I enclose herewith blue print of a speed-registering device, which I have designed, and been using successfully on the New York and Philadelphia division, (Bound Brook) of the Philadelphia & Reading R. R., while indicating high speed locomotives in passenger service upon that division. The device is not a patented one. It is of cast-brass of plan shown in cuts, with clock work to move the paper drum *C* circumferentially one-half inch per second, thus obviating the necessity of using a stop-watch. A strip of paper is placed around the drum in the same manner as that upon a steam engine indicator. The registering upon the paper is made by lead pencil, raised and lowered as the steam is admitted to and exhausted from the locomotive cylinder, as a pipe connection is made from one end of the engine cylinder to the speed indicator at *D*. The springs shown are set in loosely both top and bottom, and are the same as carried in the Tabor indicator box, as for instance, if an eighty-pound spring is used for Tabor indicator, a sixty and twenty is taken from the box, for speed device, or if a sixty pound spring is used in Tabor, then I use a forty and twenty for speed. A handle to rewind the drum spring, as well as a button to start the movement, is shown under the clock-work, and also in Fig. 5. After about three-quarters of a revolution of the drum is made, it stops automatically, to prevent the pencil point from coming in contact with the spring holding the paper upon the drum, as well as to obtain absolute uniform movement, not depending, therefore, upon the escapement to regulate the difference due to change of tension upon the clock spring, other than one revolution. The paper used is cut into strips eleven inches long by one and three-eighths wide and placed upon the drum by an assistant, located on the running board or in the cab; at the same time the paper is placed upon the engine indicator, and speed record and steam diagram are taken at the same moment, a full quarter of a minute being the maximum time to operate the speed indicator before its portion of a revolution is completed, being ample for one steam diagram. I show by blue print a portion traced of a speed card, *A* showing five revolutions per second, or one-half inch movement, or three hundred revolutions per minute, equaling sixty-one and two-tenths miles per hour, for a wheel sixty-eight inches in diameter. The portion of speed card shown at *B* indicates slip, as the increase of speed is abrupt, a gradual increase of stroke or speed is shown on a full length of paper by a gradually diminishing distance between the lines until speed is uniform. In the case of card *B* the engine diagram was condemned, due to this slip, which is an important factor and cannot easily be determined by such devices as are at times used for high-speed locomotive indicating. There can be no loss of count or incorrect registering by this means, as the upward stroke is recorded when steam is admitted to follow the engine piston, and, when exhausting, the speed indicator piston returns to its fixed position, thus completing one revolution. Indicator and speed cards are correspondingly numbered and filed, and speed obtained when convenient to do so. My experience with speed devices has shown skipping of teeth, very close attention to its working correctly, and the additional labor of caring for the stop-watch when noting revolution, and at times have been compelled to count by fours the exhaust of the locomotive, which at high speeds is unreliable, being almost a continuous blast, and slip not perceptible.

I have now original speed cards in connection with my locomotive indicating taken with this device, which has worked perfectly during the several trips. As previously mentioned, it may be placed anywhere, inside the cab away from exposure and the strong current caused by the engine speed, by simply running the connecting pipe back from one end of the cylinder. I trust it may be of benefit to some one who has been put to inconvenience for something of its kind.

Knock-Out Arguments on the Cut-Off Question.

Editor The Locomotive Engineer :

Any further discussion on "Short Cut-off" will be a waste of valuable space in your paper, since "Vulcan" has shown your readers (which many of them did not know before) that a "Corliss type of valve gear" was *identical* with the *link motion*, and should be handled the same! Also he states that when his train is too heavy to pull with cut-off at 7" and is compelled to use the 9" cut-off, that his engine uses more water than when cutting off at the 7" notch! Such "proof" as this will stand; and he further states that there is not any vacuum in the cylinders, when the throttle is partly closed (as most of us have always thought), and that there is the same amount of steam goes into the cylinders when partly closed as when wide open! Now the only thing that is in the way of always running an engine "correctly" is a failure to get a "*square exhaust*" for a "trained ear"! Could this not be overcome by his using square nozzles, same as the engines on the P. P. R?

Now, Mr. Editor, when you get hold of such facts as these, why not throw up the sponge, and admit your defeat manfully? The writer has met with a change of heart; in fact, converted to the *new faith.*

Would you be good enough to ask my old friend, E. J. Rauch, if the flat spots on the driving wheels of the "Swinerton" engine give more adhesion when flat on the rail, what about the adhesion when not flat, or during the time of one leaving the rail and the next one getting there? Also what per cent. of the time does the "little facet" have to get in its work? Do not for a moment think that any one doubts the correctness of his statement, but would like to know how it was done! See? NEW FAITH

Germantown, Pa.

Back Pressure and Full Throttle.

Editor The Locomotive Engineer:

Grant's letter in May number pleased me very much. He says he is only a fireman and not supposed to have any opinions. I am one, and his opinion of this full throttle question is the same as mine. I have been on the footboard with a great many different men. Give me the full boiler pressure in the steam chest. If I was M. M. of a road I would have an automatic device whereby the steam gauge would be connected with the steam chest the moment the engineer placed his hand on the reverse lever, closing connection to gauge on boiler until she was shut off again. I would place this on every engine that was being run with reverse lever down amongst the oil cans.

Some of the 20-year old engineers would say we can't run them. They said that when injectors, sparkers, lubricators, and the many other improvements we have at the present day were put on. They talk about back pressure. I admit there is such, but it is back up in the boiler, and they won't let it down there to do the work economically. I believe if the exhaust was muffled, some men would drop them down, and try to knock it off, so they could stick their heads out of the window and say to the fireman, "Hear her bark; pretty square, ain't she?"

I have got a 19x24 Baldwin mogul; I can hear her bark at the furnace door all I want to.

Now about working steam expansively, if all locomotive engineers knew what it meant we would have no trouble with it. Stationary and marine engineers have settled it. The late George Corliss made a fortune by it. Instead of having the governor to control the valves, we have the engineer and those who understand what working steam expansively means; see how others abuse it. Not one locomotive engineer in 500 knows what you mean when you are talking about the expansive working of steam. And not one in 1,500 can read an indicator card. If locomotive engineers would study this subject we would have better men and smaller coal bills. I have books on the subject of indicators, planimeters, etc., that I will gladly loan to any locomotive engineer, and teach him the use of same. I lent Pray's second volume the other day to one of our engineers; he brought it back, and said I might as well have given him a Latin grammar. We have too many of this class of runners in the country (for runners we must call them, they are not engineers,) that have been set up on account of long service. In marine and stationary service it is not long service, it is knowledge that counts, and if we had a little more of it on R. R's we would have no trouble about "full throttles" and spoon-shaped valves. Men will say we do not have time to study, long runs and the like. I will say to them I have a long run—190 miles—over one of the worst roads in New England, and a night run at that; average consumption of fuel nightly, 5 tons. I find a little time to look into this matter. Hoping we may do some good to some one, I say to Grant, fire away, I will help you out.

Worcester, Mass. ARNOLD.

[This fireman's wholesale charge of ignorance of locomotive engineers is no doubt based on what he sees around him. We admire this correspondent's grit and independence, but his argument would be better received by the average engineman if he made it a little more modestly.]

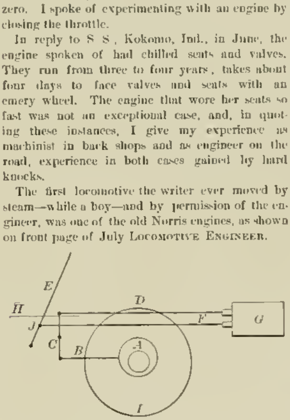
Odds and Ends.

Editor The Locomotive Engineer:

In reply to Vulcan, in July, I suppose John Alexander and myself have put our foot in it. Figures and theories are one thing and road experience is another. I know some very good engineers who don't go a cent on the center notch and full throttle business. We know that the ordinary slide valve is cheap to make, but it is a very poor substitute for the Corliss valve, and stands no show when the Corliss valve is pitted against it. Get up a valve gear for locomotives with an independent exhaust, and only then will comparison be in order. When I speak of the center notch, I mean the notch next to the zero notch, allowing that the valve has no opening *at* zero, although I have seen engines running or *trying* to run with the lever at zero. I spoke of experimenting with an engine by closing the throttle.

In reply to S. S., Kokomo, Ind., in June, the engine spoken of had chilled seats and valves. They run from three to four years, takes about four days to face valves and seats with an emery wheel. The engine that wore her seats so fast was not an exceptional case, and, in quoting these instances, I give my experience as machinist in back shops and as engineer on the road, experience in both cases gained by hard knocks.

The first locomotive the writer ever moved by steam—while a boy—and by permission of the engineer, was one of the old Norris engines, as shown on front page of July LOCOMOTIVE ENGINEER.



OLD VALVE MOTION

In the early days, Eastwick & Harrison, of Philadelphia, built three locomotives for the Philadelphia & Columbia Railroad, at that time owned and operated by the State of Pennsylvania, at present the Philadelphia Div. of the P. R. R. These engines were flyers running ahead, but did not back up first-rate. The drivers were a single pair, placed in the rear of firebox. Will some of the old locomotive experts explain their valve gear through the columns of THE LOCOMOTIVE ENGINEER? I send a line sketch of the valve gear as I saw it in my boyhood days, and must rely on my memory. The eccentrics were single, or only one for each side, and keyed fast to the shaft, the ends of the eccentric rods had strap and brasses to connect to lower end of rocker arm (no hooks of any kind). There were two valve rods for each chest, as shown in sketch, two reverse levers, one for each side of the engine, but both located on the right-hand side of the engine for convenience, and passing down through the footplate, where the lower or reversing valve rod connected to them. While running ahead the two levers were thrown forward, and held in that position by a spring catch operated by the foot of the engineer, in moving the levers forward the lower valve stem was carried with it by virtue of the connection at *J*; these lower rods remained stationary while running. To reverse the engine the engineer put his foot on the spring catches, pulled both reverse levers back when the catch would hold them in that position. *A*, eccentric; *B*, eccentric rod; *C*, rock arm, *D*, valve rod, *E*, reverse lever; *F*, lower or reversing valve rod, *G*, steam chest; *H*, foot plate; *I*, driver, *J*, connection of reverse lever and lower or reversing valve rod.

These engines were not reversed by the eccentric, but by manipulating the lower valve rod; now, what mechanical business was in the steam chest is what we want to find out. W. DE SANNO.

Tulare, Cal.

"From the Western Land."

Editor The Locomotive Engineer:

Mr. De Sanno's statement regarding the valve seat being rapidly cut away and disappearing at the rate of ¼ inch in a trip of 214 miles, prompts the writer to inquire if the valve was balanced. There is much truth embodied in his statement, that a man in charge of a shop or roundhouse should be able to take an engine out on the road, and run her intelligently after being rebuilt, if necessary. If such men were more plentiful, and doubting the statements of engineers, or differing materially with the "higher authority" who proposed to have a questionable engine haul 40 loads over a hilly division (or bribe some engineer to "screw her out" 25 pounds and do it), he could settle the matter himself by going over the road a trip on her with a good fireman. De Sanno's ideas of a tight ash-pan are well founded; many dampers could be hung in the center (similar to a common stove damper), thus avoiding the wholesale cutting out of pieces here and there to make them clear some of the machinery. Labor spent in this direction is only equaled by a good job of boiler washing. "Old Fogy" is not slow, if he is a reader of the *Master Mechanic*, we imagine we ought to sympathize with him in his possible folly, his contribution is convincing that he never let much moss accumulate on his back.

There may be whole lots of engineers that are moss-backed in Germantown; he is probably not one of this kind.

The "*Vulcan*" signature always attracts attention. He is quite correct in his pump observance. We frequently hook up the lever a notch, when possible to do so, rather than change the pump feed. It saves fuel, and adds an inch of water to boiler in comparatively short time or distance. Do not your comments on Vulcan's article substantiate what Kingsland says regarding the "old Lawrence" engines Nos. 11 and 12 on the St. Paul: "*They could run faster with less steam before they were rebuilt, and links substituted for V hooks, variable and independent cut-off.*"

The writer knows the engines well as the "2-ones" (11) and the "Quickstep," and thinks they had very large drivers in Mr. Kingsland's time, carried 110 pounds pressure, also that 115 pounds was *very high pressure* in those days. Years ago old St. Paul men concurred with Mr. Kingsland in his statement as to their economy and smart ways.

With such a valve motion, the *exhaust opening* and *closure* remain constant, and can be so arranged as not to let go of the steam at half stroke, but carry pressure on the pistons to a point where it ceases to exert much power on the crank. Does this not do away with excessive compression? And I might add, an engine running fast needs pressure to overcome the momentum of heavy and fast running piston. Shall we produce this with compression or with live steam?

Early closure of exhaust is probably bad policy, but going too far the other way causes the clearance space and ports to be filled with live steam from the boiler. This does not tend towards economy.

The writer fired an old "Dicky Norris" hook-motion engine, boot-heel fire-box and independent cut-off. Occasionally the driver would lay off a trip, and every one who run her in his stead coming from a link motion engine always told the same story—"a little the smartest they ever handled."

The Stevenson balanced valve, invented by W. Stevenson, Findlay, Ohio, carries a cut-off valve on top of main valve, all balanced in a novel manner. But to hint of this being used on a locomotive causes a howl to go up, and we are asked, What are you going to do in case of derangement on the road? This reminds the writer of the remark a French "locomotive expert" made to Joshua Rose in Paris, lately, while they were commenting on the position of valves on the French locomotives—beneath the cylinders and parallel with the track, so that they can be got at only when engine is over a pit: "*When we put the valves in, we put them in right and attend to lubrication properly, and if you in England or America have to arrange to get at valves when in service, there is something wrong with your practice or construction.*"

Will Mr. Kingsland tell us how many eccentrics the "old Lawrence" engines 11 and 12 had, and how they were arranged? W. U. JUNCTION.

Western Union Junction, Wis.

On Indicator Rigs.

Editor The Locomotive Engineer.

In your July issue Jos. E. Howell suggests an improvement in my indicator rigging (illustrated in May issue), regarding extension of reach rod to chest cover. Mr. Howell would extend wooden rod and make marks on its left side, so that the left-hand operator could also note position of lever. This arrangement might work well on engines with short arches, but an objection is that it would be in the way of the right-hand operator, where the room is so limited; and to make the improvement on the engine illustrated, the rod would have to be carried beyond the extension front, and it would then be necessary for the left-hand man to make too many moves to obtain his data when cards were taken as frequently as once a minute, often necessary where a full test is being conducted.

There is no question that the idea could be so arranged that the left-hand man might note the position of the lever, but it is not necessary where two operators are working together, and diagrams are taken from each side at the same instant. Any error of observation would be detected on the card itself if there was doubt, so that a check is not necessary.

In regard to the rigging as a whole, I will say that, after some considerable locomotive indicating, I find the method illustrated to be the most satisfactory I have used. All the data wanted can be taken quickly, and one has the satisfaction of knowing that he has seen everything connected with the test himself, and has personal knowledge of any incident that may have come up out of the general run of the test.

H. G. MANNING.

Watertown, N. Y.

Spotters.

Editor The Locomotive Engineer.

Once in a great while—a very great while—a spotter does some good—one of 'em fell off a train out West not long ago and was killed.

There's more than one breed of spotters—the man who "has the ear" of the division officers and always has a story to tell—in confidence—is the worst kind of a spotter.

I came within a car length of being a spotter myself once. It was a kind of a partnership spot between another plug-puller and me, and if you'll hold still a minute or two I'll tell you about it.

If your memory dates back to the year after the Centennial you will remember that there were several strikes and a whole heap of grief in that 101th year of the American eagle.

I thought the road I was on couldn't get the night express over the road without me, and the first job I got after they did get it over was six months afterward, and was a grub-stake job drying sand on a far Western road. My partner, Joe Johnson, got a job piling lumber in the yard—both of us had a promise of the first engine in sight.

One day the M. M. sent for us both, and we were in high feather—expecting to go running.

We met the M. M. and the Div. Superintendent, and they sprung two propositions on us.

One of us was to become a "body-snatcher"—go to every engine in the yard 30 minutes before leaving time, and if the man was not there get her ready, go out on the engine, and send the man to the office for his time. I took that job, got several engines ready, but I never went on any—I kept a private caller.

Joe was wanted as a "breath smeller." Management was satisfied that many of the *employes* were in the habit of going on duty drunk; they wanted to get rid of the guilty ones, and observing that we were both sober men, would one of us take the job?

Joe and I went out in the hall, held a council of war, and Joe decided to take it at $3 per day, and make his report monthly.

It did not look much like a job running for either of us, but there was a month's time at full pay ahead, and that was a good deal to us then.

Body-snatching occupied little of my time, so that I busied myself helping Joe. We had a pretty particular set of officers, and we were very particular with Joe's first month's report. Here it is *verbatim*, from an old copy that I keep as a memento:

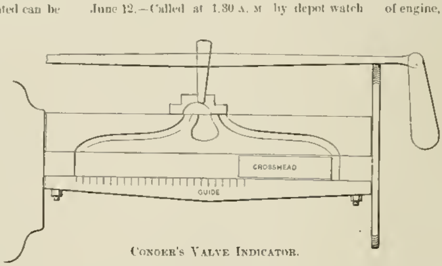
To the General Manager of the X. X. & Y. Ry.

Sir:—Your committee of one sent to investigate the report that there was much intemperance in the service, beg leave to report as follows:

June 2d, 11:30 P. M.—Saw two men carrying a case of bottled beer through yard; supposed it was going to some engine; followed them; took beer to a car on track 4, curtains all down; heard singing and boisterous talking; got on brake-wheel and looked in ventilator; saw John Doe, Supt. 1st division, T. Tool, general roadmaster, and two females—females were sitting on men's laps—all singing and drinking; called John Alexander, Ike Wilson, engineer of the 142, and Mr. William Cole, Justice of Peace, who was passing, to see, and to whom I refer you for evidence; was interrupted by special pulling out on tour of inspection. No doubt Mr Doe had drunk too much for the good of the service, but I would recommend him to mercy on account of his family - a man over 50 years of age must love his wife when he will hold her on his lap, and sing to her till midnight.

June 5.—Conductor John Smith paralyzed drunk in the yard—refer to any yard man on duty on that date. was making his brags that he was all right, and stood in with you; said he was your son-in-law.

June 12.—Called at 1.30 A. M. by depot watchman to see a drunken engineer going out on 28, went to engine, found the fireman oiling around, and engineer lying on ground asleep; fireman said the engineer had only been in 1 hour and 25 minutes, and had doubled the division four times without rest, 53 hours; fireman was an extra, and had only been out one double with him—recommend a 10 days' lay-off for this man *on full pay*, and 30 days' lay-off for officer responsible for this long time on duty.



CONGER'S VALVE INDICATOR.

June 21.—Directors' meeting, all drank heavily; seven baskets of champagne used at lunch alone; President Robins very conspicuous—breath smelled badly.

June 24.—Mr. Doe's car back in yard—he is not sober yet.

June 27.—N. Merritt, chief dispatcher, son-in-law of president, sick at Grand Central hotel, was very drunk night before; slept on billiard table—think a dispatcher who was not related to president would do better.

These are all the cases that have come to my notice, except information about amount of liquors carried to your house weekly—don't suppose I can give you inside figures on this, not already known to you. Respectfully submitted,

JOE JOHNSON, Inspector.

Of course, Joe and I expected to "take to the road" for this, but we did not. We both got engines, and our officers stopped the report from going beyond the superintendent's office, and then treated it as a joke, charging Joe's time up to construction.

In delivering the report Joe excused himself, and said if the report was found defective it was because he had mistaken just *who* were to be considered "employes."

Did you ever see a temperance notice signed by an official that was a teetotaler himself?

Did you ever see one that counted any one as an employe who had an initial behind his name?

Did you ever see a shop where the sign, "No Smoking" was conspicuous, where every petty officer that came along did not inspect it with a cigar in his mouth?

Did you ever see an official who refused to take his check out of the pay car—just the same as an "employe"?

If all spotters will follow Joe's lead, and get *proof* of every case reported, consider all men who draw pay as employes, and report all, regardless of position, the enginemen of the country will welcome them into the service, and if all are treated alike there will be need of a new crop of officials before there is of road men.

JOHN ALEXANDER.

A Wooden Indicator.

Editor The Locomotive Engineer:

Take a piece of two-inch plank, 3 or 4 inches wide, cut it just long enough to go on top of the outside guide and between the back head and the guide yoke. Take off the guide cup if it is in your way. Nail on the edge of the 2-inch strip a thin piece to come down along the edge of the guide, just wide enough to come down to the top edge of the cross-head. Mark on this thin piece a plan of the ports, exact size of the engine it is tried on, and extend the ports down to the clearance at the end of the cross-head which will represent the clearance at the end of the cylinder. Mark the bottom guide off in inches, from the point of travel of the cross-head. Make a wooden valve same length as valve of engine, and mark on the edge of valve and exhaust port, exact size. Fasten a strip on the back edge of wooden valve seat, to let the valve slide against. This valve is connected with the valve rod above by a clamp, which will move the wooden valve just exactly as the valve inside the steam chest is moved. To set it, move the engine over till the steam begins to come through the port and out of the back cylinder cock, set the back edge of the wooden valve for that position. Then move the engine ahead, see if the front edge of the valve is right, get both steam openings the same as main valve. This "indicator" will show the exact position of the valve at any portion of the stroke, whether the link is hooked up or at full stroke, and if the lap or lead is not proper for the work to be performed it can be intelligently altered. One thing will surprise most of the engineers who have never seen it tried, and that is the point in the stroke of the piston where the valve commences to admit live steam when the lever is "cut back" near the center notch in the quadrant. Try it, boys, it is cheaper than the steam pressure indicator or motion curve machine, and it shows just exactly what is going on in the steam chest.

CLINTON B. CONGER.

Lansing, Mich.

The Shovel and the Mouth.

Editor The Locomotive Engineer:

Your article in June issue on the difference between the mouth and a shovel for firing should be read and pondered on by many master mechanics who now employ officers who do "firing with their mouth," and mislead those who have to do it with a shovel; if the master mechanics mentioned would do so, and take the hint it conveys, it would not only be to the advantage of the company which employs them, but would save suffering to many an engineman who listens to and follows the teaching of the fiend "who fires with his mouth" from a soft cushion or the shady side of a roundhouse in warm weather.

If the fiend is an official, and we find he generally is, and it was worth while to look into his past, we would find that he commenced his official career through the influence of that mouth and the weakness of an official. He imagined, and does so still, that his appointment was made on account of the size of his head, and from that time assumed a fatherly manner to those under him, and a brotherly one to those over him. The first he tries to impress with the idea that he is advocating their cause with those above them, and his superiors that he is the one that keeps the men contented by his influence with them. The fiend is cunning in small things—catches straws that indicate that men are to be promoted, and about what time, and then recommends them for promotion, and tells the man that he thinks there is going to be an opportunity for some one, and he will see what he can do for him.

This mouth man is *ex-officio* a member of the stove committee, and it is at the frequent meetings of that committee that he gets in his fine work—work that is not only injurious to the company that employs him, but also to the young man who listens to it. And it is usually young men who listen, and at that time of life when it does them the most harm, by weakening their faith after trial, in work that, if properly taught, would have been to their advantage.

In time they resign from the committee, call him and all teachers cranks, and their places are filled by other young men who hope to gain his influence, and to do so refer to the puzzles that come up daily in their work, and in engine houses, and he solves them all to his own satisfaction. He is an expert on coal, and wants to be appointed coal inspector. Has made lubricating and other oils a study. Valves and valve motions have been the subject of his sleeping and waking dreams. He says the present type of locomotives is antiquated, and that the coming one will use but one pound of coal per horse-power (he is above expressing the consumption per mile). Says that the Hudson Bay & Cape Horn road is putting the Cotton fire-box on all its locomotives on the Hudson Bay divisions, on account of the cost of coal and the cheapness of ice along that division. He is a strong advocate of a valve motion gotten up by a friend of his (and every man who brings out a device is a friend) in Alaska, that takes its motion from the tender truck, and thinks his road should adopt Simpleton's driving wheels. Adds that a hollow axle with a stream of water through it would keep it cool, and that the waste water would keep down the dust and increase the comfort of traveling. Claims that one pair has the adhesion of two of the ordinary driving wheels, and that the recognized law governing friction is wrong. He tells of the wonderful performance of the Wenk locomotive—that it can run four hundred miles with an average of but one stop of ten minutes in every forty miles, and when asked if its fire, or the fire on any locomotive cannot be cleaned on long down grades, says that some can and others cannot.

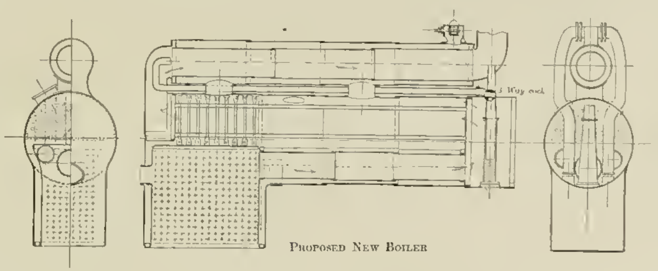
But when you come to firing he is at home. He is the man who invented firing—first proposed the use of coal as fuel, and introduced the use of a shovel as a tool for firing in place of a basket, on the X. Y & Z. road. He was sent for by the president of G. O. S. & O. road, and asked to investigate the cause of the locomotives using so much coal. He was put on as a hostler, and the Supt. and M. M. instructed to adopt any suggestions Mr. Gab might make. He told the president that the cause was that the switch lights were too small and lighted too early. But the Supt. and M. M. were old fogies, and Mr. Gab found he could do nothing and quit, and the M. M. then discharged his cousins and his aunts.

In time the experience of Mr. Gab comes to be a joke with the older men, and serves to pass the time in corner dwellings where schooners are sold and cargoes of free lunch are stored; but the young disciple listens to the words of wisdom that Mr. Gab lets fall, one of whom asks him why it is he cannot get his engine to steam, and is told by Mr. Gab that, when he was a fireman, if a man could not get steam that he was fired; that when he was on the Sandy Hook & Barnegat road, in 1821, that he was told to go and fire an old Hinckley that ran the Heron express, and that had had seven firemen in three days. He told the engineer that he was going to make that engine steam, if he had to burn the cab. "The engineer smoked a clay pipe and plug tobacco, and spit on every tenth cross-tie, and told him he had better do it," and he done it. The old man sent for him and told him that that was the first time in two days that the engine had made time. Then Mr. Gab tells the fireman that he burns too much coal, and that if he knew his business that he could get plenty of steam. That he should study the theory of combustion, and be a credit to his craft. That he intends to recommend to the old man to open a school for instruction, and that he will volunteer to be the instructor, for it is shameful the way the firemen on that road fire, and that they are wasting 25 per cent. of the coal used. The unfortunate fireman thinks that he has done wrong, and that if he asks any more questions that he will expose it and get ten days, and then goes off and Mr. Gab also—to look for the man who is to bring him down some eggs.

Now is it a wonder that fuel is wasted through improper firing under such instruction, and unfortunately it is about the only kind of instruction that many roads can give, or do give to young firemen, and at a time when they are anxious to learn, and if properly taught in the elementary principle of the work they have to do would follow it up, and advance in knowledge that would be advantageous to the company as well as to the men. Time and money are expended in locomotive designing to produce economy of fuel on all roads, yet on but few roads are any intelligent instructions given to the man who is the most important factor in the problem. A road foreman may be employed who has the knowledge and ability to teach, and may try to do so and succeed with a few, but his knowledge is looked upon as personal and not as the road's, and in using it he is apt to meet with indifference from those who will say that it is his theory only, and there are so many men that he has not the time to demonstrate to all that his story is correct. In the meantime Mr. Gab has been "firing with his mouth," and giving lectures on the admission of air above the fire, and the relative value of heavy and light fires. The fireman tries the first at wrong place and time, and the second on a locomotive without regard to its construction or work, and with, perhaps, destruction to himself. But let a road or its officers know the theory of combustion, lay it before its young firemen in a simple elementary form, and appoint a man who has faith in it to teach its application to the firemen in a practical manner, and not only will there be less talk of waste of fuel by that generation of firemen, but a producing of engineers from them that will prevent it in the future, and the occupation of the "man who fires with his mouth" be gone, and a more useful one can be found for him in cleaning windows to let in light on more useful workers.

A VICTIM

New York City.



PROPOSED NEW BOILER

Proposed New Boiler.

Editor The Locomotive Engineer:

A great deal has been done and said in regard to straight stacks, extension smoke-boxes, and single nozzles. What the results have been no person is prepared to give a decided answer. My opinion is that the advantage yet attained does not pay for the extra expense that is attached to them.

What is wanted is boilers built large enough to allow of steam being made without having such a strong blast as is usually used; for if you have got to have the strong blast on the fire, sparks which are not properly burned will be lifted out of fire and drawn into front end, and when there they have got to be got rid of, often at the expense of big fires, which cost R. R. companies lots of money.

There is one thing certain, that boilers have not been enlarged to correspond with the difference in size of the cylinders and the extra work engines have been made to do of late years. I send you a blue print of a boiler patented by Mr. Sharkey, boiler inspector of the western division of the C. P. R., which he claims will do away with leaky flues and foaming in alkali water, and with a saving of fifty per cent. in fuel.

His fire-box is connected with three large flues which run through the boiler to front end, and smoke passes through these and then back again over top of fire-box by small flues, and from there out of chimney which runs on top of boiler through steam drum, as shown in blue print, which has a 3½ or 4 inch steam space all round and full length of boiler, and is connected to boiler by two columns, which allow steam to pass from main boiler. You will see that by the time that cinders, if there are any, get to the stack, they will be dead and that smoke and gases are used for heating purposes until they are of no more use. The throttle is placed on top of steam drum and just behind stack, which is a long way from water level, and this is where Mr. Sharkey claims an advantage in alkali water.

In addition to the above benefits he claims his boiler will make ample steam to heat passenger trains with, he fears no trouble with regard to making steam, as he has so much extra heating surface, and another benefit is his mud ring, which is made and flanged out of solid plate and is the same material as boiler; this does away with unequal expansion. You will see by blue print that exhaust pipe runs into chimney, which makes the draft on fire very light, and if this is found to be not sufficient there is a three-way cock arranged in exhaust pipe so that exhaust can be run through independent pipe between steam drum and boiler and used at back end of chimney.

I have been reading John Alexander on schemes and schemers, and his warning. I would like very much to see him writing in our *B. of L. E. Journal*, as his ideas are the same as mine, and I think the majority of fair-minded men are of the same opinion.

Winnipeg, Manitoba. SUBSCRIBER.

Smith's triple expansion exhaust pipe seems to be quietly proving that it is right in principle. It is now in successful use on the Bell's Gap, Mo., Pacific, Boston & Maine, Old Colony, Kan. City, Ft. Scott & Memphis, the Wabash Western, and several other lines. In every instance where we have heard from it, it is reported as running successfully with an opening equal, if not larger than the ports, the engines steaming well and throwing little fire. More than this can hardly be asked.

The trouble between the U. P. and the engineers is all settled, and that in the very best way—by arbitration. The pay was restored to the old figure, with all back since the reduction.

In Mr. Kenyon's rule for setting slipped eccentric in last issue, 8th line from top should read "forward of axle *not* enough," instead of enough.

The Annual Present Fraud.

Last month we offered a little advice to, and mildly remonstrated with the rank and file of railroad men for imposing upon people, and now we want to belabor them again for being imposed upon.

How many of you pay out from $1 to $10 per year for presents to some one—generally far better able to buy presents than you are? A good many, we will warrant. How many gold watches, silver sets, etc., have your superintendents, master mechanics and other officers got at your hands? How many have you got at theirs?

When an official leaves the service who has been a particularly fair and just man in his dealings with the men under his orders, we have no objection to seeing him receive some substantial reminder of the esteem the men have for his management; but the idea of making Christmas, or any other presents to officers in the service, should be frowned down by the men and killed entirely by the officials themselves.

