after injury.

Fig. 5 (Case 4).—Bone fragments and second molar the source of infection.

Fig. 6 (Case 4).—Union occurring following removal of sequestrum and tooth; after thirty days.

cases, most of which had received attention that in great numbers of fractures had effected a cure.

It was noticeable that the larger number of infected fractures occurred in the mandible. Maxilla fractures barely exhibited pus-discharging sinuses.

A well-established therapeutic procedure, when anatomically possible, is to remove the infection by surgical operation. Again most writers agree that it

Foreign bodies, bits of metal, etc., were rarely found, having been no doubt removed in previous treatment. A few cases exhibited bits of shattered bone or bone sequestrums that were being exfoliated. These were removed, and union quickly followed. There yet remained cases showing no foreign bodies, no sequestrums, jaws rigidly fixed by interlocking dental splints, still evidencing no sign of union. (We have, however,

noted the occurrence of union in a few cases in which infection was present.)

One method of securing immobility appears to me to have been in itself a cause of lack of union as well as causing unnecessary loss of teeth, namely, the wiring together of the jaws by twisting ligature wire around the necks of the teeth and tying the ends to the ends of similar wires attached to opposing teeth, thus holding the jaws in occlusion. This method should be employed only as a temporary measure. Longer period of wiring causes the wired teeth to become loosened, permitting motion to the jaw, elongating the teeth; the mucous membrane becoming swollen and suppurative, often infected and discharging pus, while extraction of the teeth often becomes necessary. This is especially true when there is much loss of bone substance, the strain being too great for them.

RETENTION OF LOOSE TEETH AND POSSIBLE RESULTS

In addition to the retention of bone fragments in the areas of the fracture, we have also been advised by most writers that the teeth loosened should also be retained. One writer clearly states that "loose teeth

tered. A few pulps were not completely devitalized in appearance, but registered no sensation even when removed.

INSUFFICIENCY OF ROENTGENOLOGY TO DISCLOSE THE TRUE CONDITION

Roentgenograms do not show the condition clearly. Possibly the pulps had not been devitalized a sufficient length of time. The teeth had not changed color, transillumination and electric current giving no positive results. The roentgenogram does, however, show the relation of the teeth to the fracture, and an exploratory drill soon demonstrated the vital or nonvital condition of the pulp. The removal of these dead pulps and the filling of the root canals, as is done in routine dental practice, is practically impossible in most cases, for various reasons, and extraction was the only alternative. I am happy to say, the results were so satisfactory that my regret over the loss of the teeth soon passed away.

This statement is not intended as a condemnation of all teeth in the line of fracture of the maxillae. We observed something over 200 cases, whereas there were several thousand cases in the war. The conclusion

Fig. 7 (Case 5).—Drainage in neck injury below mylohyoid ridge—three months after injury.

Fig. 8 (Case 5).—Teeth and sequestrums removed in a thirty day period; splint with posterior fragment depressor.

Fig. 9 (Case 5).—Firm union of fractures following removal of all teeth after thirty days. Attempt to save teeth prolonged the treatment in this case.

should be replaced in their sockets, no matter how loose they appear to be in the fracture, as they will eventually tighten in place." We observed that this practice had been followed in most of our cases and found no fault with it. However, as time passed, all other causes having been removed, the teeth naturally came under suspicion. Colonel Blair, on seeing these patients, did not hesitate to condemn the teeth. My associate, Lieutenant McCauley, and I did not at first concur with him in this; but, all other means having been exhausted without result, we extracted teeth in or adjacent to the line of fracture in two or three cases and were surprised to note the rapidity with which union occurred thereafter.

The extracted teeth were carefully examined. The pulps were found to be devitalized, sometimes absent, the root-ends were resorbed, sharp-pointed like a carpet tack, or were roughened and pitted. The pericementum was destroyed from 1 to 2 mm., the root length from apex to crown. Foul odor was also noticeable.

The plan was then adopted of drilling an exploratory operation into every tooth in the vicinity of a fracture, and in nearly every instance a dead pulp was encoun-

tered. A few pulps were not completely devitalized in appearance, but registered no sensation even when removed.

desired is that if union is delayed, careful examination of the adjacent teeth should be made, possibly by an opening into the teeth. The firmness of the teeth often leads one to believe them unaffected, but it is better to have a firm union with no tooth than a firm tooth with no union.

Bone sequestrums usually exfoliate; teeth rarely do.

The conclusion regarding teeth in or near the line of fracture being identical in so many cases, we made a careful study of the matter and desire to submit extracted teeth and roentgenograms to substantiate the statement, especially since it is contrary to the usual belief.

Effort was made to retain teeth for abutments in bridgework restorations. Patients were held as long as ninety days before such teeth were extracted, but delayed union was the only result. We have found that following extraction the fracture quickly united. If partially united and springy, springiness disappeared, pus discharge stopped, sinuses closed in a few days, and the patients invariably expressed satisfaction and comfort not previously enjoyed.

CASE 1.—E., wounded, Oct. 14, 1918, arrived, April 15, 1919, six months after injury. There was no union. A sinus was

present. Roentgenoscopy revealed the teeth in line of fracture. April 19, 1919. The teeth were extracted the same day. The sinus closed, April 25, 1919. Roentgenoscopy, May 25, 1919, revealed the union five weeks after extraction of teeth.

CASE 2.—M., wounded, Sept. 29, 1918, arrived, April 4, 1919, five months after injury. There was no union. Two sinuses were present. Roentgenoscopy revealed teeth in the line of fracture, April 4, 1919. The teeth were extracted the same day. Roentgenoscopy, April 24, 1919, revealed the sinuses closed, union of fragments occurring in twenty days.

CASE 3.—B., was suffering from a bilateral fracture of the mandible, having been wounded, Sept. 29, 1919. He arrived, April 6, 1919, six months after injury. There was no union. A sinus was present in the right cheek. Roentgenoscopy, April 6, 1919, revealed the teeth in the line of fracture. The teeth were extracted. May 26, 1919, the sinus had healed, with union on the left side and a bone graft on the right side after seven weeks.

CASE 4.—D., wounded, Oct. 21, 1918, arrived, Feb. 10, 1919, four months after injury. A sinus and a springy union were present. Roentgenoscopy, Feb. 11, 1919, revealed the teeth and sequestrums in the line of fracture. The teeth and sequestrums were removed. Roentgenoscopy, March 13, 1919, revealed a union and the sinus closed after thirty-two days.

CASE 5.—L., wounded, Aug. 6, 1918, arrived Nov. 10, 1918, three months after the injury. Roentgenoscopy revealed bone sequestrums removed, drainage on neck, Oct. 11, 1918. Feb.

observation with people who are operated on for tumors of the jaw under a general anesthetic, that the death rate is apt to be very high because of lung complications due to aspiration. When time permits, local anesthetics are preferable. In selected cases, primary repair of the soft tissues can be made to great advantage but the bones should be restored immediately to their proper positions and held there. We probably had about 2,300 cases of face and jaw injuries in the war, most of them occurring between July 14 and Nov. 11, 1918. Only about 600 of these men returned to this country as patients, the remainder being discharged over there. It was chiefly due to the number of skilled dentists we had available that this result was possible. The work of Dr. Kazanjian was known to all of the Allies and I was very proud that he came from an American school. It is impossible to give an intelligent discussion, in the 400 words allotted, of the vast amount of work he has presented. The work necessitated by this war has put bone grafting of the lower jaw on a firm basis. I think the only definite rules are that it should be an autogenous graft of live bone and should be placed in a clean field. Whether one selects the rib, the tibia or the ilium should depend rather on the conformation of the bone needed than on any other consideration. The periosteum and endosteum should be preserved over as great an area as possible. The greatest danger to these grafts is not failure of primary healing but subsequent absorption which always takes place unless union is firm and

Fig. 10 (Case 7).—Sinus in left cheek due to infection by teeth in fracture area; five months after injury.

Fig. 11 (Case 7).—Five teeth in fracture area.

Fig. 12 (Case 7).—Teeth extracted; union occurring; sinus closed, after twenty-five days.

11, 1919, union had taken place. This case is used to show injury to bone. Drainage through neck was for anatomic reasons. Union in this case was delayed sixty days in the attempt to save the teeth.

CASE 6.—H., wounded, Oct. 14, 1918, arrived, March 4, 1919. Springiness of union and sinus were present after five and one-half months. The first roentgenogram, March 4, 1919, revealed teeth in the line of fracture. The teeth were extracted. The sinus was closed in ten days—April 5. Radiogram, May 2, 1919, revealed union thirty days after extraction.

CASE 7.—M., wounded, Aug. 10, 1918, arrived, Dec. 20, 1918, four months after injury. There was no union and much infection. The first roentgenogram, Dec. 20, 1918, disclosed the teeth in the line of fracture. The teeth were extracted, December 20. The second roentgenogram, Jan. 15, 1919, revealed the fracture united after twenty-five days.

Numerous other cases came under observation and treatment with similar results.

#### ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. KAZANJIAN, TAINTER AND DAMERON

DR. V. P. BLAIR, St. Louis: The lives of many patients can be saved or the convalescence period shortened by proper early treatment. Then comes the question of death or severe illness as a secondary result of the injury. It is a very old

the bone is subjected to functional strain. The fewer sutures or wires used to hold it in place the better, as fancy mortising operations give a higher percentage of failures. In the reconstruction work, dental splints are a most important item and often present most complicated problems. These have been well met by such men as Dameron and a number of others who have been working in hospitals devoted to reconstruction of the face.

DR. C. W. WALDRON, Ste. Anne de Bellevue, Quebec, Canada: I would like first to tell you how glad the members of the British, Canadian, Australian and New Zealand sections of the Queen's Hospital at Sidcup were to have the large number of American surgeons and dental officers with us for duty, and also to have those who were stationed in other parts of England come and watch our work. We certainly enjoyed their company and their help. They gave us many new ideas, and we were very sorry that Col. Sir Arbutnot Lane was unable to swing an American section around to the Queen's Hospital at Sidcup. Bone grafting of the lower jaw is one of my pet subjects. I feel that it is nothing like the problem that it was three or four years ago. In the case of fractures with a moderately well nourished bed between the end of the bones, and where the bones are of good quality and good size, free grafts are very successful. The problems in so far as mandibular bone grafting is concerned are, to my mind, now confined entirely to those cases where there is practically no tissue bed, that is not

more than two or perhaps three millimeters of connective tissue between the external skin surface and the mucous membrane of the mouth. In these cases, I feel that the pedicle grafts, as advocated by Mr. Percival Cole of King George's Hospital, London, or the osteoperiosteal grafts, are indicated as they have a much better chance of living than free grafts. Another problem is the control of the posterior fragment, where there is a tendency to fixation. That is a matter, of course, of cooperation between the dental surgeon and the surgeon. The institution of very early mobility is indicated, encouraging the patients to use their jaws to the greatest extent possible. In advocating the iliac crest as a good graft, I feel that it conforms the best with the principles laid down by the men doing extremely good work in bone grafting. It is very strong and readily trimmed to shape. We wire it in position, adopting very simple methods of preparation of the fragments. We have discarded electrical equipment. We feel that a nontouch technic, as advocated by Sir Arbuthnot Lane is advisable, and that the simpler operative methods are preferably. If the entire bone reformation is due to the activity of the ends of the fragments of the mandible, the iliac crest fulfils our desires in that being very cancellous, it is capable of being invaded by blood vessels much more rapidly than in the case of a compact tibial graft. This has been well shown by my colleagues in Toronto, Drs. Gallie and Robertson. I am glad that bone grafting is now on a sure basis. We know we shall get good results if we use reasonable care and do not operate too soon, or where there is latent infection.

DR. FRED H. ALBEE, New York: In drawing lessons from the recent war for application to civilian practice, great caution should be employed, lest many of the experiences thereby gained prove not entirely trustworthy. The type of jaw case, for instance, so frequently met in army work will rarely be encountered in civil practice. Personal experience with civilian cases of injury of the jaw has shown such cases to be usually of many years' standing, with persistent nonunion owing to extensive pathologic changes in the bone ends, such as churning, loss of osteogenesis, blood supply, etc. In the army, on the other hand, the cases of jaw injury met are usually of only a few months' duration, and are usually more favorable to union. The high vascularity of the tissues of this region and the retention, in most cases, of the osteogenic power of the jaw fragments have afforded such favorable conditions as have, doubtless, contributed largely to whatever degree of success has been attained by the use of the recently revived osteoperiosteal graft in reparative work on the jaw. Repair of the jaw with extensive loss of bone substance, however, offers great difficulties of mechanical fitting and adjustment. Such work requires an accuracy and rapidity of technic only secured by delicately adjusted motor driven instruments. The construction of a suitable framework over which to restore the contours of the face is of primary importance if the cosmetic result is to be satisfactory. The inadequacy of the osteoperiosteal graft for this purpose is apparent. Only by means of a strong fixation graft, molded and firmly inlaid into each fragment, can the proper contours of the face be restored. As a supplement to the fixation graft, of the peg or inlay type, the osteoperiosteal graft is of great service in furnishing an additional focus for bone-growth. The high percentage of failures reported by certain individuals in this work, may be attributed largely to the use of foreign bodies. Kangaroo tendon is more trustworthy than silver wire. Like the osteoperiosteal graft, the use of the pedicle graft is distinctly limited. The pedicle graft is seldom indicated or feasible. Its utter inadequacy is especially apparent in jaw cases in which there is much loss of bone. This jaw work, if it is to be ideal, should always be done, when possible, with the closest cooperation between plastic surgeon and prosthetic dentist. The statement was made that the dental splint will furnish sufficient support in all cases. Where there are teeth, that is possible, but in cases in which there is loss of molar teeth, as well as bone, it would not be of any use. Moreover, if the patient is not able to tolerate it, the splint must be removed. The greatest stimulus to healthy metabolism and proliferation of

the graft is mechanical stress. By one sure means only can this stress be brought to bear on the graft, namely, by its insertion into the substance of the host bone fragments by such an accurate inlay technic as will insure a perfect cabinetmaker fit.

## ECTOENZYMES OF STREPTOCOCCI\*

M. S. TONGS, B.S.

Intern, St. Louis City Hospital  
ST. LOUIS

The enzymes, as Beatty<sup>1</sup> defines them, are the catalysts of living organisms, and are divided into two groups: ectoenzymes and endoenzymes. The former, excreted from cells into the surrounding medium, can be detected by their characteristic properties, and the latter contained only in the cells, have to be extracted by special means.

As to the method of detection of bacterial ectoenzymes, the auxanographic method of Beijerinck seems to be the simplest. The method consists in mix-

Fig. 1.—Milk agar plate showing the digestion of casein. There are two zones—light and dark—around the colonies. Twenty-four hours' incubation at 37 C.

ing agar with any substance that can be used to detect bacterial ectoenzymes. The mixture is then inoculated with the organism, plated and incubated at 37 C., and the plate studied carefully after incubation. The presence of bacterial ectoenzymes may be shown by a zone of digestion or other change around the colonies. This zone usually appears clear and wide. By this method, Bijkman<sup>2</sup> and Buxton<sup>3</sup> demonstrated amylase, lipase, casein-splitting enzyme, etc., excreted by different organisms.

### THE AMYLASE OF STREPTOCOCCI

**Technic.**—Starch paste is prepared by dissolving 4 gm. of cornstarch in 200 c.c. of distilled water. To this solution 0.1 gm. of asparagin is added. The solu-

Starch agar is prepared as follows: From 4 to 5 ounces of nutrient agar are placed in a flask, heated until the agar is melted, and then cooled to from 45 to 50 C. Now 1 c.c. of starch paste is added to each 6 c.c. of agar. Approximately 7 c.c. are used for each plate. In the shake method, 1 c.c. of the starch paste is added to 6 c.c. of melted sugar in a tube at 45 C. This tube is inoculated with bacteria, the whole thoroughly mixed and poured into a Petri dish. In my experience the surface streak method gives a better result.

The plates inoculated with organisms are incubated at 37 C. for twenty-four hours. The digestion of starch by amylase will be shown by a clear and wide zone. The zone of digestion progresses as the time of incubation increases. Now if a diluted Lugol's solution is poured over the surface of the medium there appears just outside of this clear zone another narrow pink zone usually about 1 mm. wide. As is well known, iodine gives a blue color with starch; erythrodestrin, a red color; but maltose or leukodestrin, no color. Thus we may conclude that the clear zone and pink zone represent maltose and erythrodestrin, respec-

Fig. 3.—Starch agar plate made by the shake method showing the digestion of starch; treated with Lugol's solution after twenty-four hours' incubation. The light areas are the areas of digestion. A dark zone around this area can occasionally be seen and this zone stains pink with iodine on the original plate.

tively, the digestive products of the action on starch by the amylase secreted by streptococci. The results of my observations on different strains of streptococci are given in Table 1.

If a small portion of the medium in which starch has been digested by amylase is removed and dissolved in a tube of 4 c.c. of distilled water at 45 C., and 2 c.c. of Fehling's solution are added to this solution, which is then heated to boiling, it is usually found that the

Fig. 4.—Starch agar plate, surface streak, forty-eight hours' incubation at 37 C.

Fehling solution is reduced within twenty minutes. In each case a control should be made. A positive test would mean the presence of maltose.

#### THE CASEIN-SPLITTING ENZYME OF STREPTOCOCCI

*Technic.*—Milk, which should be free from fat, is sterilized in an Arnold sterilizer by the discontinuous method; however, it may be sterilized for five minutes at 120 C. in the autoclave. The milk should be neutral or slightly alkaline to litmus.

Milk agar is prepared in the same way as starch agar. A clear zone around the colonies indicates the digestion of the casein, but in most instances a coagulation precedes digestion and this is shown by a dark zone (Table 1).

If a small portion of the clear zone is removed and placed in 4 c.c. of distilled water at 45 C., and to this solution when cold is added 5 per cent. of acetic acid drop by drop, no precipitation takes place, which means that casein is absent.

#### THE INFLUENCE OF TEMPERATURE ON THE ACTION OF THE ECTOENZYMES OF STREPTOCOCCI

Four starch agar or milk plates are inoculated with the same culture and incubated at 37 C. for twenty-four hours in order to get an initial growth. Then the plates are kept at different degrees of temperature. The results are shown in Table 2.

In view of the results, it is evident that the ectoenzymes of streptococci become inactive at 0 C. and are able to continue their action at as high a temperature as 56 C.

Cultures 9 and 10 from the sputum and lungs, respectively, of influenza patients digested casein only after forty-eight hours' incubation and the latter had a stronger activity than the former.

#### SUMMARY

Among hemolytic streptococci there seem to be three groups: one digesting casein, one starch, and the other neither casein nor starch. Among the green-producing streptococcal organisms only two groups are indicated: one digesting casein, and the other without action on starch or casein.

St. Louis City Hospital.

### A CASE OF TUMOR OF THE PONS VAROLII\*

TOM BENTLEY THROCKMORTON, B.Sc., M.D.  
DES MOINES, IOWA

*History.*—A white lad, aged 17½ years, first came under my observation in October, 1912, complaining of nervousness and inability to walk properly, conditions which were said to have been present for a number of years but to have progressively grown worse during the previous three or four years. The family and personal histories were negative. The onset of the trouble had been insidious. At about 8 years of age, it was first noticed that the boy's right eye had a tendency to turn inward. This was progressive, so that at the end of five years complete internal strabismus was present. Vision and gait, however, could not have been greatly interfered with at the time, for it was ascertained that the lad won an egg race at a town carnival, the winning necessitating the transference of a number of eggs from one spot to another, dipping them up and carrying them by means of a spoon. An itinerant eye specialist attempted to overcome

Fig. 1.—Characteristic position of head; also the right sided proptosis, the right sided facial paralysis and the distinct lowering of the right shoulder. The left sided ptosis is more apparent than real.

the visual deformity by doing a tenotomy on the internal rectus muscle. Then because the eyeball appeared more prominent and the lids were more separated on the right

\* Read before the Section on Nervous and Mental Diseases at the Seventeenth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1919.

side, an endeavor was made to decrease the palpebral fissure. In other words, it would not be unreasonable to assume that the ocular condition at that time consisted of a complete paralysis of the external rectus, proptosis and incipient seventh nerve weakness.

Fig. 2.—Characteristic attitude assumed when standing. Note the broad base obtained by spreading the feet apart, an endeavor to overcome the ataxia (flashlight photograph).

The ataxia was of the cerebellar type, not being appreciably influenced on closure of the eyes. The so-called characteristic cerebellar attitude of the head was present; that is, the chin turned to the affected side and the head tilted to the contralateral shoulder. A double choked disk existed, more marked on the right side, and the visual acuity on this side was 6/60, as compared with 6/10 on the opposite side. There was slight involvement of the ophthalmic division of the right fifth nerve, as indicated by diminution in corneal sensitiveness, while the sixth, seventh, eighth, ninth, tenth and eleventh cranial nerves on the right side were all involved to a marked degree. Involvement of the left sixth, eighth and twelfth nerves was evident from weakness of the external rectus muscle, moderate diminution in hearing, and a tendency for the tip of the tongue to curve to the left side on protrusion. The latter condition, however, may have been more apparent than real, as the pulling aside of the paralytic right cheek caused the tongue to protrude more nearly in the median line, its curvature to the left possibly being due to the prolonged habit of being displaced by the paralyzed muscles of the right cheek. The motor pathways to the left arm and leg were involved, as shown by motor weakness, increased tendon jerks, hypertonia of the leg muscles, and an extension of the great toe by the Babinski and Chaddock methods. The crossed paralysis syndrome, indicative of pontile lesions, was

beautifully illustrated by the seventh nerve lesion of the right side associated with motor paralysis of the opposite arm and leg. The laboratory findings were completely negative as far as the blood Wassermann, subcutaneous tuberculin, urine and blood tests were concerned.

**Neurologic Symptoms.**—General Symptoms of Brain Tumor: (1) headache; (2) projectile vomiting; (3) double choked disk; (4) vertigo.

**Cerebellar Symptoms:** (1) ataxia, unimpaired on closure of eyes; (2) characteristic attitude of head; (3) reeling, lurching, staggering gait, more toward the right; (4) dysdiadochokinesia; (5) asynergy; (6) nystagmus.

**Brain Stem Symptoms:** Right: Optic, choked disk; O. V. D., 6/60; trigeminal, ophthalmic division; abducens, complete; facial, complete; auditory, almost complete; glossopharyngeal, pneumogastric and spinal accessory, all involved to a greater or less degree; motor pathways to left arm and leg.

Left: Optic, choked disk; O. V. S., 6/10; abducens, moderate; auditory, moderate; hypoglossal (?).

**Operation and Result.**—A decompression operation was performed by Dr. C. E. Ruth, at which time the entire right cerebellar lobe was exposed, first, in the hope of relieving the symptoms due to increased intracranial pressure, and, secondly, that a tumor might be found in some accessible position. Nothing, however, was ascertained as to the presence of a tumor, save an increased resistance, felt by the palpating finger in the region of the pons. Postoperative convalescence was uneventful until the sixteenth day was reached, at which time, without apparent cause, the fever rose to 103 F, unaccompanied by pain or discomfort. A hernial protrusion over the operative site became so marked as to warrant the necessity of a paracentesis, at which time 75 c.c. of clear cerebral fluid were withdrawn. Two days later the eruptive rash of smallpox appeared. Following the recovery from this disease, the patient returned to his home, where he lived in comparative comfort for almost five years subsequent to the operation. During this time his general health greatly improved, he was free from headaches and vomiting, and while a double optic atrophy slowly followed in the wake of the preexisting papillitis, he never completely lost his eyesight. Needless to state, the organic changes in the nervous mechanism produced by a growth, the first symptom of which was observed when the boy was 8 years old and which ultimately caused his death fourteen years later, never were eradicated; but the prolonging of life, with comparative

Fig. 3.—Mesial section through brain, showing pontile tumor.

freedom from symptoms which would have made death preferable, more than justified the operative interference.

**Necropsy.**—Sixteen hours after death, a necropsy was performed by Dr. D. J. Glomset, at which time the brain was obtained. The dura mater stripped easily from the calvarium save at the point of the old operative site, where the attachment of the meninges was quite firm. There was considerable atrophy of the right cerebellar lobe; but no external evidence of a tumor could be found, save that indicated by the presence of several pia-arachnoid cysts which lay along the under

surface of the brain, particularly at the junction of the transverse fibers of the pons with the medulla. After the brain had been hardened, a mesial section was performed which revealed a spherical mass 3.5 by 4 cm. in diameter, occupying the space between the superior cerebellar peduncles and the crus cerebri above, the medulla oblongata below, the transverse fibers of the pons anteriorly, and filling, practically to its entirety the fourth ventricle. The center of the mass was somewhat necrotic and showed evidence of recent hemorrhage. The tumor was distinctly encapsulated and without

Fig. 4.—Section through brain stem and cerebellum. Note atrophy of right cerebellar lobe.

great difficulty was separated from its capsule except at the point of its greatest attachment, which apparently sprang from the longitudinal fibers of the pons and their continuation downward through the medulla. The outer surface of the growth was quite irregular and nodular, the nodules penetrating the cerebellar tissue, particularly on the right side. Microscopic examination of the tumor showed that it was gliomatous.

ABSTRACT OF DISCUSSION

DR. FRANK W. LANGHORN, Cincinnati: I am interested in this case as an example of careful study and accurate localization of a basilar tumor. We should recognize the fact that there are two groups of these cases which come before the clinician, in one of which he advises early operation to save the patient's vision. Exploration which is practically harmless is not only allowable but we are warranted in taking some chances. How far we shall go after that is another matter. But there are two obstacles in the way even to exploration. There is one class of patients who will decline any form of operation, and there is another class in which the general condition is such that operation is not advisable. You are facing what will eventually be a fatal disease, the patient meanwhile being liable to suffering and blindness which may be prevented by early exploration and decompression. We should not rely on hard and fast rules, but in suitable cases explore and be guided by what is found.

**The Importance of Birth Registration.**—It certainly does not comport with the dignity, intelligence and might of our nation to have it practically the only civilized country in the world which, in much of its extent, takes less account of the increase of its citizens than it does of the birth of blooded stock and poultry. If birth registration is important in the older countries where the conditions of life are comparatively settled, how much more useful would it be in this new and vigorous commonwealth made up of so many different races and containing within its borders such a variety of climatic and industrial conditions. Is it not of the first importance for the United States to have on record the birth rate prevalent in all sections of the country, in the larger cities, among miners, among factory workers, and among the dwellers in the mountains as compared to those on the plains? This information would be invaluable not only for the statistician, physician and statesman, but also for the prospective settler. If the injunction to "know thyself" is fundamental to the best efficiency of the individual, is it not equally true of the nation, and where could this knowledge better begin than in the proper recording of the birth of its citizens? —J. H. Mason Knox, The Importance of Birth Registration to Determine Infant Mortality, *Journal of the American Public Health Association*.

**Clinical Notes, Suggestions, and New Instruments**

CALIPER EXTENSION IN THE TREATMENT OF FRACTURES OF THE FEMUR

JOHN E. CANNADAY, M.D. (CHARLESTON, W. VA.)  
Major, M. C., U. S. Army; Chief of Surgical Service, Base Hospital  
CAMP SHERMAN, CHILLICOTHE, OHIO

A good many years ago Ransohoff introduced the use of ice tongs to secure proper traction in certain cases of fractures of the femur. This treatment stood the test of time, and has been widely adopted. Later, Besley, and also St. Clair, introduced a modification of the ice tong—the caliper which has been extensively used during the world war. This caliper, as ordinarily used, has quite sharp and slender points, which may penetrate the bone cortex too deeply and enter the spongy bone, giving rise to the possibility of osteomyelitis; or, one point may become loosened, while the other penetrates deeply into the soft bone. And, in event of the constancy of the traction being disturbed, the caliper points may become altogether detached from the bone.