There are not only too many men willing to start such lists, but there are altogether too many foremen and master mechanics about our shops that encourage and aid in such work. The next time there is a list stuck under your nose, asking you to contribute to the purchase of a watch or a diamond stud for some official who gets about four times as much pay as you do, just say to the *lister* that you don't believe in "standing in" in that way, and won't give a cent; and when a list is passed for some unfortunate co-employe or his family, don't plead poverty, but invest your present-money in charity—it will return to you after many days—the present never will. This present business goes to extremes sometimes, we recently dropped into a roundhouse with an engineer just getting in off a night run, and the night foreman flushed a list on him—it was to purchase a suit of clothes for a certain minister in the village and was headed by the master mechanic for $5, and the foreman for $1—this was to bait the men.

Our engineer read the foreman a lecture, said that the M. M. was the only employe of the company who belonged to that particular church, and told him to tell the M. M. in the morning, that if the list was passed among the men he should go to the general manager about it. This engineer had considerable moral courage, and told us afterward that he intended to break up that present business, the pay car seldom passing without a case coming up—he called it "the invisible blackmail."

Subscription lists for charity are noble monuments of man's humanity. Subscription lists for presents for officials in office are humiliating evidences of man's degradation and weakness.

Put your shoulder behind the one, and your foot upon the other.

Cab Doors.

No one knows exactly why locomotive cabs are built with inward opening front doors. Some don't think about it because they never saw them hung any other way, and most of the enginemen of the country grin and bear the inconvenience, satisfying themselves that it is part of the business—a disagreeable part.

When the doors are swung from the outside corner of the cab "in," the door on either side, when partially opened to admit air, makes a deflector to shoot all the air, smoke and cinders—especially cinders—across the cab and into the face of the man who does not want air—or cinders either.

Many a fireman, wringing with sweat, is riding over the country cooped up in a cab that might be kept cool if it was not for the deflector that would blind the engineer.

Front doors that open outward from the side next boiler are not in the way of anything in the cab, do not become deflectors of dirt, and can be opened any desired amount, and the air will go directly back through cab for the benefit of the man who wants it, and without annoying the man who does not want it. The door then becomes a deflector to catch and deposit cinders outside the cab instead of inside, and, while the outside opening door delivers air, and dirt, in direct proportion to the opening, the inside opening arrangement delivers air in direct proportion to the opening, but all the cinders that strike the door.

Some builders go so far as to put a small door in the lower panel of the door, so that men can get air without so much dirt.

It is cruel to prevent a half-suffocated fireman from opening his front door for a little air because the engineer is cool enough.

Long Hours.

We have been requested repeatedly to ask for and publish letters from railroad men all over the country as to the number of hours worked by men in the motive power service. We have not done so, because we know that most roads, or rather the management, object to the publication of such facts as would point out their roads as running locomotives with men who have been on duty 40 or 50 hours, and would take revenge on the men for so doing.

There is little doubt—in fact, no doubt—that a man on duty, running or firing a locomotive for more than 12 hours without rest, is too tired and worn to use all his faculties at their best, and many a fearful accident has been caused by such arrangements; but where men are paid by the mile it is as often the fault of the men as of the management, and before indiscriminate blame is attached it would be well to look to the real cause. An average of 60 to 70 hours per week is enough service for any engineman, and they should get full pay for that. It is next to impossible to avoid extra work and extra hours in "rushes," but for a steady thing they are elements of danger.

On every division where there is a chance to make extra time by "sticking to the engine," there will always be found a hog or so who wants to make 27 hours a day, and sleep down hill. We have no objection to the time hogger, but have to the average superintendent who gauges every other man's powers of endurance by the hogs.

Signals and Engineers.

The unsatisfactory and slipshod state of discipline in the train service department of the average American road was well illustrated this week in the long delays to passenger trains at the Jersey City terminus of the Central of New Jersey, on the day the new interlocking was first used there. Passengers by the hundred got out and walked a mile or so to reach the ferry. The signals are simple and admirably arranged, and the explanatory circular had been duly issued to the engineers, but they had not thoroughly studied it, and consequently nearly all of them were so slow and cautious that they hindered each other greatly. Those who were not cautious ran past signals with the temerity of a baby playing with a pistol, though, with the usual good luck, few switches were torn open. The simple trouble was, of course, that no one had seen that the engineers *understood* their circulars. Probably they signed the usual receipt reading, "Order No. — received and understood." It would seem to be about time that intelligent superintendents take measures to explode this farce. An employe signing a statement which he does not fully mean or fully believe, is encouraged to other breaches of discipline. It is, to be sure, not a specially easy task for an old engineer to study a complicated system of interlocking for the first time, but there should be a great improvement over the present state of things on most roads.

The above wholesale charge of lack of discipline of the engineers employed on a large passenger-carrying road is from the *Railroad Gazette*, and is so manifestly unjust on its face that we investigated a little.

The signals and interlocking switches mentioned were put up by a reliable firm; the engineers were amply instructed in their use, and an attempt made to use them before the apparatus was complete, the men who were to handle it properly posted, and where the plan of the time card made it impossible to handle the trains over the tracks

The Central Railroad of N. J. runs something over 280 passenger trains out of and into the Jersey City depot daily. The depot shed is open only at one end, and has fifteen tracks from which all these trains arrive and depart. They go in on one side and leave from the other. In order to switch the trains from one side to the other a track was laid from the center each way *across* and leading into these tracks, and the plan was to have each locomotive that came in to kick her train back down this track to a regular switching track known as "track 10," the engine to follow out and go to the house by another track.

At the signal tower all the tracks come down to and enter the main line tracks, six in number, and the tracks from the *in* side *crossed* the outgoing ones.

Every train that went out or came in blocked every other train going in either direction.

As the interlocking system calls for the movement of several levers for each train, and many of the trains are timed to leave at the same time—five or six at a time in busy time of day, it was simply impossible to handle them during the busy hours.

The company tried to use the system for a couple of days, but gave it up and replaced the hand levers. Instead of the engineers "running past signals with the temerity of a baby," the engineers were the only men who kept cool, one man showing his good sense and cool head by refusing to run his engine past a signal and over a misplaced switch on the positive order of a badly rattled general superintendent who was getting desperate.

If all the engineers of this road are fools or ignoramuses, we fail to note the signs among a large acquaintance there. If the failure was due to improperly instructed men, it seems to us as if it would be cheaper to instruct them than to remodel and change the tracks and switches, as is being done.

No investment will pay a road better than a careful, complete and intelligent analysis of the water used for locomotive boilers. When the peculiarities of the water in each tank are known, excessive use of bad waters may be avoided by the engineers, if it does not pay the company to change the source of supply or the location of the tank itself. Several instances have come to our notice where most of the water stations on a road were moved or abandoned within the first five years of the road's operation—generally to secure better water or to get a self-filling or "gravity tank." Young engineers of tests can make themselves a reputation, and make it pay the company far better, by going into the analysis of the feed water, than in wasting the grey matter of their brains upon comparative tests of the link as against the general master mechanic's patent radial gear, or anybody's traction increaser. By the way, engineer of tests seems to be a regular office in our motive power force now-a-days, and there is little doubt that the engineer of tests has come to stay—let him tackle the feed-water problem—there is millions in it—millions of tons of mud and scale.

On June 29 a passenger train on the N. Y., N. H. & H. road was thrown down an embankment by a poorly spiked frog or rail, the section men, working without a flag, had been replacing old rails with new. There was a clear track for two miles, and they could see the approach of the train in time to spike the rails sufficient for safety, but appeared to think two spikes in a frog were enough. As a rule trackmen are paid the lowest living wages, and selected without regard to ability or intelligence. The foremen are generally selected from the best of the men, but the ability of a foreman to drive his men is oftener the cause of his promotion than his knowledge of the business of keeping up track. The section foreman whose ignorance or carelessness caused this wreck deserves to be under arrest, as he is, but the roadmaster over him is as guilty, yet he has to keep his track up inside of a certain fixed outlay of money, and no doubt employs the best men he can for the money.

Books Received.

THE CRANK: Its Motion and True Value for Transmission of Power in Practical Engineering. By F. Lenggenhager, Ph.D., Late Engineer to the Maritime Stations of the Austrian Empire. D. Van Nostrand Company, 23 Murray and 27 Warren Streets, New York. Price $1.50.

This author is no doubt a crank, and, therefore, ought to be able to write well on the crank subject—yet he fails to do it.

We do not remember of ever having seen a worse garbled-up mess in book form.

The author tries to prove all the way through the book that a very large per cent. of the power developed in the cylinder of a steam engine is lost at the crank, and goes into figures and tables and formulæ to prove his position.

To a mechanic the book has no value whatever, except as a curiosity. It seems to have been published in the interest of the Pitt engine, which contains a complicated device to take the place of the crank.

ASKED & ANSWERED.

(30) S. A., Talmage, Neb., writes:

Please give a list of books suitable for enginemen; not only about the locomotive, but general. *A.*—Write for a catalogue to the publishers of mechanical books who advertise in this paper.

(31) E. R. F., Waverley, N. Y., writes:

Will you please tell me in the August number of THE LOCOMOTIVE ENGINEER where I can get a paper showing and naming each piece of machinery on a Rogers locomotive? Please state price. *A.* The names of parts on a Rogers locomotive are the same as on any other. We know of no paper or book giving the names of every piece. Perhaps Alexander's Ready Reference or Forney's Catechism will come as near to it as anything in print.

(32) C. L. Dennis, Belsena Mills, Pa., asks:

(1) Where can the tallowed hemp piston packing be bought used by the P. R. R. Co.? (2) What will prevent white, hard scale in locomotive boiler? *A.*—1. We do not know who keeps tallowed hemp. 2. Depends upon what causes scale, white, hard scale is usually caused by a deposit of lime, and has been in a measure prevented by the use of crude oil. We do not believe that a boiler scale mover can be produced that will act the same in all cases, any more than a suit of clothes can be made to fit all people. The intelligent way to treat scale is to begin with an analysis of the water, and then designing a preventer or remover to fit the particular case.

(33) C. S. C., Watertown, Wis., writes:

On page 3, July issue, your paper states that "The E. T. V. & G. are running a six-inch nozzle in their consolidations", on page 5 you also say that the Strong engine on the Erie has her nozzles bushed to 3⅜. Their diameters compare as follows: 36 inches to 11 39-100 inches. What is the difference in back pressure on pistons? or what would be the increase of back pressure in cylinders on the "consolidations," if 3⅜ nozzles were substituted for the 6-inch nozzles? *A.*—The only way to accurately tell this would be to apply an indicator and test the difference that way.

(34) Frank Parker, Sanborn, Iowa, writes:

Will you please explain why, in turning a pump plunger ¼ eccentric, you set your centers over 1-16", where, if you had an offset of ⅛" before turning, you would set your centers ⅛" to turn both ends true. Where and what is the difference? If you will kindly answer this through your questions and answers, you will oblige several of the boys. *A.*—As we understand your question, you refer to the necessity of changing the center punch marks in the ends of the plunger in order to turn an offset to fit the lug in crosshead, when it is not in line with center of pump. If you wished to do this you would have to set its centers over the full ¼ of an inch. If you wish to turn both ends true, it is necessary to change the centers back to the center line of the rod, because they have been left out of center in turning the offset.

(35) Ignoramus, Raton, New Mexico, asks:

What is the cause of holes wearing oblong in back flue sheet? Is it caused by rolling or by the heat, as the front sheet does not wear so bad but they all wear the one way. *A.*—This trouble is often complained of, and if any of our readers know anything of the subject we would be glad to hear from them. That the holes in fire-box tube sheet should get out of round more than the front seems probable, and may be for two reasons. One is that they are calked very much more at that end, and another that when the crown bars are placed fore and aft, as they are in many cases, the front end of bar rests on the back flue sheet and the sling stays are not properly put in, the pressure on the crown sheet has a tendency to squeeze the flue sheet down and make the holes oblong.

(36) M. H. W., Dickinson, D. T., writes:

1. Has there ever been an extension front used with short nozzle and petticoat pipe? If so, how did it act? 2. Do you think that an engine with extension front would steam better if the top of diaphragm was farther away from flue sheet of boiler, as is the case in O. I. & W. front end shown in July issue of your paper? In most front ends the top of diaphragm starts from just above top row of flues and runs down so that there is very little space between end of flue and diaphragm; would it not be better if there was more space? 3. What would be your opinion of a front end with diaphragm and dead plate as used on O., I. & W., but with an upright plate about five or six inches from flues and with a space between edge of plate and smoke arch, and so arranged that the draft could be regulated by raising and lowering plate something as is done by petticoat pipe? 4. I am firing an 18x24 Baldwin "hog," with extension front. This particular front has a tendency to fill up at the bottom, back of nozzle, so that bottom row of flues is choked—what causes this and how can it be remedied? *A.*—1. Yes, and it did nearly as well as the short arch. 2. You do not give enough *data* for one to have an idea of how your diaphragm is located. Diaphragms have been placed in about all the different positions possible to conceive, and do well in many of them, conditions have much to do with it. 3. No good, any arrangement that is capable of being monkeyed with will not stay a success. 4. When the diaphragm is in proper place there will not be anything between flues and exhaust pipe to cause or allow cinders to accumulate.

The London & Northwestern Railway Company, the most important and perfectly organized road in Great Britain, has just issued a new regulation, whereby every person in the employ of the company, from the general manager down to the very humblest greaser, is entitled to an annual holiday of eight days on full pay. The other English companies are about to follow suit. Would it not be well if the great railroad corporations here, which profess to earn so much larger profits than the English railways, were to follow this excellent example set by the old world, and remove the muzzle occasionally from the ox that treadeth the corn?—*Daily Paper.*

We tried to say *two* several times in the proof, but the printers still made us say that the Webb had but *one* exhaust to a revolution—at last accounts she had two.

Air-Brake Practice.

FIFTEENTH PAPER.

By J. E. PHELAN.

We propose to make this our final paper on "Air-Brake Practice," as published in THE LOCOMOTIVE ENGINEER, for period commencing early in 1888, and ending with current number.

We do not stop now because the subject is exhausted, for there are vital points about "Air Brake Practice" not yet treated fully here.

The Westinghouse automatic brake is destined to fill a most extensive field in the future commerce of the world, and any man who imagines himself a graduate in knowledge pertaining to the Westinghouse automatic air brake, by going along quietly for a few years with ears and eyes open, and mouth ready to ask pertinent questions, will early learn what an important study this may be, and how knowledge pertaining to same may be gained from year to year as progress continues.

We wish here to call attention to the importance of utilizing all available braking power at all times for needs of service.

Any observer on an engine under motion, where two engines attached to a train as double-header, without braking appliances on either engine in use, can always notice how difficult it seems to make a desirable stop, under conditions most favorable when the extra weight is not added in form of an extra engine.

Similar conditions may be noted where heavy sleeping cars or dining cars are in regular service. The braking force does not always seem to increase in proportion to weight of train, while harsh application of brakes often seems necessary where good results should come from light application of air to appliances.

In service, occasionally an engine will make a trip with one car, or a heavy engine make a trip with two coaches, and where braking power is exerted without using any braking power on engine, it becomes a tedious and uncertain matter at times, stopping without use of braking power on engine. The use of tender brakes is required in all well-regulated service, but the matter of utilizing the power in driver brakes remains a matter of doubt to many minds when relating to stops in ordinary service.

Those having experience know how uncertain the matter of stopping becomes when one or two cars are required to stop a heavy engine when running at high speed. On the other hand, with a good working driver brake and tender brake, such a train can be stopped with ease without using the brakes on train of one or two cars. This is simply a matter of controlling the greater weight by its own braking power, or the greater weight controlling the lesser. While to stop engine and one coach or two coaches with use of car brakes only, it requires the lesser weight and power to hold back the stronger force in motion. Imagine a cat overcome by a rat—of course, all that may be necessary is to get rats enough.

The matter of a heavy engine controlled by one or two car brakes presents an extreme view not common in practice, but will answer for illustration of the principle.

In practice the weight of the engine is overcome by train brakes where driver brakes are not used.

But does it not stand to reason that each brake has enough to do in controlling the weight in motion of car to which applied? At least, such circumstance is greatly to be desired, and when once in practice on an intelligent basis, will greatly simplify braking at all times, and give most effective work for lightest application of power.

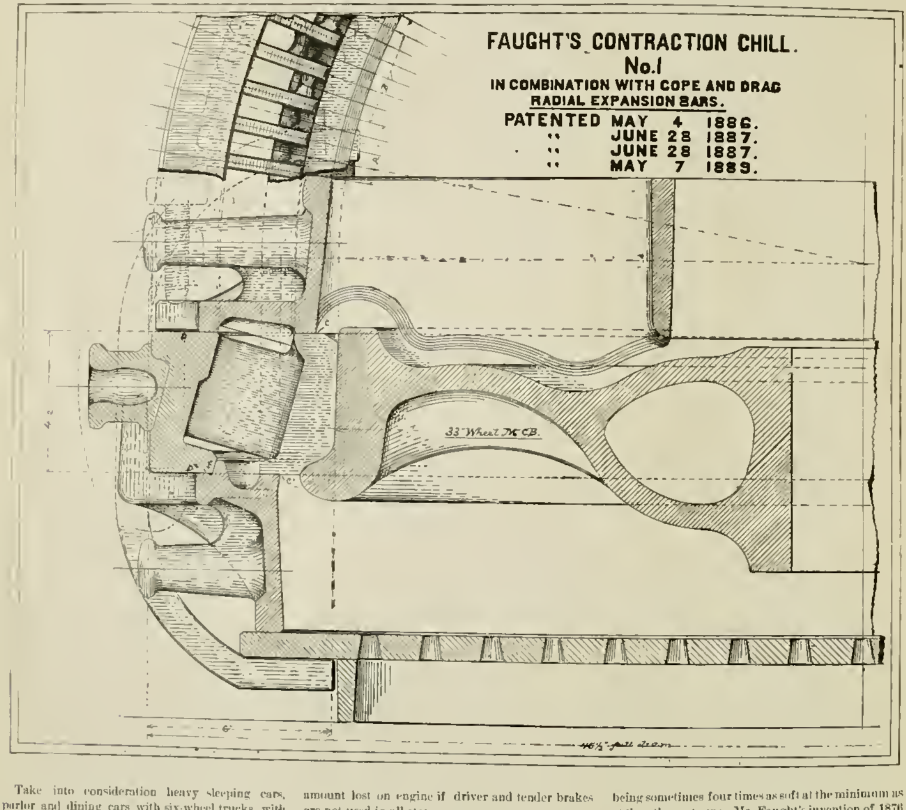
The demand on part of engineers in service for excessive air pressure can most reasonably be overcome by furnishing means for accomplishing desired results with moderate air pressure.

Take for example a modern ten-wheel passenger engine weighing 110,000 pounds, plus a loaded tender weighing about 70,000 pounds. Should this total weight, 180,000 pounds, in motion exert its own braking power, or should train brakes be taxed for the purpose in addition to exerting braking power for cars to which attached?

or 90 per cent. of the weight of the car at track under wheels to which brakes apply.

For example, take a car weighing 72,000 pounds, and having a total of twelve wheels. This gives 6,000 pounds resting on each wheel, or a total of 48,000 pounds resting on the eight wheels to which brake shoes ordinarily apply, hence, our braking power can be exerted on but 90 per cent. of 48,000 pounds, where, if brakes are applied to all twelve wheels, we should exert a braking power equal to 90 per cent. of 72,000 pounds, or total weight of car.

Say we have a train of six cars, composed of dining car, parlor and sleeping cars, and all averaging about 72,000 pounds each, with total of twelve wheels under each car, but with brakes applying only to eight wheels under each car. Under such conditions we absolutely lose one-third of the available braking power of the train, plus an equal



Take into consideration heavy sleeping cars, parlor and dining cars with six-wheel trucks, with brakes applied to but eight wheels under each car out of a total of twelve wheels under each car of this kind.

Usually, leverage is adjusted to apply a braking force on passenger cars equal to 90 per cent. of the weight of car *at track under wheels to which brakes are applied.* With a passenger car having four-wheel trucks, or a total of eight wheels under car, with brake shoes applying to all the wheels, we may exert a braking power equal to 90 per cent. of the total weight of the cars so equipped.

But with a car with six-wheel trucks, or a total of twelve wheels under the car, and brake shoes applying to but eight wheels out of a total of twelve, we cannot safely apply to the eight wheels a force equal to 90 per cent of total weight of such a car. In this particular, we can safely exert braking power equal only to 90 per cent. of weight of car resting on wheels, to which brake shoes apply,

amount lost on engine if driver and tender brakes are not used in all stops.

In other words, under such conditions, the matter is equivalent to running two ten-wheel passenger engines as double header on six cars, and requiring the six cars to do all the braking for such ponderous weight.

We are glad to know that a commencement has been made in applying brakes to all the wheels under heavy cars, and without going into this matter any further at the present time, we advocate brakes on engine tenders and driving wheels as well as on all wheels under all cars in train, and kept in condition for use, and for *daily* use in all stops—service or emergency.

Braking power cannot be made too effective.

All appliances in daily use, and properly cared for, can be relied on to much better advantage for emergency, than so-called emergency devices seemingly available for emergency, but generally out of order when needed most urgently.

Faught's Improvements in Contraction Chills.

Probably most of our readers are aware that some thirteen years ago there was invented in the city of Philadelphia, a car-wheel chill that became smaller on its inside diameter when it was subjected to heat, as in casting a car wheel. The object of this invention was to construct a chill that would remain in contact with the tread of the wheel, until the mass became solid. The old form of chill, a solid ring, produced chill enough, but the instant it became hot, it began to expand, and, as it was pinched by the clamps between the cope and drag, it would follow the line of least resistance, leave the wheel on one side, and remain in contact on the side having the tightest clamps, making not only an uneven chill, but a wheel out of the round. The hardness of the uneven chill varied more than its depth, being sometimes four times as soft at the minimum as at the other extreme. Mr. Faught's invention of 1876 consisted of an outer and an inner ring, connected by radial arms, the inner ring being divided between the arms, leaving each spoke or arm to support a section of this ring. When this chill was used, the heat expanded the sections of the inner ring and the arms, before it was communicated to the outer ring, the expansion carrying the inner ring towards the center, thus keeping the chill in contact with the wheel longer than by the old style. Although wheels so cast were a marked improvement, the chill was not perfect, as it had a tendency to get out of the round itself, with the heat and rough handling of the foundry, and, as the inner ring section was firmly clamped between the cope and drag, the movement of the sections was retarded and the chill expanded unevenly. Mr. Faught's first improvement consisted in tying the arms together, alternately at top and bottom, as shown at B, Fig. 1. This helped in a great measure to prevent uneven expansion, and kept the chill itself round.

In June, 1887, Mr. Faught patented a great improvement, which he calls "The suppression of the mould." This consists of clamping the *outer* ring between the cope and drag, enclosing the space between the arms in the mould, and leaving the inner ring of sections entirely free to move inwards, no clamping being done on them. The mould having a slotted chill is thus restored to the conditions that would exist in one with a solid ring chill; preventing the rush of air through the slots keeps the dust and dirt from being carried to the tread of the wheel, maintains the pressure desired to keep the mould from dropping, and preserves that quietness necessary to a good casting.

This arrangement is shown very plainly in both illustrations, the ring is free at C and C², but bars tends to force the chill toward the throat, and the heat has to go up the inclined bar and down the outer rim before it can expand it. This plan makes a perceptible difference in the length of time before the chill "lets go" of the wheel. These improvements have made the present radial bar chill much superior to the older devices, but Mr Faught did not rest satisfied with the perfection of the radial chill, but eclipsed all his former efforts in the invention of the secant bar chill, which he calls his

INCREASED CONTRACTION CHILL.

This chill is fully shown in Fig. 2, and the sections are arranged the same as in the radial chill, the cope and drag clamped to the outer ring, expansion bars entirely enclosed in the mould, and the isolation of the lower part of the outer ring from the heat.

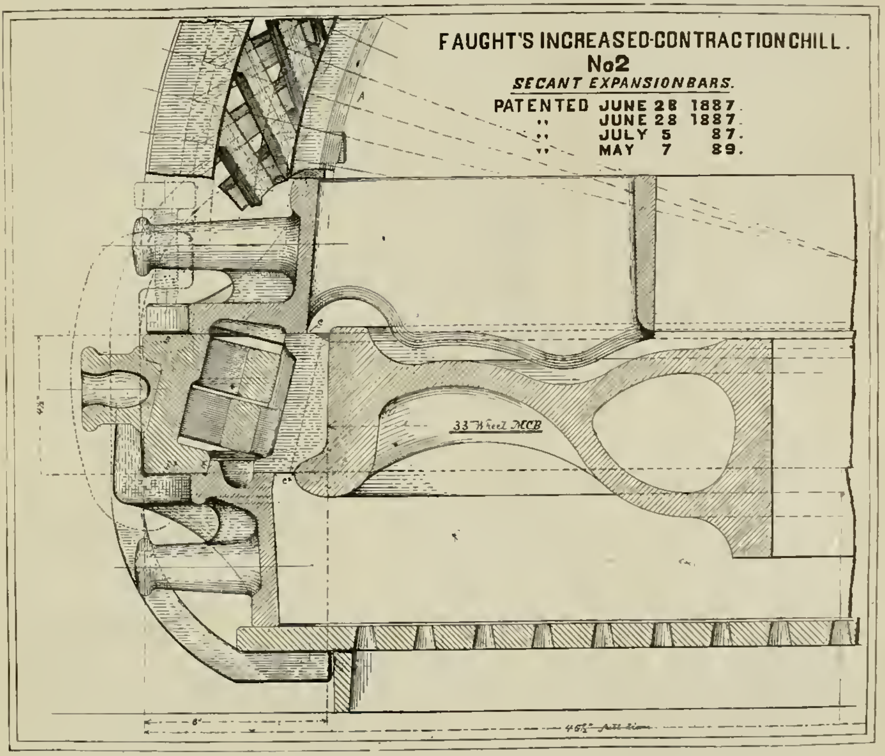
The improvement in the expansion bars is the simple application of a geometrical rule.

it strong, and prevents its getting out of round.

That wheels made in contracting chills are more evenly chilled, and more uniformly round, is now almost universally acknowledged in this country, many roads specifying wheels made in these chills for all cars put in service, and the problem has resolved itself down to a matter of perfecting, simplifying, and cheapening the chill.

We do not hesitate to say that the next generation of railroad men will look upon the inventions of L. R. Faught as one of the greatest improvements to rolling stock made in many years, as it will increase the safety, length of service, and strength, and decrease the cost of cast-iron wheels, making possible their use under the enormous loads we are now piling upon our cars.

Now that his chills are upon the markets of the world, we bespeak for him the recognition and remuneration that his research, industry and inventive ability deserve.



clamped firmly at D and D². The arrangement has also a tongue with a taper fit at E, that, in combination with the outer closing snugs on the drag, entirely obviates the uneven joining of the chill and mould, resulting in what is known as a "lapped" wheel.

Of course, the longer the radial bars, the more contraction is secured before the outer ring begins to get hot and carries the whole chill away from the wheel; but to get them very much larger than the wheel reduced the capacity of a foundry very much, so that economy of size was a feature not to be lost sight of. Mr Faught overcame some of this by the depression of the bars, so that the heat has to travel through more iron before it begins to expand the outer ring. The metal at the bottom of the chill begins to get hot first, as the first metal poured comes in contact with the lower part of chill, the expansion of the lower part of ring first caused the chill to "lift" slightly, thus taking the pressure off the throat of the wheel—just where it is wanted the most. The angle of the

The arrangement of these bars is plainly shown in the sectional view at A, in Fig. 2.

In Fig. 3 is shown one section of the inner ring with its secant bars, and it requires no mechanical

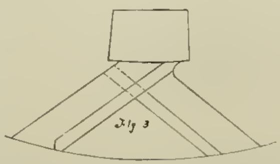


Fig 3

ability to see that the lengthening of these expansion bars would force the block as much farther than would the lengthening of a simple radial bar behind the block. The bars and blocks being conjoined or interlocked, like a girdered bridge, makes

On July 24th the steamship City of Rome started across the Atlantic with a delegation of American working men and women, known as the Scripps League Expedition, to inspect the usages and customs in the different branches of industry in Europe, and write up the differences for the columns of the different newspapers belonging to the league.

There were forty people representing as many trades, all under the charge of a manager and editor. The locomotive engineers are represented by Joseph Thorp, the oldest engineer on the Mobile & Ohio road, he learned the machinist trade before becoming an engineer, has run for 18 years, of late years as "special" engineer. Bro. Thorp is 38 years of age and a member of the B. L. E.

His comparison of European shops, locomotives and roads with our own ought to be interesting and instructive.

There is a great deal of comment and complaint among the patrons of the Central R. R. of New Jersey, about the way the Westinghouse air-brakes are handled, and there is good reason for most of the kicks, but the kickers do wrong to lay all the trouble to the engineers. We ride thirty miles daily on the road, and have taken particular notice of the brake service. It is almost impossible to find a train of cars made up where there is any evidence at all of careful adjustment of the levers under cars, some of the pistons go clear out, and then don't set the brake, others travel 8, 6 or 3 inches, according to circumstances.

It is impossible for an expert to do good work with air where this condition of things exists. All leverages should be so adjusted that the pistons will have nearly a uniform travel; then the pressure in brake cylinders will be approximately the same, the braking force the same, and release occur at the same time throughout the train. A few of the engineers do handle the brake as if they were leading a refractory young bull, and the traveling engineer should ride with them and do a little explaining.

We have been on several trains within the past few months, when the trains left terminal stations with disabled air-pumps. There is no excuse for this; on roads where they make a study of air-brake service extra pumps are on tap at every roundhouse, and a machinist and his helper will put a new pump in place of your old one in from ten to twenty minutes.

Wm. J. McCarthy, of Menominee, Mich., has got a patent on the idea of placing an iron house, or cage, over a switch stand, that can not be entered or escaped from except the switch is set for the main line. It does not make provision for a man leaving the switch open after his train has entered a siding and staying in the fort himself. We believe that the original idea was to so arrange the trap that if the switch was left wrong the man inside would be killed—not so bad an idea after all. Now if this inventor will perfect a device that will cage the flagman who don't flag, or kill him if he don't get back a reasonable distance, he will be doing mankind a service.

F. C. Robinson, a friend and correspondent of this paper, formerly general foreman of the Wabash shops at Danville, Ill., and now master mechanic of the Atlantic & Danville road, was in this city the latter part of July, selecting tools for his new shops, now building at Portsmouth, Va.

About the time this paper was started, Bro. Robinson was running a locomotive, but once given a chance to show what was in him, he forged to the fore; he was a missionary for THE LOCOMOTIVE ENGINEER on the Wabash, and has already sent in a batch of converts from his new field.

The past month has been crowded full of fatal accidents, the most of which are attributed to broken wheels or defects in the track. Better wheels must be used under our heavy rolling stock. A six-dollar cast wheel becomes a powder magazine under a 60,000 pound car running at 30 miles per hour. Just how carefully the details of track kept up by men working from 12 to 14 hours per day for about one dollar, is not known, but railroad managements seem to do little if any figuring on this subject.

The neat little rig shown on another page to indicate the location of the valve was put upon a locomotive several years ago by Clinton B. Conger, to enable him to study valve motion. He says the boys all laughed at him, but he learned considerable by its use just the same. Except in case of broken stem of valve yoke, it will prevent a man hunting on the wrong side if something is wrong.

John W. Cloud, Secretary M. C. B. Association, announces that the revised rules of interchange of cars are now ready for delivery. Goes into effect September 1st. Prices: 25 copies, $1.00, 50 copies, $1.75; 100 copies, $3.00, to which will be added the cost of postage when sent by mail.

Many engineers predict that the Denver Convention, in October, will be the longest session ever held.

The president of this company was slightly jumbled up in the wreck on the New Haven road on June 29. He says he don't object to playing hide and seek on his car among a lot of cast-iron chairs if it is going to do anybody any good, but when forced to so perform because of some one's carelessness, does not enjoy it.