The traction as it is ordinarily made, with the caliper handles in line with the femur, prevents the full extension of the leg at the knee and thus interferes with both passive and voluntary motion.

Having in mind some of these defects, I have had made a pair of calipers intended to be used in a vertical position. The points are blunted and slant toward the front, so as to give the proper pulling angle. Each is equipped with a guard ring which is an effective substitute for the tubular guard used by Hurley.<sup>2</sup> It allows only one-fourth inch of the point to enter the bone. At the angle formed by the junction of the base of the caliper point and the handle, a traction ring

Calipers for use in vertical position

has been attached, and above, on the handles, a locking device in the shape of a hinged cross bar with a set screw. This not only holds the caliper points securely in contact with the bone, but also precludes the possibility of their becoming loosened from their hold on the condyles of the femur.

A NEW STANDARD SOLUTION FOR SAHLI'S MODIFICATION  
OF GOWER'S HEMOGLOBINOMETER \*

VICTOR C. JACOBSON, M.D., BOSTON

The clinical estimation of hemoglobin, judging by the variety of instruments made and used for that purpose, is still a source of dissatisfaction, especially in a general hospital where such determinations are made in large numbers daily.

The criteria for any instrument to be used in the clinical laboratory are, first, sufficient accuracy, and, second, simple and expeditious operation. To be perfectly satisfactory for clinical purposes, an instrument need not be absolutely accurate. But simplicity of operation is the sine qua non of any apparatus destined to become of routine use in a busy clinic.

Various methods of measuring hemoglobin have their adherents, but the Sahlí modification of Gower's instrument, in spite of its shortcomings, is probably the most widely used. The principle involved in Sahlí's method is simple: A measured quantity of blood is treated in a calibrated tube with tenth-normal hydrochloric acid, in order to change its hemoglobin into brown acid hematin. It is then diluted with water until its color corresponds to that of a standard solution of acid hematin, the latter representing a 1 per cent. solution of normal blood.

The standard solution, as Sahlí states, is only a suspension and not a true solution. A sediment forms after long use or in a shorter time if the tube is not filled aseptically, and the clouthing, of course, detracts from its accuracy. Sahlí apparently had a fair degree of success in keeping the solution without a change in shade over two years, though the solution was kept in the dark most of the time. However, the standard tubes which have been available in this country during the past three or four years either were not made according to Sahlí's directions or else the inevitable simply happened, for they faded. In a busy laboratory the apparatus is bound to be left in the light, in the aggregate, over long periods of time. Consequently, in a hospital where many are used, scarcely any two are of the same shade. A solution, of course, can be restandardized by comparing it with a group of normal bloods, but with a constantly changing color intensity in the standard tube it is, to say the least, time consuming to keep up with the color changes.

It is my purpose here to suggest the substitution for a standard hematin hydrochlorate solution of a solution of

greater color-fastness. Gallic acid,  $C_6H_2$   $\begin{matrix} \text{COOH} \\ | \\ \text{OH} \\ | \\ \text{OH} \\ | \\ \text{OH} \end{matrix}$ , when

treated with sulphuric acid assumes a deep brown color. Tannic acid,  $C_{14}H_{10}O_5$ , which is 2 molecules of gallic acid minus 1 molecule of water, when dissolved in water and exposed to the action of oxidizing agents or molds is changed to a similar brown color. These solutions, compared with one of acid hematin, are of identical color, both to the naked eye and in the chambers of a Duboscq colorimeter. While kept in a clean, stoppered container (not primarily sterile), with a drop of 95 per cent. phenol for each 20 c.c., the color intensity has not changed during a period of ten months' exposure in a sunlit window, while one of Sahlí's tubes faded markedly in three days and was colorless in a week.

One hundred c.c. of a 20 per cent. aqueous solution of tannic acid or a 1 per cent. solution of gallic acid, to each of which have been added from 5 to 10 drops of concentrated sulphuric acid, on gentle heating for a minute gives a deep brown color which reaches maximal intensity after about two hours. This solution can be diluted to any desired strength.

The chemistry of tannic acid and gallic acid is little understood and doubtless is very complicated. Dr. Louis E. Levi of Milwaukee has kindly given me his opinion of the reactions involved in obtaining the brown color: "Gallic acid treated

with sulphuric acid produces rufigallic acid (hexa-oxyanthracinon) of a brown color. Tannic acid in the presence of dilute acids, both organic and inorganic, produces gallic acid. This gallic acid, or the gallic acid which always is present in tannic acid, is changed by sunlight and dilute organic acids to rufigallic acid. Therefore, I conclude that the color (brown) in tannic acid is due to the formation of rufigallic acid."

Utilizing this similarity of color, I have prepared standard tubes of "rufigallic acid" which are in use on the medical wards of the Peter Bent Brigham Hospital. There are various methods of making a "standard" solution: A 1 per cent. solution of blood from each of a group of normal individuals can be mixed together and the composite sample called "average normal"; or, a 1 per cent. solution of blood from a robust young adult with a high normal erythrocyte count can be called "high normal," and the readings of other normal persons being from ten to twenty points lower, an "average normal" for that solution can be estimated, such a figure being the one always used in computing the color index. Comparison with Palmer's carbon monoxid method is probably the best way to standardize the solution.

I suggest, therefore, the use of a solution of rufigallic acid as a standard for the Sahlí-Gower instrument, in place of the rapidly fading suspension of hematin hydrochlorate.

## HEAD RESTS FOR NEUROLOGIC OPERATIONS\*

A. W. ADSON, M.D., AND G. G. LITTLE, M.E., ROCHESTER, MINN.

## THE CEREBELLAR HEAD REST

The cerebellar head rest serves two distinct purposes: First, it holds the head in a prone position so that it can be tilted at all angles, thus giving good exposure of the cere-

Fig. 1.—Cerebellar head rest, illustrating head piece and ether mask.

bellum and cervical spine. Second, it is arranged so that the jaw can be moved freely, the nose and mouth are exposed, and an adjustable ether mask can be attached to the frame to enable the administration of ether by the inhalation method without difficulty. The administration of intrapharyngeal or intratracheal anesthesia is also made possible by

\* From the Pathological Laboratory of the Peter Bent Brigham Hospital.

1. Sahlí, 11: Treatise on Diagnostic Methods of Examinations, Philadelphia, W. B. Saunders Company, 1911.

\* From the Mayo clinic.

removing the mask and inserting the intrapharyngeal or intratracheal catheter and attaching it to the anesthetic machine.

The ether mask (Fig. 1 *d*) is easily adjusted; it is secured in position by the curved edges, *J*. A short tube permanently fixed to the mask provides a means of attaching the ether tube, *k*. It also directs the flow of ether toward the center of the mask.

Fig. 2.—Cerebellar head rest: head in position, with ether masks removed, exposing the nose, mouth and chin.

The headpiece (Fig. 2 *c*) is secured to a ball pivot and may be tipped at any angle. It may also be moved toward or away from the table along the supporting frame, *a*, by loosening the threaded collars, *h*, which, when tightened, hold the headpiece at the required height. The headpiece is locked to the standard, *b*, by tightening the collar, *e*, by means of the handle, *f*.

The supporting frame, *a*, is attached to the Balfour operating table; it is secured by a clamp, *i*; the swing leaf, *x*, of the table is lowered. The headpiece, having been formed to fit the forehead and cheeks, provides a comfortable rest for the patient's head, and leaves the nose and mouth uncovered

Fig. 3.—Cerebellar head rest: head in position, and ether mask attached and connected with the anesthetic machine and blower.

except for the detachable ether mask; the anesthetist is thus permitted free access to the patient's mouth.

The head rest and frame are attached to the operating table and connected by a flexible tube to the etherizing apparatus (Fig. 3 *l*); this is supplied with air from the motor-driven pump, *n*, through the flexible tube, *m*; the motor cord, *p*, plugs into a standard lamp socket.

THE GANGLION HEAD REST

The ganglion head rest is arranged to prevent the head from wobbling from side to side during operation. The head is held in the erect position and may be raised or lowered or turned from side to side by the use of the adjustable frame and universal joints. The base plate (Fig. 4 *a*) is secured to the swing leaf, *j*, of the Balfour operating table by a

Fig. 4.—Ganglion head rest, illustrating its attachment to the swing leaf of the Balfour table, with the various adjustments.

clamp, *i*. The swing leaf may be adjusted by the ratchet bar, *k*. The headpiece, *b*, has a spherical surface adjustment in the cup, *c*; it is secured in position by the thumb nut, *f*. The spring fingers, *g*, are adjustable and hold the patient's head in position. The upright, *d*, is hinged on *a* and supports *c*, which may be adjusted for height and angle positions through the rod, *e*; it is secured by fingers, *g*, to the headpiece, *b*. By adjusting the table, the swing leaf *j*, rod *e*, members *c* and *d*, swiveling piece *b*, and the fingers *g*, the surgeon may hold the head in any position desired.

**Open Safety Pin in Gastro-Intestinal Tract.**—The account of an open safety pin passing through a baby's intestinal tract, in THE JOURNAL, July 5, prompts me to suggest treatment I have used for years; when a child has swallowed a fish hook, open safety pin, pins, pennies, or any material that is apt to lodge in the intestinal tract, I put it on a milk, brain and mucilaginous diet. Twice daily, I give a large dose of olive oil followed with the official Seidlitz powder—the size of the dose in proportion to the size of the child. If the stool is watched carefully for a few days, one will see results. Most of the time, the foreign substance is incorporated within a soap ball; and in any event, I can imagine that the little soap balls are just the right shape to bear the foreign substance on and out of the many folds of the mucosa of the intestinal tract. Let it be called a ball-bearing method. I have removed articles by this method that have had points protruding in such a way that it would not seem possible for them to pass along without their penetrating and lodging in the intestinal wall.—R. C. FAUST, M.D., Deary, Idaho.

## THE QUEST OF A HEART FUNCTION TEST

H. B. CONRAD, M.A., M.D., WINSTON SALEM, N. C.  
Lieutenant, M. C., U. S. Navy

Early in the war, Sir James Mackenzie<sup>1</sup> proposed that in the examination of the hearts of applicants for military service more stress be laid on how the heart responds to effort. He says that if the applicant can undergo severe bodily exertion without distress, it is fairly safe to assume that any irregularity or systolic murmur present is without significance. This is not new, but it lends great emphasis to the examination of the circulatory apparatus as a whole and to judging a heart by the circulation it can maintain. Heretofore, cardiac examination has concerned itself principally with detecting imperfect valves, sclerotic arteries, and dilated or hypertrophied myocardium. The function tests were developed to detect inefficiency of the heart in maintaining the circulation and impending heart failure.

In 1915, Swan<sup>2</sup> reviewed the heart function tests proposed up to that time. Tigerstedt, Stone, Goodman and Howell, and many others have sought to arrive at a formula from the interrelation of different phases of the blood pressure reading that would give an index of the cardiac efficiency.

The tests that seem to offer most promise are those based on the reaction of the heart to bodily exertion. Exertion in the presence of a markedly inefficient heart brings on palpitation, dyspnea and distress. The search has been for any sign or signs brought out on exertion which would indicate minor degrees of cardiac inefficiency. According to Circular 21 of the Surgeon-General's Office, the rapidity of the pulse and respiration persisting two minutes after hopping a hundred times on one foot should be viewed with suspicion. However, according to Mackenzie<sup>3</sup> and the observations of Barringer,<sup>4</sup> it is only in an extremely limited number of cases that the pulse rate after exercise is of value in determining cardiac efficiency. Following Graepner,<sup>5</sup> Barringer<sup>6</sup> has sought from the blood pressure curve following exertion to determine what he calls the "cardiac reserve." The rise of blood pressure after exercise normally takes place in thirty seconds. If the heart's capacity has been exceeded during the exercise, the height of the blood pressure is not reached for sixty or seventy seconds. The amount of exercise measured in foot pounds that can be undergone without this delayed rise is the index of cardiac reserve. It seems to make no difference which group of muscles is employed in the exercise. The work which the average man between 20 and 30 years can perform without showing a delayed rise is from 6,000 to 12,000 foot pounds. In inefficient hearts it frequently drops to 1,000 foot pounds or less.

Kahn<sup>7</sup> has recently applied such function tests as deal with pulse rate and blood pressure following exercise to over 200 cases, including the normal, tachycardias, bradycardias, neurocirculatory asthenias, etc. His results appear definite. But before such function tests can be of significance in these diseases, the relation of the test to cardiac failure must be more firmly established. Hence the most urgent need just now is a function test with an established relation with heart failure. This will require observation over long periods. It may be that prolonged observation will establish the delayed rise of blood pressure after exercise as a test of definite diagnostic and prognostic value. It may be that some other evidence of a weakened circulation will be discovered and made use of. But whatever test develops, its diagnostic value will be in the insight it gives us into the heart's ability to maintain the circulation, and its prognostic value in the foresight it gives us of heart failure. It will deal with the circulatory apparatus as a whole and not as made up of nerves, arteries, muscle and valves.

## A NEW ASPIRATOR

H. B. PHILIPS, M.D., NEW YORK

This aspirator, designed principally for thoracentesis of the pleura, consists of a bottle, a suction pump, a dial manometer, a needle holder with different sized needles, and connecting rubber tubing. It is an extension in usage of the Philips emphyema apparatus for simple thoracentesis of the pleura. It incorporates in the usage of the apparatus the advantages offered in the original emphyema apparatus.<sup>1</sup>

## OPERATION

The needles, needle holder and connected rubber tubing, up to the first glass connecting rod, are sterilized. The selected needle is now forced firmly on the needle holder, and the tubing of the holder connected to that of the bottle. The clamp just distal to the needle holder is shut, and a negative pressure of 40 mm. of mercury is produced in the closed system, by means of the suction pump. The needle is now very slowly introduced into the skin, and when the orifice of the needle is entirely beneath the superficial layers of the skin, the clamp next to the needle holder is released. The needle is now forced, very slowly, into the tissues. Emphasis is placed on the words "very slowly," for it is

Aspirator for thoracentesis of pleura.

possible, by so doing, to stop the needle when the orifice is almost flush with the parietal pleura, which will be indicated by the appearance of the aspirated fluid, in the glass connecting rod, next to the needle holder. In this way the danger of traumatizing the lung by the aspirator needle is made minimal. The pleural fluid will now flow into the bottle under the previously established negative pressure. The lung will expand gradually. As it expands, naturally the negative pressure will diminish. It can be increased, at will, by aid of the suction pump. The desired amount of fluid is aspirated, and the desired negative pressure produced in the system, which now includes the pleural sac, before the needle is withdrawn. Thus an expanded lung, in a pleura with a measured negative pressure, is assured at the end of the procedure.

## Therapeutics

A DEPARTMENT DEVOTED TO THE IMPROVEMENT OF THERAPY,  
A FORUM FOR THE DISCUSSION OF THE USE OF DRUGS  
AND OTHER REMEDIES IN THE TREATMENT OF DISEASE.

### SUGGESTION

Suggestion is not only a potency in treatment, but also a potent cause for error in therapeutics. In originating and perpetuating mistaken ideas in therapeutics, suggestion acts in two ways: Working on the patient's mind it endows any remedy, no matter how inert, with curative powers; and, by affecting the mind of the physician, it makes him see therapeutic success where he confidently looks for it. Furthermore, the *vis medicatrix naturae* keeps alive not only our patients, but also therapeutic fallacies and panaceas. Any remedy, even though it be worthless, that a physician uses frequently in his practice, appears to him highly successful because of the fact that most patients have the natural tendency to get well. The Frenchman's saying, "The extremes touch each other," finds a good illustration in the fact that, in therapeutics, optimism is as bad as pessimism, if not worse. The former engenders the latter. What we need is an open minded yet critical attitude, an abiding hope and unconquerable enthusiasm, accompanied by the perpetual question mark: Is it true?

### THERAPEUTIC TECHNIC

As there is always a best way of doing things, there must be a best way of obtaining a certain therapeutic result. Most of us use remedies in a particular manner, because we happened to get into the habit of doing so, and without reflecting whether our accustomed way is the best way. It has well been said that, if surgeons paid as little attention to their technic as physicians do, surgery would be much less popular and less successful.

### USE AND ABUSE OF CATHARTICS\*

(Continued from page 1215)

#### CATHARSIS AS A CAUSE OF CONSTIPATION

##### CONTRAINDICATION OF CATHARSIS IN ACUTE PAINFUL CONSTIPATION

In acute constipation, accompanied by severe abdominal pain, surgeons are agreed that purgatives are pernicious.<sup>9</sup> In this condition, the patient is not in danger because his bowels do not move; a person may have no bowel movement for a week without danger. The patient's danger lies in the condition that produces the pain as well as the obstipation. If the bowels can move, they will do so without recourse to drastic measures; if they cannot move, drastics will do great harm. When there is a complete mechanical closure of the lumen of the bowel, no cathartic, however strong, is capable of overcoming the obstruction. Instead of producing a bowel movement in these cases, the increased peristalsis forces intestinal contents back into the stomach, increasing the foul vomiting so

characteristic of the condition; while at the same time the driving of the intestinal contents against the obstruction aggravates the damage existing at that point, leading to dilatation, sloughing, hemorrhages, and even perforation. If the obstruction is due to paralysis of the bowel from localized inflammation of the intestine, especially if the infection involves the peritoneum, the patient's comfort and safety depend on diminution of peristalsis; for not only is rest required for cure, but also the danger of general dissemination of the infection throughout the peritoneal cavity is lessened. Should the obstruction be due to spasm, increasing the peristaltic activity by means of cathartics merely serves to increase the spasm and the obstruction. We may, therefore, formulate this therapeutic axiom: Violent abdominal pain unattended by diarrhea contraindicates the administration of a purge.

What, then, the practitioner may ask, is to be done in cases of acute painful constipation? The proper treatment is outlined by M. L. Harris<sup>9</sup> as follows:

Wash out the stomach with warm physiologic salt solution or dilute soda solution and keep it empty. Then empty the lower bowel by means of enemas, so that the entire intestinal tract may be placed as nearly at rest as possible. It is unnecessary to feed these patients for a time, for they never die of starvation; but they do need water, and this should be administered subcutaneously in the form of physiologic salt solution, from 1,000 to 2,000 c.c. in the twenty-four hours. This treatment places the patient under most favorable circumstances to aid nature in bringing about a cure; and, if operation is found necessary, he is in the best possible condition for it.

#### ROUTINE USE OF CATHARTICS

The routine administration of cathartics before operation has of late been attacked, most especially by Alvarez,<sup>10</sup> on the following grounds:

1. Danger of dissemination of infection throughout the peritoneal cavity, in case localized infection exists.
2. Increased absorption of toxins and greater bacterial activity by reason of the fact that undigested food has been carried down into the colon to serve as pabulum for bacteria, and that liquid feces form a better culture medium than solid feces.
3. Increased distention of the intestine with gas and fluid, when it should empty. This is especially true when magnesium sulphate is used, as Alvarez and Taylor<sup>11</sup> have shown by experiments on rabbits. The danger of soiling the intestine is greater than with solid feces.<sup>12</sup> The small intestine is practically always empty twelve or more hours after a meal; hence an operation in the morning surely does not require purgation to clear the small intestine. The colon in which feces may stagnate can easily be cleared by enemas; and these need be given only to those who are definitely constipated, or who are to undergo an operation on the lower colon or on the pelvic organs.
4. Psychic and physical weakness produced by dehydration of the body, disturbance in the salt balance of the system, and the loss of sleep occasioned by the frequent purging during the night preceding the operation. As Oliver Wendell Holmes<sup>13</sup> says:

<sup>10</sup> Alvarez, W. C.: Is the Purgation of Patients before Operation Justified? *Surg., Gynec. & Obst.* **26**: 651 (June) 1918.

<sup>11</sup> Alvarez, W. C., and Taylor, J. B.: Changes in Rhythm, Irritability and Time in the Purged Intestine. *J. Pharmacol. & Exper. Therap.* **10**: 365 (Nov.) 1917.

<sup>13</sup> Holmes, O. W.: *Currents and Counter Currents in Medicine*, Boston, 1861, p. 37.

\* This is the second of a series of articles on the pharmacology, physiology and practical application of the common laxatives and cathartics. The first article appeared October 18.

<sup>9</sup> Harris, M. L.: Dangers from Indiscriminate Use of Cathartics in Acute Intestinal Conditions. *J. A. M. A.* **44**: 622 (Feb. 15) 1905.  
Quain, E. P.: Some Observations on Catharsis. *J. A. M. A.* **59**: 27 (July 6) 1912.

If it were known that a prize fighter were to have a drastic purgative administered two or three days before a contest, no one will question that it would affect the betting on his side unfavorably. If this be true for a powerful man in perfect health, how much more true must it be of the sick man battling for life.

5. Increase in postoperative distress and danger: thirst, gas pains, and even ileus. The widespread postoperative use of saline infusion, in its various forms, testifies to the body's need of fluid immediately after operation. How much greater must this need be when, by means of liquid bowel movements a few hours previously, much fluid was abstracted. The weakening of some parts of the bowel, and making others more irritable, in other words, the upsetting of the gradient of intestinal muscular forces,<sup>14</sup> predisposes to flatulent distention, and gas pains. The changes described, as well as the absence of solid matter in the bowel, makes resumption of colonic activity much more difficult; and this favors the development of ileus. The purged bowel is notoriously irresponsive to further purgation, and hence, in emergency, might not respond to an appeal by cathartics, when without previous exertion it would have done so.

6. After all, however, the most important and conclusive objection is contained in the sentence used by nearly all who write against preoperative purgation. "Every surgeon has noticed that the emergency patient who comes to the hospital in need of immediate operation has as good postoperative recovery and as uneventful a convalescence as the patient who is, so-called, properly prepared. It makes little difference whether it is a case of acute appendicitis or a crushed limb requiring immediate amputation."<sup>15</sup> If this is true, and the evidence is so strong that those who believe otherwise would have to bring proof to the contrary, then routine preoperative purgation must be relegated to our professional sins of the past.

Henry T. Byford<sup>16</sup> agrees, in the main, with advocating the discontinuance of routine preoperative purgation and dieting. He would, however, empty the bowel in those who are habitually constipated. Regarding postoperative purging, he believes that early purgation is required in those cases in which sufficient intraperitoneal traumatism has occurred to give rise to danger of subsequent adhesion, as peristalsis actually helps to maintain a permeable canal until the adhesions have formed and the danger of obstruction is past. When, on the other hand, there has been resection or extensive repair of the intestine, purging should not be employed until a certain amount of intestinal exudate has had time to seal up the intestinal suture line.

Regarding the utility of using cathartics in postoperative ileus, we might quote Alonzo Clark:<sup>17</sup>

When purgatives succeed, they simply show that peritonitis, if present, was not extensive enough to preclude recovery. If the intoxication is severe enough, the bowels will never move again and the patient will die, no matter what is done.

14. Alvarez (J. A. M. A. 65:388 [July 31] 1915) has shown by means of experiments on excised intestinal segments, that the intestinal contents move from the more active and more irritable regions of the intestine above to the more sluggish, less irritable regions below. This he calls the intestinal gradient. The regular uninterrupted progress of material in the bowel depends on the smoothness of this gradient.

15. Peet, M. M.: Rational Preoperative Treatment with Special Reference to Purgation, J. A. M. A. 7:1:175 (July 20) 1918.

16. Byford, H. T.: Purgating Before and After Abdominal Section, J. A. M. A. 7:2:474 (Feb. 15) 1919.

17. Clark, Alonzo: Pepper's System of Medicine, Philadelphia, 2:114, 1885.

Perhaps nowhere is the routine use of cathartics more firmly entrenched than in obstetrics. The dicta, "The bowels should be opened on the second day," and "When fever occurs, the bowels should be opened immediately," form the basis of orthodox precept and practice. That this custom should be abandoned is advocated by McPherson,<sup>18</sup> who showed that routine purgation after confinement is not only useless but harmful. Of 322 women who were not purged, only three had fever (and one of them had a mammary abscess); most of them had normal bowel movement; and those who did not were given an enema every third day. Of 322 women who were delivered by the same technic and the same operators but were purged in the usual routine manner, twenty-eight had some fever. He concludes that low grade fever of the puerperium may be due to catharsis, to the stirring up of colonic bacteria, and to the spreading about the mother's soft parts of loose diarrhetic movements. He also finds that, when fever develops in the puerperium, purgation does not help matters much, and occasionally makes them worse. While there may be occasional need for cathartics in the puerperium, McPherson condemns their routine administration.

For the abstraction of fluid from the system, cathartics still form a part of the time-honored routine treatment of dropsy. Drink restriction, however, seems more rational than drastics for diminishing the amount of fluid in the system; furthermore, to produce an artificial diarrhea in a waterlogged patient, who is moved about in bed with much difficulty, is a veritable torture,<sup>19</sup> and quite unjustifiable in view of the poor results obtained. Thus Gee<sup>20</sup> says: "Purgatives in dropsy are not of much use. The practice is a survival. If we cannot act upon the kidney, we should do nothing to add to the patient's discomfort."

Routine detoxication by way of the bowel has almost universal endorsement in the treatment of uremia. Still, even here it should not be used in a thoughtless manner. Many of these patients are afflicted with vomiting and purging. In such, cathartics would obviously be contraindicated. Drastic catharsis may set up an exhausting diarrhea.

From the foregoing discussion it may seem that the day for the use of cathartics is past. This is by no means the case. A measure like this, used from time immemorial, must have some intrinsic value, and everyday medical experience has established it indisputably. One thing is certain, however, the day for routine purgation has passed. When mixed (like artists' colors) with brains, cathartics still form one of our most important means of diagnosis and treatment.

#### TYPES OF CONSTIPATION IN WHICH CATHARTICS ARE USEFUL

For bed patients, to antagonize the natural tendency to constipation engendered by recumbency, cathartics are probably desirable. They generally do no harm, as, with convalescence, the normal condition of the bowel returns spontaneously. When a person previously in robust health is suddenly taken with severe illness, evacuation seems to be especially indicated. The change in the patient's condition is bound to inter-

18. McPherson, R.: The Routine Use of Cathartics during the Puerperium, Bull. Lying-In Hosp., New York, 11:118 (May) 1917.

19. Hirsch and Wagner, in Krause-Garré: Lehrbuch der Therapie Innerer Krankheiten, 2:522.  
20. Gee, S. J.: Medical Lectures and Aphorisms, Oxford Univ. Press, 1908, p. 268.

fer with the proper digestion of the food ingested a short time previously. Here, our forefathers in medicine employed emetics as well as cathartics. We may at least feel justified in hurrying through the intestine the material, whose proper digestion has become impossible by the change in digestive functions. Cathartics, even castor oil, should be avoided in typhoid fever and in measles. In these conditions, if evacuation is insufficient, enemas will have to suffice, as the production of diarrhea has been found to be distinctly detrimental.

We should, of course, avoid the routine use of cathartics, even in bed patients. Let us use them only when we must. The traditional use of calomel as the "initial purge" is probably unnecessary, and that of salines undesirable. When a cathartic is indicated in a bed patient it is generally because of deficiency in peristalsis, produced by lack of bodily movement. Hence, agents that stimulate peristalsis, as, for instance, cascara sagrada, should be employed rather than the salines, which are notoriously unreliable in bed patients, because they merely increase the bulk and fluidity of bowel contents without having much effect on peristalsis.