Probably no improvement of the locomotive made in the past 20 years—unless it is the injector—has met with such success as balanced valves. Almost everywhere we go we find them in general use or being tried.

What is the matter with "vestibuling" between the engine and tank, in districts where the blaze in the headlight freezes stiff from November till April?

The new freight engines for the Montana Northern, a division of the U. P., are consolidations, 22x28, with a 72-inch boiler, designed by Mr. Cushing.

Historical Locomotives

TENTH SKETCH.

From time to time we have shown up some of the early locomotives originated at the Norris Locomotive Works, Philadelphia, and with this issue show one of the last ones they built. This engine and tender were built October, 1860, for the Eastern Texas R. R., of which S. H. Witmer was superintendent, and she was named for him. During the war the "S. H. Witmer" was captured by the Federals, and used in the service of the United States Government, but was, at the close of the war, sold to a private party, and used for a number of years.

Pumps, cast-iron; ball valves, plunger, 1¾" diameter.

Steam ports, 13"x1½".

Exhaust ports, 13"x2½".

Lap, ⅝"; Link motion, iron case-hardened.

Lead, 1/16"; Radius, 66".

No inside lap; eccentrics 12½" diameter, 4½" throw.

Travel of valve, 4½".

Crank-pins (main), 3½" diameter by 3" long, by 2½" diameter by 2½" long.

Other crank-pins, 2½"x3".

Cylinders, steam chests, dome, checks, sand-box casing, and bands covered with Russia iron, brass mouldings.

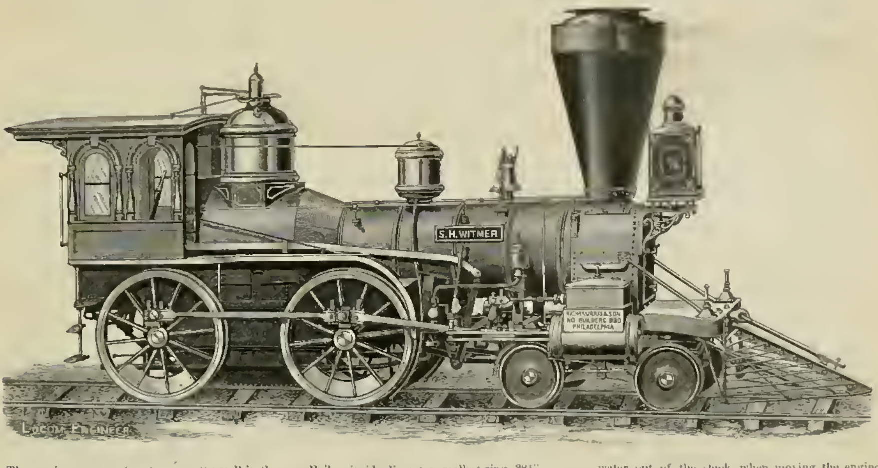
Frames, 4" wide, 2" thick or deep sides and top of No. 9 iron, frame covered with 3/16" iron, brakes on each wheel.

Weight, 20 gross tons.

Tried October 19, 1860.

The N. P. road are putting in the new style Baker heaters in their cars. Although they spent a great deal of money experimenting with steam heat, they are not satisfied with it for long trains of ten or twelve cars in their cold climate—all the locomotive wants to do to pull the train.

A muffling device in the front end of the N. P. engines does not seem to prevent the throwing of water out of the stack, when moving the engine after a long stand. Some of the boys have an old canvas tarpaulin that they stretch from the sand-box to the headlight to catch the scum, from the house to the train.



The engine represents a type pretty well in the advance of locomotive building thirty years ago, well remembered by old-timers, but hardly understood by the younger portion of railroad men. While sizes have more than doubled, the general plan of the American 8 wheeler has not undergone much change—just observe the difference in size of this locomotive's parts, and the ones you are now familiar with. The following data was taken from the original order books of the works:

Engine and tender, "S. H. Witmer," built for and sent to Eastern Texas R. R. Gauge of road, 5½ feet. Fuel, wood.

Cylinders, 13"x22", horizontal.

Drivers, 60", axles, 6", wrought tires, 2½" thick.

Truck, 28", axles, 4", cast-iron, chilled.

Tender, 8-30", axles, 4", cast-iron, chilled.

Tubes, 100, of copper, 10 feet 6 inches long, 2 inches diameter.

Boiler, inside diameter smallest ring, 38½".

Plates, 5/16"; tube sheets, ½" back, 7/16" front.

Boiler shell, 54" long, 48" wide; throat, 30" deep, largest diameter waist, 47⅝".

Stack, Yankee, 16 feet from rail.

Piston rods, 2½" diameter, wrought-steel.

Steam pipe, 4½" diameter inside (of copper).

Fire-box, ¼" iron plates; 48" long, 39" wide, 61" high; crown sheet, 3/16", iron.

Wheel base engine and tender, 36 feet 6 inches.

Wheel base engine (alone), 19 feet 8½ inches.

Diameter and length driving axle journal, 6 inches by 8 inches.

Diameter and length truck axle journal, 4"x7½".

Diameter and length tender axle journal, 3½ inches by 5½ inches.

Cab of oak (varnished.)

Tank capacity, 1,700 gallons, bottom, 3/16" iron.

The boys on the Lake Shore are getting to like the plan of lagging and jacketing the boiler-head in the cab. It is cool in summer, and comfortable enough in winter, they notice that they do not take cold so easily in getting off to oil or do other outside work—there is not the change in temperature.

Baldwin's have recently delivered 40 heavy passenger engines for the Mo. Pacific, several small engines (wide gauge) for South America and Cuba, a number of mining engines, and some street car motors for a suburban road at Denver, Col.

Watson & Stillman, of this city, have brought out a small hydraulic jack for use in renewing journal brasses under cars; it is small, neat, capable of lifting six tons, and is much quicker than the little old screw jacks universally used for this purpose. It is provided with a neat side handle for carrying.

The Knoxville, Cumberland Gap & Louisville Railway was opened on the 22d day of August. A coach, containing fifty-six prominent citizens, went through a faulty trestle, killing three and wounding forty-one. Rather a bad advertisement for a new line.

Angus Sinclair will sail for Europe on the 25th. He has been taking lessons in French and reading up on the compound. Next year's discussion on the compound locomotive will find him loaded.

An alligator wrench will often save many dollars in the cost of delay caused by a breakdown. We could never see much reason for refusing to furnish them for locomotives.

The N P Railway will soon commence the building of extensive shops at Tacoma, Washington. The plans are already in the hands of the Supt. of Motive Power.

The Traveling Engineer.

By J. E. Phelan.

FIRST PAPER.

No matter what his title may be—be it Road Foreman of Engines, Road Foreman of Machinery, Inspector of Locomotives, or other title with similar duties to perform, such genius is always best known among railroad men as the Traveling Engineer.

This innocent official is often used by clever engineers as a convenient scarecrow to stave off undesirable deadheads seeking something better than a tie pass out of or into the country.

At odd times, but often, the traveling engineer makes the most convenient mark for censure or condemnation when a necessary rule is to be enforced or some little innovation started about general service, requiring an extra ounce of exertion aside from the well-worn routine, but they get there some how.

We have known real smart individuals to take it for granted that an engineer would be reported for drinking simply because such a fact or assertion had been made in lodge or division meeting, where such assertion accidentally found expression in hearing of the traveler.

less influenced by a fellow feeling for associates, with ability to comprehend all that is good and commendable, while at same time showing nerve enough to condemn false methods and lawless practice wherever found.

Few positions in railroading are better advertised among engineers and firemen than this one, and few positions so generally misunderstood, even by men attempting such duties.

The duties of the position of traveling engineer vary on different railroads.

On certain roads the duties confine this titled individual to work about the shops, but mainly with most roads the duties lie on the road away from shops and headquarters.

Rule 222 of Transportation Rules of Northern Pacific R. R. reads: "The Road Foreman of Machinery is the representative of the Master Mechanic on the road, and his instructions relative to the care of engines, loads of engines, and use of fuel, and all other matters in the Machinery Department, will be obeyed."

Instructions to Road Foremen of Machinery issued by Supt. of Motive Power on same road reads: "The revenue of transportation is earned in movement of trains, hence the proper condition of engines to perform this duty to a maximum capacity is of first importance.

Single vs. Double Nozzles.

On this page will be found two sets of indicator diagrams taken from engine 404, on the Northern Pacific Railroad, one when equipped with a single, the other with double nozzles. The upper set of diagrams were taken when using the double nozzles, the lower with the single. It will be seen that at full stroke, when working hard on a start, there is a slight back pressure caused by the single nozzle, but that it entirely disappears when engine is cutting off short of full stroke.

These diagrams were taken by O. H. Reynolds, chief draftsman of the road, and a mechanical engineer who could, from his own experience with the indicator in locomotive practice, enlighten the enginemen of the country, were it not for his besetting sin of excessive modesty. The cards shown show good steam distribution, and remarkably good valve setting, and are a credit to the motive power department of the road.

This is the sensible way to investigate the single nozzle, which has not shown improvement enough to secure the adoption of the single nozzle on the N. P., but, so far as the cards go, one is as good as the other; the single breed is cheapest to make, however.

The 404 has 18x24 inch cylinders, valve travel 5¼", ¾" outside lap, and is line and line inside.

The diagrams are reduced to $\frac{4}{9}$ the original size, the originals being about two and a quarter times larger.

In the bright imagination of some men, the individual filling the position of traveling engineer embodies the principles of a sewerage system, through which flows all the slime of scandal or contemptible gossip current about bar-rooms, depot platforms or roundhouses, into the general office of the R. R. Co., regardless of conditions or circumstances.

The fact that men attempting to fill the position of traveling engineer occasionally or often interpret the duties of the position to require such services is simply to be deplored.

Few in service can find opportunity to do more harm or cause more trouble than the traveling engineer, if so inclined, where such work is tolerated by the management.

No official on the pay-rolls of a R. R. Co. can be of more benefit to the requirements of good service than the traveling engineer. This position should at all times be filled by men of accurate judgment and honest motives, who possess courage enough to speak the truth at all times, or when necessary show sense enough to maintain judicious silence.

If this position cannot be filled in a creditable manner it better be abolished.

Working daily among engineers and firemen, few men have better opportunity to observe commanding traits among this class of associates than the traveling engineer. Few men are given a better opportunity to represent or misrepresent engineers and firemen than the traveling engineer.

A man cannot make a success of the position un-

"Road foremen should know the condition of all engines, and report to the division officials whatever may be found that interferes with the economical and proper performance of same.

"The use of fuel must be watched, with a view to the strictest economy, and the instructions to engineers and firemen in this respect should be constant. The delivery of fuel to engines, and its quality, should also be noted.

"The proper use and care of engines, the use of oils, condition of air-brake apparatus, smoke-stacks, ash-pans, wheels and tires, the condition of water machinery and water supply, are all matters to be noted, and defects reported upon in such manner as to insure attention.

"On passenger and freight trains note the use of air-brake apparatus, and instruct train men how to use it.

"The trials of new engines, and new men on engines, will generally be under the charge of Road Foreman of Machinery."

This and more embodies the main duties of the traveling engineer on the N. P. system.

Such a position can be raised to a plane of decency and respect or it can be made the target of ridicule and contempt.

Much of course depends on the way a man occupying the position is built. A man occupying the position of traveling engineer cannot expect to suit everybody, and should not even try to do so.

First know how to judge correct methods and proper principles, and insist on such being practiced and observed, together with all rules of the company designed to insure good service.

Practical and thorough knowledge of firing, and the proper maintenance and management of locomotives, is absolutely essential to success. Backed by an intelligent understanding of such principles, and possessed with a fair degree of self-reliance and assurance, a man may fairly count on success.

Starting in the performance of such duties, however, a man had better show a disposition to gain knowledge and experience from others than to assume to know it all.

One mind and one set of faculties can never be equal to the results of combined observation and discernment of many minds.

A man starting in with ability to glean from the knowledge of others can make far better success in any position than the "thing" who knows all that may be worth knowing from Adam's time to the coming of Gabriel.

It does a man good occasionally or often to admit learning a new phase in practice. It is but justice to the man imparting knowledge gained to get due credit for the same.

Look around and note the principles of men who have failed in advancing in the line of duty or who fail to accomplish desired results, and you find men rendered incapable of doing justice to others through selfish or mercenary motives, or else men so dense in their mental machinery that a ray of understanding becomes discouraged before tapping at the door where reason is supposed to dwell.

The travelling engineer works among and becomes associated with engineers and firemen who, in general, as a class, have no superiors in appreciation of fair treatment.

No class of men more readily understand whether a superior in position is fitted for the place occupied or adapted by experience for duties to be performed.

An occasional specimen, however, two-thirds mercenary, will always find fault with the travelling engineer. But such specimens must be classed among those impossible to suit, and handled about as an engine of very poor design. The builder in either case is responsible for imperfect design or poor material. Time alone will demonstrate the quality of material.

Pedrick & Ayer, Philadelphia, are moving into their new shops. They are working every man they can, and are behind with their orders.

An Ingenious Drill.

We illustrate on this page an ingenious drill, designed by Pulaski Leeds, Supt. Motive Power of the L. & N. Ry.

The device, as shown, can very properly be called a radial attachment for a drill press, but can be used any place, and driven by flexible shaft or otherwise.

Fig. 1 shows it as applied to the drilling of set-screw holes in eccentrics from the inside of the axle bore, and without boring a hole through the outside bearing of the eccentric; this prevents the set screws from working out and catching in the oil-holes of the strap, stripping the motion on that side.

This tool can be put to work in any small space, where even ratchet tools will not go, and is found very convenient about frames, especially in patching, as it can be made to work from the inside of a pair of jaws, in the end, or under the frame.

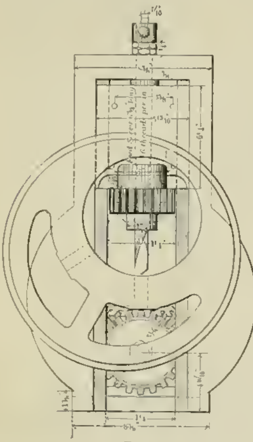

Fig. 1

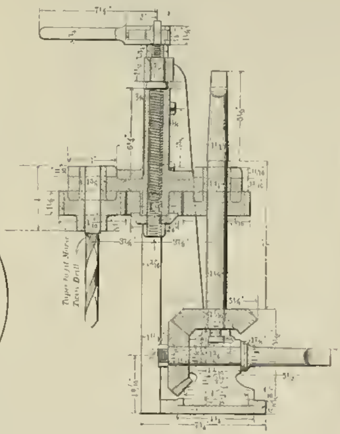

Fig. 2

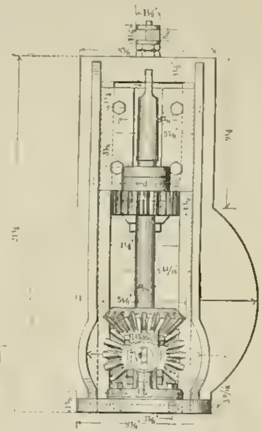

Fig. 3

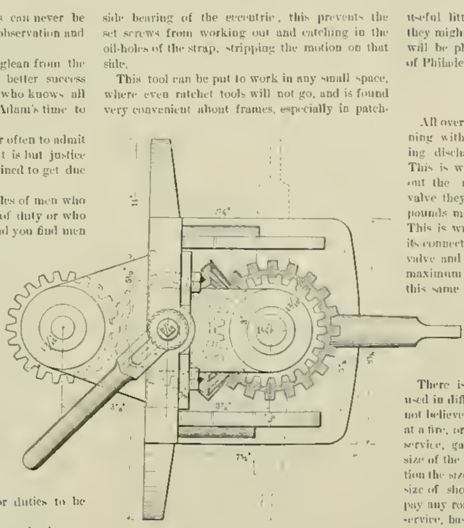

Fig. 4

Fig. 1 shows a front view of the tool, and shows the frame. Fig. 2 is a sectional side view, and shows the arrangements of the moving parts; as will be seen, there is a horizontal as well as a vertical taper spindle to drive the tool. When the work is done by the vertical spindle, the other simply runs idle, and when it drives, it does so through the vertical, the object being to drive from the most accessible point; the lower spindle shown in Fig. 2 can be turned around to any angle, as shown by dotted lines in plan view, Fig. 4.

The feeding is done by the screw at top, which moves the crosshead in frame up and down; the crosshead carries a small idle wheel at the bottom, which meshes into the one on the driving spindle and the one which forms the chuck for the drill; these gears are shown in plan view, Fig. 4.

Of course, by shortening the drill, a great deal of work can be done in very cramped places.

We believe that this tool will prove one of those useful little repair shop devices—universal jigs, they might be called—that will become popular. It will be placed on the market by Pedrick & Ayer, of Philadelphia.

Bad Practice.

All over the country we find the engineers running with the new engineers' brake and equalizing discharge valve in the full release position. This is wrong, some think that by thus cutting out the use of the 20-pound pressure retaining valve they thereby charge their trains with 20 pounds more air for use in case of an emergency. This is wrong where a pump governor is used, as its connection to air pipe is above the piston of the valve and it will slow the pump down as soon as maximum pressure is reached there—you can have this same pressure under train, and twenty extra pounds in the engine drum to insure release, by running with handle of valve in "running position" or with indicator spring against the first stop.

There is a great deal of difference in the fuel used in different parts of the country, and we do not believe that any set rule of so many shovelfuls at a fire, or for a mile, can be settled upon for all service, gauging the number of shovelfuls by the size of the cylinders, and leaving out of consideration the size of fire-box, quality of fuel, service and size of shovel is also a little "unsartin." It will pay any road to issue special instructions for their service, based on well-established laws of combustion, but modified to fit the case in hand.

On a recent raid on the Baldwin Locomotive Works, we noticed on many boilers in its erecting shops, a new arrangement of wash-out plugs, instead of the plugs being screwed directly into the boiler sheet, they screwed into a brass shell that was bolted by a flange to the sheet.

All the prominent locomotive works are busy, and the prospects of business for the next six months are good.

A Reading Flyer.

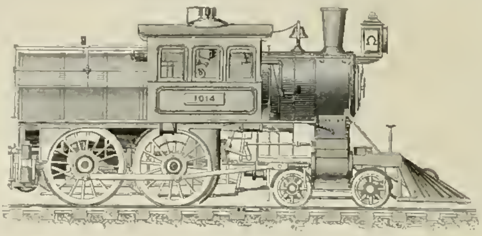
We publish on this page two views of the P. & R. Ry.'s fast express engine 1014. We publish this for two reasons; one to show those who have been asking us "What is a Wootten bake-oven like?" and one to show the style of engine doing the fast work between Philadelphia and Atlantic City—a train that has caused considerable talk among the traveling public on account of the high rate of speed.

One correspondent sent us the picture used, and noted on the margin: "Extension back on fast roads, extension fronts on slow."

Another wrote: "I have rode over the Philadelphia and Atlantic City on the *fastest* regular train run in America."

The distance is 55.2 miles and the fastest train makes the run in 68 minutes, which is very lively time for a regular diet.

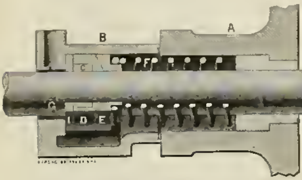
The Pennsylvania's No. 19, leaving Jersey City at 4.13 P. M., has but 64 minutes to make Trenton, including station time there; this is a distance of 55.9 miles. This speed has been regularly made for the past twelve years, and no one seems to know of it or notice it.



A READING FLYER.

The Wootten locomotive is a unique piece of machinery, however, and those not familiar with them will be interested in the cuts. The engine is the same as any 8-wheeler, the boiler being the only "Wootten" part of the machine.

The following dimensions were kindly furnished by the Baldwin Locomotive Works:



THE EXCELSIOR PACKING FOR VALVE STEMS.

The principal dimensions of locomotive No. 1,014, built by us for the Atlantic City Railroad, are as follows:

Gauge, 4' 8½".

Fuel, anthracite coal.

Boiler, of steel, 9-16 and ⅝ thick, 57½" diameter at smoke box end, straight top longitudinal seams, triple riveted, circumferential seams, double riveted.

Fire-box, Wootten pattern, 102" long 96¼ wide, of Otis steel; crown sheet, ⅜", tube sheet, ½", side and back sheets, 5-16" thick; two fire doors, crown sheet supported by stay-bolts, ⅞ diameter, with heads and copper washers underneath crown, and bolt riveted over outside of shell; combustion chamber, 33¾ long.

Tubes, 324 in number, 1½ diameter, 9' 2¼ long.

Working steam pressure, 160 lbs.

Smoke-box with register in door and baffle plate; Wootten style.

Weight in working order on truck, 33,050 lbs.

Weight on main driving-wheels, 31,450 lbs.

Weight on rear driving-wheels, 30,690 lbs.

Total wheel-base, 20' 5⅝".

Driving-wheel base, 6' 6".

Cylinders, 18⅛ diameter by 22" stroke.

Steam ports, length, 16¾, width, 1¼"; bridges 1¼.

Exhaust ports, 16¾" x 3¼".

Valve travel, 7"; outside lap, 1¼; inside lap, 1-64"; lead, 1-16".

Driving-wheels, 68½" outside diameter; centers, 61½".

Tires, 3½" thick by 6¼" wide.

Driving journals, 7" diameter by 10" long.

Truck, four-wheeled rigid center pattern, with steel-tired wheels, 30" diameter.

Journals, 5¼" by 10".

Tender, eight-wheeled.

Tender frame, iron.

Tank capacity, 3,500 gallons.

Trucks with square wrought-iron frames equalized.

Tender-wheels, steel tired, 33" diameter, journals, 4½" by 8".

The locomotive is equipped with Philadelphia & Reading Railroad Company's pattern steam reversing gear.

Detroit sight-feed lubricator.

Balanced slide valves.

United States metallic packing.

Channel side rods with solid ends.

Westinghouse quick-acting automatic brake for driving-wheels, tender and train.

Westinghouse train signal.

Post & Company's headlight, with illuminated side numbers.

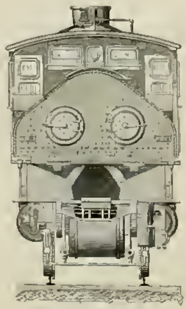
Bearings throughout are of Ajax metal.

A Fireman's Dream.

A short time ago the writer stood with Master Car Builder Barber at the coach shops of the N. P. road at Como, and watched with great interest the process of cleaning old brass. All brass trimmings, like door locks, sash locks, grip racks and car lamps are simply held in a steam-heated tub till thoroughly hot, and then dipped into a vat containing some cleaning compound, then into a vat of clear water, and dried in sawdust, all the pieces come out just as if they were new, bright as a dollar. We are informed that the process in no way hurts the springs, etc., in the locks.

Pieces like the blackened and blistered burners of coach lamps come out looking like such work when new, and just off a buffing wheel. The process was so simple, and the results so brilliant and satisfactory, that it made quite an impression on our mind; and that night, as we covered up head and ears to escape the assaults of the Minneapolis mosquito, we dreamed.

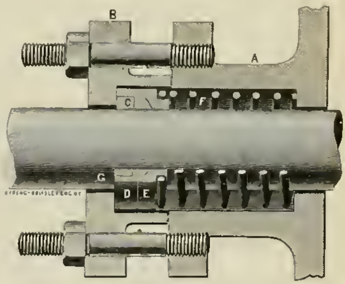
We were firing again, way back to the time when we first commenced trying to keep steam for old Paddy Flynn, with nothing better for fuel than ice with slivers in it; yes, it was the old 8-spot, double dome (brass), sand-box (brass), wheel covers (ditto), chests and cylinders (the same), and so forth, and so forth. We were coming into headquarters, and we looked into our seat-box at the collection of



WOOTTEN FIRE-BOX.

boxes of tripoli, rotten stone, emery, acid, sperm and lampblack, and wondered whether we had better scour in the afternoon or scrub her paint. We notice Paddy is slowing down, why, how's this? Yes, he's going in a big pit of something hot, and the track goes right through it. Paddy reaches over, and taking us by the nape of the neck, like a cat does a kitten, gets on top of the cab. Down we go into the scalding vat, up, out, down into another, and Paddy restores us to our seat. But what has happened to the "tray"? she is as bright as a gold dollar from the mint; there is no work for us to do this lay-over, alas! and alas! Ah! what's this? Paddy gives us a $5 bill, same one he borrowed two years ago; bliss indeed; but he is slowing down again, here's a line along close to the side of cab, easy enough to reach, and raisins, grapes, watermelon, cigars and chewing tobacco on it. Why, you bet we will just fill up the tank boxes—and we do.

Then we approach the terminal station, there's a big crowd there, and the minute the old three stops the train and then leans back against the bumpers, as though she were tired, a crowd of pretty girls in white come out and strew flowers in front of the left-hand gangway, and help us off, and give poor old Pat an order from the M. M. to take her to the house himself, and then pin bouquets on us, and escort us to a white carriage, where, seated on the petal of a pond lily, is our best and only girl; and we get in, and sixteen little bench-legged fairies fly away with us to—we are just wondering where, when we recognize the voice of the colored porter informing us that it's the last call for breakfast—if he had let us alone a minute more we should have been in heaven.



THE EXCELSIOR PACKING FOR PISTONS.

The Excelsior Metallic Packing.

This style of packing has been in use for a number of years on several roads, always with good success, but its systematic manufacture and sale has not been pushed until this year, when Watson & Stillman, of this city, commenced its manufacture. It depends on soft metal for all its steam-tight joints, no ground joints being used, it has less parts than any other metallic packing we know of.

The two rings, *C* and *D*, are the anti-friction rings, which fit tight against the face of the case *B*, and also between themselves, as shown.

The ring *E* and spring *F* serve to hold them in place when rod is on back stroke.

A patent concave copper packing ring is clamped between the faces of *A* and *B*.

The steam pressure keeps the rings tight on the rod and closes them up when they wear. It is claimed that the pressure on the rod is greatly relaxed when engine is running shut off—a feature that has enabled this packing to become a success on mountain roads where others have failed. The steam rings *C* and *D* are prevented from turning and presenting both openings at the same place, by a rib on one and a groove on the other—not shown in cuts.

The packing case on valve stems has a cellar into which the packing can go as the rod settles.

We recently saw a set of this packing that was taken out of a Jersey Central engine after a year's service that the engineer declared was as good as new.

The man who is going to lay a sea-serpent smoke-stack the full length of the train, and make "the flyer" look like a rocket on a drunk, is with us again.

The Smith Exhaust Pipe.

We have received from the secretary of the Smith Triple Expansion Exhaust Co. the following letter, which, if the work performed was the same in each instance, shows a remarkable saving of fuel by the use of the Smith device.

Bell's Gap Railroad Company.
Clearfield & Jefferson Railway Company,
Office of the General Superintendent.

Bellwood, Pa., August 3d, 1889.

Henry Lear, Esq.,
Sec'y S T E. P. Co.,
Doylestown, Pa.

Dear Sir · Referring to the Smith triple expansion exhaust pipe, at present in use on our Bell's Gap R. R. engine, No. 14, I beg to enclose you herewith a comparative statement of coal consumed by engine No. 14 and B. G R. R. engine 12, the latter being a consolidation freight engine of the same weight and type as engine No 14 The coal used was placed on the engines at the same tipple and was from the same colliery. I would further say that the pipe is giving good satisfaction, and we trust you will forward the additional pipes ordered as early as possible, to oblige,

Robert G. Ford, Gen'l Supt

Correspondence

On Measuring Indicator Cards.

Editor The Locomotive Engineer.

In Mr. Cyrus F Richmond's third paper on "Indicating Locomotives," in the August number of your paper, I notice the statement that, in measuring the length of ordinates on indicator cards, "a scale must be used that corresponds to the number of spring that was used."

Such a scale is convenient, but not necessary.

The "No of spring" to which Mr Richmond refers, represents the number of pounds pressure per square inch which one inch vertical movement of the pencil on the card will show with that spring.

Hence the indicated pressure at any point on the card can be obtained without the use of such a scale as Mr Richmond mentions, by simply measuring the corresponding ordinate in inches and any convenient fraction of an inch, and then multiplying the reading by the "No. of spring" used.

For instance, if the No. of spring was 80 and the length of ordinate is 1½ inches, then the pressure was 80 times 1½, or 120 lbs

Brainerd, Minn. Frank M. James

Can you tell me where I can get some indicator diagrams taken from locomotives, that I may study them up and thereby learn something of them. Hoping the L. E. great success, and to see the profession of steam engineering go up, I am,

Somerset, Ky. J. S. Johnston.

[The cause of pins heating in the center of bearing first, is the springing of the brass by the key Forcing the key between the end of the rod and the brass makes the center bind the pin, heats all, and produces just what our correspondent has observed—key carefully]

A Little More Cut-Off.

Editor The Locomotive Engineer:

There has been so much debating pro and con of late about the question of full throttle and short cut-off, that it is time some one *side-tracked* the whole business Each correspondent evidently thinks he is right and all others wrong. That is human nature. Why can't you agree on some happy medium, and let up on this paper and pen quarrel. I used to watch the reverse lever when I was firing extras on one of our prominent Ohio roads, and I always had the easiest trip with the man who hooked her back close to the center notch (always providing the engine was a good steamer and she was pumped in any decent kind of manner.

A saving of nearly 11 tons of coal in six days' work.

Chuck for Holding Packing Rings.

The accompanying engravings hardly need explanation, sizes being given, and the use of the device obvious. The chuck is placed on the spindle of lathe, same as a face plate, projecting out far enough to turn the deepest blank: the jaws are forced out evenly by the cone, and the cone held by the jamb nut, as shown; the jaws have shoulders on them to hold the rings true while the face or side is being trued up. This device was gotten up at the N P. shops at Brainerd, some years ago, and they are in use at all the shops on the road, giving good satisfaction.

We are informed that there will be an attempt made at Denver to have a law passed prohibiting members of the Episcopal church or the democratic party from becoming members of the B. L. E. We hope this will not become a law, and trust the members will sit down upon it—still, it is as reasonable and as fair as the laws against the firemen —just about.

Packing Ring Chuck

About the Heating of Pins and Bearings.

Editor The Locomotive Engineer:

I have been taking the Locomotive Engineer since January, and must say I like it very much Think it the best paper of the kind I ever saw

I would like to ask you some questions, as I don't profess to know it all, but am trying to learn all I can. I have been noticing for some time the heating of pins and bearings of different kinds, and seems to me that they always get hottest in center, and get hot in center first. Please give the cause I have had old locomotive engineers tell me the same thing about pins and bearings.

(The Lord deliver me from the man who will let his water get almost out of sight and then try to get her slopping it out of her stack in the shortest time possible.) This full throttle and short cut-off business will work on a level road and it will work on a hilly road on level stretches and such favorable places, but it *won't* work with all kinds of engines on all kinds of roads with all kinds of trains in all conditions of weather, and all the engineers, firemen, master mechanics, etc , in creation couldn't make me believe otherwise. I have always studied to make the best possible use out of fuel when firing with men who handled the throttle, reverse lever and pump or injector intelligently, have had good success. With these *I don't care how just so I get there* men I have nothing to say, only that *I* got there This coal saving business is not confined entirely to full throttle, etc , by any manner of means. I guess you will admit that a fair per cent. of it is due to intelligence in pumping or working injectors.

As to engines riding bad when working with full throttle and cutting off very short, I believe they are worse with a light train than with a heavy one, and I know that some engines are worse than others.

How about center of gravity, heavy counterbalances and lost motion in various places? I think they all contribute to make an engine roll, dance and hippity-hop around when cutting off short. I will say in conclusion that I work an engine in the notch that takes her over the road on time, be it down among the oil cans or in the center. I don't ride hobbies, but I do advocate economy W R. Cline.

McArthur, O

Dangers with the Air-Brake.