#### SYMPTOMATIC CONSTIPATION

There are patients suffering from symptomatic constipation rather than from the essential form, such as those with minor degrees of chronic intestinal obstruction, and those whose bowels do not functionate properly because of chronic appendical or gallbladder disease,<sup>21</sup> who can keep themselves comfortable for an indefinite time by more or less habitual use of cathartics. In such patients the constipation usually begins later in life. They generally suffer from abdominal discomfort, frequently pain, and at times from violent attacks of indigestion. They occasionally have diarrhea alternating with constipation. We must also add to this category sufferers from carcinoma of the bowel, as well as those afflicted with inflamed hemorrhoids or other painful anorectal diseases. Of course, in all of these, etiotropic therapy should be resorted to whenever possible, and surgery or massage may in appropriate cases rescue the sufferer from becoming a slave to the purge. Yet there are many who will not resort to radical treatment, or cannot have it, who can, by submitting to such enslavement, make themselves comfortable. Among those who cannot have radical treatment must be classed cases too obscure to enable one to advocate operative measures. With many a physician it is a rule of practice to prescribe to patients suffering from a chronic tendency to abdominal pain a course of laxative treatment. This procedure is not only of therapeutic but also of diagnostic value. The most useful drugs for this class of cases are either salines or oils. For painful anorectal conditions, sulphur probably also deserves consideration. We can very well understand how the liquid, or very soft bowel contents, resulting from the administration of these agents, may slip by or through a narrowing, or an adherent or otherwise disabled portion of the intestine, with less difficulty than more consistent matter would. This lessens the violence of peristalsis required from the proximal segment of the bowel, and, with it, colic or other distresses resulting therefrom.

<sup>21</sup> These may produce constipation by causing stenosis, or else by upsetting the intestinal "gradient" (Alvarez), a lower portion of the intestine having become more irritable than the portion above it.

It may also be that we reestablish a disturbed intestinal gradient by increasing the irritability of the bowel above an abnormally irritable segment. As various cathartics have special action on certain intestinal segments, for example, podophyllum on the duodenum and aloë on the colon, we can understand why, with certain patients, one cathartic, and with other patients another one, acts best. More detailed knowledge of these specific effects of purgatives on special portions of the intestine is desirable, especially as we now can localize, by means of roentgen rays, the seat of disturbance in the patient's intestine. Had we this knowledge we could predict with scientific precision which cathartic will act better in a certain patient.

The constipation of those crippled by age, incurable infirmity, or chronic systemic disease, such as kidney, liver, heart or lung affections, likewise requires habitual catharsis. The constipation, generally produced in these cases by the abnormal mode of living forced on them by their disease or debility, is liable to aggravate the underlying disturbance, thereby resulting in a vicious circle, which may be broken in on and prevented by maintaining sufficient evacuation of the bowel.

Sufferers from a weak or diseased intestine, or a weak constitution, who need habitual catharsis—just as a person with weak ciliary muscles needs eyeglasses, or a person with a weak leg needs a crutch—should have such cathartic prescribed for them with at least as much care to fit them properly as is taken in refracting a patient's eye. For habitual use, whenever possible, pill form should be preferred because of its convenience. This form of administration is, of course, impossible for those who need oils or salines; but for those who do not require softening of the stools the purgative pill must be considered ideal. The study of the best composition of such pills will be taken up later. One thing may, however, be emphasized here, namely, that a habitual pill generally needs not to be given daily. In the interest of economy, not only financial but functional as well, we should lay down the rule that the dose be taken only in the evening of those days on which no bowel movement occurred. This secures a bowel movement at least every second day, which is commonly sufficient, and saves many a dose of drug.

(To be continued)

## New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

W. A. PUCKNER, SECRETARY.

**ANTISTREPTOCOCCUS SERUM** (see New and Nonofficial Remedies, 1919, p. 272).

The Gilliland Laboratories, Inc., Ambler, Pa.

*Antistreptococcus Serum*.—The serum of horses which have been immunized with virulent strains of hemolytic streptococci; it is preserved with 0.3 per cent. of purified three cresols. Each package bears the statement: "No U. S. Standard of Potency." Marketed in 10 Cc. syringes, 20 Cc. injecting packages with Yale pump, and in 50 Cc. injecting packages.

Dosage: From 10 to 200 Cc. Better results seem to be obtained from the early intravenous injection of 100 Cc.

## TUBERCULOSIS IN HEALTH RESORTS FOR THE TUBERCULOUS

The fear of infection from contact with tuberculous patients is still widely prevalent among the laity. This phthisiophobia has often presented an obstacle to the institution of desired relief measures in the management of the tuberculous. The "fear born of ignorance" is not directed to these unfortunates alone. Even today it is frequently a difficult task to secure a suitable site for any contagious disease hospital in the vicinity of human habitations. The dread with which such an institution is still contemplated cannot be dispelled by exhortations or governmental edicts. The absence of special dangers in the environment of hygienically managed sick persons must be demonstrated in ways that will bring conviction to those capable of independent reasoning.

The experience of a community frequented by tuberculous individuals who live with and among other residents, with no attempt at segregation of the sick from the well, ought to contribute convincing data. A survey recently made of the indigenous incidence of tuberculosis at Saranac Lake in the Adirondacks affords a striking illustration.<sup>1</sup>

This settlement has grown from small beginnings in the pioneer days of the late Dr. E. L. Trudeau into a health resort of prominence for patients afflicted with tuberculosis, especially of the pulmonary type. About one fifth of the total population of several thousand persons is made up of individuals who went to live at Saranac Lake for their health. According to the statistics gathered in 1917 by Ames<sup>1</sup> under a fellowship grant of the Trudeau Foundation, the indigenous morbidity and mortality from tuberculosis were low, only 0.3 per cent. of living cases being found among the native born and 0.9 per cent. among previously healthy residents. The few facts on record for European health resorts likewise indicate that tuberculosis does not increase among the native population after tuberculous patients reside in a community, despite the assump-

tion that a concentration of infectious foci might increase the occurrence of clinical manifestations of the disease even in the presence of better hygienic surroundings. The health resorts of Colorado are not regarded as a menace to the residents. From the consensus of evidence, Ames ventures the logical conclusion that there is a minimum of danger of infection of healthy adult residents of resorts frequented by tuberculous patients. In harmony with this finding is the attitude of the inhabitants. Fear is absent. Education through observation and experience has dispelled phthisiophobia. The tuberculous person in such enlightened communities is free from the stigma that so often is a barrier to his progress, even after health has been restored.

## SCURVY IN ANIMALS

Much of the recent progress in the science of nutrition is directly attributable to the results of experiments on the lower animals. More recently, the dog, cat and rabbit, long classic subjects of feeding trials, have been replaced by smaller species, including the mouse, rat, guinea-pig and pigeon. How large a part these animals have played in establishing the rôle of vitamins in the diet, readers of THE JOURNAL have had repeated occasion to learn. Yet whenever a research, concluded through the use of some single species for investigation, brings some striking new fact of nutrition, one almost instinctively asks whether the finding is of more general application, particularly in the case of the human animal.

Lately scurvy has been the subject of lively interest among investigators. Definite symptoms, resembling in several details those found in infantile scorbutus, can be induced in the guinea-pig by dietary deficiencies. Most striking thus far are the predisposing effects of exclusive cereal diets, the curative or antiscorbutic potency of fresh fruits and vegetables, and the loss of this valuable property of foods through certain methods used in their conservation, notably heat and desiccation. It is reported that in the recent campaigns in Mesopotamia the British forces in some places were afflicted with scurvy as the result of the constant and exclusive use of dried foods.<sup>1</sup> Since the dehydration of vegetables gives promise of possibilities of conservation of crops and economy in transportation, considerable interest has been focused on the use of products thus preserved. Of course, as Prescott argues, the bearing of the animal experiments on the use of dried vegetables in the army or elsewhere is of secondary matter, since it is only under most unusual conditions that a diet would be made up entirely of dried foods, and then only for limited periods. It is more than likely that, even so, improved methods of drying may succeed in preserving the antiscorbutic potency of fresh vegetables.

1. Ames, Forrest B.: A Tuberculosis Survey of the Residents of Saranac Lake, New York, *Am. Rev. Tuberc.* 2: 37 (June) 1918; reprinted in the thirty-fourth Annual Report of the Trudeau Sanatorium for 1918.

1. Prescott, S. C.: Dried Vegetables for Army Use, *Am. J. Physiol.* 19: 573 (Sept. 1) 1919.

So long, however, as the guinea-pig experiments confront us, the danger of scurvy is an important academic question, even if not a national or regional menace. Can the more recent observations on guinea-pig scurvy be repeated in the same way in other species? It has long been known that scurvy can develop in the monkey, the analogue of man in various physiologic reactions. At the Lister Institute of Preventive Medicine in London, Harden and Zilva<sup>2</sup> have duplicated, by the exclusive use of heated foods in monkeys, the untoward scorbutic symptoms so easily developed in guinea-pigs in a comparable way. Furthermore, orange juice has again proved its antiscorbutic potency in this species also. It seems demonstrated, therefore, that scurvy in the guinea-pig, monkey and man alike is occasioned by the lack of a specific vitamin that is not stable toward heat. Added confidence is accordingly acquired in the informational value of the animal experiments.

---

#### THE FATE OF SALICYLATES IN THE BODY

One of the fundamental requisites in the rational, as contrasted with the purely empiric, use of drugs is a knowledge of precisely what happens to them in the organism, as well as of what pharmacologic effects they exert. In the long run, the influence of a potent substance may depend not only on its immediate manifestations but also on delayed reactions due to accumulations of an active compound. Some foreign substances are very promptly excreted; others tend to be stored to a greater or less extent, so that they can manifest cumulative effects; still others are in some measure destroyed within the organism. Scientific therapy must be based on a knowledge of the fate of the drugs that it employs.

The older literature on the salicylates, one of the most widely used groups of therapeutic agents, gives the impression that the salicyl radical leaves the body virtually unchanged.<sup>3</sup> According to the more recent investigations of Hanzlik<sup>4</sup> and his collaborators at the Western Reserve University School of Medicine, however, about 20 per cent. of salicylate administered to normal human individuals is destroyed, since the loss cannot be accounted for in sweat and feces, or by retention in the body. According to the view of Hanzlik and Wetzel,<sup>5</sup> this destruction is not associated with any special organs, but appears rather to be dependent on the general functions of metabolism. It goes on in excreted organs and apparently in tissue pulp. The power to destroy salicylates is by no means limited to the organs of the higher animals; for Hanzlik and

Wetzel have recently ascertained that weak solutions of sodium salicylate gradually deteriorate unless they are protected from microbiotic forms by means of efficient antiseptics. Yeasts and fungi can destroy the drug.

If the destruction of the salicyl group is a function of metabolic activity in general, it might be expected that the disappearance of salicylates will be facilitated wherever metabolism itself is augmented. In harmony with such a hypothesis, Hanzlik and Wetzel note increased loss of administered salicylate in fevers, principally in rheumatism and tuberculosis. In nephritis, in which the retention of the drug because of diminished renal excretory capacity might expose it to a greater chance of destruction by the tissues, the theory seems to be confirmed by the observed facts. Drug habitués addicted to the use of alcohol and morphin were found to excrete much less salicyl than normal persons, owing perhaps to an acquired power of their organisms for increased destruction of drugs.

It is a fact familiar to therapeutists that a low concentration of salicyl in the blood and tissues, which must be the result of smaller doses of salicylates and related compounds, is not an effective antiseptic within the body. The destruction of the drug may afford the reason for this and also indicate why large doses are required to secure therapeutic effects.

#### REACTIONS TO CHILLING OF THE BODY SURFACE

There can be little doubt that chilling of body surfaces may become a contributory factor, if nothing more, in the etiology of pharyngitis, tonsillitis, rhinitis, etc. Although popular writers on health topics tend to decry the fear of drafts as something unworthy of a present-day adult, it will not be easy to convince an unprejudiced observer that the dread of danger from exceptional exposures belongs to the category of hygienic superstitions. Pathogenic bacteria undoubtedly exist on the mucous membranes of the nasopharynx frequently if not continually; yet it is only at certain times that they unfold an undesirable activity.

What makes the mucosa more susceptible to microbial activities after undue exposure of the exterior of the body? One of the familiar explanations of the reaction to cutaneous chilling is that the blood, being driven away from the surface of the body, is directed inwardly so that congestion of the internal parts and organs results. The assumed vasodilatation with its stasis of the vessels in the mucous membranes is thereupon supposed to alter the resistance of the latter to bacterial invaders. Strangely enough, this hypothesis fails to conform with certain facts that have lately been discovered by Mudd and Grant<sup>6</sup> at the Washington

University School of Medicine. They have shown ingeniously by direct measurement of the temperature of the skin and of oral and pharyngeal mucous membranes that it actually falls with chilling of distant areas of the body surface and rises again when the person is warmed externally. There is no congestion such as one has been led to expect from much of the current literature on the subject. On the contrary, to quote the St. Louis investigators, their experiments show that chilling of the body causes reflex vasoconstriction and ischemia in the mucous membranes of the palate, faucial tonsils, oropharynx and nasopharynx.

These unexpected findings call for new assumptions to explain the genesis of the "sore throat." We can only reiterate the latest hypothesis presented by Mudd and Grant for criticism. It seems not improbable, they say, that the ischemia incident on cutaneous chilling, by decreasing cell respiration, or by retarding removal of the products of cell metabolism, or by increasing the permeability of the epithelial cell surfaces to bacterial products, or by decreasing the local supply of antibodies, or by altering the media of the tonsillar crypts and folds of pharyngeal mucosa in which bacteria are living, or by a combination of such factors, so disturbs the equilibrium between the host and the micro-organisms as to excite infection. The fact that ischemia occurs where congestion has been assumed heretofore to arise is an important contribution; the discussion which has followed this fact must still be regarded as nothing more than a working hypothesis.

## Current Comment

### ADMITTING OUR LIMITATIONS

Ecclesiasticism in medicine, fortunately, is practically a thing of the past. Mystery is left to the quack and the "patent medicine" maker. Modern medicine is not sacro-sanct. There are still, however, some physicians who seem to think that, in medicine at least, open confession is not good for the soul. At fairly regular intervals THE JOURNAL receives protests from correspondents against the misuse by some of the cults and "pathies" of the published statements of well-known physicians. A few days ago a physician sent in a booklet that is sold by a chiropractic concern for the use of the followers of that trade. The booklet, of course, eulogizes chiropractic and damns scientific medicine. The peroration contains a quotation credited to Dr. Richard C. Cabot and said to be taken from his "Layman's Handbook of Medicine." It is to the effect, briefly, that the number of specific drugs is limited and that, in most cases, nature, with some help from the physician, accomplishes the cure. Our correspondent was disturbed because he thinks statements similar to that credited to Cabot will break down the public's confidence in scientific medicine. He says, further, that Osler is another man whose public statements have the same tendency. He even inquires, facetiously of course, "Do you suppose Cabot is

employed by the chiropractors to write such literature?" Some of us are likely to forget that scientific medicine does not suffer from a frank admission of its limitations. Such admissions in any science mean progress. Incidentally, one of the greatest indictments against proprietaryship in medicine is the fact that such proprietaryship stifles medical progress because all alleged successes are played up and all failures ignored. Supposing we do admit the limitations of modern medicine. What of it? These limitations exist and it is not only foolish but dishonest to pretend they do not. Yet, in spite of these limitations modern scientific medicine has more to offer the human race in the prevention and cure of disease than all the cults "pathies and fads in existence, and deep down in its inner consciousness the public knows it. Of course, fakers will glibly quote any statement made by reputable physicians that can be twisted into a depreciation of scientific medicine. So, too, will the devil continue to quote Holy Writ.

### LEPTOSPIRA ICTEROIDES AND YELLOW FEVER

In the course of the interesting studies of Noguchi of the Rockefeller Institute of Medical Research on the etiology of yellow fever, it has been demonstrated that the micro-organism *Leptospira icteroides*, which he regards as responsible for the disease, conforms with the well known characteristics of the yellow fever virus in respect to transmission by mosquitoes. Symptoms and lesions closely resembling those of yellow fever in man may be induced in guinea-pigs by the bite of female stegomyia mosquitoes that have previously sucked the blood of animals experimentally infected with *Leptospira*.<sup>1</sup> Noguchi has confirmed older observations that even under natural conditions the percentage of mosquitoes that become infected with the organism of yellow fever by sucking the blood may be very small. He estimates that a single female stegomyia may take up not more than 0.01 c.c. of blood, whereas it requires from 0.1 to 2 c.c. of blood from a patient at the height of the disease to transmit the infection to a nonimmune person. In other words, according to Noguchi,<sup>1</sup> a mosquito occasionally becomes infectious by taking up the one or two micro-organisms that happen to be circulating in the peripheral blood of man, and it is these occasionally infected few that carry the disease. Noguchi has secured further information of value in regard to the behavior of *Leptospira icteroides*. This organism is associated in its development with blood serum, which is supplied by the blood-sucking insect. It cannot survive the concurrence of other "less fastidious organisms, such as bacteria." For this reason, the comparatively aseptic body cavity of the stegomyia furnishes a secure shelter for the parasite which, owing to its capacity to penetrate bacteria-proof filters, probably soon pierces the tissues of the alimentary tract after it enters the mosquito and reaches a spot favorable to its maintenance. The temperature range favorable for the multiplication of *Leptospira icteroides* is from 18

1. Noguchi, Hideo: Etiology of Yellow Fever, IX, Mosquitoes in Relation to Yellow Fever, J. Exper. Med. 30: 401 (Oct.) 1919.

to 37 C. (64.4 to 98.6 F.), with an optimum of 26 C. (78.8 F.), at which it remains viable for a long time. Accordingly, Noguchi points out, the climate in most tropical countries, where yellow fever flourishes, offers optimum conditions both for *Leptospira icteroides* and for the mosquito that harbors and nourishes it.

#### THE EFFICACY OF ANTIRABIC TREATMENT

In the warfare that modern medicine still is called on to wage against the studied hygienic agnosticism of a variety of cults of nonmedical "healers," the statistics of the elimination of disease by vaccination and other modes of sanitary prophylaxis are always a weapon of strength. There is a never-failing source of satisfaction to medical men in the continued demonstration of the blessing conferred on humanity by Pasteur's discoveries. Year after year the records of the success of the antirabic treatment inaugurated by him bring evidences of the indisputable efficacy of therapy based on science rather than on occult phenomena and mysterious personal potencies. During 1918 no less than 784 persons received antirabic treatment at the bacteriologic institute in Lyons, France. More than half of them had been bitten by animals actually demonstrated to have been suffering from rabies. There was not a single death among the patients treated. Since 1900 more than 11,000 persons from the vicinity of Lyons have received antirabic treatment. Only ten persons have failed to be protected, representing a mortality of 0.08 per cent.<sup>1</sup> Of course, those who still proclaim disease to be a myth and who deny the menace of micro-organisms will find nothing remarkable in this record. Fortunately for mankind, those who are so unlucky as to be victims of attacks from mad animals are rarely content to make a trial of "absent treatment" or allied methods.

#### SOME FEATURES OF INTESTINAL PARASITIC INFECTIONS IN CHILDHOOD

So long as an adequate inspection of the children in a group of public institutions can show an incidence of intestinal parasites ranging from 18 to as high as 90 per cent. of the juvenile population in such places, the problem of these infections demands careful study. The figures just quoted were the result of an examination made by De Buys and Dwyer<sup>2</sup> of the stools of nearly 600 persons in seven institutions. The observations indicate that the symptoms commonly regarded as indicative of the presence of "worms" are by no means dependable for purposes of accurate diagnosis. Thus, grinding of the teeth, scratching of the nose, disturbed sleep, ravenous appetite and lassitude were observed in noninfected as well as in infected children. Consequently we are ready to agree with the investigators who established these facts that a necessity exists of emphasizing the importance of a tenable diagnosis

before subjecting any person, and particularly small children, to the ordeal of unnecessary medication to eliminate intestinal parasites. Either the parasites or their ova should be searched for and found prior to the enforcement of anthelmintic therapy. The eosinophilia, valuable though it may undoubtedly be as an indication toward the diagnosis of infection with intestinal parasites, is of course not pathognomonic. None of the more familiar parasites seem to have a definite eosinophilia; and infection with each of them has been demonstrated to occur in the absence of eosinophil increments in the blood. In the group of cases examined by Du Buys and Dwyer, *Trichuris trichiura* was the parasite most frequently found. The other species were, in the order of frequency, *Ascaris lumbricoides*, *Hymenolepis nana*, *Oxyuris vermicularis*, *Strongyloides stercoralis*, *Necator americanus* and *Hymenolepis diminuta*. It is reported that the personal habits and environment of the children seemed to have a direct bearing on the frequency of intestinal parasitic infections. It is significant that, of the institutions studied, they were the most prevalent in those in which systematic medical inspections were never made. From the standpoint of the public health, such facts call for prompt recognition and corresponding official action.

#### NEWSPAPER PROMOTION OF MERCURIC CHLORID POISONING

At regular intervals, to use an ancient metaphor, medical science is butchered to make a newspaper holiday. Few poisons have been so thoroughly investigated as has mercuric chlorid. No other poison has been so popularized by the lay press as has this particular drug, beginning with the case of the Georgia banker of several years ago and, today, concerning the Detroit children dramatically poisoned by a mentally deficient mother with dramatic aspirations. It may be well to recall that no one has contradicted the statement of Sansum<sup>3</sup> based on good experimental evidence—utilizing Carter's and other known methods of treatment—that "it would appear . . . that when 4 mg. or more of mercuric chlorid per kilogram of body weight has entered the tissues at large, death regularly occurs, and that we have no adequate grounds for believing that death is preventable by any known form of treatment." A moment's reflection concerning the recent cases will suggest to the intelligent physician what the facts and the possibilities were. He needs but to bear in mind that the actual amount of mercury received and retained by each child is unknown; that it was several days before any treatment at all was administered, and that almost two weeks had elapsed before the children were brought to Chicago to receive such ministrations as the sensationally advertised specialist might have given them.

## Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

### COLORADO

**New Officers.**—At the forty-ninth annual session of the Colorado State Medical Society, held in Denver, October 7-9, under the presidency of Dr. Francis H. McNaught, Denver, the following officers were elected: president elect, Dr. Frank R. Spencer, Boulder; vice presidents, Drs. Walter S. Chapman, Walsenburg, Josephine N. Dunlop, Pueblo, Guy C. Cary, Grand Junction, and Burgett Woodcock, Greeley; secretary, Dr. Crum Epler, Pueblo (hold over); treasurer, Dr. William A. Sedwick (hold over); delegate to the American Medical Association, Gerald B. Webb, Colorado Springs, and alternate, Dr. Horace G. Wetherill, Denver. The 1920 meeting will be the golden anniversary of the society. The meeting will be held at Glenwood Springs, in September, at a date to be fixed later.

### DISTRICT OF COLUMBIA

**Medical Society Makes Drive for Building Fund.**—The District of Columbia Medical Society is making a drive to raise \$35,000 during October, this amount being the balance needed to complete the society's building fund of \$75,000. The building is to be located on a downtown site which has been purchased. The first floor will be composed of an auditorium seating 600, two committee rooms, two offices and cloakrooms. The second floor will have a library and banquet hall. An important feature will be facilities for registering visiting physicians so that they may obtain their mail at the building.

### FLORIDA

**Examination of Schoolchildren.**—The work of examining the 200,000 schoolchildren of Florida started, October 1, under direction of the child welfare department of the state board of health. Each child will be given a thorough examination, and through a careful follow-up system parents will be notified of any defects to be corrected, with suggestions looking to the physical welfare of the child.

**In Registration Area.**—Efforts of Dr. Stewart G. Thompson, vital statistician of the state board of health, to place Florida in the death registration area were successful last week, when Dr. Ralph N. Greene, Chattahoochee, state health officer, received notification from the U. S. Bureau of Census that the recently completed check showed that more than 90 per cent. of the deaths in this state are registered.

**Personal.**—Col. Raymond C. Turck, Jacksonville, will retire from active practice when he returns from France, according to statements in letters to friends. Colonel Turck was twice gassed, and was awarded the Croix de Guerre, a citation from Marshal Pétain, and the Distinguished Service Cross for gallantry in action.—Dr. W. A. Klaxton, who saw several years' service at the front with the Canadian forces, has lately received his discharge and is now laboratory man of the state board of health at Tallahassee.—Lieut.-Col. William J. Bue, Gainesville, in charge of the base hospital at LeMans, France, during the war, has been discharged from service and has accepted the appointment of assistant state health officer of the state board of health.

**Florida Opposes Leper Colony.**—Acting under the authority of an act of Congress, the U. S. Public Health Service has been seeking an appropriate place in which to establish a national leper colony. After a long, exhaustive survey of the whole country it has finally selected two islands off the coast of Florida. Now the governor and many citizens of Florida are making a strenuous fight against the proposition, claiming that it will injure the good name of Florida as a health and pleasure resort. The islands in question have been pronounced most ideal for a leprosarium. Cedar Key, opposite which the islands are located, was at one time quite a prosperous center on account of the fishing industry. It is reported, however, that this industry has fallen off considerably and that the town is favorable to the dedication of these islands for this humanitarian purpose.

### ILLINOIS

**Conference of Charities.**—The State Conference of Charities and Corrections will be held in Decatur, October 24 to 26, with headquarters at the Orlando Hotel. Among the chief topics of discussion will be family, rural social service, conference extension, the child, correctional program, a plea for mental clinics for schools, and community service.

**Personal.**—Capt. Bellenden S. Hutchinson, V. C., Canadian A. M. C., medical officer of the 75th infantry, a practitioner of Mound City and Chicago, who served for four years with the Canadian Forces and is said to be the only American born officer to receive the Victoria Cross, the highest award for bravery in England, is on leave and visiting friends in Chicago and in Mound City.—Dr. Joseph De Silva, Rock Island, is reported to be seriously ill at St. Anthony's Hospital, Rock Island, suffering from septicaemia.

**Banquet to Pana Physician.**—Members of the staff of the Juber Memorial Hospital, Pana, and ladies were guests, October 3, at the supper served at the hospital, at which Sister Marie, the new sister superior, delivered an address on the general betterment of the hospital. The banquet also marked the organization of the staff of the hospital, the present officers of which are: president, Dr. John H. Miller; vice president, Dr. Roscoe C. Danford, and secretary, Dr. Frederick J. Eberspacher.

### Chicago

**Personal.**—Dr. Arthur W. Stillians has been appointed head of the department of dermatology in Northwestern University Medical School.—In the suit brought by Mrs. Dell Nichols against Dr. Daniel A. K. Steele, in which \$50,000 damages was claimed because of alleged loss of voice, said to have been due to a surgical operation by Dr. Steele, the jury in the superior court, October 11, brought in a verdict in favor of Dr. Steele.

**Resignations from the Faculty of Loyola University School of Medicine.**—The following physicians have resigned from the faculty of the Loyola University School of Medicine: Dr. Lawrence Ryan, dean and professor of surgery; Dr. William J. Butler, professor of medicine; Dr. John S. Nagel, professor of genito-urinary diseases; Dr. George W. Funck, professor of pharmacology, Dr. Arthur W. Stillians, professor of dermatology, and Dr. William D. Zoethout, professor of physiology.