Editor The Locomotive Engineer:

A train of twenty-five loads (four air) running 30 miles an hour, broke in two behind second car just as we opened out in bottom of sag. We were two car lengths ahead of hind end before we realized what had happened, and had to hustle to get out of the way. The engineer put his valve at lap, but I think he should have used reservoir pressure to *help* release brake, and so have a better chance to get out of way. We run many trains with only three or four air cars. Is not the possibility of accidents of this character worthy your attention?

Goodland, Kan. WILL. MCLELLAN.

[With automatic brake, the danger referred to is not great for such a break; had the engine been provided with an automatic driving brake, the probabilities are that she would have been held against the train.

The beauty of the automatic is this fact, that the cause of danger—the parting of the train—is the very thing that sets the brake, and prevents the broken sections from separating far enough to do damage.

Your engineer did right in putting the valve at "lap," for he then preserved his reservoir pressure to release the brake when the opening in the train pipe was closed

The placing of valve at "full release" could not "help" let the brake off, unless it could maintain a pressure in the train pipe *greater* than that in the auxiliary drums, by turning his valve to release, he would have simply wasted air at the open hose, and not been in position to release brakes when the train pipe was finally closed.]

Explanation of the Valve Gear of Eastwick & Harrison Locomotive.

Editor The Locomotive Engineer.

The "mechanical business" in the steam chest of the old Eastwick & Harrison engines (with some of which, on the Balto. & Ohio R. R., the writer was familiar in his earlier and their later days), and about which your correspondent, W. de Sanno, wants to find out, was *a movable reversing block*, which was interposed between the valve and the cylinder valve face, or what would be such in an ordinary engine, and was moved forward or backward for forward or back motion respectively, by a rod corresponding with that marked F on his diagram The valve worked on the upper face of this block, and the lower face of the block fitted truly against the cylinder valve face

Five ports were formed in the reversing block, the central one passing directly through it, and being in communication with the cylinder exhaust port and the exhaust cavity of the valve, in either position of the block Near each end of the block there was a port which extended vertically through it, and in the forward motion position of the block these ports stood directly over the cylinder steam ports, thus enabling the valve to admit and exhaust the steam in the usual way. Adjoining these direct ports were two back-motion ports, set the same distance apart as the cylinder steam ports, but extending through the reversing block in opposite directions, that is to say, the bottom opening of each port was at the opposite end of the block from its top opening

When the block was moved into position for back motion, the bottom openings of the ports last mentioned communicated with the cylinder steam ports, and steam admitted to the port at the front of the valve passed to the back end of the cylinder, and *vice versa*. In other words, instead of reversing the position of the valve, as in the then and present standard practice, the movement of the block reversed the position of the steam port openings, relatively to the valve, and thus enabled one fixed eccentric to serve for both forward and back motion

If time permitted, the above could be made clearer by a sketch, which would also indicate what is, however, perhaps self-evident, viz., that the unavoidable cramping of the back motion ports prevented the engine from backing as well as she would go ahead. J SNOWDEN BELL.

Pittsburgh, Pa.

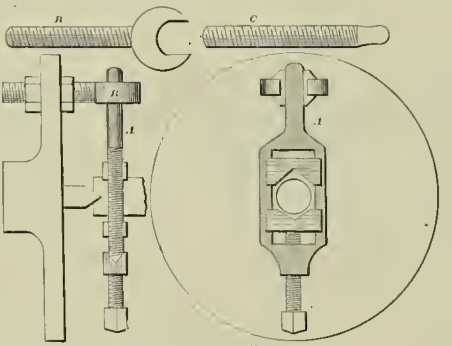
A Lathe Dog Kink.

Editor The Locomotive Engineer:

Will you allow me to contribute something to "Shop Kinks"? There is great trouble with the ordinary lathe dogs in use, in their tendency to twist around and throw the work out of the lathe, also in the slack in the hole or slot in the face plate promoting the evil.

To overcome this trouble, I made a lathe dog as shown in *A A*; it is an ordinary die dog, except that the shank is straight, as a driver I used a stud with a forked end. *B B* shows two views of it, and how it is secured to the face plate, and engages the dog; also used a plain stud, *C*, in my work, as it often happens we get work with a hole in one end, like a guide block, the stud *C* has two nuts on it; put it through your work, set up the nuts and use the forked stud *B* as a driver. In turning and cutting taps, put the work in the lathe and give the stud a twist, which takes up all slack between the fork and shank of dog. Make the studs about 6 inches long by ¾ diameter.

Inasmuch as lathe shears look better to be clean and bright, I had two brackets made out of 1x¼ iron, and bolted them on the back part of the lathe carriage, to which was secured a shelf about ten



A LATHE DOG KINK

inches wide and the length of the carriage. It made a very handy place for lathe tools, oil can, etc and was always in front of the work. To keep chips off the floor, get dirt-box made no wider than lathe shears, and as long as you please, get two hook-bolts to hook over the web cast between lathe shears, and put nuts and washers or strip of flat iron on underside of box and draw it up tight against bottom of lathe, hinge the opposite or back side of box to facilitate cleaning it, and you can keep everything neat and clean in and about your lathe.

These things are not patented; use them.

W. DE SANNO,

Tulare, Cal. Engineer and Machinist.

About Lift of Pump Valves.

Editor The Locomotive Engineer:

Will you kindly give me, through the columns of your paper, the following information as to which of the following arrangement of pump valves will give the best results, in general service:

Lift of lower valve........ .... ⅛"
" top or middle valve......... $\frac{5}{16}$
" check valve.... .... ¼"
Or lower valve .. .. ¼"
" top or middle valve... .... . $\frac{5}{16}$
" check valve. .... ⅜

Ft. Worth, Tex. Signed, G T

[There are many conditions that ought to be taken into consideration when talking about pumps. A pump will do well on a slow run that would be useless on a fast one, and one exactly right for a fast run will not do as well as one differently arranged on slow work; but to answer the question which way one will work best and give best general results, is the one that has ¼" lift on lower valve. We do not think the one with ⅛" on lower valve could be run with any satisfaction on a fast train; it would knock a pump all to pieces in a very short time. Before any one can give good advice in a matter of this kind, it is necessary to know size of plunger, size of valves, also size of air chambers on both sides of pump, and what are the limit of speed the engine is to run, as well as size of wheel.]

Don't

Editor The Locomotive Engineer:

I would say a word to firemen. If a strange man goes out in place of your regular engineer, *don't* start in to tell him how to run the engine; just keep right along at *your* work. If he handles the engine different from Charley, but gets there all the same, notice where they differ, and which have the best points, if he thinks best to carry lots of water, and you find the engine steams just as well, *don't* tell him Charley only carries half a glass. I ran for another man once, and I believed in keeping the glass up within an inch and half of the top. The fireman spoke to me about it, and said Charley only carried a little in the bottom of the glass, and sometimes very little in sight, and he banged the coal to her right along; *he* did not believe in the full glass. We might say right here, Charley is off the road for trying to keep the glass empty, but it was a *bar-room glass*. I supposed a case to this fireman: Suppose something should happen that the water would run out of the tank suddenly? With low water in boiler you would be on your back; or, again, you were switching and dropped off the track; tank hose gets torn off; no water in boiler, you must pull your fire and die right there. When it comes to steaming, a boiler full of water is not so sensitive to the pump or injector. I just supposed these and other things to him, and he is now a high-water convert. If your strange engineer *don't* start from a station in two movements, to wit: pull out the throttle, and pull up the lever in the center—*don't* tell him that is not the way Charley does—and then step over and haul up the lever on your own responsibility, as I had a man try on me once. If you are on time freight, have your fire in such a condition that the engine can git up and git, and if your new man handles the throttle and lever each a little at a time, and she steams just as well, and you get there just the same, put on your *thinking* cap, and for decency sake, when you go back, and some one asks you how about the new man, *don't* shrug up your shoulders, try to look wise, and say he is N G If you live long enough to be "sot up," be merciful to the engine, ninety-nine times out of a hundred the first thing a young runner does is to get an old hammer-hardened (so-called soft hammer), and set screw wrench, and just go after the rods, and the side rods get the worst of it, *don't* do it. If any one asks you how is the old 11? don't say she would be all right if she was fixed up, but she is all in pieces; perhaps you have been firing this very engine, and have just discovered her faults; at the same time the engine has been doing good work right along. Now this idea is not confined to firemen. I had occasion once to turn my engine over to another man while I was off on a trip. She was a 15x22, 48 inch wheel, and was used for special service It was not an uncommon thing to make fifty miles an hour with her on a special. I had to run her side rods loose; this fellow—and he was an old runner—would not have things that way, and called the attention of other men to her; he keyed up everything, took her out on a *freight*, and melted the babbitt out of her rod brasses. *Don't* condemn things you know nothing about; *don't* say that such and such an engine has too much lead, or she has no lead, or her valves want some of the lap cut off I went to the slate one day in the roundhouse to look at a report a young runner had made about an engine that had just been rebuilt, new fire-box, etc., but she was unfortunate in falling into this fellow's hands. "Engine 0 wants her valves squared in six inches; she is not square; she don't steam, the engine is no good, in fact, she is not safe "

(Signed) JOHN DOE

"And the villain still pursued her." *Don't* begin your engineer's life by kicking, finding fault with every engine that is unfortunate enough to fall into your hands, *don't* try to be wise by reporting a lot of imaginary work; *don't* try to walk like an old, broken-down engineer; *don't* ring in your experience amongst a lot of old footboard stagers —you have had no experience worth speaking of, *don't* come in and say *I* had a picnic, got laid for twenty-six, and old Willis held me two hours in the sand cut; when, if the truth was known, Willis got tired waiting for you to show up, and found you in the sand cut, beating the life out of your sand pipe, trying to make the engine steam. If any one asks, "What do you know?" just tell him that you know less than you did when you was firing, and that you *don't* know half as much as you will in ten years hence, *don't* get a wrench and heave on a set screw as hard as you would to screw up the nuts on the draft rods of your tender; *don't* try to wear a hat that is two or three sizes too large for you; *don't* imagine that because a man is not a Brotherhood fireman, or engineer, that he is a dumphool, and *don't* know anything about an engine; when you see a new valve motion, *don't* call it a "monkey" motion, simply because you do not understand it. Be a sensible man, and *don't* forget these admonitions; *don't drink whiskey*, but *do* read THE LOCOMOTIVE ENGINEER, and be happy, "and you will get there, Eli!"

Tulare, Cal. W. DE SANNO.

Reminiscences of Some Old Valve Motions.

Editor The Locomotive Engineer.

I note what is written in August number of the LOCOMOTIVE ENGINEER, under head of "From the Western Land." It is my opinion that a locomotive built with either a drop or V hook did do more and better work with less steam than they could do after being rebuilt to a link As I understand W. U. Junction, he was well acquainted with the engines in question. If so, why should he ask me to say how many eccentrics the 11 and 12 had, and how located or arranged, unless he wants to see if I know anything about these engines? Well, Mr. W U J., as to the number of eccentrics, there were four, same as our link engines now have, and set in same relation to the crank, providing cap and head of valve were the same Now, W U J may ask if there were but four eccentrics, what gave motion to the cut-off? Please remember, these engines in question were *inside* connected the motion for cut-off was given by an arm on forward crank-pin, this arm extended towards the center of axle At this end of the arm was a pin, the center of which was *not* over the center of axle, but remote from it enough to make the required motion. A rod was connected to this pin in the arm and to the lower arm of a rocker set on the running board, the upper arm of this rocker was curved to fit the length of a radius rod that connected to and gave motion to the valve stem. The end of this radius rod that coupled to the curved upper rocker arm was connected to a block that was fitted to this curved arm. In working, the farther this block was raised from the center of this rocker, the finer the cut-off When the sliding block was dropped so its center came just opposite the center of rocker, there was no motion to valve, but the ports down through the cut-off valve were, or should be, wide open. I have found them *not* wide open when in this position Now, all this is nothing new to W U. J. if he knew the engines well, and should he reply to this, I would like to see him sign his name, it might be I may know him I further know more about the old St. Paul R. R, back to the time it was the La Crosse & Milwaukee R R If there are any of your readers who were on deck about them times, would like to hear from them.

I note about the Stevenson balance valve casing or riding valve cut-off, *all balanced*. Why is not this something good for a locomotive, notwithstanding the *howl*, and where is the M. M who has confidence enough in the good qualities of a good V hook motion for main valve, with a riding valve cut-off to advocate its goodness by giving it a trial? I well remember of running a Fairbanks engine in New Hampshire about 1855, that had the V-hook and reversible cut-off, but not on the back of the main valve, but like the Lawrence engines 11 and 12, and it will be admitted, I think, by most engineers, that a man is full as likely to run as fast the first year as any in his railroad life and I can assure you, Mr. Editor, I never saw that engine run, but what she would feel an *outward* movement of the throttle. This, I would say, indicated freedom in working the steam. I have seen many link engines, some that were not so affected. It did not seem by their action that a *wide-open throttle* gave any more life to the engine than when half open. Was it not a small wheel Taunton, V-hook, variable cut-off, engine with which Jim Wood, on the N Y Central R. R, made his first fast time years ago—the then fastest time over that number of miles ever made in the U. S.?

What is wrong with this riding valve cut-off motion? My limited knowledge of railroading, gained in an experience since 1851, says there is nothing The regular *howl* of too many pieces and parts to *make* and *keep up*, that was the old tune, but to-day we ought to be able to put up pieces and parts with steel and with case-hardening, and by using lead packing, to give this—*the lost valve motion*—a good, solid, fair trial, for when I think back to the time of 1855, I can remember some cases where it required pretty good movement on part of conductor to get onto the last of four cars when starting out from a station. I would go some way to see one of our first-class locomotives, equipped with cut-off, say 18x24, 66" wheel, boiler 60, steam 180°, all other parts being equal, buckle onto a passenger train, and see what she could do with it as compared with an engine of like dimensions with a link I give these dimensions of engine and pressure of steam, as in the days just mentioned of the V-hook there was no such engine built or such pressure carried H. KINGSLAND

Ft. Scott, Kan.

An Air-Brake Puzzle.

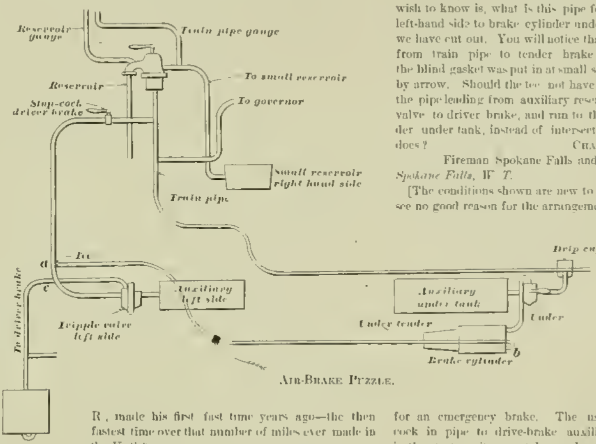
Editor The Locomotive Engineer.

I have been a subscriber to your valuable paper for some time, and have read it with a great deal of interest, especially the articles on Air-Brake Practice, by Mr. J. E. Phelan, and I would like, through the columns of your paper, to get a little information on an air-brake kink which has been, and still is, a sticker for us *all* here, as it was for the man who came with the engines and set them up. He left here, leaving us no wiser on the point than when he came, and the blind gasket was placed in the union shown in accompanying sketch at his suggestion.

The brakes are fitted up on two new Baldwin engines, as shown in sketch, and I will proceed to explain to you how they worked. In the first place, when the engines were all set up and in steam, the pump was started, and 80 pounds of air pressure jumped up, the small stop-cock below engineer's valve was opened, and the tender brakes set themselves. Right here is where the circus commenced. We kept altering the positions of the four-way cocks on the triple valves, but all of no avail; releasing the engineer's valve would set either the driver or tender brakes, and by applying the brake with engineer's valve, some would release and others apply. We found that in placing handle on triple valve on left side in vertical position, all brakes operated very well, but but not satisfactory. Later on the blind gasket was placed in union where hose connects between engine and tender on left side, the handles on triple valves placed in horizontal position, small stop-cock to driver brake left open, and everything is now serene, with the exception of the pointers on the air gauge, which both indicate the same when brakes are not in use, when engineer's valve is in position while running. Now what we wish to know is, what is this pipe for, running on left-hand side to brake cylinder under tank, which we have cut out. You will notice that it runs direct from train pipe to tender brake cylinder, and the blind gasket was put in at small square indicated by arrow. Should the tee not have been put into the pipe leading from auxiliary reservoir and triple valve to driver brake, and run to the brake cylinder under tank, instead of intersecting the line it does? CHAS A SMITH.

Fireman Spokane Falls and Northern Ry

Spokane Falls, W T.



AIR-BRAKE PUZZLE.

[The conditions shown are new to us, and we can see no good reason for the arrangement. The extra pipe running from *A* to *B* is an innovation, it was evidently intended to tap the driver brake pipe at *C* so as to use that pressure for an emergency brake. The use of a stop-cock in pipe to drive-brake auxiliary is wrong in the start, as it cannot be used as an emergency brake, as the drum is not charged when cock is closed. Where the driver brake is used for emergencies only the driving brake cylinder should get its air from the auxiliary on tender or the stop-cock should be placed between the auxiliary drum and the brake cylinder as at *C*, so that the drum and triple valve will always be charged. We should recommend the removal of that extra pipe, as its hose is liable to wear or rot out and prevent the use of driving brakes; it is also in the way.

We can see but two reasons why the pointers of double air gauge should not show difference of pressures: the gauges may be wrong or the feed valve stuck *open* Remove the plug under the service stop notch, and look at this. It is encouraging to find locomotive firemen who grasp such subjects as this, and go to the bottom of it—want to know the reason why. We have ignored his modest request to use only his initials. Modesty keeps many bright men in the shade, while they ought to be out where the sun can shine on them.]

One of our subscribers, Clarkson Maynard, located away off at Nagpoor, C P., British India, writes us that he will soon send us some articles on the road service of the British-Indian Railways. There is now no country in the world having a line of railroad, where THE LOCOMOTIVE ENGINEER does not go—talk about your "long-felt wants," even the Chinese are crying for it!

CONTENTS.

The Oldest Man.

The "oldest man" clause, for which the engineers fight so vigorously in every agreement made with the roads, is so manifestly unjust, and so plainly a damper on ability and merit, that it is a relief to see a clause such as the Wisconsin Central engineers have in their schedule, which reads:

"In promoting engineers to higher grades, the question of merit and competency for the service required must be considered paramount to age or rank." In regard to promotions:

"In making promotions, past record, competency and good habits shall take precedence over length of service, but any manifest case of injustice in promotion shall be subject to appeal by the Grievance Committee to the General Superintendent, and from him to the General Manager, if necessary."

The seniority rule is a combination of force to keep the ability of all the men in the service on a par with the poorest; if the "oldest men" are the best posted and most experienced engineers, they have nothing to fear from the younger ones. The only good thing the seniority rule does is to check the advancement of cousins and aunts, and other pet stock; but, after all, there is not much of this, and it could be easier cured for in some other way.

The seniority clause is a humiliating confession that those men who should, from their experience, be the best men in the service are afraid to stand a competitive examination—to be tested. There will be less of these clauses written in the future than in the past—and there ought to be.

John Livingston.

We have been repeatedly asked to help crucify Mr. John Livingston, alleged president of the Railway Shareholders' Association, who is making a howl about railroad men getting passes, and making considerable fuss one way or another—on paper. It has been discovered that this individual has sought passes from some of the roads himself, offered several radical remedies for strikes and strikers, offered to settle the Q trouble, and tell who hit Billie Patterson. If Mr. John Livingston is what he pretends to be, and is, indeed, a living thing in the shape of humanity, he is an egregious ass. We are inclined to think Mr. John Livingston is some stuffed stool-pigeon for a fool foundry, a detective agency, or a newspaper. Ten to one he is making his kick to get the labor press and the labor leaders on record with some very inflammatory and indiscreet language. Our advice to the enginemen of the country is to simply forget that such a mummy exists, do your duty to your employers—the company—your officers and yourselves, and rest assured that the management of the roads will see that your delegates get to the conventions and home again—as they always have.

Don't be so tender of your "rights" as to froth at the mouth because an outside cur snarls at your bone—he won't get it.

A Surface Condenser on Locomotives.

There are few railroad men who will not admit that we pay too little attention to protecting the steam chests and cylinders of our locomotives; they are practically uncovered and open to the cooling and condensing effects of our rigorous winters—a pretty good surface condenser. Perhaps there will be some light thrown upon this matter some day, and when there is we surmise that we will find one cause of the greater efficiency of English coal over ours—their chests are (as a usual thing) in the smoke arch and the cylinders under it.

We are pleased to note that Mr. Stevens, of the Lake Shore, is extending the lagging on cylinders clear around instead of only in front, and lagging the sides of steam chest. We want to see an engine tried with her whole saddle, cylinders and chests covered with mineral wool and cased in. We are of the opinion that such an arrangement would show a plain saving on any road in our 40-below districts. It is the pennies that make up the dollar, and it is the attention to details that make any machine an economical success.

A Great Work.

No other country on the globe supports such a costly and invaluable statistical publication as Poor's Manual of the Railroads of the United States. This work is issued annually at $6 per year, contains 1,700 pages numerous maps, and all the statistics and data that any person could desire about all the railroads in the country, a list of the officers, gauge of track, length, length of sidings, number of locomotives and cars, cost per mile, debt, interest paid, receipts, expenses, and a brief history of the road and its management.

The 22d annual number is about to issue from the press, and from the advance sheets we are enabled to give our readers a few figures showing the magnitude to which the railroad interests of the country have grown.

Railroading now has more invested capital and employs more men than any other industry or calling; this work estimates the number at 936,000 as actually employed on the roads, of course, this is not more than one-fifth of the people who live off the earnings of the roads.

We cull a few items of interest from among the thousands to be found between the covers of this great work.

The total number of miles of railroad in the United States at the close of 1888 was 156,082, of which 7,028 miles were constructed during the year—the rate of increase being 4.7 per cent.

The funded debts of all the lines at the close of the year aggregated $4,624,035,023, a sum of $437,091,907 in excess of the total of 1887.

The other forms of indebtedness of the several companies at the close of the year equaled $306,952,589, against $294,682,071 for 1887, the increase being $12,270,518. The total share capital and indebtedness of all kinds, of all the roads making returns, equaled at the close of the year $9,369,398,954.

The cost per mile of all the roads making return, as measured by the amount of their stocks and indebtedness, equaled very nearly $60,732.

The gross earnings or receipts of all the lines (including elevated roads) from which returns were received for the year, equaled $960,256,270, of which $251,356,167 were received from transportation of passengers; $639,200,723 from transportation of freight, and $69,699,380 from the transportation of mails and express matter, profits of leased lines, and other miscellaneous sources of revenue. In the latter sum are included the gross earnings of elevated railroads.

The gross earnings of all the lines for the year ending December 31, 1887, equaled $940,150,702, the increase for the year 1888 equaling $20,105,568, or 2.14 per cent.

The earnings per mile from which full returns were received in 1888 equaled $6,540.

The net earnings of all the lines for 1888 equaled $301,631,051.

The amount of interest paid in 1888 equaled $207,124,288.

The amount paid in dividends in 1888 equaled $80,243,041.

The number of persons transported in 1888 by all the lines was 451,353,655, against 428,225,513 for 1887, the increase for the year being 23,128,142.

The number of passengers carried one mile in 1888 equaled 11,190,613,679, against 10,570,306,710 for 1887.

The distance traveled by each passenger in 1888 equaled 24.78 miles; in 1887, 24.68 miles.

The amount received per passenger per mile equaled 2.246 cents in 1888, against 2.276 cents in 1887.

The number of tons of freight transported on our railroads in 1888 equaled 590,398,317, against 552,074,752 tons in 1887. The value of the tonnage moved in 1888, estimating its value at $25 the ton, equaled $14,633,957,925.

The number of tons transported one mile in 1888 equaled 70,423,005,988.

Engines on the "Soo" are fitted with a speed recorder, that not only publishes a record of speed run, same as the old Dutch clock, but also shows on a gauge in the cab the speed the locomotive is making at the time.

Cost of Air-Brakes.

We have before us a new pamphlet, just issued by the Westinghouse Air-Brake Co., in which they announce a great reduction in the price of their brake.

Formerly, it cost $300 to equip a locomotive, now it costs but $275. Passenger car equipment has come down from $138 to $100; freight car from $50 to $45.

Most of the prices for repairs have been greatly reduced; for instance, on air pumps, which have always sold at $200, a reduction of 37½ per cent. has been made, bringing them to $125; air hose coupling have cost $5, now they cost $2.50. We only hope that the reduction will serve to extend the field of this, the greatest of all safeguards to American train service.

There are invested in this brake in the United States alone, a capital of over $10,000,000, and this, by constant attention and repairs, is kept fully up to the original investment all the time.

The recent developments of the brake for freight service has made its use possible where it was impossible, and increased the efficiency of the device nearly 100 per cent. Before the invention of the quick-action triple valve, it took from 90 to 100 seconds to apply the brake to a full train of 50 cars—now they apply in *two* seconds. Before, there was an element of danger in handling long trains with the brake—now we can handle 50 cars as safely as ten.

A boiler maker with a great deal of experience tells us that it is his opinion that the cause of fire-box tube holes getting out of round is because it is the usual practice for boiler makers, in rolling leaky flues, to commence in the center, where they are the worst, and roll toward the corners, and in putting in new tubes it is customary to commence at the bottom and work up, each lower row of tubes springing the sheet a little until at the corners and top, stretching the metal enough to force the holes out of round.

ASKED & ANSWERED.

(37) C. H. R., Cape Girardeau, Can., writes:

According to my understanding of a theory, there is more pressure on the axle when crank is above it than below it. Pressure would be greatest on back of axle if engine was running forward, and on front of axle if running backward. Am I right or wrong? *A.*—We know of no practical reason why the weight or pressure on a locomotive axle should be different with the pin above or below the axle. In running ahead, of course, the axle pushes against the frame and draws the train, thus increasing pressure on the front of the axle, and in backing puts it on the back, for the same reason; practically, it would be very hard to find the difference in any of the cases stated.

(38) C. W. C., Toronto, Can., asks:

Will you kindly give me the diameter of the largest locomotive driving wheel that was ever made, and the fastest time the engine made. I think, if I am not mistaken, about a year ago there was a locomotive built in the old country with driving wheel 9 ft. 6 in., and made a distance of 80 miles in one hour. Also, largest size driving wheel on passenger engine that is running in America. *A.* The largest driving wheel we have heard of was the one of 10' 6", described on the first page of this paper for March last; there may have been larger ones built, but we do not know where. The largest wheel we know of in passenger service in America is six foot—years ago, the Camden & Amboy used to use eight-foot wheels.

(39) G. H. F., Springfield, Mass., writes:

Please tell me the most simple way to find out the horse-power of a steam boiler, and will you also please tell why they always use a curved link on a locomotive? Why could they not use a square link without any circle? *A.*—The horse-power of a boiler has always been an uncertain thing, without much uniformity of rule regarding it. The American Society of Mechanical Engineers have decided that the evaporation of 30 pounds of water per hour, under a pressure of 70 pounds, is equivalent to a horse-power, and is called a commercial horse-power. Links are curved in order to make the valve cut off equally when hooked up. Straight links are often used where the engine works at full stroke all the time, the office of the link being simply to reverse. The Allen link, much used on locomotives in Europe, is straight, but has compensating toggle joint in the stem that equalizes its cut-off.

IN THE ROUNDHOUSE AND REPAIR SHOP.

Editorial Correspondence.

WISCONSIN CENTRAL.

In his rounds for items of interest the writer headed for the Northwest early in the month, with designs upon the Wisconsin Central and the Northern Pacific.

The Wisconsin Central road runs from Chicago northwest, through the State of Wisconsin, to St. Paul, with a line from Abbotsford almost due north to Ashland, on Lake Superior, and another running south from Stevens Point to Portage, in all 775 miles. They have in service about 150 locomotives, and, having been bought and rebuilt under men of ability, they are not just like any engines you see any place.

The motive power is under the superintendence of John Player, but Mr. Player was in Europe, studying compound locomotives and compartment carriages, so I found the main shops at Waukesha in charge of General Foreman Alva Mitchell.

The Waukesha shops are entirely different from any other railroad shops I have ever visited. The boiler shop, smith shop, wood shop, foundries, etc., are each in separate buildings, especially well lighted, and so situated as to admit of their being enlarged without crowding other buildings, and the shops requiring the transfer of heavy pieces—like boilers—being across the transfer table from the main shops, while shops for light work, like the tin shop and brass foundry, are on the other side.

The main shop is a long, one-story building, built, as all the shops are, of white brick. In the front, and up a stair, are located the office of Superintendent of Motive Power, the General Foreman's office, drafting-rooms, etc. These rooms are lighted from the front, and the balcony in front of the doors overlooks the shop from an elevation of about twenty feet.

HANDY CRANES.

Standing at this end of the shop and looking down its length, we find on the right hand twelve stalls, each connected with the transfer table outside; over these stalls two huge traveling power cranes are hung. Either of these cranes can pick up a complete locomotive and carry it off, and they do all the "jacking up" there is to do. One of these cranes will pick up a boiler and set of frames complete, while the workmen roll the wheels away and place their blocks where they want the boiler and frame to stand.

Of course, such cranes as this have to be supported on heavy framing, and the heavy frames at the shop end of the big cranes serve to support one of the tracks for another set of traveling cranes of much smaller size and capacity. These cranes are strong enough to pick up any piece of a locomotive except the boiler, and driving wheels, frames, etc., are taken from the large open aisle back of the pits to any of the heavier machine tools, such as driving wheel lathes, slotters and the heavier planers and lathes, which are all arranged along this open aisle. Any man on these tools can pick up and place his work on his tool, and take it out and back alone.

Over the lighter tools another and a lighter set of traveling cranes are located, that will pick up and handle all light work to and from all the light tools. These two sets of cranes are handled by hand, and are located above the shafting, so that it is only necessary to avoid the belting with the load, and, as the tools are all arranged in rows, it leaves clear paths for handling work.

Every pit in the shop had an engine on it, and the shop seemed full of men, the machine shop is under the immediate charge of W. S. O'Brien.

In the roundhouse I stumbled on to traveling engineer R. McVicar, and found in him a progressive engineer who is proud of his profession, and desirous of seeing the engineers of the country place themselves upon a higher plane as skilled mechanics.

DESIGN OF LOCOMOTIVES.

The locomotives of this company are mostly 8-wheelers of modern build and design. On the sides of the extension fronts will be found no unsightly hand-hole plates to punch cinders through; the only hole provided for this purpose is under the number plate in the front door—the number plate coming off with the plug. This makes a neat arrangement, and provides all the poking facilities necessary.

The arrangement of check and branch pipes are peculiar on this road, and are spoken very highly of by all the enginemen we talked with. The check is a pipe check, and is located in the branch pipe close to the injector, or just outside of the cab, the pipe makes a gradual descent along the boiler, and turns down well in front where checks are usually located. Instead of a check, there is a globe valve here, and below it an elbow tapped into the boiler. By shutting down this globe valve the injector or check can be removed or repaired, and it is claimed that in the coldest weather—and they have 40 below there—that this pipe never freezes up, being open to the boiler, and without downward bends to form traps.

TRUCK BOX OILER.

They use a very neat and ingenious tender-brass and oil-box, designed, as was the branch pipe arrangement, by Mr. Barnes, a former master mechanic.

The brass nor the truck box have no oil-holes through them, but the brass has a recess cast in its top, with oil-ways running down to the edges of the brass, and between it and the box, on the inside of the box and above the axle, a hole is drilled in line with the axle to the center of the box, and there communicates with the oil-way on top of brass. To the side of box is bolted a square cast-iron box, holding about half a pint of oil, this is filled with wool, its cover bolted on, and a filling-hole left on top. On the side next the box, and near the bottom of the cup, a small copper pipe is screwed into oil-box, this pipe extends through the hole in side of axle-box when the cup is bolted to it, and delivers the oil to the recess in the brass. Thus the oil is always clean, there are no holes to stop up, and the oil is delivered to the axle as it goes under the brass, and not on top, where the load tends to keep the oil off the axle. This is one of the best devices for oiling trucks I have ever seen, it is clean, neat, and sure.

CINDER HOPPER.

The cinder hopper under arch is a large, straight pipe extending down toward center of track, it is closed by a taper plug entering it from below. Formerly this plug could be opened and closed from the cab, but now they are arranged to open by a lever worked from the ground, and held in place by a clamp and set screw. Designated places having been arranged as the only place where cinders should be dumped, the handy cab lever was taken away to prevent the boys being tempted to disobey orders.

The Newth ash-pan is used—the bottom formed of cast-iron slats like a window shutter, but these have also been arranged to dump only from the ground.

A recent fire at the Ashland roundhouse had sent four locomotives to this shop for new wood work and new paint, and illustrates the bad plan of keeping oil and storehouses near shops and roundhouses.

IMPROVED COAL BOARDS.

The coal boards are in the form of doors hung by heavy hinges at each side of the tank, and held together in the center by a heavy bar, the doors themselves being two-inch oak, heavily ironed. These coal boards are higher than the tank but have a good-sized arched opening at the bottom. They open in, or toward back of tank, cannot be lost or stolen, keep dusty coal from flying, and will hold back the coal from coming into cab in a considerable of a collision. They help complete the storm curtains in winter, a short curtain being used between back of cab and these doors, and curtains to the gangways beside the regular back curtain.

The transfer table has no propelling power at present, being designed for an electric motor that will soon be put in.

The shops are lighted by electricity throughout, an independent plant being provided for this purpose.

The tools are driven by a fine Brown automatic engine.

In going over this road we experienced our first train robbery, one man and a pair of revolvers got into our sleeper, and touched three men for their watches and money. The porter was active and noisy, and the robber, taking a shot at him, jumped off.

The Northern Pacific.

This great road reaches from the Mississippi River and the great lakes to the Pacific Ocean, and has 3,280 miles of road, and upwards of 500 locomotives.

The road is the busiest one in the Northwest, the freight men being run very hard, and every engine that will turn a wheel in service.

The general offices are at St. Paul, and in the office of Superintendent of Motive Power Small we found the neatest and best board for keeping track of engines we have ever seen, the board was designed by Chas. Craig, who was chief clerk of this department under Mr. Cushing.

It is laid off in small shelves about an inch deep and six or eight long, and is as high as a man can conveniently reach, and the top slightly inclined back. The districts of the road and the shops are arranged in vertical rows, and the engines designated by blocks of wood about one inch square and three long, these blocks have in large plain, red characters, the number of the engine, the rest of the data in smaller type and black, something like this:

259 **18 X 24 - 4 - 62**
N. Y. Locomotive Works. 1883.

This tells the number of the engine, size of cylinder, number of drivers and their size, the make and date of building.

To the right of this is placed a cube, on each face of which is printed one of the words, Pass., Freight, Switch, Good, Fair, Poor; thus, by using two of these is added the information what service employed in, and what condition of repair.

Mr. Small is having another set of blocks prepared that will tell whether provided with driver brakes, whistle signals, etc.

If engine 259 is in service on one division and is transferred to another, the set of blocks are placed under the column headed by that division's name; if she is reported in poor condition, the cube is turned from fair to poor; if she goes into a shop, her block is placed under that shop name.

The whole device occupies little room, is quickly changed, and tells a great deal.

The main shops of this company are located at Brainerd, in the northern part of Minnesota, but the coach shops are located near St. Paul, at Como.

I spent a very pleasant afternoon at these shops, but will be obliged to use what information I picked up there at another time, as I was after locomotive repair shops and locomotives themselves.

The road from St. Paul north is a dusty and sandy one, and I should say a very hard one on machinery. On the way up I rode on a locomotive equipped with Cushing's reverse lever, which was illustrated in this paper last year; it works very well, the engineer being able to set the lever in any position without disengaging it from the quadrant.

BRAINERD SHOPS.

At Brainerd we found extensive shops, substantially built of white brick, heated by steam, and fairly well equipped with tools and full of work.

The engines employed by this company are mostly moguls for freight and eight-wheelers for passenger, but the new passenger engines are heavy ten-wheelers.

As fast as they go into the shops they are relieved of the big stacks, known as the Cushing stack, and get straight stacks and extension fronts; the old stacks cost in the neighborhood of $65.00, and were very expensive to keep up—the extensions need very little repairs.

The Brainerd shops are under the management of Master Mechanic A. Bardsley, who has been with the road for a good many years. The shops are not so different from other shops as to need description, except that they are large and not crowded together; the pits in the main shop are arranged at one side as usual, and over them—or rather at the rear of them—is hung a light shaft especially arranged to use rope belting to drive cylinder borers, valve-seat facing machines, portable drills, etc. There is a small turn-table in the center of shop, big enough to turn a truck on.

SOME KINKS.

This road has lots of very bad water on the western divisions, causing much trouble with injectors. Mr. Bardsley takes the old style Monitors and cuts them in two just back of the overflow pipe and joins them with a large brass nipple; then they can be taken apart same as in the later style of Monitors with flanges.

The front end door is flattened in center to just the size of the number plate and turned true, the plate being laid flat against the door, this prevents the plate getting knocked off every time they strike a cow, but makes it a little harder to clean.

In the boiler shop they are cutting off the leg of fire box on a number of old moguls, and converting them into six-wheeled switch engines by placing the back axle under the box, and taking out the pony truck.

They use steam cylinder packing with adjustable bull ring, the center of bull ring being lightened by being cast with a recess inside.

All about the place are evidence of this company's fights with Jack Frost, snow-plows and flangers stand around in every vacant spot. There is everything from a board on a pilot to the steam rotary.

All the engines are provided with Jerome metallic packing for valve stems and pistons; it runs a year without attention.

We noticed in some new eccentric straps a large cellar is provided.

The new straight stacks are made of sheet steel and riveted fast to the stack saddle, no joint being provided between stack and saddle; this looks neat and gets the cost of stack and saddle down to less than $20.00.

Rocking grates are used with fingers 12 inches long and very large; we should think this would be a good plan, as it reduces the number of rockers, and consequently the number of connections.

The front ends are arranged with deflector ahead of the nozzle, substantially as shown some time ago in the D. L. & W. engines; single and double nozzles are used, preference being had for the double, the claim being that the engines steam better—I cannot understand this.

INGENIOUS BLACKSMITHING.

The blacksmith shop is under the charge of N. W. Wheatley, is large and well conducted. Side rods are here forged up so perfect that they are not finished at all except at the end for the strap; they are larger in the center than at the ends, the edges beveled, and look, when painted, just as good as a machined rod—indeed, I could not believe they were not until I examined them critically.

Mr. Wheatley is anxious to try his hand at fluted rods, and feels sure he can forge them to exact size.

Old tire is used up for tools, solid-ended wrenches for track and for engine use are made in dies and used without other finish, ball pene hammers are made of this steel for twenty cents each, and used without even grinding the face.

Springs are neatly got up, and we noticed that, instead of welding a strip upon the top leaf to keep the hanger from slipping toward the band, the leaf is turned over, and an oblong projection punched up that answers the same purpose, is neater and cheaper.

All the roundhouses of this company that we visited have a pit running around the house at back of pits, in which are located the water and steam pipes. I should think that in event of that common incident of an engine going against the back wall, that this pit would tend to increase the damage liable to be done; still it might simply serve to stop the engine and save the walls.

Extensive car shops are located here, the new saw and planing mill being the best one I have seen, every machine being thoroughly piped to an exhausting system that carries every bit of sawdust or shavings away, leaving a perfectly clean shop.

The main machine shops at Brainerd are under the care of general foreman H. Tomlinson.

The entire upper floor of the large office building is used for drawing rooms, M. M.'s office and library. The drafting rooms are under the care of O. H. Reynolds, who takes especial pride in his department of the business, and can turn to a drawing of any detail of any engine on the road in a moment.

The largest and most elaborate blue printing frame I have seen is here in use; the glass is about 8x4 feet, the prints turned out being very uniform and perfect.

A NEGLECTED OPPORTUNITY.

There is a very large library room here, with several cases well filled with books, all the principal periodicals of the country, and numerous drawing tables for students. While this is free to all employes of the company, we are sorry to have to record the fact that it is very little used; not a single apprentice is trying to learn drawing, and few books are taken home. It seems a shame that this library, with its hundreds of dollars worth of mechanical books, so eagerly hungered after by so many ambitious men in other places, here lies almost entirely idle.

FARGO.

Two hundred and seventy-seven miles west of St. Paul, and just over the Minnesota line in Dakota—North Dakota, if you please—is the busy little city of Fargo.

Fargo is division headquarters for several roads, but the Northern Pacific is the only one having any important shops here.

These are quite extensive, well built, nicely located, and the cleanest that I saw anywhere along the road.

They are under the management of master mechanic S. L. Bean, ably assisted by general foreman Wm. Hawser.

It was hot the day I spent at the shops, but twenty-two snow-plows standing in Indian file beside the roundhouse, bore mute evidence that the inhabitants of Fargo are not knee-deep in June all the year around.

INGENIOUS TOOLS.

Wm. Bretting, now in a similar position at Brainerd, was formerly foreman of tools here, and many evidences of his ingenuity are to be seen. One, a lathe attachment for turning solid cross-head pins, works nicely, despite the fact that it was made of such material as old hand-car gears.

A flue-hole cutter of ingenious design is here used, the knives being plain cutters held to the central arbor by a band shrunk around them.

A very handy kink of Mr. Bean's is a device for separating the valve stem from the rod when corroded fast. This consists of a clamp made to pinch the valve stem and a heavy fork to go over the stem and against the coupling or sleeve of the rod, these two clamps are held in place by two bolts, on which are loose nuts; the forcing apart of the clamps by turning the nuts breaks the joint.

A key-hole in the sleeve and behind the stem, prevents the necessity of such a device, but where there are no such holes the fits are often ruined by pounding.

This shop, like several others we noticed along the road, is continually threatened by fire from the proximity of an immense wooden coal chute.

In the shop the usual work was going on, but here and there little evidences of improvement show themselves. Division master mechanics on great systems like the N. P. have not got the opportunity to show their personal ideas that master mechanics on little roads have—they must keep within the standards.

A neat swing crane of home make has recently been put up, so as to cover a large floor space and the big wheel lathe.

Being a great country for sand and dust, Mr. Bean has recently made some experiments to keep dirt off the guides, by fastening a plate of sheet-iron on the back of the top of Laird guides, allowing it to extend below the lower one considerably; he has got rid of considerable of the dirt, which generally comes from between the tracks.

The Fargo shops, like all the others on the road, are heated by steam, and the ample display of heating surface in the pits and about the tools, bear evidence that the forty-below stories the boys tell are not all fairy tales.

CASE-HARDENING.

The blacksmith shop here is a very neat one for a small shop, and they do some of the nicest work in case-hardening links, etc., that I ever saw. The work comes out of the furnace clean and bright, without that scaly, scabby look so common; broken pieces showing a clean $\frac{1}{16}$ of hardened surface.

The plan followed originated in the shop, the result of some investigations by Mr Bean and the foreman. The receipt is as follows:

For an ordinary set of links and pins, take of salt, 15 pounds; sal-soda, 4 pounds; dissolve these in water. Then take of oxide of manganese, 1½ pounds; rosin pulverized, 1½ pounds, pulverized charcoal, 1½ pounds, these last three mixed together, then mix all the ingredients together and pack around the work in the box, being careful to have the pieces entirely surrounded with the compound. The addition of a few small limestones helps matters, but is not necessary.

Heat very slowly, or the cover of box will be blown off. A wood fire is considered best. Nine to twelve hours in the furnace does the work.

MANDAN.

A few miles west of Bismarck, and across the Missouri, lying between it and the Heart River, in an arid basin, lies Mandan, where are located the shops of the Missouri Division.

Mandan, like Fargo, is at one end of two engine districts under one master mechanic, so that one half the engines are not running where the M. M. can see them or they can easily get to the shops.

If the Fargo shops were at Jamestown, and Mandan shops at Dickinson, an improvement would be made, but, like lots of other things in a new country, they were built just where they are, and nobody seems to know why.

The Mandan shops are on about the same general plan of those at Fargo, being, however, a little further apart.

They had just lost 700 feet of coal chute, 3,500 tons of coal and twelve cars by fire; the chute was far enough away to save the shop.

The Mandan shops and the motive power of the Missouri division are under master mechanic J. E. Phelan, who is well known to the readers of this paper as the author of a popular series of air-brake articles.

The back shop is looked after by gen'l foreman T. W. McFarland, and the car department by J. F. Pilcher.

FROTHY WATER.

This division, 215 miles, has the worst water to contend with I have ever seen. Not so much in the scale-making line as in causing foaming; the water in the water glasses looks like sour milk.

It is very hard on the sheets and tubes, pitting, cutting and grooving them like acid.

All the engines have mud drums and blow-offs on them, surface blow-offs and the old stand-by on the water leg; these cocks are globe valves, and arranged to be handled from the running board when running; the men blow their engines out very thoroughly several times over the road, and every boiler on this division is washed out every hundred miles, even the switch engines at Dickinson get washed out every 24 hours.

Such water makes the expense of boiler repairs very high. The only thing found to stand the corroding effects is "Kalemein" flues, made of a peculiar white metal, but very expensive, a set costing from $600 to $800.

When I was there, this whole district was suffering from a water famine—many freight trains being obliged to wait at tanks for water.

DROP PIT.

Mr. Phelan has just completed a drop pit in his roundhouse that is designed to save lots of work, an old hydraulic jack with a broken flange will do the letting down and replacing act.

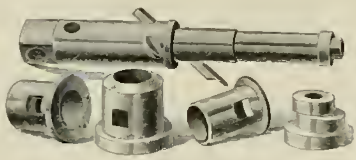
Most of the new passenger engines on this division are heavy ten wheelers of Baldwin make, with a wagon-top boiler having radial stays.

In the tool room I observed that one of the principal jobs was the renewing of tubes for injectors—Monitors being chiefly used.

In the boiler shop they are building a fair-sized lye vat, to cut the grease off work, such as used at the Renovo shops of the P. R. R.

WASHING HOT.

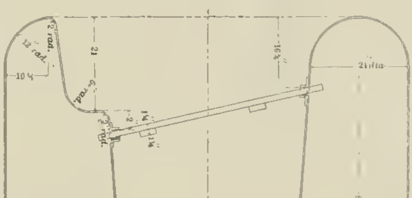
I was greatly surprised at the results here and at Dickinson, where they take engines with steel fireboxes to the house red hot off the road, knock out their fires, blow out, wash with cold water, fill up, fire up and have them ready for service inside of two hours, without a case of cracked sheets or other trouble from this cause. No doubt these engines would steam better and throw less smoke if they had brick arches, but the arch gets hot enough to warp sheets and melt out soft soft plugs, during the blowing out and washing periods.



VANCE TUBE CUTTER

Several feed-water heater and purifier men have been up there, met the enemy, and—are theirs. The Rushforth heater and circulator did just what was not wanted—stirred up the water from the bottom—it made the engine foam worse.

The Smith purifier, a pair of drums inside the boiler, designed to receive the deposits of impurities and keep them out of the boiler, did little better, there being no deposit of scale, but an excess of something that looks suspiciously like milk shake.



MORE ROOM IN THE TANK.

DICKINSON

Is something like a hundred miles west of Mandan at the entrance to the "bad lands," and is the center of Mr. Phelan's domain; there is here a small repair shop and large roundhouse, mostly new, steam-heated and in good shape. J. W. McQuay has just got off his locomotive to become general foreman here, and has considerable of a chance to clean house—and is getting there steadily.

The coal used in this country is good, but not the best. I noticed that every pile of cinders from the extension fronts was inclined to burn, not only themselves, but the ties and any pilots that might scoop up a handful of them. I should think that a cinder chute from the side of the arch, where the cinders are blown out with water, would be the thing for such coal and conditions.

J. A. H.

Vance Tube Cutter.

Last year we illustrated this tube cutter in its old form, but it has been so much changed and improved that it is, in fact, a new tool.

As will be seen, the cutter proper is all complete in the upper cut, ready to be used in cutting out tubes for that size, and by changing the sleeves shown below, and the washer on the end to keep the tool central, four different sized flues can be cut with the same tool.

The Vance cutter has no rollers or small parts to get out of repair, but is a heavy tool for hard service. The body of the tool is placed in the tube to be cut off, the knife placed in the inclined slot and driven through the tube, inside the sheet, and then the tool revolved one revolution, shearing off the tube and leaving so neat a finish as not to require scarfing to weld on safe ends.

This tool is made by the Vance Tube Cutter Co., Geneva, N. Y., who will furnish lists of upward of fifty roads using the device.

More Room for the Fireboy.

On this page will be found a new plan of water tank designed by W. T. Small, Supt. Motive Power N. P. Ry., for heavy consolidation locomotives.

When these big engines are provided with tenders in proportion to their size, the room to throw coal ten or eleven feet was too small; the gangway could not well be widened, for that meant longer wheel base, and if any longer, could not be turned on the tables in use.

Mr. Small got around the problem nicely, by taking a corner off the water leg on the fireman's side, and inclining the coal boards in such a way as to give more room on that side, and still store the same amount of coal.

Men who are trying to cover a ten-foot fire grate from a two-foot gangway, with an unused brake staff on the left side, which cannot be removed because it is "standard," will appreciate this kink.

The Greatest European Railroad.

At an after-dinner speech at Crewe, before the visiting American engineers, Mr. F. W. Webb, locomotive and car superintendent of the London & Northwestern Railway, stated the following: The company has a capital of $528,000,000; annual revenue, $51,700,000; and annual expenditure, $26,500,000. The number of persons employed by the company is 60,000; in locomotive department, 16,000; miles operated, 2,500; stations, 800; signal levers in use, 30,000; lamps lighted every night, 13,500; cabins, 1,400. The number of passengers carried annually is 57,000,000; weight of tickets issued, 50 tons; number of tons of goods and minerals carried, 36,000,000 annually; engine mileage per year, 55,525,334. Last month, with a mileage of 4,750,000, they had with the passenger trains only one hot crank-pin, and with the goods trains two such failures, and they had only one failure of a connecting rod for both goods and passenger trains. The number of tons of water consumed was 20,000 per day; coal used, 2,700 tons per day; pounds of water evaporated per pound of coal used, 7.45. During the year, beyond the ordinary services they had run 41,314 special passenger trains, 47,238 special goods trains, 78,285 special cattle and mineral trains; total, 166,832 trains. The company owns 58,000 freight cars, 5,600 passenger coaches, 3,200 horses, 3,100 carts, 2,500 locomotives and 20 steamships. Crewe engine works occupy 116 acres of ground, the covend area being 36 acres. While it may require an actual personal inspection of these lines and works to obtain a full realization of their dimensions, yet the above general statement and a comparison of it with some of our largest American railroads will show the extent of railroad operation under one management on a little island not much larger than New York State.—*Ry. Gazette.*

Questions and Answers for Engineers and Firemen.

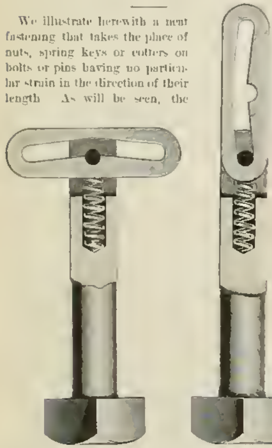
Geo. W. Cushing, Supt. Motive Power and Machinery of the U. P. Railroad, has prepared a book for distribution among his enginemen. It is in the form of examination questions and answers, and covers a wide range of subjects, including combustion, air-brake practice and break-down emergencies.

Anything and everything of this kind tend to the education of enginemen—if the enginemen only try to absorb some of the information thus offered.

The time is fast coming when engineers will be selected on competitive examination; how will you stand when that comes?

Wright's Bolt Fastening.

We illustrate herewith a neat fastening that takes the place of nuts, spring keys or cotters on bolts or pins having no particular strain in the direction of their length. As will be seen, the



fastening cannot become separated from the bolt, will go through any hole the bolt will, and stay in any position fixed by the tension of the spring. We should think this bolt would be particularly useful in brake rigging for cars and tenders.

It is made by the Wright Manuf'g Co., Phila., and sold by Pedrick & Ayer, of the same city.

Fairbanks & Co., of this city, have favored us with one of their new catalogues for 1889. This firm are the sole agents for the Handcock inspirator, of which there are probably more in use, in stationary practice, than all other forms of injectors combined. This firm have recently placed on the market a very complete line of brass and iron plug cocks packed with asbestos; if they can make a plug-cock that can be used for a blow-off for locomotives, and that won't stick, shut or open, and will let a man get within forty feet of it after it has blown five minutes, they will have made themselves immortal to the railroad men of the country.

It is estimated that the presence of $\frac{1}{16}$ inch of scale causes a loss of 13 per cent. of fuel; $\frac{1}{4}$ of inch, 38 per cent., and $\frac{1}{2}$ of an inch of scale, 60 per cent. The Railway Master Mechanics' Association of the U. S. estimate that the loss of fuel, extra repairs, etc., due to incrustation, amounts to an average of $750 for every locomotive in the Western and Middle States.—*Exchange.*

On the N. P. road and the Wis. Central we observe the use of an intermediate check valve about midway in the length of the branch pipe, the line check being dispensed with. On the Wis. Central the branch pipe has a globe valve next the boiler, in place usually occupied by check, and the pipe bends up from this instead of down, as is the usual practice; this leaves no trap for water to freeze in, as the the check in pipe is well back next injector.

On the N. P. road, as soon as a passenger train arrives at a station where engines are changed, the car repairers—galvanizers—put out a blue signal flag or lamp on a post provided for that purpose, and then proceed to inspect the wheels and running gear of the the trains; when they are through the signal is removed, and a gong rung, to signify that they are through, and the train can be moved without danger to them.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO. X. | NEW YORK, OCTOBER, 1889. | 1.00 per Year or 10c. a copy.

A Modern Passenger Locomotive.

Historical locomotives are interesting, and it is not the purpose of the paper to abandon the series, but to continue them a little more thoroughly mixed up with modern practice.

The subject of the accompanying engraving is a first-class modern passenger locomotive recently built by the Rhode Island Locomotive Works for the Cincinnati, New Orleans & Texas Pacific. Gauge, 4' 8½". Fuel, bituminous coal. The drawings are complete, just as made by the works to build the engine to, and below are the complete specifications, so that our readers who are not as familiar with building as they are with repairing, running or firing, may see just how the new locomotive is planned and got out.

TUBES

231 2" O. D., 10' 7" long. Material, Franklinite steel No. 12, B. W. G. copper ferrules at fire box end. Placed 2.7" centers in vertical rows 2⅛" apart.

CYLINDERS

18"x24", exhaust ports, 17"x2¾", steam ports, 17"x1½" (1 13-16" at seat). Allen Richardson valves. Lap inside, 0", lap outside, 1 3-16"; travel (full), 6¼"; maximum cut-off, 20½"; minimum cut-off, 1½". Lagged with asbestos.

CONNECTING RODS

Best mild steel; main rod solid, fork end on back; parallel rod solid ends, made extra deep in center of rod. Oil cups, R. I. L. W., needle index cups of large size, and cellars.

CRANK PINS

Best hammered iron, case-hardened and ground. Sizes, main, 5½" diameter x5"; parallel, 5" diameter x3½".

SMOKE-STACK

R. I. L. W. style; taper inside from 15¼" to 18"; jacketed by an air space; height from smoke-box, 50"; total height from track, 14' 2⅛".

THROTTLE

Balanced type, wrought iron dry pipe; all steam ducts from boiler to cylinder made ample for high piston speed.

WHEEL BASE.

Driving, 9' 1". Engine, 23' 2". Engine and tender 44' 8½".

TENDER.

TANK.

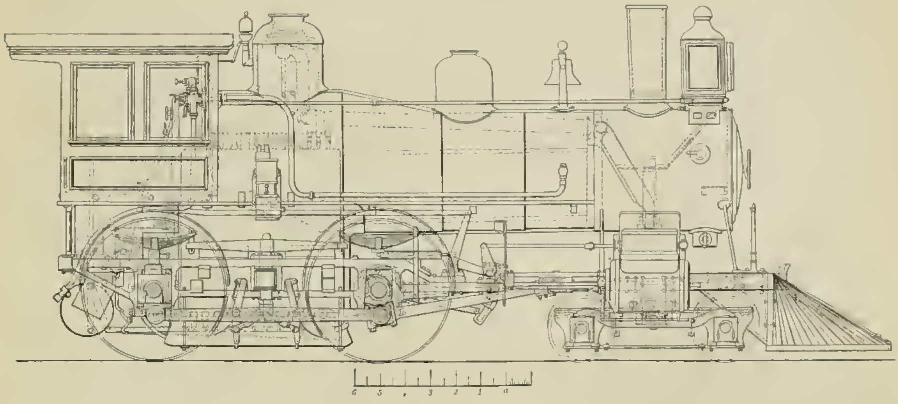
Tank iron, all plates ¼" thick; capacity, 3,500 gallons water; 4 tons coal of 2,240 pounds.

FRAME.

Oak, 12" deep, strongly braced.

TRUCKS.

Two 4-wheeled center bearing with side bearings on back truck; wood bolsters supported on 4 full elliptic springs.



BOILER.

Wagon top with deep fire-box and extension arch. Material, best Shoenberger steel, ½" thick; throat sheet, ⅝" thick. Waist, 56" diameter at first course. Seams, double-riveted circumferential seams, double riveted with welt strips on long seams. Designed to carry 170 pounds. Back head of boiler made a perfect circle, the top and sides of wagon top made of one sheet. Boiler lagged with asbestos plaster.

FIRE-BOX.

Material, best Shoenberger fire-box steel. Crown, ⅜"; back, ⅜"; sides, 5-16", and tube sheet, ½" thick. Size at ring, 78⅛"x35⅝". Water space, 3" at sides, 3½" at front and back. Crown bars, 6½"x¾", placed 4¼" spaces; ends forged on bar. Stays, ⅞"x1"; four top rows drilled ½" deep from outside to detect breakage. Furnished with fire-brick arch supported on four water tubes. Fire door, 16"x18", R. I. L. W. special door with adjustable inlet and steel deflecting plate for air.

HEATING SURFACE.

Fire-box crown	29	square feet.
Vertical surfaces	128	" "
Tubes	1,315	" "
Total	1,472	square feet
Flue area	4.14	
Grate area	19.19	

CROSSHEAD.

Four-bar type of cast-steel, brass bearings top and bottom.

DRIVING WHEELS

68" diameter, Krupp crucible steel tires, 3" thick, both pairs flanged. Total play on track, ¾".

DRIVING AXLE

Best hammered iron. Journals 7½"x8".

ENGINE TRUCK

4-wheel, rigid center, wrought-iron. Wheels, Krupp No. 1 crucible steel. Tires, 30" diameter.

FRAMES

Sizes, main frame, top rail, 3½"x4"; main frame, bottom rail, 3½"x3"; front rail, 3½"x1½"; over pedestal jaws, 3½"x5". Pedestal jaws held at bottom by thimbles and 1¼" bolts, all braces welded on.

GRATE

Rocking bars with dump plate front, fitted with suitable rocking levers, latches, etc.

GUIDES

Of best cast-iron, 4-bar pattern. Top guides, each 4" wide x2½" thick; bottom guides, each 3" wide, angle section.

PISTON.

Solid type, with spring ring packing, rod 3" diameter, of best steel, pressed into piston, and held by nut.

WHEELS.

Double-plate chilled, 30" diameter. Tender furnished with 3 tool boxes; coal space floor of iron; 2 brass tank cocks, strainers, etc.; safety chains front of each truck; Westinghouse air-brake on both trucks, with Meehan-Ross shoes.

GENERAL FEATURES OF APPLIANCES.

BRAKE.

Westinghouse automatic, class Z, for drivers, tender and train, with Meehan-Ross shoes all around.

PACKING.

U. S. metallic on piston-rod and valve stem.

FEED-WATER.

2 Monitor injectors, No. 8 R. H. and No. 9 L. H. Copper piping all around.

COMBINATION STAND.

Brass, R. I. L. W. type, placed in cab, containing an automatic closing valve in case of breakage. This stand contains all starting, blower, heating, steam lubricating, bell ringer, etc., valves, thereby saving numerous holes in boiler sheet.

LUBRICATOR.

Nathan double-sight feed for cylinders and single feed for air pump.

SAFETY VALVES.

Two 2½" Crosby encased pop valves.

WEIGHT.

Engine in running order (2 gauges water)..	102,000	pounds
Drivers " " " "	66,000	"
Truck " " " "	36,000	"
Engine and tender in running order (2 gauges water) .	172,000	"
Tender in running order . .	. 70,000	"

TRACTIVE POWER

Per 1 pound M E P on piston = 114 4 pounds Adhesive weight on drivers estimated at 22% ($\frac{1}{4\frac{1}{2}}$ about) of absolute weight is 14,530 pounds. Using 160 pounds as initial pressure in cylinder, the point of cut-off making the treative power equal the above adhesive weight, is 7-16 stroke

To an inquiry about the service this engine was performing, Mr. Meehan, Supt. of M. P. & M., courteously replies as follows

Editor The Locomotive Engineer:

Replying to your favor, inquiring about service of engine 85, would inform you that this engine is in express passenger service between Cincinnati and Somerset The time and number of cars varies per train, and, owing to the heavy grades and curves on our line, I am in doubt if I could give you any information that would appear favorable, compared with the record of other engines of this class on other roads. I will, however, say that on trains 1 and 2, the engine pulls from five to seven cars, being composed of one baggage, one mail, two coaches and the remainder Pullman sleepers. Trains 5 and 8 contain from ten to twelve cars, made up of one baggage, one mail, one express, two coaches and the remainder Pullman sleepers. The distance of the trip is 158 miles, and the schedule is as follows: No. 1, 4.40; No. 2, 4 50; No. 5, 5.40; No. 8, 5.15; making an average respectively of 33.9, 32 7, 27.9 and 30.1 miles per hour. This includes several stops, and, by allowing for these, I find that the speed would be as follows: No. 1, 40.9, No. 2, 43.9; No. 5, 36.5, No. 8, 40 3. The engine consumes 55 lbs. of coal per engine mile, and considering the fact that we have 60 feet grades, and 6 degree curves, I consider this performance equal to others in similar service.

I trust the above will enable you to make some kind of report on the engine, but if not, I shall be pleased to give you any information that you desire thereon, if you will state specifically what you require.

JAMES MEEHAN, S. M. P & M.

Half Section Detail, Looking Back *Half Section Through Guides, Looking Back* *Half Section Through Cylinder.* *Half Front View*

The Traveling Engineer.

BY J. E. PHELAN.

SECOND PAPER.

The main duty generally attributed to a traveling engineer is that of educating engineers and firemen to proper performance of duty, *i. e.*, looking after the competent handling and care of engines in service. Herein lies a principle that should never be lost sight of.

Time was when running an engine was in an experimental stage—when it was supposed that a locomotive engineer possessed ability gained by some mysterious hocus pocus not known to the ordinary mind. At that time it was customary to throw out a string into the atmosphere somewhere, baited with a piece of liver, to catch the first specimen hungry for a job.

Such specimens once employed, it was necessary to have a traveling engineer to give information concerning which way the lazy cock went on and off, and when the water reached the top of the stack. Such and various other important points of necessity had to be imparted to the specimens.

Time was when the main qualification necessary to secure a position as locomotive engineer was the possession of gall enough to claim experience, with nerve enough to depend on the traveling engineer firemen or head brakeman to impart desired information, after position once gained and name on the pay-roll.

At that time trains ran tri-weekly, and an individual could find time to get around at an ordinary way station, and have some friend—foreman or otherwise—walk him around a ten-acre lot to sober him up—when the trip continued would reach the terminal on time.

This is not a fancy sketch, but simply places quiet facts in cold type.