### MARYLAND

**Personal.**—Lieut.-Col. William J. Coleman has returned to Baltimore after twenty-eight months in hospitals in France and Germany as a member of the Medical Corps. Dr. Coleman went overseas with the 116th Field Hospital and served in Alsace at Evacuation Hospital No. 8, near Verdun, at Coblenz, and later at Neunahr, Germany, where he had charge of an American Hospital.—Dr. Charles L. Mattfeldt, Catonsville, health officer of the First District, is seriously ill at St. Agnes Hospital, suffering from a carbuncle.

**New Clinic at the Johns Hopkins Hospital.**—Dr. Winifred H. Smith, Baltimore, has announced that work will be begun in the spring on a woman's clinic at the Johns Hopkins Hospital, which will offer facilities for study and observation in obstetrics and gynecology. The clinic will have a large staff in charge of Dr. J. Whitridge Williams. A one-story and two-story building connected by a corridor will be remodelled into a large five-story structure. The work is to cost approximately \$400,000. The greatest expansion will be in the obstetric department, in which in addition to accommodations for 150 patients, extensive facilities for research and experiment, with laboratory equipment, will be provided. A new nursery will be equipped. These plans also contemplate a building which, if constructed at present prices, would cost at least \$1,500,000, and would be seven stories high. Such a building would enable all departments of the dispensary to be in operation simultaneously.

**Women Physicians Visit Johns Hopkins.**—During a recess in sessions of the International Conference of Women Physicians in New York, thirty-five distinguished women physicians from foreign countries visited the Johns Hopkins Hospital recently and studied facilities at the institution. The general program for the day was arranged by Dr. Florence R. Sabin, Baltimore, who received the delegates. The first inspection was of the gynecologic department, where Drs. Howard A. Kelly, Guy L. R. Lunnner and Thomas S. Cullen acted as pilots. At the Harriet Lane Home, an exhibition of children's diseases was prepared. Dr. John J. Abel, Woodlawn, gave a short address on the general subject of physiology, followed by a talk on dietetics by E. V. McCollum. Dr.

George L. Streeter gave a talk on embryology. Luncheon was served at 1 o'clock, after which Dr. Adolf Meyer, Baltimore, head of the Henry Phipps Psychiatric Clinic, lectured on the work of his department. The remainder of the afternoon was devoted to a study of the obstetric department.

#### MICHIGAN

**Full Time Health Officer Elected.**—Dr. David Littlejohn, St. Joseph, has been elected full time health officer of Flint, succeeding Dr. J. S. Craig, who declined to qualify for the position.

**In the Hands of the Law.**—John F. Roehl, chief inspector of the state health department, is said to have arrested three men of Detroit, September 10, suspected of practicing medicine without a license. They are John W. Wood, Paul Lewis and Tom Kresanthopolis.

**Typhoid at Muskegon.**—An investigation just completed at Muskegon by the engineering department of the state board of health, at the request of the city physician, shows that there have been twenty-five cases of typhoid fever in the city since February 3. The source of the disease is believed to be the water supply.

**Serum Tests at Kiefer Hospital.**—Dr. Henry F. Vaughan, health commissioner of Detroit, announces that twelve tests in the Herman Kiefer Hospital will be placed at the disposal of the Wayne County Cancer Committee, of which Dr. J. Henry Carstens is chairman, that a thorough test may be made of the Koch cancer serum.

**The Passing of Oak Grove Hospital.**—The directors of the Oak Grove Hospital, Flint, announce the contemplated retirement of the institution from the field of psychiatry at the expiration of its corporate life, April 28, 1920. It is hoped that the building and grounds may be kept as a city park in the possession of the public in perpetuity, otherwise the property will be sold as a high school site.

#### MINNESOTA

**Personal.**—Drs. Herman W. Froehlich, Oscar F. Melloy, Andrew J. Paulson and Lawrence F. Fisher, all of Thief River Falls, have associated in practice, and the entire east end of the second floor of the Citizens State Bank Building is being remodeled for their accommodation. A total of twelve rooms will be devoted to the various lines of work of these physicians.—Dr. Robinson Bosworth, St. Paul, has been elected president of the Mississippi Valley Sanatorium Association.

**New State Officers.**—At the fifty-first annual meeting of the Minnesota State Medical Association, held in Minneapolis, October 1-3, under the presidency of Dr. George Douglas Head, Minneapolis, for the following officers were elected: president, Dr. John H. Adair, Owatonna; vice presidents, Drs. Edward M. Clay, Renville, Claude B. Lewis, St. Cloud, and Henry C. Cooney, Princeton; secretary, Dr. Earle K. Hare, Minneapolis (reelected); treasurer, Dr. Frederick L. Beckley, St. Paul; delegate to the American Medical Association, Dr. John W. Bell, Minneapolis, and alternate, Dr. Alfred E. Spalding, Luverne.

**Society Loses Charter.**—Cancellation of the charter of the Brown-Kedwood Medical Society was announced by the Minnesota State Medical Association at its recent meeting in Minneapolis, on account of its failure to try Dr. Louis A. Fritsche, New Ulm, who was removed from the office of mayor by Governor Burnquist on charges brought by the public safety commission. After this action the state medical association passed a resolution giving the society three months in which to bring Dr. Fritsche to trial. As this was not done, the council recommended charter revocation, and this was supported by all excepting two member of the House of Delegates.

#### MISSOURI

**Negro Physician Fined.**—September 12, Judge Ralph S. Latschaw is said to have affirmed the fine of Dr. B. B. Paekson, Kansas City, for writing prescriptions for habit-forming drugs in violation of the federal antinarcotic law.

**Ex-Service Physicians Organize.**—At a meeting held in Kansas City, September 29, physicians who were formerly in the military service organized, and Dr. George E. Bellows was elected temporary chairman, and Dr. Ernest G. Stark, temporary secretary.

**Few Take Tuberculosis Treatment.**—Although under a recently enacted state law, it is possible for persons suffering from incipient tuberculosis to obtain free treatment at

the State Sanatorium, Mount Vernon, the average number treated at that institution is only 198 while it has a capacity of 300. In the children's building with a capacity of eighty patients, only thirty-five are under treatment.

**Personal.**—Dr. John C. Murphy, formerly gynecologist in the St. Louis City Hospital, has been honorably discharged from the Army and will reside in New York.—Dr. Fred W. Bailey, St. Louis, has been elected post commander of Walter Reed Post No. 136, American Legion.—Dr. Edward L. Cooley, St. Louis, announces that the appearance of his name in the catalogue of the St. Louis College of Physicians and Surgeons is unauthorized as he has no connection whatever with that institution.

#### NEBRASKA

**Announces Medical Examiners.**—The secretary of the department of public welfare has announced the following board of medical examiners: Drs. H. J. Lechnoff, Lincoln, E. T. McGuire, Mead, and J. E. Pratt, Fairfield.

#### NEW MEXICO

**State Society Meeting.**—At the annual meeting of the New Mexico Medical Society held in Albuquerque, October 3 and 4, the following officers were elected: president elect, Dr. Hugh V. Fall, Roswell; president, Dr. Charles A. Frank, Albuquerque; vice presidents, Drs. Chester Russell, Artesia, Frank E. Mera, Santa Fe, and Franklin H. Crail, East Las Vegas; secretary, Dr. Frank E. Tull, Albuquerque; treasurer, Dr. John W. Elder, Albuquerque; delegate to the American Medical Association, Dr. William T. Joyner, Roswell; alternate, Dr. Charles H. Churchill, Madrid. Roswell was selected as the next place of meeting.

#### NEW YORK

**Personal.**—Dr. William A. Holla, Tompkins Corners, has been appointed coroner of Putnam County, succeeding Dr. Parker, deceased.

**Central State Physicians to Meet.**—The annual meeting of the Medical Association of Central New York will be held in Syracuse, October 30.

**Conference on Child Welfare Legislation.**—The regents of the state of New York held a two day conference on child welfare legislation in Albany, October 17 and 18. Among those present at the conference were representatives of labor, health agencies, manufacturers and merchants.

**New State Hospitals.**—The governor of New York, September 13, dedicated the site, and broke ground for the new state hospital for the insane, about 6 miles from Utica. The building when constructed will house more than 3,000 patients, and for this construction the expenditure of \$2,000,000 has been authorized.—Plans are being developed by the hospital development commission for a state psychopathic hospital for New York City, which will be the research department of the state hospitals for scientific studies into the cause and treatment of insanity.

**Establishment of a Dental Clinic in Public Schools.**—A determined effort is being made by the committee on oral hygiene in the First District Dental Society in the City of New York for the establishment and operation of a free dental clinic in every public school in the city of New York. The adoption of the plan of procedure was followed by the adoption of the same plan by the second district society. Letters have been sent to every minister, every principal of a public school and every teacher, asking them to promote the signing of petitions for this purpose and themselves to work for the establishment of the clinics in oral hygiene.

#### New York City

**Personal.**—Dr. Charles Gluck has returned from service in the army and has resumed his practice in Manhattan.—Dr. William A. P. Garrigues has been appointed consulting neurologist and psychiatrist to the Manhattan State Hospital for the Insane, Ward's Island.—Dr. Samuel Lloyd has returned from service in France and has resumed the practice of medicine in this city.

**Permanent International Exposition of Municipal Equipment.**—In connection with the opening of a permanent exposition of municipal equipment in Grand Central Palace, a convention was held during the week of October 20, at which a demonstration was given of the pasteurization of milk and the testing of clinical thermometers. The permanent features of the exposition include a model hospital section, a health center and other exhibits having to do with public health administration.

**Nonmunicipal Hospitals Report Large Shortage of Funds.**

The annual report of the nonmunicipal hospitals of this city shows that these institutions face a deficit of more than \$3,000,000. This deficit is due to the increased cost of hospital operation. The daily cost of maintaining nonpaying patients has risen from \$2.02 in 1914 to \$3.13 in 1919, an increase of 58 per cent. For 1919 the per capita cost is estimated at \$3.50. Last year these hospitals gave free care to 147,422 patients, aggregating 1,202,078 free days. The cost of maintenance for the forty-six hospitals belonging to the association in 1918 was \$9,073,065.

**NORTH CAROLINA**

**Typhoid Develops After Negro Camp Meeting.**—A negro camp meeting was held at Tucker's Grove, Lincoln County, the latter part of August, and more than fifty cases of severe typhoid fever has developed among the negroes in attendance as the result of drinking from a local water supply of questionable character. Two deaths had resulted up to September 20.

**District Physicians Meet.**—At the annual meeting of the Eighth District Medical Society, held in Greensboro under the presidency of Dr. John A. Williams, Greensboro, Winston-Salem was selected as the next place of meeting, and Dr. Frederic M. Hanes and Dr. Wingate M. Johnson, both of Winston-Salem, were elected president and vice president, respectively.

**Personal.**—Drs. Lester C. Todd and Hamilton W. McKay have been added to the staff of the Crowell Urological Clinic, Charlotte.—Dr. R. G. Keiger, Statesville, who has been in charge of the North Carolina bureau for the treatment and prevention of venereal disease, has resigned and has been succeeded by Dr. Millard Knowlton, who has recently been doing work in the United States Public Health Service in Montana.—Dr. James R. Gordon, Raleigh, for six years chief of the bureau of vital statistics of the state board of health, has resigned to engage in stock farming. The bureau will be coordinated with the bureau of epidemiology, and both will be under the charge of Dr. Frank M. Register, Jackson, who recently succeeded Dr. Auley M. Crouch, Raleigh, as state epidemiologist.—Dr. Thomas Stringfield, Waynesville, has been appointed inspector-general, N. C., X. G., with the rank of colonel.—Dr. J. A. Moore has been appointed instructor in histology at the University of North Carolina.

**OHIO**

**Appropriation for Influenza.**—At the meeting of the Cleveland City Council, October 6, an appropriation of \$12,000 was authorized to be used in influenza prevention work.

**Crile Endows Chair at Western Reserve.**—It is reported that Dr. George W. Crile has given \$100,000 for the endowment of a chair of surgery in Western Reserve University Medical School.

**Academy Reopens.**—The fall session of the Cincinnati Academy of Medicine was inaugurated, September 29. Dr. Charles A. L. Reed, delivered an address advocating a wider co-operation of medical men in political affairs of the nation, state and municipality.

**An Industrial Medicine Department Announced.**—It is announced by the president of the University of Cincinnati that \$30,000 of the \$100,000 to be raised by the Ohio business men for support of the Department of Industrial Medicine in process of affiliation with the University of Cincinnati has been raised. Under the auspices of the department, a series of lectures on housing was begun on Thursday evening, October 2.

**Personal.**—Dr. Jonathan Forman, who recently resigned from the position of assistant professor of pathology in the Ohio State University College of Medicine, Columbus, has been appointed teaching professor of physiology in the Medical School of Harvard University.—Dr. Thomas H. Kelly, Cincinnati, was operated on for appendicitis, October 2.—William H. Peters has been reappointed health officer of Cincinnati.—Dr. Phillips A. Jacobs, Cleveland, has been elected coroner of Cuyahoga County.

**Exceed Requirements of Hughes Act.**—The counties of the state, almost without exception, are going beyond minimum of the Hughes act in establishing the new district health department, which will begin operation, January 1. Almost all counties have provided for more workers than the health commissioner, nurse and clerk required by the law. Many of the counties have provided for a salary of from \$3,000 to

\$4,000 a year for health commissioners, and staffs of three or more nurses, and a deputy and sanitary inspectors as may be required by local conditions.

**PENNSYLVANIA**

**New Hospital Plans.**—Following the convention of the National Tuberculosis Association held at the Bellevue-Stratford, October 9 and 10, a movement is on foot to have the city appropriate \$500,000 for a municipal tuberculosis hospital with 500 beds.

**University Hospital Gets Many More Subscriptions.**—Subscriptions received since the close of the University Hospital, October 15, have brought the total up to the \$558,292 mark. The belated subscriptions are being received so rapidly that campaign managers believe the drive may reach its \$1,000,000 goal.