The time has come, with railroads developed into giant systems, when it takes a clear brain in a well-shaped head to successfully manage a locomotive.

Large systems must be managed economically to be profitable. "The revenue of transportation is earned in movement of trains, hence the proper condition of engines to perform this duty to a maximum capacity is of first importance."

It is a self-evident fact that a competent and reliable engineer is a prime necessity in securing duty of engines to a maximum capacity at least cost consistent with such duty.

If it is supposed that a traveling engineer, by sitting on an engine, and looking wise, or, on the other hand, talking like a poll parrot to a native, can impart brains and ability to an engineer in charge, the one who supposes such grand transformation possible, has more imagination than common sense.

It has been said that good engineers are born, not made—the same can be said regarding traveling engineers.

A man who will draw pay as an engineer, and expect a traveling engineer to come along and tell him what to do, or how to do it, is lacking in the necessary qualifications for success.

The plain duty of a traveling engineer is to see that engines are kept in proper repair and in good condition for maximum duty. Also to see that engineers and firemen do duty for which they are employed.

If an engineer or fireman, through lack of opportunity, fails to know or practice correct principles, the traveling engineer must do his part in giving necessary advice and instructions.

If the traveling engineer should be asked a question, and necessary knowledge not at hand for answering, he should not look wise, and play bluff, but look up the desired information, and when found, later, make proper statement, giving and gaining proper and profitable information.

We claim that it is the duty of engineers and firemen to seek information regarding proper performance of duty.

We claim that it is not the duty of a traveling engineer to knock information into minds not having energy enough to seek what may be needed.

The traveling engineer should not run a mental coffee-house to furnish grub and potion to devil-may-care individuals.

The traveling engineer should be in position and fully equipped to help those who help themselves.

Everything consistent with proper methods, should be done by the traveling engineer, to assist engineers or firemen in the proper performance of duty, before condemning any one as incompetent.

The occasional subject with swelled head, fully graduated in all that is knowable, yet persisting in practicing incompetent methods, should be handled without gloves.

One field the traveling engineer can always find open for action, and study, *i. e.*, embracing the introduction and application of new devices or improvements on appliances in use. In such field the traveling engineer should be a pioneer, fully mastering details, and always standing ready to impart reliable instructions concerning the same.

Found the Trouble at Last.

There is no such a thing as comfort, satisfaction or peace of mind on a locomotive that will not steam freely.

Both men will get hot the first time they miss a meeting point or stall, and are so out of sorts with everything and everybody, that they care very little what else happens. The writer used to fire for a man who was usually in possession of a poor steamer. He was a pretty good runner, as runners go, but he had an eternal itching to get in the front end, and "make her steam"; as a consequence, she was subject to congestive chills. It was not so comical then as it seems now, the ways old Gorman had of getting even with her. The engine was named San Pedro, numbered 37; Gorman, being an expert handler of profanity, took most of his spite out in swearing: when the 37 would lean up against a hill, and then lay down, Gorman would leave her wide open, start the blower, and get off and sit down beside the track, remarking, among the oaths, "Salt Peter, 37 degrees below zero; I wish lightning would strike her this minute, and weld her to the track!"

Another time, when reminded that there was a pin or tank-box getting hot, he would make no efforts to relieve it, simply saying, "Thank the Lord there's *something* hot."

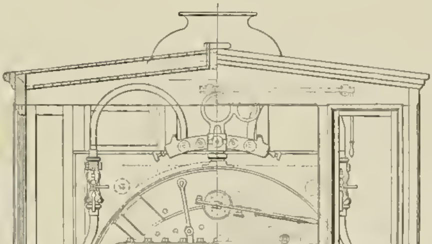
Gorman laid off for ten days once, and a young runner split her nozzles, got a smaller draught-pipe, and made her steam very freely. When Gorman got back, the first trip he was surprised to hear her pop at every mile-post.

"Sonny," said he, turning to the writer, "did that young feller go monkeying in her front end?"

"He did, and she steams immense," said the scoop artist. Gorman lapsed into silence for half an hour. "Sonny," remarked Gorman, with a twinkle in his eye, as he got off at the terminal station, "Sonny, you take her up to the house, and get the boss boiler maker to take out them bolts in the front door, and put in rivets, and head 'em down, fix her so's I can't get in there noway."

The Young Men's Institute, at 222 and 224 Bowery, this city, furnish a good deal of amusement and instruction for a very small amount of money. The full arrangement has just been announced, and includes evening classes in drawing, both free hand and mechanical, and also classes in arithmetic and steam engineering. For a very few dollars per year a young man may enjoy not only these privileges, but those of the library, the gymnasium, the bath rooms, etc. Young railroad men with leisure on their hands, when in the city, will find time and money expended in this direction but bread cast upon the waters, that will return after many days.

Outline of Valve Motion.



Half Section Between Drivers Looking Ahead. *Fig. 2* *Half Back View*

H. M. T., of Philadelphia, sends us a sketch of a car coupler on the plan of the Miller hook, except that the draw-bar is pivoted at the end of car, in place of as near the center pin of truck as possible, asking our opinion of the device. It will not couple on a curve, and will uncouple under the same circumstances. Practically the same device has been tried and abandoned many years ago.

Taunton, once famous as a locomotive building center, is doing nothing at all in that line now.

Changes in Design of Class "P" Engines of the P. R. R.

The Pennsylvania road have recently turned out some new class "P" engines from the Altoona shops.

The new engines are somewhat changed from the former style of the same class; some of the changes being improvements, others being very doubtful.

The old class "Ps" had 54″ boilers, the new have 62″—an improvement—the cylinders in each case being 18½ x 24.

The new engines have heavier frames and improved spring hanger arrangements.

The fire-box is of the Belpaire style, with the dome setting in the center of boiler, ahead of the wagon-top, and is covered by a plain, smooth casing, English style, rounded entirely over; nothing in dome but throttle.

On the wagon-top, just ahead of the cab, there is an oblong casting, something like the safety valve casing on the Webb engine; this carries the pops and the whistle.

The cab is perfectly plain outside, no panels, beading, cornices or gewgaws—an improvement—it is small and very low, has no ventilator on the roof, and a seat from which a man cannot reach anything—not an improvement.

The square top of Belpaire form of wagon-top fills the cab very full; makes it hot and crowded.

The throttle lever is so set that it carries the runner's wrist over a brass plate or plug, that is always hot—not an improvement.

The throttle stem is in the end of boiler, a cross-piece lever and extra rod run from it around and on top of boiler to the throttle lever—extra pieces—the gland is within six inches of the back partition of the cab, making a very unhandy thing to pack—not an improvement.

They have got the engineer's brake valve high up and clear back on the corner of the wagon-top—unhandy to reach and disagreeable to handle.

They have done away with gauge cocks and use two water glasses, placing them on the boiler head—behind the engineer, the runner must turn around and lean back to the end of cab to see them—a dangerous thing on a road like the P. R. R., where men must watch signals very closely.

On both the engine and tender the large wooden steps are used, such as are common in England.

On the tank head next the gangway there are two rods on each side, that extend from the deck to top of tank for hand holds. On the cab a large rod runs from the bracket to top of cab—a great improvement on our little, dangerous and slippery steps and handles.

There is a Sellers injector on the right side and a Monitor on the left—the piper seemingly trying to see how many bends he could get in the polished copper pipes.

These locomotives, seven in number, now on the N. Y. division, were all equipped with balancing plates, for their Allen-Richardson valves, that were suspended from the chest cover from a single connection at the center. All of these plates broke loose in the first few trips, and they are being repaired by putting in plates held by bolts in the usual way.

The number of passenger journeys taken in Great Britain in 1888—exclusive of season ticket holders and commutation journeys—was 742,830,000. During the year there were 905 people killed and 3,826 injured; this is only one killed out of 6,942,336 carried, and only one injured for 527,577 carried—including passengers and employes.

Improving Sand Pipes.

On the E. T., V. & G. they have, in a great measure, done away with the trouble caused by damp sand collecting in the lower end of sand pipes, by putting a **T** in the pipe above the running board, and connecting an elbow and nipple to it, simply turning the latter down.

This, it is said, allows of a circulation in the pipe, and prevents the gathering of moisture in the lower end. If it does, it also prevents a lot of soft hammer profanity.

Indicating Locomotives.

By Cyrus F. Richmond.

FOURTH PAPER.

The card shown in August issue of The Locomotive Engineer was a very easy one to obtain mean effective pressure from, for the reason that it was so regular in form. The nearer it approaches to a rectangular shape, the easier it is to work up. But in indicating locomotives one will find all sorts of shaped cards, and it requires patience and good judgment to work up the cards correctly without the use of a planimeter. Too much pains cannot be taken—the habit of saying, "That is near enough" will not do at all in this case. "Near enough," if not handled with care, would make a test of value only as a curiosity. So, in laying out the ordinates and locating the points at the end of each, it is quite essential to use a hard pencil, and make as fine lines and points as possible. It will also be necessary to use great caution in measuring the lines, and for that reason it was stated in last paper that a scale must be used that corresponds to number of spring that was used in indicator, and I still believe it *necessary* for a beginner to use said scale, and then it will not be so easy to make mistakes. The method suggested by Mr. F. M. James is correct, and he admits the above correct, and it is generally believed to be the safest method for beginners, surely it requires less calculating, consequently less chance for errors.

Fig. 4 is a copy of a locomotive diagram quite common in form for high speed and early cut-off, and, it will be noticed, of somewhat irregular shape, and not so easy to obtain mean effective pressure from as those that approach nearer the rectangular form. After laying off the ordinates, a little study is required to arrange the diagram into a more regular form for measuring the ordinates.

We have added the part *a* shown by dotted lines, and discarded the part *b*, thus making about an equal exchange of area, and obtaining a more regular shape. Similar changes have been made with *c* and *d*, also *e* and *f*. Now it could be made still better by changing more of the irregular lines, exchanging area where convenient. This requires some practice as well as good judgment; but after a few cards have been worked up in this manner the changes will readily occur to one, and the eye will soon become trained to exchange areas with exactness. We do not advocate this method as being absolutely correct, but believe it to be practically so.

We have now introduced the subject of indicating locomotives, and have tried to explain the reading of cards and methods of determining mean effective pressure from them, which was as far as was intended to carry the subject in these papers. There yet remains a great deal more to be said, but believe it would not be interesting to those who have had no experience with indicators.

Now it may be asked, of what value is such a subject to engineers and firemen, whose only business is to get over the road on time, and bring the engine in with her full complement of drivers, rods, levers, etc? To that I would answer: Stop calling yourself engineer until you are willing to spend a little time investigating the "mysteriousness" going on in the cylinder, when you are gliding along at a fifty-mile gait. Is it not a valuable, as well as interesting fact, to know the power a locomotive develops at various speeds, and the best methods of obtaining its greatest power with the least consumption of coal?

Fig. 5, which, like 6 and 7, is reduced one-third in size, shows a very poor handling of throttle and reverse lever, which, if practiced to any extent, would be one way to exhaust the coal mines, and make the poor fireman's back ache. It will be noticed that the boiler pressure is 125 lbs., while the initial or pressure in cylinder at beginning of stroke is only 56 lbs. for one end, and 57 for the other, and the steam is admitted for twelve inches of the stroke.

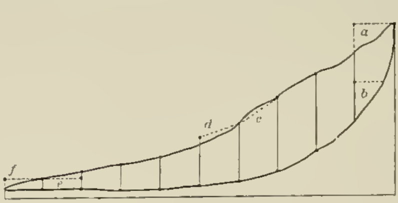


Fig. 4

The cause for such a low pressure in the cylinder in this case was mainly due to a partly closed throttle, which "wire-draws" the steam, that is, expending its force in trying to get through a small opening. We think it would have been better—if it was desired to "hold her in"—to pull up the reverse lever, say to 6-inch notch, and open the throttle wider, thereby getting nearer boiler

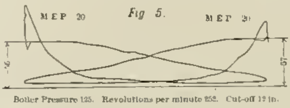

Fig. 5.

Boiler Pressure 125. Revolutions per minute 252. Cut-off 12 in.

pressure in cylinder at beginning of stroke, and allowing a greater expansion of the steam.

Fig. 6 shows a much better handling of engine, running at same speed precisely, there it will be noticed boiler pressure is 145 lbs., and initial pressure 125 lbs., which is a loss of but 20 lbs., or rather within 20 lbs. of boiler pressure.

This card shows what is called "initial expan-

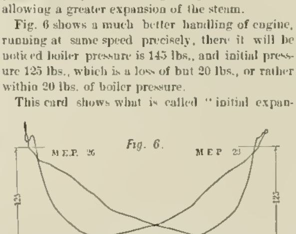

Fig. 6.

Boiler Pressure 145. Revolutions per minute 252. Cut-off 6 in.

sion," which means a falling of pressure in cylinder before steam is entirely cut off, and is caused by the gradual closing of port common to any slide valve—the cut-off taking place when piston has traveled but six inches, and the widest port opening is had when piston has traveled but one inch of its stroke.

Fig. 7 shows a card that was taken when running

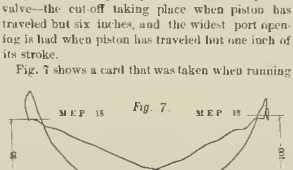

Fig. 7.

Boiler Pressure 113. Revolutions per minute 312. Cut off 8 in.

at more than a mile a minute, with a boiler pressure of 113 lbs., and initial pressure at one end 100 lbs., and 95 lbs. at the other, and shows good handling of engine. And so I might run on and pass judgment on indicator cards before me—that were all taken from a locomotive—for a day, and they would fill up one issue of the paper, but I believe the subject is now being well presented by various writers, and my hopes will be realized if the few papers by the writer have furnished some students with food for thought, and will start them in the right direction for progress.

Elementary Lessons on First Principles.

FIRST LESSON.

It is not the purpose of these articles to instruct old students of steam engineering, but to present in the plainest possible language clear explanations of some of the first principles that are not understood by the average of young men in our shops or upon our locomotives.

Most of the books upon these subjects are too deep for men not well up in the higher mathematics, or the subjects are enveloped in a shroud of mysterious motion curves that frighten off our too timid students.

Engineers and firemen, as well as the average railroad mechanic, are familiar with many features of the locomotive as a whole or in detail, know that they must be so and so, but, asked to give the reason—the why and the what—and they are lost; they are like the savage that knows that for a time the sun has hid her face, but what caused the eclipse is, to him, a mystery.

Suppose we commence lesson number one with the

ANGULARITY OF THE CONNECTING ROD.

What is known as the angularity of the rod affects the motion of the piston, and makes it necessary to change the motion of the valve to correspond to the irregular motion of the piston.

Let us look up the why. On page 3 is an outline sketch of the crank-pin path, main rod and piston. Now it is perfectly plain that when the crank-pin is at 1 or at 4 the piston will be at *D* or *C*, the extreme end of the cylinder. As the piston and crosshead are keyed solidly together, we will consider only the motion of one, as in this case their motions are exactly the same. The angularity of the rod always decreases by increasing the length of rod; so in this case we show the rod but half the usual length, as compared to the proportions of other parts; this will serve to show the effect of angularity more plainly. Now, suppose we start the pin from 1 in the direction of the arrow, at 2 the crank has traveled over one-quarter of its path, or 90° of the circle, but the piston has failed to get to the center of the cylinder, and is at the point* marked *A*, and not until the pin reaches point 3 does the piston complete half its stroke, and arrive at *B*—the pin has made more than half its extreme travel back and forth, but the piston has got behind.

This is because of the angularity of the rod; if it reached from the point 2 to the point *B*, it would have to be longer. Let us follow it and see what becomes of the uneven motions, from 3 to 4 the crank travels less than a quarter revolution, but the piston reaches the dead center at *C* at the very moment the crank gets to 4—it has caught up.

Let us see *why*. Remember that when the pin is at 1 and 4, the rod is in line with the center line of the cylinders, and not at an angle to them, and that its angularity is constantly changing in degree, becoming *more* as it goes away from the dead points at 1 and 4, and *less* as it approaches them.

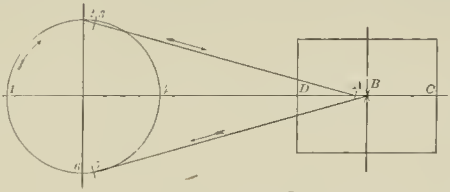
Let us follow the piston back from *C* to the center of the cylinder at *B*. You will see that the pin has only got to 5; the constantly increasing angularity has made the piston travel a full half stroke before the pin has got to the quarter; the piston reaches *A* again when the pin gets to 6, the quarter, but the moment the pin gets past 6 the angularity of the rod commences to decrease till it reaches 1 again, which it does by the time the piston is at the end of the cylinder at *D*.

Now, you see, the pin has to travel from 5 clear around to 3, in order to make the piston go from the center of the cylinder to the back head and to the center again, while it only has to go from 3 to 5—a considerable shorter distance—to make the piston go from the center of the cylinder to the front at *C*, and back to the center. Something is working unevenly. What is it?

The fly-wheel, in a stationary, and the moving weight of engine and train in a locomotive, act as governors that prevent uneven impulses given to the pistons from affecting the regular rotary motion of the crank pin, and, as that is coupled to the piston by the main rod, the result is that the pistons travel unevenly; not only do they stop and start at each end of the stroke, but they make one-half their journey quicker than they do the other half. In a full revolution of the crank the piston will always travel the *least* while the crank is making the half revolution furthest from the piston, and travel the *most* while making the half revolution nearest the piston.

In locomotive practice it is customary to place the center line of cylinders slightly above the center line of the wheels, and this increases the angularity on the lower half of the crank-pin's path, and decreases it in the upper half, but this change is so slight that locomotive builders, as a rule, ignore it.

The motion of the valves of a locomotive are derived from eccentrics fixed upon the axle, and coincide more nearly with the motion of the main pin than the piston, so that something must be done with the valves to equalize the point of cut-off for the uneven motion of the pistons. In the ordinary link motion this is done by changing the point of suspension, or saddle-pin, of the links, upon which the next lesson will treat.



ELEMENTARY LESSONS ON FIRST PRINCIPLES.

An Improved Throttle Latch

In the issue for June last we published a drawing of the very efficient throttle lever latch designed by Mr. R. D Wade, Superintendent M P of the R. & D. road.

Since that time Mr. Wade has made a decided improvement in the device, that prevents the throttle being accidentally opened, or from flying open when once pushed shut, whether screwed down or not.

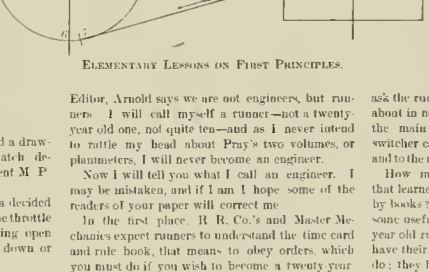
As will be seen, the throttle lever contains a screw that is forced down upon a sector, to hold the throttle in any given position, no notches being used, the device can be adjusted to the very place wanted.

The improvement consists of a single notch in the sector, in proper position to hold the throttle closed. On the end of the screw is a loose collar, forced down by a spiral spring; the moment the lever is shoved forward this collar snaps into the notch, and secures the lever against accidental opening

The collar is prevented from coming off the end of the screw by a pin through the end of screw and a slot in the collar.

In order to move the throttle out of the closed position, it is necessary to turn the handle—and thus the screw—three full turns; this lifts the collar clear of the notch. The handle is then screwed down so as to grip the sector, by a very slight turn to the handle.

This arrangement makes the neatest and safest throttle we have ever seen.



IMPROVED THROTTLE LEVER.

The B. & O have been trying coke as fuel on some of their passenger engines, with fair results. Coke is used considerably in England for suburban work, and is a very desirable fuel, it is so clean, throwing little smoke or cinders. Baldwin's have lately delivered 12 engines to the road especially designed to burn coke.

Look over the questions and answers in another column, and if you think you can suggest changes that are improvements, or see statements that are wrong, write us about it. Mr. Cushing will appreciate criticism.

We must again ask our correspondents to keep their articles down below the two-column limit. Long communications are crowded out, we have dozens of them on hand.

Correspondence

Runners vs. Engineers.

Editor The Locomotive Engineer:

This is the first time that I ever tried to be smart and take part in the discussion going on in your spicy little paper. I see a letter in August number entitled "Back Pressure and Full Throttle," referring to Grant's letter in May number. Now, Mr. Editor, Arnold says we are not engineers, but runners I will call myself a runner—not a twenty-year old one, not quite ten—and as I never intend to rattle my head about Pray's two volumes, or planimeters, I will never become an engineer.

Now I will tell you what I call an engineer. I may be mistaken, and if I am I hope some of the readers of your paper will correct me

In the first place, R R. Co.'s and Master Mechanics expect runners to understand the time card and rule book, that means to obey orders, which you must do if you wish to become a twenty-year old runner. They don't care a continental whether you are acquainted with Pray's second volume, and planimeters, or not (the M. M will look after those fellows); what they want is men to handle the locomotives on the trains economically, which you cannot do if you run them by Theory, and you have not got to have Pray's second volume, or Corliss valves all twisted up in your head to do it, and I will prove it

He says that he lent Pray's second volume to one of our engineers. The runner he lent it to is the man that runs the engine the 190 miles (on a freight train at that) over one of the worst roads in New England, at an average consumption of five tons of coal nightly. Now, Mr. Editor, don't you think this very good for a runner that would understand a Latin grammar just as well as Pray's second volume?

I have taken a train out of a terminal station two hours behind these Theory engineers, and find them on the up grades, making 12 or 14 miles per hour, and if their engine could speak United States it would say

"Darn-your-Theory!
Drop-me Down!"

I have helped these fellows up the grades, but not on Theory, when Theory gets his train over the last grade he gazes at his coal pile, and tells his fireman how light she is on coal; when he gets his train in the yard, puts his engine in the house, he makes out his time and finds that he has been 12½ hours making the trip, which means two hours extra time for each man employed on the train. This is no small item. The runner gets his engine in the house after pushing the steam expander on the up grades, he finds that he has been 10½ hours on the trip, which means no extra time, but a larger coal report, caused by pushing Theory up the grades.

A short time ago one of our men, who was always thinking about expansion and indicator cards, went out on his run. Thinking more about expansion than his running, he got over 37 miles of his trip all right, but after a stop pulled out with his mind away from his work; if it had been on his work he would have seen a switch set for a siding not far ahead of his smoke-stack The switcher was taking some cars out when he saw the steam expander coming towards him; the runner on the switcher stopped, and whistled, as a runner will in a case of this kind, the switcher went back where it started from with the cars, thinking the young steam expander would stop; he did stop—on the tender of the switcher—and then had the gall to ask the runner on the switcher what he was thinking about in not having a flag out—thought he was on the main track all the time; runner on the switcher called his attention to the track he was on, and to the rules in regard to passing through the yard.

How many twenty year old runners have we that learned the business and made a success of it by books? I don't mean to say that we cannot get some useful information in these books Twenty year old runners, when they start out on their runs, have their minds fixed on what they are about to do; they have not been up all night rattling their brains about indicators, planimeters or Pray's second volume, but they have learned, as I said before, to obey orders, take their trains over the road safely, and in case of a breakdown on the road to fix it in a very short time, and not block the road up when there is no need of it.

If the steam in the cylinders blows by the packing, they know which side it blows by on, they can tell you how air gets in and out of a brake cylinder, they can explain to you the different parts of the air brake, and tell you what they are for; if their engine does not run free and do the work it ought to, they can go to the M M. and tell him what the trouble is they know a little something about combustion (which is as important as steam expansion), they know enough to keep their cylinder cocks closed running in and out of stations, and by highway crossings, and several other little things the runner has learned, not by book knowledge or theory altogether, but by practical knowledge and common sense.

Mr Editor, who is it that runs the trains by the stations with the engine in the back gear, and, after the brakes are released, backs his train back to the station after standing the passengers all up in front of their seats (two minutes lost by this move), and out of twenty stops it will occur ten times? Who is it that runs their trains to the stations, and in making the stops finds that the brakes are not going to stop the train, and have to use the reverse levers to stop at the proper place? I think I hear you say it is not the "runner."

You may ask what is the reason of these kind of stops. There are a number of reasons. In the first place, Theory may be expanding steam too close to the station, and the old Westinghouse windmill does not get a show to do a good job; the reason for the second stop is that the Theory engineer has made so many applications of the air, that there is very little braking power left to stop the train. I have seen these kind of stops made with good working air pumps (this is what the runners call "steamboat stops").

They ought to learn something about the triple valve, which connects the brake pipe to the auxiliary reservoir and the latter to the brake cylinder. I don't mean to learn it all out of a book, and write it for some paper, and try to make us believe they have big heads; what I do mean is to go to repair shop, they will find one of these triple valves there, take it apart and tell us what they find. This is what I call practical knowledge, and you will not find it in Pray's second volume. the runner understands the air-brake, and when he wishes to stop at a station, he applies the brake at a proper distance from the station, with moderate force, the train is stopped gently and without inconvenience to the passengers, while, if they are thrown on with the utmost force possible, the train is jerked in a manner that is disagreeable.

Now about working steam expansively. Arnold says that if all locomotive engineers knew what it meant, we would have no trouble with it; I will agree with him there; they have got to learn it the same as the runners did. We have a number of twenty year old runners in this country who learned the machinist trade and then went firing a locomotive.

Arnold pays a compliment to the stationary and marine men at the expense of locomotive runners—says in that service knowledge counts, not years of service. I am inclined to think we all look through misfit spectacles at other trades than our own. I know a number of men in the stationary service that are discharged locomotive engineers, men who studied theory nights and worked at it running on the road so much, that they run by danger signals, and into other trains. Now they are in the stationary service, they are not "runners."

Marine service I know nothing about—only what I see on the road. These theory engineers will have an indicator card all snarled up in their heads, oceans of water in the smoke-stack, the front windows in the cab all plastered, and all they want is a compass to lay with the quadrant to let them know which way they are going; this is marine service on the R. R. The trouble with these kind of men is they try to be *too* smart, let them take for a study something that will help them to become "runners."

Let them find out what relation one part of the locomotive has to the other; get posted on the air-brake, so that they can tell what the several parts are for, and then, if they meet with an accident on the road, caused by the air-brake failing to work, they can give a description of the working of the brake. If they have to go to court in a case of this kind, they would have to tell the lawyers something, to let them know that they understood their business. They would have books and theory in the same room with them (not Pray's), and if they could say nothing they would say that the company was responsible for having a man handling something he knew nothing about. They would not ask you about Pray's second volume or to read indicator cards, as they have nothing to do with a locomotive runner. The twenty-year-old runner would answer all of these questions satisfactory, and there would be no theory mixed in it.

Arnold says we have too many of this class of runners in the country. I don't think we have. These are the men that help pay the dividends, these are the men that don't let the nuts all rattle off their engines and tenders before they tighten them up; they don't have to steal the car inspector's oil to make their oil report look smaller than the theory man's. There are a good many straws in a broom, and the runner is not any of the short ones; they are down where they are of some use.

Arnold says to Grant, "Fire away and I will help you out." I can't see where he has helped him out, so far. He tells us that he believed as Grant did; he tells us what he would do if he was M. M. (I never thought the M. M.s were so far behind the times). The next letter he writes I hope he will explain some of his theory, then I think he will be doing some good, and tell the runner how it happens that he is firing a 19 x 24 Baldwin Mogul (on a night run at that) over one of the worst roads in New England. You might say that he has not had enough of practical knowledge. How much does he want? He has been hearing her bark at the furnace door about six years, that's all.

Now, Mr. Editor, you say that this fireman's wholesale charge of ignorance of locomotive engineers, is no doubt based on what he sees around him; you should have said on what he had "seen" around him; he has not been on this "worst road in New England" but a short time. You also speak about his argument; I fail to see any; it is Grant's argument. What would you call these twenty-year-old men—engineers or runners? I would call them the same as the dictionary calls them, and as they have proved themselves to be, by long years of faithful service to the traveling public, as well as the company in whose employ they are—"locomotive engineers."

I say to Arnold, as he says to Grant, "Fire away, Arnold," and when your turn comes to be set up, if your head is not rattled or your eyesight is not impaired, so as you can stand the color test, the M. M. will give you a chance to show the twenty-year-old runners what you can do. Hope you will have the same luck that we are having to become twenty-year-old runners. H. T. R.

Hoosac Tunnel, Mass.

[We hope our correspondents will not become extremists, and each go too far in the direction of his hobby.

Every word that H. T. R. says of the requirements of the service is true, a man does not have to know anything about indicating to become an expert locomotive engineer.

The more an engineer knows of the details of his chosen profession the better for him; it may help him up in the scale in after years.

We look upon the indicator for locomotive service just as we do upon watches and clocks, only in a lesser degree.

The indicator card is the only way to thoroughly measure the work done in the cylinder of a steam engine, and adjust the mechanism to do the most effective work, it is not necessary that an engineer know how to make, adjust, or lay out the dial of a watch, but it is necessary that he know how to read the time denoted on the face.

It would be better if all engineers knew how, in a general way, to read indicator cards, and know by them what an engine was accomplishing or could accomplish—they can learn this easily and without even knowing what an indicator or a planimeter looks like.

The indicator is a measuring instrument, just the same as a two-foot rule is—a man might guess pretty close that a stick was three feet and one inch long, but he would never know for sure till he measured it.]

Detectives.

Editor The Locomotive Engineer:

Members of Uncle Sam's standing army are called soldiers, and they are regulated by hunger and the articles of war.

The members of the standing army of the railway corporations are called detectives, and are regulated principally by their own ideas, and the fears and follies of weak-kneed officials who employ them.

Once upon a time—fairy story style—there was a railroad, and that railroad had shops, and those shops were filled with men. They were not all wise men—machinists at $2.25 per day cannot be expected to be wise; wipers at 98 cents hadn't ought to be accused of knowing anything—and they were of devious and varied bloods; some there were from the land of Sweden, which is over against Denmark, and some of the tribe of Ham, from the village of Nianzin-on-the-Congo, and others were gathered from Italy, and Amsterdam, and Arkansas, and Vermont, and the rest of the odd corners of this universe, and one or two were from New Jersey. They were a motley crew, and they earned every cent they got.

But lo and behold, there appeared among them one day an apostle of a new creed, and he preached them a new faith, and he told those sore-eyed suckers from Missouri that they were a great people and the chosen of the Lord, and he gathered in their shining shekels, and took them into the fold and bade them eat of the bread of life—just as if they hadn't been living off bread and water long enough.

And when he had departed into the outer darkness, each and ev'ry one had swore upon a pasteboard altar that they were men and brothers, and would give their voice and their votes to men whose names should be revealed to them, and who would make laws requiring wages to be $6 per day and four hours a day's work.

And then they made mysterious signs to each other, and elected a grand desk pounder, a worshipful door slammer, and a grievance committee, and lo and behold, they were as one man(?)

Then they met upon the ninth hour of the seventh day and initiated other men into the mysteries, and called the roll and went through the order of business—and it transpired that upon each and every time when the order of business called for the "report of the grievance committee," there was no report forthcoming, and many there were who marveled thereat, and some murmured amongst themselves.

And it came to pass upon a certain day, there arose one man, who had sorrel-complected hair and a large mouth, and he denounced the grievance committee as lazy and inefficient, and disloyal, and no good, and asked that they be forthwith removed and sat upon, and another committee appointed in their stead. And when the faithful adjourned there was a new committee, and the sorrel-complected rooster was the head thereof, and the whole order was the tail.

And straightway the head man of the committee arrayed himself in purple and fine linen, and traveled up and down the land, and the foreman had to hire a new man to run the bolt cutter.

And when the faithful gathered themselves together again, the grievance committee had a report—and it was written upon a great scroll, in red ink, and it was to be continued in our next; but it started in something like this:

"Long-suffering and benighted brothers of the faithful few: Robbed of your rights, stripped of your manhood, with the heel of the oppressor upon your necks, look up! there is light, there is hope, there is plenty, if ye will but demand it. We must resist our oppressors, demand our rights, and assert our independence. If this order will follow the advice of this committee, in one week from to-day not one foreman who now lords it over you shall remain in the shops, not one man shall work there unless he belongs to the faithful. I shall carry the keys of the shop in my pocket, and each of you will come and go as gentlemen and brothers, and not, as menials and serfs, sneak up to the clerk and get your little brass checks—there will be no clerk, no checks. I have been forth upon the highways and the byways, and the men at all the other shops are clamorous for reform, they await your action, gentlemen. Will ye be men or serfs?" Etc., etc.

Then there arose a mighty cheer, and also a gray-haired old backslider in the rear seat, who asked that the report be received and that a committee be appointed to wait on the officers of the road, asking for an increase of pay. The head of the grievance committee denounced him as a traitor, and said the matter of pay was immaterial now, what was wanted was control of the shops and road—once make them feel our power and they will grant us anything. See?

And it came to pass that the next day an edict went forth that there would be a strike the following day, at 11 o'clock, for "good and sufficient reasons," and every man in all the shops of the road who belonged to the faithful struck, and many men who didn't want to be called scabs, they struck—but it was a tame strike.

The road service was not affected—it was a shop strike—but the officials of the road at once telegraphed to the Lieutenant-General of a Standing Army of Detectives, and forthwith the yards and shops were patrolled by an armed mob, under the guise of the law, with orders to carefully guard outgoing trains.

The company first thought of stopping trains, practically told the strikers they couldn't, and dared them to do it—then they wanted to.

I was pulling a row of cars out of a station 200 miles from the scene of the trouble among the shop men, and when I came down to go out the next morning, the strikers' committee interviewed me. They wanted me to refuse to go out, to strike without a grievance, get expelled from the brotherhood for sympathy for them, and lose a pretty good job, in a country where jobs were scarce and grub high. I kicked. I told them to keep their strike down to the men affected, and asked what grievance they had. Not one of them knew. One said, "We were ordered to strike from headquarters, and any man that don't strike is a scab. See?" I saw where his eye was, and hit at it—but it had been moved.

Then I went over to the engine and got ready to go out, when there came down half a dozen men with revolvers and shot-guns, and climbed on the cars and stood around the engine.

I knew several of them, they were bums about town, local toughs, men who never did an honest day's work in the town, and were the last men you would think would be selected as "protectors."

The strikers kept off the company's ground, but were within a few feet of us. When I started to pull out, two of the worst toughs got up in the gangway between the engine and tank. I stopped and asked the biggest one where he was going

"Got orders to protect this train," said he.

"Well, get back on the train and protect it," said I

"I've got orders to ride here, and I'm going to ride."

I commenced to get hot. "Not with me, you won't."

"Look-a-here, smarty," said the bluffer, "d'ye see that?" and he flopped the lapel of his coat over to show me a detective's badge.

I hereupon swore a mighty swear, declaring I didn't need protection from any low-down detective agency, or anybody else, and if I did need it, could protect myself. I wouldn't run the engine if it took a lot of armed bums to protect a man against a lot of apprentice boys, that were his personal acquaintances.

Then the superintendent came and ordered me to run that engine out of town, and that devilish quick, or he'd get someone that would. I told him to go plumb to Halifax and get somebody.

Then the master mechanic came and I explained the situation, and he went over and talked low to the superintendent.

I heard him say: "Now listen to reason; if you take him off that engine there won't be a wheel turning by night; you will have to take them all off. If you send out them deputy sheriffs on his train, you will have to send them out on all of 'em; now you let him alone."

Then they asked me what I wanted, and I told them I wanted to be left unprotected—never was a protectionist—and they hauled off their "detectives," and I went out "all by my lonesome"—and the strikers gave me three cheers, and didn't yell "scab."

That strike was dead in two days, half the men came back, the places of the others filled, but the detectives were everywhere "protecting the company's property" at $5 each per day.

And they stayed for more than three months. Every few nights there would be an explosion, or there would be an attempt to burn the shops. The lynx-eyed detectives were continually finding switches broken open and misplaced.

One night an officer of the road crossed the yard, and caught two of his "protectors" building a "scare" fire under the coal shute—and the next day they were gone.

I don't believe the strikers ever caused a cent's worth of damage, but the detectives busted up several cars and engines, and got pretty big pay for doing it.

Between the strike agitator and the strike annihilator—who both live off the strike—the poor striker is indeed like the grain of buckwheat—"crushed between the upper and the nether millstone."

Judas Iscariot was a detective, and the class that do the dirty work in strike times are very much like him—only worse. Judas, however, committed suicide—if I was a detective I should "go and do likewise." JOHN ALEXANDER.

Faster Time.

Editor The Locomotive Engineer:

In last month's issue you give a few figures in reference to the "Reading Flyer's" time to Atlantic City.

Engine 39, West Jersey Ry., Theodore Stratton engineer, George Bennett fireman, has been doing better than that all summer

Their run is to make 64 miles in 70 minutes with three dead stops; engine has cylinders 18 x 24.

The "Flyer" referred to makes no stops.

Engine 39 is one of the ordinary engines of the W. J., and on several occasions has had to beat this record, when being held on a block, or some similar delay. H. P. LIPPINCOTT.

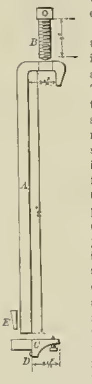
Bridgeton, N. J.

Another Good Spring and Equalizer Kink.

Editor The Locomotive Engineer:

If the patience of your readers will stand a description of one more of our spring "kinks," we will promise to give you a rest on the spring question in the future.

The arrangement referred to is used to pull down equalizers for the removal of, or placing in clips between equalizer and gib. It is used in place of the hook and bar arrangement mentioned in your May, 1889, issue, by Mr. A. T. Hooker, of Chattanooga, Tenn. The hook referred to requiring rather too much scientific (?) pulling on the bar by all the machinists, helpers and wipers in the house. Then, too, all first-class railroad companies now have Westinghouse driver brakes attached to their engines, and, where this is the case, the hook and bar cannot be used, owing to the space below engine frame being occupied by air cylinder. We used these hooks before air-brakes came into use.



The best tool we have been able to find for the purpose mentioned, is to take a piece of 1½" square steel and have it bent in form of **A**. This piece has a boss on top, through which passes a 1¼" x 5½ steel screw *B*; the foot *C* can be made of either steel or iron, a small, sharp-pointed set-screw passing through it, as shown. This foot has small projection on bottom, as shown at *D*, which holds pin used in adjusting to engines of different built frames. This jack is placed in position by placing the long steel piece perpendicularly beside air cylinder, close to engine frame, allowing the hook at top to drop over between equalizer and fire-box; this allows the tempered point of large screw to rest on top edge of equalizer. The foot is then slipped up an upright piece until point of small set-screw strikes bottom of lower rail of engine frame, and fastened in this position by driving home the wedge. As pressure is applied to point of large screw, the point of small set-screw is pressed into frame, which prevents it from slipping. The hook at top prevents the arrangement from slipping there, and the equalizer can easily be screwed down as far as desired.

This contrivance can be easily and quickly set, and is absolutely safe. We believe that safety and dispatch in doing the work should be considered while making tools, rather than original cost, for a good tool soon pays for itself.

We would like to talk with Bro. Hooker a little in regard to the jack for removing front driving springs, mentioned by him in your issue of March, 1889, for, if he adjusts this arrangement as stated by him, viz.: by removing pin at top and placing it in lower holes through side strips, we are afraid he had some trouble, owing to lack of space for top of inside strip between top of spring and boiler shell. L. C. HITCHCOCK

Minneapolis, Minn.

[No danger of anyone getting tired of new kinks to help them in their daily work. This paper wants to hear from every mechanic in the country who knows of an easier way or short cut in doing running repairs.]

Indications of the Indicator.

Editor The Locomotive Engineer:

Arnold, from Worcester, Mass., comes boldly to the front in August issue. I quote: "Not one engineer in 1,500 knows what the working of steam expansively implies," or "can read an indicator card." Well, why should they be able to do so? and do railroad officials expect it of them? I very respectfully, and with due reverence, call your attention to article in THE LOCOMOTIVE ENGINEER, in July issue. You will see a mention of two leading trunk lines, one double-track, the other a four-track road, that never, or, until recently, ever "indicated" an engine in their service. This recalls another article in regard to outside cups on steam chests on the M. C. R. R. That road cares very little about their firemen knowing too much of the indicator, or they would have moved these cups a boiler length nearer the stoker, and lessen the risk of losing one every bad, rainy and dark night. If this aspiring Arnold would write a letter of similar character to that of his "Pray"-ing one, and address it to the managers of all roads in the country, calling their attention to the fact that the indicator was seldom used, and he, an expert, was ready to instruct master mechanics, and lead them into the mysteries of the second volume of Pray, no doubt all the engineers would unite in Pray-er, and resolve that the country was saved from ruin, and dividends on watered stock would exceed two per cent. It is the phool American runner that is to blame for it, because he don't know enough to be called "*engineer*." Committees would no doubt be appointed, and petitions *Pray*ing that the reading of indicator cards be first in the general order of business at all their meetings.

How many engineers would ever be guaranteed in purchasing one now? for their watches are, in many cases, not non-magnetic The jeweler with the right kind of watches is always mentioned in the circular, announcing that their—the engineers' —watches are no better than "Waterburys."

The indicator and card may be entertained for a short time by the "super," who would soon ask "if it would get any more cars over the road." If it would not they have no use for it, let the indications be what they may. Brother engineers and firemen who get over 190 miles of road with 5 tons of coal (I know of many engines that require 10 tons every 90 miles), if you want to understand the indicator, follow these suggestions: Read Richmond's articles on the indicator in THE LOCOMOTIVE ENGINEER, get a copy of Le Van's Steam Engine and Indicator Practice, price 50 cents. Give Clinton B. Conger's idea a little attention (see page 6, August issue this paper). Hemenway's Steam Engine Economy and Indicator Practice is the best known work on the indicator. If the roads buy indicators and indicate engines, the pay for this expense must come out of something, pay-roll or freight receipts. Get all the knowledge in a general way you can, it may serve you in time to come. The indicator is not new, but it has come to stay. Why should you be expected by a fireman to know all about an indicator, when many new locomotives, fresh from the works, show no signs of ever having an indicator attached? If the man that makes an engine ignores it, should you be rebuked for following the example set by the builder. Will *Arnold* converse with the M. M. of his road, and find out how many times the Baldwin he fires has been indicated of late; also send THE LOCOMOTIVE ENGINEER cards of a 19 x 24 Mogul that hauls a full train 190 miles with 5 tons of coal? C. S. STRAW.

Watertown, Wis

Fred B Armstrong, of Camden, N. J., an old air-brake man, writes us his approval of the decision come to about the air-brake puzzle in last issue, and adds that, in running automatic with the old three-way cock, it is often an advantage to be able to have excess pressure to release; this can be had by temporarily closing the stop-cock between the reservoir and the three-way cock—where there is one.

The several correspondents who have inquired for the address of the makers of King's oil cup, shown in June number, will find them by addressing the Springfield Brass Co., Springfield, O

With the Schenectady, Baldwin's and the Pennsylvania people all working on the problem of compounds, we shall expect results that amount to something before another year.

The Pass System.

The agitation of Mr. John Livingston against the issuing of passes to anybody except Mr. John Livingston, and especially against the issuing of passes to railroad men attending conventions, shows more momentum than that usually given to the agitation of a known crank.

There is little doubt that the different railroad managers would gladly combine with any man or body of men who give reasonable promise of abating in a measure the pass nuisance, much less the abolition of it altogether.

The pass system has been abused, a case where the old proverb about riding a free horse to death has been literally carried out.

Everybody wants passes, those having the least reason for having passes want them the worst.

The Interstate Commerce Commission have attempted to restrict the issue of passes and confine their use to actual employes of the road; their efforts have been partially successful, and given the railroad officials an excuse for refusing passes to many persons otherwise hard to refuse.

But a remedy is never a cure, poultices on the outside of the pass cancer will never bring it to a head—it must be cut out, root, limb and branch, by the knife.

If every passenger carried over our roads paid fare, the companies could make money on their passenger business at one-half the present rate per mile.

It costs just as much to haul an alderman with a pass as a human being with a ticket.

The only way to stop the pass trouble is to do away with them for any purpose—not even using them for employes in the service of the company.

If the master mechanic finds it necessary to send an engineer and fireman over the road deadhead, let him give them an order for tickets, regular tickets be issued to them, and the mechanical department charged with them, at regular rates, on the books of the transportation department. It costs just as much to haul the engineer and fireman as it does any other two passengers.

If fares were down to one or two cents per mile, the brotherhoods could well afford to pay the fare of their delegates, then if any delegate wanted to take his wife he could pay her fare.

Most railroad employes dislike to pay fare—don't like to do it ourselves—but railroad men are more than half human, anyhow, and would soon get used to doing what other people do. There is no more reason why the family of a trainman should be carried free over the road than that the trainman should make a couple of trips without pay—what a kick there would be if some official asked that.

As long as one employe gets passes, all should; the general manager has no more excuse for using the pass privilege on his own road, or in asking it from other roads, than has any section laborer. If it is wrong for one it is wrong for the other.

About the only way to cut off the pass business is to make some such law against them as now stands against counterfeit money.

Railroad employes are not the worst pass fiends in the world. The press, the pulpit, the legislature, the bench, and all those institutions which influence the people, or are supported by the people, for the benefit of the people, are more or less influenced in favor of the roads by the use of passes, the abolition of the system would place all these where they belong—on a level with the people.

The pass system is wrong, and the ethics that it has taught is for abolishment, but a convenient evil is hard to give up.

Railroad men could but be benefited by a complete change in this direction, as it would reduce the fares they would have to pay, make the companies more prosperous, and the chances of higher pay better.

A Condition, Not a Theory.

From the general discussion going on everywhere, it is evident that most of the delegates to the engineers' convention will go thoroughly "instructed" on the subject—perhaps to the detriment of more important subjects—of the election of a grand chief.

This fight will be quite bitter, and, we regret to say, somewhat sectional. It will make little difference who is elected to office, if he is a good man, the opposition to Mr. Arthur do not seem to be united upon a candidate, so that his chances for re-election are reasonably sure—as election chances go.

We should be glad to see the order drop two-thirds of its secrecy, and commence open discussion of subjects tending to elevate the members in their calling.

We should be glad to see the qualifications for membership restricted, so that a man who was honest, temperate, industrious, and had shown by a year's work on the road that he was a capable engineer, could come in, and could not come in if he did not have these qualities.

We should be glad to see the order honest enough, generous enough, and just enough to declare that, if a man was true to the obligations of the order, it was none of the order's business what else he was true to.

We should be glad to see a regular order of business for subordinate lodges that called for the discussion of local changes in rules, time card and bulletin orders. This would insure more familiarity with changes, a universal understanding of rules and the settling of all points of dispute, thus reducing the chances of mistakes, the dangers to the men and to the public, and be to the welfare of the companies.

The brotherhood must be carefully and intelligently handled in the future, to keep itself in the position of the best labor organization of the country; conditions are changing, we must meet those conditions.

That the order has done good in times gone by, there is no question from any quarter. We trust the future will put the past in the shade.

Trucks on the Wrong End.

The belief is very common among American locomotive builders, designers and engineers, that it is almost absolutely necessary that trucks should be placed ahead of driving wheels to insure safety, and any runner on our roads would proceed carefully around curves when backing up.

On the London, Brighton & South Coast road, in England, they run a class of engines with four coupled wheels, 6 foot 6 inches in diameter, and a single truck with 4 foot 6 inch wheels; the drivers are arranged ahead, the front axle being just back of the smoke arch, and the truck under the fire-box. These engines were designed by Mr. W. Stroudley, the engineer of the line, and haul heavy and fast trains. The cylinders are $18\frac{1}{4}$x26, pressure 150, grate area, 21 square feet; total heating surface, 1,500 square feet. They haul 25 carriages, and run the 30 miles between Redhill and London in 40 minutes—20 miles of this being up a grade of 21 feet per mile—and the 51 mile run to Brighton is made on one run with 17 or 18 carriages in 62 minutes from start to stop.

We should not like to ride on a fast train over our rough and crooked roads pulled by one of these locomotives, but their success in England goes to prove that there are lots of things that won't do in one place will do in another.

Master Mechanics' Report.

Secretary Sinclair has sent out the Report of the Proceedings of the 22d Annual Convention of the American Railway Master Mechanics' Association, held at Niagara Falls, the 18th, 19th and 20th of June.

The work is uniform in size and style with the former issues of the report, contains over two hundred pages, together with a list of members and a complete index.

These reports, preserved from year to year, make a very valuable acquisition to any mechanic's library.

Secretary Sinclair is to be complimented on the neat and quick work he does with the reports.

"A Tale of Two Cities."

On the 16th of this month the 26th annual convention of the Brotherhood of Locomotive Engineers will convene at Denver, Col.

Denver, the "Queen City of the Plains," nestles at the foot of the great Rocky Mountain chain, whose massive brows are crowned with the eternal snows; before her stands the vast range, with its cool breezes, pure waters, living springs and hidden treasures of untold wealth—there is a future there. Behind her stretch hundreds of miles of arid plains, covered with stunted sage, wastes of sand and whitening bones, here and there is a little oasis, but the desolation predominates—that is the past, a history of the road.

It will be well if each delegate, on the night before the convention meets, will forget the squabble for office and the studies of rhetoric, and in his heart liken the great brotherhood to the City of Denver.

Put the arid plain of the past behind him, just as the pilgrims to Denver have put the plain behind them and the city, and look at the mountain of the future in the foreground.

It promises well; there are many chances for improvement and for wealth there, golden treasures as yet undiscovered—but there are pitfalls and precipices as well.

The city of Denver was built in a short time for a city so fine and so large—it is just the age of the brotherhood.

It was built because it was necessary for the best interests of the people of the territory about it—so was the brotherhood.

The pressing necessity of the times that called for hurried building and little examination of the materials used were the same in each case.

Denver is growing out of her "boom" time. She must now advance more slowly, build more solidly, and look to details more carefully—and so must the brotherhood.

Magnificent buildings have been reared in Denver upon the sand, they face unpaved, unsewered and unguttered streets—so stand many of the institutions of the order.

Denver is fair to look upon, especially from a height or a distance, her streets are wide, her buildings fine, her trees green and her parks pleasant and cool—not unlike the brotherhood.

But, while the city has her palaces, she is not without her hovels, she has a "Capitol Hill" upon one side, but "Poverty Flats" on the other, for the beautiful west side there is an offset in Wauzee street and the Chinese quarter—and still the city is like the brotherhood.

The representatives of the city of Denver are seeking to clean up the bad places, to run sewers through Poverty Flats; to heal the ulcers in Wauzee street; to pave the streets, and thus guard the health and happiness of all the members of the community—will the representatives of the order do the same?

Let us hope that they will forget the plain behind, and turn their faces toward the mountain of the future.

Let us hope that they will see their duty clear to remove every obstacle that hinders the advancement of any member of the order; let us hope for the repeal of every unjust law—not justice for the order alone, but justice for everybody.

The necessity for the rush to keep up to the railroad building in supplying men belonging to the order is past.

As Denver is obliged to clean up, go slower, and make some foundation improvements in order to hold her reputation as a city of the first order, so must the brotherhood be more particular about the selection of her material, build better foundations and provide for the drainage.

Every Man for His Trade.

Pedrick & Ayer, makers of railway repair shop tools, recently moved out of their old shop to a commodious building of their own, but the pressure of orders and the accumulation of work has made it necessary to reopen the old works as a repair shop. The firm have worked up a heavy trade in stationary repairs, piston and valve work, much of which is done at night, and the doing of which is in the way of and a detriment to the regular business of manufacturing. Now the older tools will be located in the repair shop, and the new work not affected in the least by repairs. A few years ago this firm started in to build special tools for repair shop work, the field was barren and seemed to most railroad men an unprofitable one, but one of the men was a thorough mechanic, and the other a thorough business man; they pooled their issues, but each attended to his end of the business, and let the other alone, if a man came in with drawings, or a model of a new machine, or suggested a change in an old one, Harry Ayer just opened the door and said, "Go right down in the shop and see Dan"; if, on the other hand, a purchasing agent came into the shop, and asked for 90 days' time, 60 % off or a chance to pay in store orders, Dan Pedrick just pointed to the stairs and said: "Go right up and see Harry." A mechanic usually has little business ability, and, as a mechanic, has little need of it; a business man may be a good one and not be able to bore a round hole with an auger, and don't need to.

It is the combination of abilities that makes a complete whole.

The engineers and firemen of Great Britain have a common brotherhood. Their *Journal*, published at Leeds, is an interesting one. Last month they issued a special number, containing a history of locomotive development. This work has been compiled by Mr. Clement E. Stretton, the society's consulting engineer, and is without doubt the most complete history of early English locomotives which has ever been placed before the public.

The price has been placed at only three pence, or six cents in U. S. coin—a cheap way of securing instructive reading.

ASKED & ANSWERED.

(40) T. E. H., Winslow, Ark. T., asks:

Where can I get the paint used on window signs to represent frosting? I want to ornament my side windows. *A.*—Mix stale beer and common epsom salts just thick enough so as not to "run" when used on a vertical surface; paint on with a brush. It can be removed by using hot water.

(41) Jno. S. Mills, Danville, Ill., asks:

Will you kindly send me, if possible, the questions asked by some good road, in examination on machinery—western road preferred. Also, questions on time card, if not too much trouble, and oblige. *A.*—The U. P. Ry. questions and answers, by Mr. Cushing, published on pages 10 and 11, are the best we know of.

(42) Woodstock, Westville, Wis., asks:

How many quadrants had the old Lawrence engines? Of course this means reverse levers as well. I saw a long time ago a Dubs engine at Winnipeg, Manitoba. She had a regular multiplication table on the quadrant. For what purpose? All these figures were intended for something. *A.*—All the Lawrence engines we have heard of had **V** hooks and independent cut-off, which required two quadrants and reverse levers. The multiplication table spoken of by our correspondent was no doubt one of the old style quadrants, that not only had the points of cut-off marked, but the points of release and compression as well.

(43) F. Hochbrunn, N. Y., writes:

I notice a good many straight shot stacks are two or three inches larger at the top than near the bottom. Can you tell me what advantage such stacks have over a perfectly straight stack? *A.*—Experiments go to show that the heated gases in the front end tend to reheat and expand the steam after it leaves the nozzle, and that in a large, straight stack, the escaping steam did not impinge against the stack until near the top. Where the exhaust does not fill the stack it acts as a loose piston, and does not make (in the language of the road) a strong pull upon the fire, and where it fills the stack for but a short distance its pull is jerky and uneven, and where it fills the stack it is more uniform and even. As the escaping steam is a piston constantly increasing in size, it was found best to make a taper stack for it to work in—where the proportions are right we believe they have produced a steadier blast on the fire and freer steaming engines.

(44) J. D. E., Denver, Col., writes:

All over the engine I fire is branded this puzzle, "8-30-C 397." What does it mean? *A.*—Baldwin's plan of shop numbers tell a great deal; the first figure tells the total number of wheels under the engine—yours is an 8-wheeled engine; the letters tell the number of wheels that are drivers. A for single pair of driving wheels, C for two pairs, D six, and E eight. The size of cylinder is indicated by the next figure; commencing at 12, the numbers run to 40, using *even* numbers only. These numbers denote the size of cylinder from 9 to 22, inclusive; thus, 30 means 16 inch cylinders. The last number gives the total number of that particular style built by the works. The fraction $\frac{1}{4}$ means a truck at each end of the locomotive, $\frac{1}{3}$ Forney style, so that, by the combination, you can tell the number of wheels in the truck as well. Thus, if there was $\frac{1}{3}$ after 30 in your number, it would show that there was a pony truck back of the fire-box; if it was 6-40$\frac{1}{3}$ C it would prove that the engine had no truck in front, for the 6 says six wheels all together; the C says four wheels coupled, and the $\frac{1}{3}$ a truck back of the box.

(45) I. T. U. D., Muckwonago, Wis., asks:

Does the crossed position of eccentric rods call for any change in position of *saddle* pin? If so, why not put up the blades or rods so that they will remain in a crossed position all the time? The continual changing of eccentric rods from an open to a *closed* and *crossed* position during each revolution of shaft must call for a remedy, to offset the consequent bad effect on valve. Is this probable bad effect on valve from alternate open and crossed position of the rods remedied through any peculiar design of the links or attachments to same? *A.*—Locomotives having rockers are not rigged with crossed rods; the rods are never crossed when the engine is on the forward center. The position of saddle pin is never moved from center line of link except on account of the angularity of the rod. If the eccentric blades were put up crossed, it would decrease the lead as the link was hooked up. Of course, the rods are crossed when engine is on back center, nothing is done to compensate for this, as it is an advantage. It would be impossible to put up the rods so that they would remain crossed while the engine was in motion.

Some Suggestions in Locomotive Design.

BY H. WESTON, RY. ENG'R.

While engines remain in present form they probably have reached the limit of speed at 70 or 80 miles an hour, the irregularity and imperfections of the roads putting severe restrictions on the planning or form of the locomotive. At present time, if, on account of improper roads, we cannot plan our engines for the attaining of very high continuous speeds, the alternative seems to be to increase capacity for heavy work, and the hauling of long trains. This may not directly serve the public to their liking as an increase in speed, and yet the running time of a train between points that include a number of intermediate stops may be considerably diminished if we have an engine heavy and capable of starting away from a station quickly, attaining its maximum speed after a few revolutions of the drivers, and not crawling out at a snail's pace, as the greater proportion of engines do, even when they are performing their best. This increased capacity for heavy work means a marked saving to the railways—indirectly to the public. If trains are heavier and longer, the number is reduced, thereby increasing the facilities of the road, promoting its efficiency, and prevents its being blocked by an excessive number of trains.

There is a chance for much improvement in the construction of an engine for heavy work. In the first place, boilers can be high and larger, thus giving an increase in power derived from them. Theory and practice prove that a high center of gravity in the boiler will make the engine steadier. The inequalities of the road or rails are transmitted through the wheels and springs to the frames, we may say, from the end of the short arm of the lever, the center of gravity of boiler is at the end of long arm, consequently the higher the center of gravity of boiler the more the force required to move it. Now, if boiler is so high that this force is not capable of swaying it, then irregularity transmitted to the wheels will be absorbed by the spring, and the engine will ride steadily.

In our engines, and especially in those for heavy work, the frames are a very important factor, and, in present practice, are far from what the service requires.

With a change in frames, longer journals might be available, thus giving a great improvement in cool running. Probably there are no engines, stationary or marine, where so heavy a strain (all elements considered) is put on so small a journal as in our ordinary locomotives.

When the long journal is possible, the width of shoes can be increased. All engineers realize the advantage of as long a life in these things as is possible to secure. The strains which are thrown between the jaws of the frames are tremendous.

When there is lost motion, every alternate stroke of engine tends to increase it and cause fast wearing.

In our engines for heavy service we should have at least six or eight driving wheels to utilize all the weight available, thus securing as much adhesion as possible, and avoid the crushing weight thrown on them when a smaller number are used, destructive to the wheels and rails. If railway officials realized the importance of a large coupled wheel base, there would be less destructive effect on rails. Such a proportion of weight as is common on the forward truck is a needless waste. Four-wheeled trucks should be retained as a guide, but sustain less weight.

A proper arrangement of securing cylinders to prevent any lateral motion or springing is important. Quite an amount of trouble has been caused in this way by cylinders throwing back and forth out of line.

The iron for a cylinder should be the best obtainable, and receive careful attention in casting. In quality it should be as hard as is consistent with a fine, even grain, free from air-holes, sand or grit.

The efficiency of a system of standards to work to is being fully realized, and should be carried out in quality and standards, from which can be secured the highest service.

The use of patent metallic rod packing gives such fine results that it seems strange it is not in use in every engine in the country. Piston rods on which I have put this packing, after having run a year continuously, have come into the shop, I might say, as perfect as when they were new Whereas, with the common packing a rod is badly grooved and worn within a few months, requiring constant attention and repacking, the metallic, on the other hand, requires no attention except to see that the nuts do not loosen, and to give the rod a slight oiling.

The running of a fine finishing feed over a rod, and then draw-filing by a machinist who knows his business, is the only proper way of securing the best results in working. The practice of filing a rod in the lathe is barbarous. If common packing is used, filing in the lathe does not make so much difference, as the packing soon grooves the rod; with metallic packing, draw-filing is important.

The use of the large, square bar, or two bars, for a guide, gives a more perfect form of crosshead, for the reason that the plan of cross-head can be such as to give a chance for easy and perfect adjustment, and the keeping of the piston rod working in proper line, which it rarely does when the common form or four-bar guide is used. They necessarily are so near together as to prevent the use of any but a solid head, and practically no chance for adjustment. Lost motion is destructive to the life of any machine, and also prevents it from giving the best satisfaction while running, and in a crosshead it causes much wear on piston rings, rod and rod packing, which becomes a serious matter in practice. Every one must admit that the use of a solid link is much preferable to one made of six pieces, provided it can be easily made. This can be done by forming a steel link to nearly the required size, and then, by the use of a special machine, grinding them and the blocks to their proper fit after they are hardened.

A slight modification, that will allow of large link pins, will be a great improvement over the present style.

The irregular exhausting of such a large proportion of locomotives shows plainly the want of a more efficient construction of valve connections.

The expense caused by the sucking of cinders through the exhaust is sufficient to make the best method of preventing the evil sought and used.

On some boilers built at the Trenton Locomotive Works many years ago, both flue sheets were curved out, for greater strength.

Northern Pacific Cinder Hopper.

On this page will be found drawings of the chute or gate used under the extension fronts of the N P. locomotives

Fig. 1 is a side view of the device—molasses gate

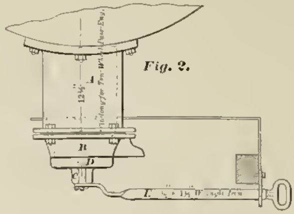

Fig. 2.

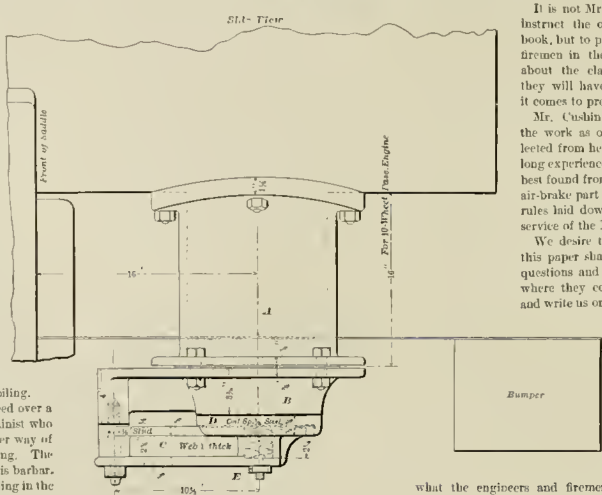

Fig. 1.

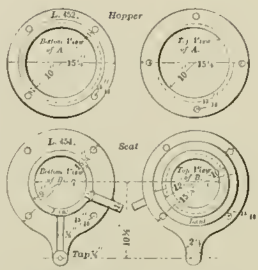

Fig. 3.

Northern Pacific Cinder Hopper.

the boys call it—showing the general arrangement. As will be seen, the valve is hinged to a bracket extending back from the lower ring of the hopper; to adjust this stud to make a fit between the hopper and the valve under all the changes of road service would be impossible, so the only office of the arm is to support the disk that closes the opening, this is a loose disk with a stem extending down into the arm and inside the coil spring shown, which keeps the disk face tight on the hopper face. Fig. 2 is a front view, and shows the operating handle, which can be located on either side; it also shows a projecting rib that keeps the disk in place when off the hopper, and prevents its cocking.

Fig. 3 shows the details of the device, sizes and all. It is much neater than the usual slide that has to be driven in and out with a coal-pick, is always tight, and easily operated.

Questions and Answers for the Examination of Engineers and Firemen.