**Personal.**—Dr. B. Franklin Royer, Harrisburg, for ten years associated with the Pennsylvania State Department of Health and acting commissioner of health for one year following the death of Dr. Samuel G. Dixon, has recently been elected chief executive officer of the Massachusetts-Halifax Health Commission which was recently incorporated under an act of the provincial legislature of Nova Scotia.

**Street Crossing Campaign.**—As a result of statistics given to the Rotary Club by Capt. W. B. Mills, assistant superintendent of police, that organization has started a "cross at crossings" campaign and 30,000 posters will be distributed throughout the city. According to Captain Mills, 53,000 persons were injured at street accidents, last year. Of these, 253 were killed outright, 960 were run down by trucks, 2,298 by touring cars, and 1,408 by trolley cars. Of the total number, 2,250 persons were injured because they did not use street crossings.

**RHODE ISLAND**

**New Hospital for Washington County.**—Washington County is to have a hospital at Wakefield, under a charter just issued by the secretary of state. The institution will care for all citizens in the southern part of the state. The South County Hospital Association is the name of the corporation, which will establish and maintain the institution with the aid of voluntary support.

**CANADA**

**Personal.**—Dr. Robert M. Mitchell, superintendent of the Weyburn Mental Hospital, Saskatchewan, has been on a tour of inspection of mental hospitals in the United States and Canada. Among other places visited in Canada were Toronto, Coburg, Whitby, Kingston and Brockville; in the United States, New York and a branch of the Rockefeller Institute in Baltimore.

**Medicolegal Case.**—An unusual case is being tried in the supreme court of Nova Scotia. The plaintiff is suing three doctors of Sydney Mines for damages, alleging negligence and malpractice on the part of the defending physicians for the death of one of his children. The death of the child took place in September from diphtheria, and no antitoxin was administered. One of the defendants is the medical officer of health of Sydney Mines.

**Expenditure on Venereal Diseases.**—The federal government of Canada has set apart \$200,000 for the venereal diseases campaign. Of this amount \$10,000 is to go to the National Council for the Suppression of Venereal Diseases; \$10,000 for the Dominion Department of Health; the balance of \$180,000 is to be distributed among the various provinces of Canada in ratio of population, provided the provinces are willing to devote an equal amount for the same purpose.

**Advisory Board on "Patent Medicines."**—An order in council has been approved at Ottawa, appointing the following members as an advisory board to the department of health on proprietary medicines: Dr. Alexander D. Blackader, Montreal, professor of pharmacology, McGill University; Dr. Robert D. Rudolf, professor of therapeutics in the University of Toronto; Dr. A. McGill, chief analyst for the federal government at Ottawa; Dr. E. W. J. E. W. Lecours, professor of pharmacy, Laval University; Dr. Charles F. Hebbner, dean of the College of Pharmacy, Toronto.

**GENERAL**

**Division of Medicine, National Research Council.**—Dr. Henry A. Christian, Boston, has been appointed chairman of the division of medicine of the National Research Council. This will make it necessary for Dr. Christian temporarily to

move to Washington, D. C. He has been granted a year's leave of absence from his position at the Peter Bent Brigham Hospital and Harvard Medical School.

**Southwest Physicians Elect Officers.**—At the annual meeting of the Medical Association of the Southwest, held at Oklahoma City, October 6 to 8, the following officers were elected: president, Dr. Ernest F. Day, Arkansas City, Kan.; vice presidents, Drs. Horace Reed, Oklahoma City, G. H. West Robinson, Kansas City, Mo., William H. Denderick, Hilt Springs, Ark., and Walter T. Wilson, Navasota, Texas, and secretary, Dr. Fred H. Clark, El Reno, Okla., for the sixteenth consecutive term.

**Military Surgeons Elect Officers.**—At the annual meeting of the Association of Military Surgeons of the United States, which was held in St. Louis, October 13 to 15, under the presidency of Col. Henry P. Birmingham, M. C., U. S. Army, New Orleans was selected as the place of meeting for next year, the time set being three days immediately preceding the meeting of the American Medical Association. The following officers were elected: president, Lieut.-Col. Joseph A. Hall, M. C., O. N. G., Cincinnati; vice presidents, Asst. Surg.-Gen. John W. Kerr, U. S. P. H. S., Washington, D. C., Capt. Frank L. Pleadwell, M. C., U. S. Navy, Washington, D. C., and Brig.-Gen. Francis A. Winter, M. C., U. S. Army, Washington, D. C., and secretary-treasurer-editor, Col. James Robb Church, M. C., U. S. Army, Washington, D. C., reelected.

**Bequests and Donations.**—The following bequests and donations have recently been announced:

New York Society for Ruptured and Crippled, and Nursery and Child's Hospital, New York City, each \$50,000; St. Luke's Hospital, New York City, and Tarrytown, N. Y., Hospital, each \$25,000 by the will of Mrs. Mary J. Kingsland.

Woman's, Lyngby, St. Luke's, Sydenham, Presbyterian and Children's Hospitals, New York City, and three additional hospitals, to be named by the testator's son, \$300,000 each by the will of Solomon Schwasi. A large part of the estate of the testator is to be used in the establishment of the Solomon Schwasi Memorial Hospital.

For a city hospital at Monticello, Ill., to be known as the John and Mary E. Kirby Hospital, a bequest of \$100,000 and the residence property of the late John Kirby.

Fund for the restoration of the San Diego Mission, a donation of \$1,000 from Dr. Marshall O. Terry, New York City.

**Legislation for Instruction in Hygiene.**—A bill to encourage instruction in the hygiene of maternity and infancy and for the promotion of instruction and care in maternity through state cooperation has been introduced in the United States Senate by Senator Morris Sheppard of Texas. The bill provides for an appropriation of \$480,000 to be divided among the states which meet the requirements of the measure. For the next fiscal year, ending June 30, 1921, \$1,000,000 is appropriated with increased amounts for the subsequent five years, after which the annual appropriation is to be \$2,000,000. The administration work is placed with the children's bureau of the U. S. Department of Labor and the various states are required to appoint commissions to conduct the work. The circulation of information on this and allied subjects is the principal purpose of the act. Aid also is provided for colleges and universities for extension courses. A similar measure recently was introduced in the House. The measure has been referred to the Senate Committee on Public Health for consideration.

## FOREIGN

**Deaths in the Profession Abroad.**—Dr. R. Rodríguez Méndez, expofessor of hygiene at the University of Barcelona, director of the *Gaceta Médica Catalana* and member of the editorial staff of the *Revista de Medicina y Cirujía Prácticas* of Madrid since its foundation in 1877. His pupils and other friends recently published an important *libro de honor* in homage to this eminent Spanish hygienist.—Dr R. E. Bion of Zurich succumbed to chronic nephritis assuming a fulminating course, probably the result of infection of the finger on two occasions, compelling amputation, aged 52.

**Graduate Courses on Pulmonary Tuberculosis at Paris.**—It is announced from Paris that a course on pulmonary tuberculosis has been arranged at Paris to be given three times during the year 1919-1920, by specialists, including Drs. Bezançon, E. Rist, G. Kuss, E. Sergent, P. Teissier and L. Bourgeois. Each course is to cover six weeks, commencing October 15, April 15 and June 15. The courses will be eminently practical and will include physical diagnosis, pathologic anatomy, social hygiene, and the technical administration of dispensaries. The lectures will be held in the afternoon and the mornings will be devoted to individual

work in hospitals or dispensaries in the services of the physicians giving the course. The courses are open to all physicians of France or the allied nations or friends of France. For further details address Dr. E. Rist, 5 rue de Magdebourg, Paris. The Rockefeller Commission for the Prevention of Tuberculosis in France has recently announced that it has a limited number of stipends at the disposal of French physicians in charge of the medical service in a preventorium in France, or officially designated by the provincial or municipal authorities or local committees to take charge of such a dispensary.

## LATIN AMERICA

**Gorgas Honored by Academy of Medicine.**—The newspapers of Lima describe the session held at the National Academy of Medicine at which Major-Gen. W. C. Gorgas was made an honorary member of the association.

**New Sanitary Improvements in Peru.**—The government of Peru is about to submit to congress a contract made with American firms for putting in sewers and water supplies in twenty-four of the most important towns of that country.

**Clinical Yearbook of Chilean Hospital.**—The physicians of the Hospital del Salvador of Santiago de Chile have recently organized and have published the "Anuario Clínico de la Asociación Médica del Hospital del Salvador," a well printed volume of 164 pages. Nineteen authors describe interesting cases encountered or discuss the early diagnosis of pregnancy, etc. Dr. Alvaro Covarrubias P. describes his trip to the surgical centers of the United States and his visit to the headquarters of the American Medical Association in Chicago.

**Organization of the Profession in Colombia.**—The *Repertorio de Medicina y Cirujía* of Bogotá has long been preaching the necessity for organization of the entire profession in the Republic of Colombia, and the Sociedad de Pediatría recently took the lead in drawing up a constitution and by-laws which were presented at the Fourth National Medical Congress, in August, with the hope of concrete action. They are published in full for discussion in the latest issue of the *Repertorio*, which in its preceding number reproduced the proposed code of medical ethics. (It was reviewed in these columns at the time, page 1170).

**Ninelieth Anniversary of Founding of the Brazilian Academy of Medicine.**—The Academia Nacional de Medicina de Brazil held a special meeting recently to celebrate its ninetieth anniversary. The Durocher gold medal was awarded on that occasion to Dr. Raul Pacheco for his work on "Eclampsism." In his address on receiving the prize he emphasized the high minimal pressure which he found constant in fifty cases of what he calls eclampsia, a condition which, if prompt measures had not been taken, would almost certainly have developed into typical eclampsia. He insisted that the usual examination of a pregnant woman is not adequate. Besides testing for albuminuria and the Wassermann reaction, the physician should determine the arterial pressure, and particularly the rise in the minimal pressure which is a premonitory sign of eclampsia. The fluctuations in the maximal pressure are inconstant and unreliable from this point of view. The address of the president, Dr. M. Couto, was on illiteracy, which he deplored as so prevalent in Brazil and told how it is a potent factor in the morbidity and mortality of the country, and is proving a serious obstacle to diffusion of enlightenment in matters of preventive hygiene.

**Veneral Disease in Panama and the Canal Zone.**—August 25, there was opened by Major Polgar A. Boroec, M. C., U. S. Army, a venereal clinic at Santo Tomas Hospital, Panama. This clinic will be run on the same general plans as institutions of similar nature in certain sections of the United States, giving modern examination and treatment free to all infected persons who present themselves. So far as is known this is the first free clinic for the treatment of venereal disease to be opened south of the United States, but it is believed that the marked success which is attending this one will shortly warrant the establishment of a second one in the city of Colon.—A meeting of representative and influential citizens of the Republic of Panama and the Canal Zone, was held, September 25, at the National Institute, under the auspices of the Panama Canal Health Department, over which Colonel Fisher presided. The object of the meeting was to consider a program prepared by a committee for minimizing the spread of prostitution and the reducing to its possible limit the spread of venereal disease in the Canal Zone and the cities of Colon and Panama. Colonel Fisher read the program agreed on, which, after being adopted, was ordered to be printed and circulated among the gentlemen present.

## Government Services

### Resolutions for Investigation of Walter Reed Hospital

Further efforts are being made by the House of Representatives for the investigation of Walter Reed Hospital and St. Elizabeth's Hospital, both in the District of Columbia. Two resolutions for this investigation are now pending. Charges of mistreatment of soldier-patients have been made.

### Appropriation for Medical Department

An Act making appropriations for sundry civil expenses of the government for the fiscal year ending June 30, 1920, and for other purposes includes for the Medical Department:

**Artificial Limbs:** For furnishing artificial limbs and apparatus or commutation therefor, and necessary transportation, \$50,000.

**Appliances for Disabled Soldiers:** For furnishing surgical appliances to persons disabled in the military or naval service of the United States prior to Oct. 6, 1917, and not entitled to artificial limbs or trusses for the same disabilities, \$1,000.

**Trusses for Disabled Soldiers:** For trusses for persons entitled thereto under Section 1176, Revised Statutes of the United States, and the act amendatory thereof, approved March 3, 1879, \$1,500.

### Awards for Bravery

The British Military Cross has been awarded to Raymond H. George, Captain, R. A. M. C., Chicago, for bravery in action, with the following citation:

The work done by this officer throughout the operations east of Néppe forest was invaluable. His aid post was constantly subjected to heavy shelling, but by his coolness and splendid example to his staff he succeeded rapidly in evacuating large numbers of wounded. By leaving his aid post and moving about in the open with complete disregard for his personal danger, he enabled the wounded to be gotten away at a time when heavy shell fire was endangering the lives of many of his patients.

Maurice L. Allen, Cleveland, who served with the British Forces has received word that the Military Medal of Great Britain has been conferred on him by King George for conspicuous bravery during the drive in 1918.

The Legion of Honor has been awarded by the French government to Dr. William G. French, Washington, D. C., in appreciation of his work in the children's bureau which he established in Paris, as a war relief measure.

Egbert M. Townsend, Lieut., M. C., U. S. Army, Tilton, Ga., has received the following citation:

An officer of exceptional courage and devotion to duty, showing great disregard of personal safety went about on the battlefield and gave first aid to soldiers who were wounded and unable to reach the first aid station; this being done in the face of violent enemy shell fire. After being severely gassed in the Verdun sector, Lieutenant Townsend requested that he be not evacuated, although his condition necessitated same. As soon as he had slightly recovered from the effects of gas, Lieutenant Townsend requested that he be sent back to his post. The devotion to duty and courage shown by this officer is meritorious of the highest praise.

Malone Duggan, Major, M. C., U. S. Army, San Antonio, Texas, has been cited for courageous and meritorious service at the front.

While on duty with the 6th Division, Major Durgan displayed great courage as regimental surgeon in that he advanced with the unit and made possible the evacuation of wounded to well-prepared stations in the rear.

Harold E. Clark, Captain, M. C., U. S. Army, Detroit, has been cited in orders for distinguished conduct in action.