Last month we mentioned the fact that Mr. Geo. W. Cushing, Sup't M P. of the Union Pacific, was about to issue a small book of questions and answers to the employes of the motive power department of his road.

It is not Mr. Cushing's idea to instruct the older men by this book, but to put young men and firemen in the way of finding about the class of knowledge they will have to possess when it comes to promotion.

Mr. Cushing does not claim the work as original, but as selected from here and there in his long experience, and adapting the best found from any source. The air-brake part was adapted from rules laid down in the mountain service of the N. P. road.

We desire that the readers of this paper shall look over these questions and answers, and see where they could be improved, and write us on the subject. Mr. Cushing is one of the kind of men who will be glad if the article calls out discussion, criticism and argument, and discussion and argument are, of all things, what the engineers and firemen of the country need to indulge in.

Mr Cushing says in his

PREFACE.

This book of questions is designed to aid in the line of examination for engineers who may be hired, or men promoted on the Union Pacific Railway.

The questions may be varied, as the answers will be, but the points referred to are a few of those important for each man in charge of a locomotive in service to know. Many experienced engineers are able to suggest other, and perhaps more suitable questions The writer wishes to meet the level of his friends, the firemen, who are to become engineers

G. W. Cushing,
Sup't Motive Power.

QUESTIONS AND ANSWERS.

First five questions refer to personal record.

Ques 6—What are the principal duties of an engineer before attaching his engine to train?

Ans.—To examine the engine carefully, to see that all set screws are in place, and rod keys secure; that the engine is equipped with all necessary signals, firing and hand tools; the necessary supply of water, fuel, sand and stores, also to take a look at the flues and crown sheet.

Ques. 7—What is important in carrying water in the boiler, as to height and regularity?

Ans. To carry water and steam in the top gauge cocks when working steam, and as uniformly as possible.

Ques 8—What is important in carrying water on grades, and approaching a summit?

Ans.—To carry the water sufficiently high to be sure that the front ends of tubes are not exposed, and in pitching over a summit to have sufficient water to cover and protect the crown sheet after finding its level from the front or low end of the boiler.

Ques. 9.—Should it be necessary, after pitching over a summit, to pump up a gauge or more of water, what should be the condition of the fire?

Ans.—The fire should be kept bright and burning freely

Ques 10.—Why is this important?

Ans—To prevent chilling the flues, causing them to leak

Ques. 11—Should you have ample water, after pitching over, what should be the condition of the fire?

Ans—It should be leveled and settled down, and covered over sufficiently to prevent unnecessary waste of steam or fuel.

Ques. 12.—Should the pump or injectors fail on the road, what would you do?

Ans.—First, smother down the fire, stop promptly, take off the hose, and raise tank valves to ascertain that they are connected, also see that the strainers are clear. If all is found clear, then try the injectors again; and if the engine has a pump, take it down and see that the valves are free, and would also run water through the feed pipes. When all is open and free, put them up and try them again.

Ques. 13.—Should the water in the boiler get too low to allow you time for the examination, what would you do?

Ans.—Draw the fire and send a messenger to the nearest telegraph office for assistance.

Ques. 14.—Should the water in the boiler become disturbed and foam, what would you do, and how would you ascertain whether it was foaming or being overpumped?

Ans.—As soon as the water is discovered discharging from the stack, would at once shut off and ascertain the height of the water solid. Should the water drop below the second or third gauge, would conclude there was foaming, and would again gently open the throttle. Should the water again rise and discharge from the stack, would put on both injectors, open the surface blow, when one is provided, and run carefully, allowing the bad water to be worked off through the surface blow, being very careful not to work the water in sufficient quantities through the cylinders as to endanger knocking out the heads, and would occasionally shut off to see that the water was not being thrown off faster than the pumps or injectors were supplying it. By this means the bad water would, in most cases, be worked out, and, with gentle usage, would again settle.

Ques. 15.—Should your engine break down on the road, what are your first duties?

Ans.—I would see that my engine and train were properly protected by sending flagmen in both directions, if on a single track, and if close to a siding, get on it as soon as possible, if it can be done without disconnecting engine.

Ques. 16.—Should the blow-off cock be blown out, or be broken off, or a hole be broken in the boiler in any way, what would you do?

Ans.—Draw the fire promptly, and send a messenger to the nearest telegraph office for assistance. Would then disconnect and get the engine ready to be towed in when assistance arrived.

Ques. 17.—What portion of the engine would you disconnect in such a case?

Ans.—Take off main rods and valve rods.

Ques. 18.—What do you consider the best practice in the use of steam on a locomotive?

Ans.—By using steam expansively to the fullest extent practicable considering the size of train and condition of road.

Ques. 19.—Is there any other gain by working engine with full throttle?

Ans.—We get practically a full boiler pressure in the cylinder.

Ques. 20.—What is important to observe in setting up or adjusting wedges?

Ans.—To have them so neatly adjusted that there will be no thump of the boxes, and, at the same time, not so tight as to cramp and not allow them full and free play on the pedestals.

Ques. 21.—How would you go about setting them up?

Ans.—Would place the engine at half stroke on the right side, block the left wheels, admit a little steam, and thump the boxes hard away from the wedges. Would then get under and put the wedges up solid with a short wrench, and make a side mark on the pedestals at top of wedge, then draw them down equally a scant one-eighth of an inch. Go over the left side in the same manner.

Ques. 22.—How would you keep up or adjust the side rods of a ten-wheel or a consolidation engine?

Ans.—Would place the engine on a level and straight track, and on a dead center, then slack off all keys on that line of rods, would then key the main connection first, leaving it sufficiently free on the pin to be moved laterally by hand, then adjust the front and back ends in the same manner; before starting to key up rods, would see that wedges were properly set up.

Ques. 23.—Why would you place the engine on exact dead center, and begin by keying the main connection first?

Ans.—In order to insure keying the rods of proper length to allow them to pass the dead or rigid points without strain.

Ques. 24.—Can the side rods be keyed too long or too short when not standing on dead center?

Ans.—They can.

Ques. 25.—If too long or too short, at what point of the stroke will the strain be?

Ans. While passing the dead or rigid points.

Ques. 26.—Should you slip the right back motion eccentric on the road, how would you reset it?

Ans.—Would place the engine on exact dead center on right side, place the reverse lever in full forward gear, and make a mark on the valve rod at the stuffing-box gland; then place the reverse lever in full back gear, and turn the slipped eccentric until the mark on valve rod came to its original position, being careful to see that the full, or throw of the eccentric was in position nearly opposite the forward eccentric, then secure it there.

Ques. 27.—In what way does the mark you made on the valve rod, while in forward gear, aid you in setting the slipped eccentric?

Ans.—The forward motion eccentric being in proper position, by placing the reverse lever in full forward gear the valve is brought into proper position on the ports, and the mark gives the position of the valve when the back motion eccentric is in its proper position, thus setting the slipped eccentric by the good one.

Ques. 28.—Should a valve yoke break, how would you test in order to determine which side was disabled?

Ans.—Would first place the engine at half stroke on the right side and admit a little steam to the cylinders, then move the reverse lever from back to forward motion, and if the steam could be shifted from the back to the forward cylinder cock, would conclude that the right yoke was good, and would test the left side in the same way.

Ques. 29.—Why would you place your engine at half stroke on the side you wished to test?

Ans.—In order to get the full movement of the valve over the ports on that side.

Ques. 30. After locating the broken yoke, how would you disconnect?

Ans.—Would take off the steam chest lid, place the valve over the ports, and block it there securely; replace the lid, take off the valve rod, take off the main rod, block the crossheads, and proceed with half train to next telegraph office, report and give judgment as to whether the engine would take entire train to its destination.

Ques. 31.—Should you blow or break out a cylinder head, how would you disconnect?

Ans.—First, take off the valve rod and close the ports with the valve, and secure it by cramping with the stuffing-box gland, take off the main rod and block the crossheads.

Ques. 32.—How would you proceed to block the crossheads securely?

Ans.—By placing crosshead at one end of stroke, and placing a block between end of crosshead and guide blocks to prevent it from moving, would secure the block to the guides with cord to prevent any danger of its falling out.

Ques. 33.—Suppose your engine had some patent metallic valve rod packing, and you had no gland to cramp the valve stem, what would you do?

Ans.—

Ques. 34.—Should the cylinder packing drop and blow badly on the road, how would you determine which side was down?

Ans.—In starting from a station, would notice the right crosshead, and if the blow occurred when it was leaving each extreme end of the stroke, would locate the blow in the right cylinder.

Ques. 35.—In case of the use of piston packing ring, which cannot be set out, blowing so badly that you could not haul the train, what would you do?

Ans.—First, take off or disconnect valve rod and close the ports with the valve, and secure it by cramping with the stuffing box gland, take off the main rod and block the crosshead, proceed with as many cars as I could haul.

Ques. 36.—Should you be running an engine which had but one pump, it being on the right side and connected to crosshead, and that side became disabled so that it would be necessary to disconnect it, the injector be too small or fail to supply the boiler, what would you do to avoid drawing the fire and being hauled home?

Ans.—Would disconnect the piston from the crosshead on the disabled side and take it out, put up the main rod and work the crosshead, which would give the use of the pump.

Ques. 37.—How should an injector be started?

Ans.—First, open overflow and feed cock, and see if water comes through the former freely, then open the steam valve gradually until water ceases to pass through overflow, but passes through check valve into boiler.

Ques. 38.—How should an injector be stopped?

Ans.—Close the steam valve gradually and shut the feed pipe cock.

Ques. 39.—How should an injector be converted into a heater?

Ans. Open the feed pipe cock, shut overflow and permit a little steam to enter the injector through starting valve.

Ques. 40.—In case of failure of injectors, what would you do?

Ans.—I should endeavor to ascertain the cause of the failure; if a broken joint, leak in pipe or obstructed strainer, I should examine all connections and parts in the injector.

Ques. 41.—Failing to get injectors to work, what would you do then?

Ans.—I should draw fire and protect boiler.

Ques. 42.—Should you break a top rocker arm, how would you disconnect?

Ans.—Take off the valve rod and broken arm, close the ports, and secure the valve with the stuffing-box gland and disconnect as in the case of a broken cylinder head.

Ques. 43.—Should the bottom rocker arm break, how would you disconnect?

Ans.—As a rule would not take off eccentric straps, but with an engine badly worn and loose in link hanger, so that the link could play about freely when running, would take off eccentric straps and disconnect as in case of broken cylinder head.

Ques. 44.—Should you break a link hanger, how would you disconnect?

Ans.—If but a short distance to run and no stopping or shifting to do, would run in without disconnecting, after cautioning the crew to keep the train under good control and stop promptly when signaled to do so. But if a long distance to run, would fit a block on top of link block, in proper position, and endeavor to make the run in this way; if it became too troublesome, would disconnect as in case of broken cylinder head.

Ques. 45.—In what way would you have lost control of your engine with broken link hanger, in case it was not practicable to run with link blocked up?

Ans.—Would only be able to reverse one side of engine.

Ques. 46.—Should you break an eccentric strap, how would you disconnect?

Ans.—Take off both eccentric straps on that side, and disconnect as in case of broken cylinder.

Ques. 47.—Should you break the back section of a side rod on a six-wheel connected engine, what would you do?

Ans.—Would take off both back sections, and run in with main and forward wheels connected, with about two thirds of the train.

Ques. 48.—Should you break a forward section, how would you disconnect?

Ans.—Would take off all side rods and run in without train.

Ques. 49.—Should you break a back or front section of a side rod on a consolidation engine, how would you disconnect?

Ans.—Would take off both back or front connections, as the case may be, and run in with two-thirds of train.

Ques. 50.—Should you break a middle connection on a consolidation engine, how would you disconnect?

Ans.—Would take off all side rods and run in without train.

Ques. 51.—Should you break a main crank-pin close up to the wheel, how would you disconnect?

Ans.—Would take off all side rods, and the main rod on disabled side, and run in without train.

Ques. 52.—Should you be running an engine which had a slide throttle valve, and it would strip or disconnect inside the boiler partly open, how would you manage?

Ans.—Would reduce the steam pressure within easy control, and state the trouble to the crew, and caution them to act promptly when called upon to do so. Would work the train, if freight, to the nearest siding, and back it off. If passenger, would keep the pressure within easy handling, and work the train to the nearest telegraph office, report and ask for orders.

Ques. 53.—Should one of the forward tires on a ten-wheel engine break, how would you manage?

Ans.—Would jack the wheel up the thickness of the tire, take out the oil cellar, and cut a block to fit the bottom of the box and journal sufficiently thick to hold the axle up in its place when resting on the pedestal brace; would then run in without disconnecting, provided the rod had not been bent or damaged by the broken tire. Would take in full train.

Ques. 54.—Should you break a main tire, how would you manage?

Ans.—Would first send messenger to nearest telegraph office and ask for assistance. Would then block up the axle and wheel the thickness of the tire, slack off the side rod keys, and run in carefully without train.

Ques. 55.—Should the back tire break, how would you manage?

Ans.—Would take off the back section of rods, block up the axle, run very carefully, especially around curves, to nearest telegraph office, report and ask for orders.

Ques. 56.—What causes steam chests to give out generally?

Ans.—Reversing engine suddenly without steam pressure in the chest will frequently cause them to burst.

Ques. 57.—Why does this result?

Ans.—The necessary cooling of the water and steam on metal surfaces being removed, a gas is formed by rapid friction, and possibly the explosion of this gas is the cause.

Ques. 58.—Should a steam chest burst or break, what would you do?

Ans.—If the steam chest leaked too badly to run the engine, would break the joint in steam pipe on disabled side by removing bolt, and insert a piece of sheet metal or board between the joints, and screw up the bolts again; take off valve rod and main rod, and block the crosshead.

Ques. 59.—Should you break a front driver spring or spring hanger, what would you do?

Ans.—Would take the spring out, run the back drivers upon wedges to take the weight off the forward drivers, and block between the top of driving-box and frame, then run the forward drivers upon wedges to take weight off the back drivers, pry up the end of equalizer and block it level.

Ques. 60.—If a back spring?

Ans.—Would proceed same as in case of front spring, but in reverse order; would not take spring out if there was no danger of its falling to pieces, as it would consume too much time.

Ques. 61.—What size wedges would you use to run your drivers upon, and how would you get them when needed?

Ans.—I would use wedges of oak about three feet long and four inches square, eight or ten inches of the top of wedge straight for wheel to rest on, and would see that I always had them on my engine ready for use.

Ques. 62.—In case of failure of water supply in tank under ordinary circumstances, what would you do?

Ans.—I should endeavor to reach a siding to leave my train and run to a water tank, except it was practicable to obtain a supply from some pond or stream near by.

Ques. 63.—If tank valves become disconnected from rods, what should be done?

Ans.—Would change the injector to a heater, obtain a good pressure in the feed pipe, then open the feed cock suddenly and blow the valve out.

Ques. 64.—Is there any risk of burning or bursting the hose in the operation?

Ans.—Yes; the starting valve and heater cock should be closed immediately after blowing out the valve.

Ques. 65.—In case of snow blockade and water low in tank, what would you do?

Ans.—If practicable, I should endeavor to shovel snow in tender, and in this way make water enough to keep engine alive.

Ques 66.—In case it was not practicable to do this, how would you proceed?

Ans.—I should keep the engine alive so long as the water lasted, and then should take down all water pipe connections that could possibly be damaged by frost, and blow boiler out clean, and be careful to leave no water standing in legs of boiler.

Ques 67.—What further would you do to protect your cylinder from damage by frosts?

Ans.—I should open cylinder cocks, slack off cylinder covers, and blow out or drain off what water was in cylinders

Ques 68.—In case you should burst a boiler tube on the trip, what should you do?

Ans.—I should endeavor to plug the flue with the means provided, and stop the leak

Ques 69.—In the case of use of water grate and the bursting of one of them, what would you do?

Ans.—If I was about to lose my water, should draw the fire to protect the boiler from damage

Ques. 70. In case of failure of spark arrester and the throwing of sparks to a dangerous extent, what would you do?

Ans.—I should report the difficulty to headquarters, and request to have train reduced to avoid using full power of engine, and in this manner reduce the danger of throwing sparks

Ques. 71.—In case of partial failure, ordinarily, of spark arrester or ash-pans, what is your duty?

Ans.—I should report to the nearest terminal point where such things could be repaired.

Ques 72.—What do you know about the draught arrangements in smoke-box of a locomotive?

Ans.—

Ques 73.—Why are exhaust pipes necessary in the smoke-box of engine?

Ans.—For a proper draught from the fire-box through the tubes.

(*Concluded next month.*)

IN THE ROUNDHOUSE AND REPAIR SHOP.

The Santa Fe has got their new Strong engine.

The N. P. road use sheet metal signal flags altogether.

The Masons have given up locomotive building entirely.

During the last fiscal year the Westinghouse Air brake Company have sold brake equipment to the amount of $3,300,000.

We would say to correspondent who inquired about size of drivers that the class K locomotives on the P. R. R. have wheels six foot and six inches in diameter.

Once more the newspapers announce that the Grant Locomotive Works will be removed from Paterson, N. J., to Minneapolis, Minn. They are building nothing at present.

Pedrick & Ayer, of Phila., are getting out the patterns for an extra heavy cylinder boring and facing machine, recently designed by P. Leeds, Supt. M. P. of the L. & N. Ry.

The Hinkley Locomotive Works are no more. All the machinery has been sold and removed from the shops, and the latter will be torn down to make room for an immense plant for the Electric Railway Co.

We have received large photos of two D., L. & W. locomotives, taken by Albert Bruen, an amateur of no mean ability. Among a large collection in our possession, they show the best work and are the clearest.

In times of peace prepare for war, is the proverb the railroads are now living up to, in making repairs to their snow plow and flanger equipment. The weather prophets promise a winter of harvests for snow-plow builders.

J. E. Lonergan, 211 Race street, Phila., manf'r of safety valves, oil cups, checks, etc., has moved his brass foundry to the fourth floor of his new building next door, and will lengthen the store room and office of his old place to occupy all the space formerly used as a foundry.

Mr Geo. Small has designed a new form of compound locomotive. The device will contain a new form of Strong boiler, having but one fire-box, in a large corrugated steel tube. Four cylinders will be employed, and steam got in and out of them by a modification of the present Strong valve gear.

The Pond Machine Tool Co. have recently furnished the N. Y. & New England with one of their heavy machines for turning steel-tired wheels with a tool cutting the full width of the tire at once; the machine weighs 23 tons. This road has also ordered one of their 79' driving wheel lathes with double quartering attachment.

A new car service valve has recently been put on the market by the Mason Regulator Co., of Boston, to fill a want expressed by several railroads and car-heating companies. It is to reduce the pressure separately for each car from the main service pipe, in which the pressure is reduced from the locomotive boiler to about 30 lbs. By its use a more uniform pressure can be obtained in each car throughout a long train. The cost will be very low.

Wm. Miller, locomotive superintendent Natal Government Railways, Durban, South Africa, writes Watson & Stillman, of New York city, that he has seen their advertisement of Vreeland's Transfer Jack in THE LOCOMOTIVE ENGINEER of February, 1889, and asks information and prices, with view to adopting on his road. He adds: "I may mention for your guidance that the gauge of our railway is 3 feet 6 inches, and the diameter of our largest engine wheels is 3 feet 2 inches."

The engineers, as an organization, have kept out of the proposed plan of federation of all railroad orders; but in many localities all the orders are signing articles of confederation for the system of road on the particular locality. The latest instance reported by the daily press is that of the employes of the Union Pacific system. The federated firemen, brakemen and switchmen have recently won some decided victories, and kept still about it—a grand improvement in itself. If federation properly governed it would be a good thing—the principle is all right.

The Rue Manf'g Co., of Phila., makers of the well-known Little Giant injectors, and the Rue boiler washing and testing apparatus, have recently moved their shop into the magnificent new factory building at 209 Race street, recently erected by J. E. Lonergan, the well-known oil cup manufacturer. The new shop has four times the floor space of the old, and some new tools will be sprinkled in among the old. Manager Colvin, while kicking in the orthodox way against the hard times, acknowledged that he was out of two sizes of injectors, and all hands making full time.

Angus Sinclair, Secretary of the American Railway Master Mechanics' Association, sailed for Europe on the morning of the 25th. His many friends—in and out of the association—tendered him a farewell banquet at Duke's Hotel, Hoboken, N. J., on the evening of the 24th. Angus Sinclair came to America from Scotland fifteen years ago, and sought employment as a locomotive fireman, a business he had followed in Europe. From the scoop he has worked himself up to the position of the foremost writer on American railway machinery. This he has done by the steady application of the "try, try again" rule, and both his record and position are ones he may well be proud of. He has sent out the following notice to members: "I expect to sail for Europe on September 25, to be absent seven weeks. I have to request members who have business to transact with this office to postpone it till I return, and if this cannot conveniently be done, to submit it to President Briggs, Memphis, Tennessee."

GEO. WESTINGHOUSE, JR., PRESIDENT. | T. W. WELSH, SUPT. | JOHN CALDWELL, TREASURER | W. W. CARD, SECRETARY | H. H. WESTINGHOUSE, GENERAL MANAGER

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 170,000 cars. This includes 75,000 freight cars. Orders have been received for 20,000 of the improved quick-action brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, MANAGER | JOHN B. GRAY, AGENT. | C. C. HIGHAM, GENERAL SUPT.

THE AMERICAN BRAKE COMPANY.

NEW YORK OFFICE, 160 Broadway, JOHN B. GRAY, Agent.

THE WESTINGHOUSE AIR BRAKE CO., Lessee,

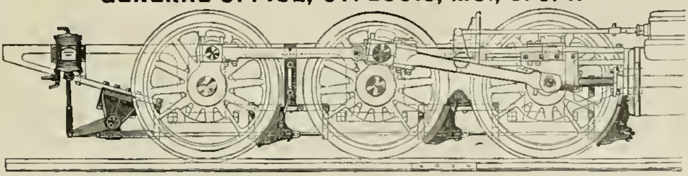
CHICAGO OFFICE, GRAND PACIFIC HOTEL.

MANUFACTURERS OF

LOCOMOTIVE BRAKES.

GENERAL OFFICE, ST. LOUIS, MO., U. S. A.

BRAKES Made to Order for any Special Form or Class of Engine.



All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear and Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM or AIR.

DIXON'S

GRAPHITE

PIPE JOINT

GREASE,

For Steam or Gas Pipes, Bolts, Screws, etc.

Far Better and Cheaper than Red Lead.

Makes a tighter joint than red lead, that can be opened with perfect ease many years after.

No longer any necessity for BROKEN PIPES, STRAINED TONGS or LEAKY JOINTS.

Put up in 1 lb., 5 lb., 10 lb., 25 lb. & 50 lb. packages.

JOSEPH DIXON CRUCIBLE CO., JERSEY CITY, N. J.

THE "LACKAWANNA"

Locomotive Grease Cup

Specially adapted for use on

CRANK PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws.

Engineer can see at a glance whether Feed is on or off.

Tested on locomotive crank pins in hard daily service, with but one filling in one to four weeks.

Our "Lackawanna" Compound, specially recommended for these cups, is unaffected by heat or cold, having worked successfully at 30 below, and 95 above zero.

LACKAWANNA LUBRICATING CO., SCRANTON, PA.

IMPROVED UNIQUE AUTOMATIC SIGHT FEED LUBRICATOR.

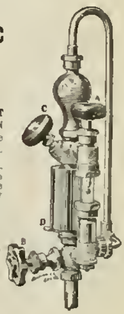
Guaranteed to be the SIMPLEST AND BEST WORKING DEVICE ON THE MARKET for lubricating the valves and cylinders of air pumps.

All our air brake cups are furnished *complete* and are ready to attach when received. There are no valves or pipe to be supplied by the user.

ALL WE ASK IS A TRIAL.

Send for illustrated pamphlet, fully describing above, before purchasing.

Unique Lubricator Co., MANSFIELD, OHIO.



SINGLE CONNECTION.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

Main Office: FRANKLIN, PA. Refineries: FRANKLIN, PA. OLEAN, N. Y. ERIE, PA. OIL CITY, PA.

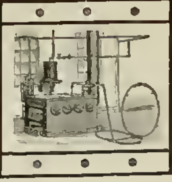
Has just been issued by us, with descriptions of Air-brake Governors, Pressure Regulators, etc. Send for one to

MASON REGULATOR CO., BOSTON.

JENKINS BROS., Agents, NEW YORK, PHILA., CHICAGO.

PEDRICK & AYER
MANUFACTURERS OF SPECIAL
Tools for Railway Repair Shops.
CIRCULARS ON APPLICATION.
1001 Hamilton St., Philad'a, Pa.

Apparatus for Heating, Setting and Removing Tires



A very complete arrangement for putting on new Tires, or taking off old ones, without removing wheels from under the engine. Will do all the work connected with tire heating, setting, removing, shimmering and replacing. With this apparatus and system of doing the work, less than one-tenth of the time is consumed, and the paint on the wheel centres is not injured.

VOL. II, NO. XI. NEW YORK, NOVEMBER, 1889. 1.00 per Year or 10c. a copy.

The Drawing Lessons.

On another page will be found the first paper of what promises to be a most interesting series of articles on mechanical drawing and sketching, by Orville H. Reynolds, chief draftsman of the Northern Pacific Railway. Mr. Reynolds has "been through the mill," and knows all about the difficulties in the way of apprentices and mechanics, the want of time and the want of money.

He will therefore confine his articles to the use of the fewest number of instruments possible, tell you how to make most of them, but recommends their purchase, and proposes to use as examples of work just such work as will come up in the shop in every-day practice. He will write for you, using no algebra, no formulae, and when he calls a thing by a strange name will tell you what it is, and what it means, in a way that will be both interesting and instructive.

Get yourself a set of tools and follow these articles; it may result in your going higher, must result in good, and cannot possibly do harm.

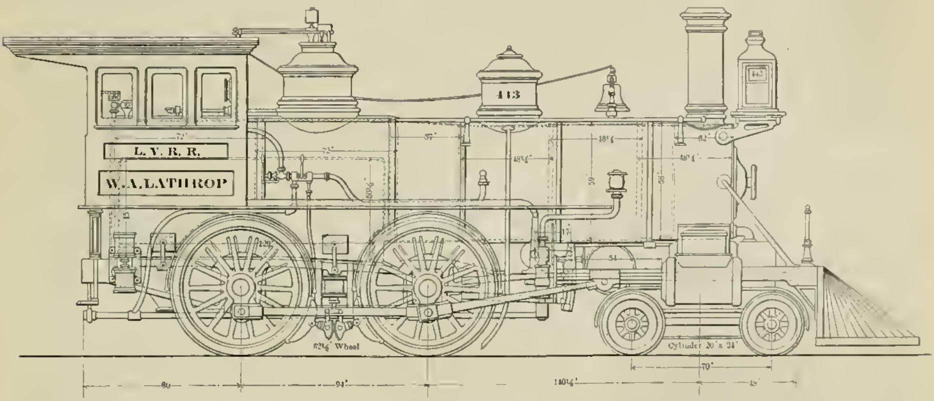
The Dark Ages.

We are in receipt of an instruction book, issued by the Union Pacific Railway, governing the instruction and examination of all employes interested as to the construction and use of the Westinghouse air-brake.

The day of shop and road mysteries has passed away; the day of ignorance, erroneous ideas, stupidity, looking wise and guessing at it, are happily on the wane.

Every effort is being put forth by the most enterprising railroads to educate their trainmen; little books are given free, where a disposition to discuss and use them is manifest. There will soon be forthcoming valve motion models, sections of brake valves, injectors and lubricators. The engineers, machinists and firemen of the future must know the *why* of these things; those who do not, will or cannot learn will have to quit railroading. How are you fixed? Are you posted? If not, why not?

On the C. Ry. of N. J. they are trying, with good success, a large exhaust nozzle with a cone in the center, the cone being supported on a threaded post that admits of its being raised and lowered. By this arrangement the exhaust is made to flare out and fill the stack, allowing the engines to steam with a larger opening than before the cone was tried.



A Lehigh Valley Locomotive.

The locomotive W. A. Lathrop, shown on this page, was built at the Delano (Pa.) shops in May, 1889, by John Campbell, M. M. Her sizes are marked on the drawing, and principal dimensions given in the following specifications:

Cylinders, 20"x24".

Steam ports, 16"x1¼".

Exhaust port, 16"x2½.

Valve travel, 5".

Links, steel with wrought-iron blocks, case-hardened. Radius, 72".

Driving wheels, cast centers with steel tires, 3½ thick, 5¼" wide; diameter, 62½".

Driving axles, steel, 8½" diameter, journals, 8 diameter, 8½" long.

Crank-pins, steel.

Main-pin bearings for parallel rod, 5"x3½ wide.

Main rod bearings, 4½"x4½ wide.

Parallel rod, back end bearings, 3¼"x3½.

Piston rods, steel, 3¼" diameter.

Guides, steel.

Crossheads, steel, with bronze metal gibs.

Journal bearings, all of bronze metal.

Engine truck axles, forged iron, 5½ diameter, journal bearings, 5 x8".

Truck wheels, 30" diameter, open pattern, steel tire, cast center.

Tender trucks, solid frames with M. C. B. standard axles, 30" diameter, open pattern, steel tire wheels.

Tank capacity, 3,000 gallons.

Engine wheel base, 22ft.x5¼.

Total wheel base, engine and tender, 47ft.x6¼".

Weight of engine with fire and water, 101,100 lbs.

Weight on driving wheels with fire and water, 73,100 lbs.

Weight of tender with fuel and water, 54,000 lbs.

Boiler, steel; shell sheets, ½" thick, fire-box sheets, ⅜ thick, diameter of smallest boiler ring, 58". All lap seams with inside lap pieces.

Length of fire-box, 129, width, 42½, height back, 45"; front, 50½".

Length of chamber, 5.

Length of boiler, 20 ft. 2". Supplied by two injectors and one pump.

The engine is equipped with the improved air-brake, also for steam heating.

Fuel, anthracite coal.

The left-hand injector can be started from the right side by a lever that connects to its lever. Special comforts are provided the engine men. Lehigh Valley engines are among the best finished machines running on the Atlantic seaboard.

We are indebted to Mr. Henry A. Richards, of Pullman, Ill., for spending a full half day showing us through the shops of that place.

Elementary Lessons on First Principles.

SECOND LESSON.

Let us just go a little out of our way to say that where the link motion is used on a locomotive without a rocker it is called a

DIRECT-MOTION ENGINE,

and the eccentric that is in gear, for instance the forward eccentric, when engine is running ahead, leads, or is ahead of the crank-pin, while the forward motion eccentric on an *indirect* engine, or one employing a rocker, follows the crank-pin, or is behind it, when engine is running ahead. Most locomotives running in America have rockers, and are therefore indirect motion engines.

Returning to the subject of the

SUSPENSION OF THE LINK,

you must remember that the angularity of the rod makes the piston travel unevenly, and that the angularity of the eccentric rods makes them move their ends of the link unevenly, and that these motions are tied together by the link, and the combined motion between the two points used to move the valves.

There are a great many other things to take into consideration in designing a link motion, any of which would distort the motion; but we will not go into these now, as the object is to explain *why* the link hanger stud is located behind the center of link, not to teach you *how* to lay it out

The ordinary link motion is not the best expansion gear, but it is the simplest and cheapest reversing gear known, and has almost superseded all other forms of motion for locomotive work

It is impractical to set the link motion to cut-off *exactly* square for all points of cut-off in both backward and forward gear, but it can be set to cut-off pretty nearly square where it is liable to be used the most; and, to enable it to do this, other points of cut-off are often left a little out.

We have seen that in practice the wheel moved in a steady and uniform motion, but that the piston moved further during one-half the stroke than during the other half, and consequently must move faster during one-half the revolution of the wheel than during the other half.

The eccentrics are set nearly quartering to the pin, so that when the pistons are moving the fastest, when sweeping through the center of the cylinders, the valves are moving the slowest; while, on the other hand, when the pistons are at the ends of their travel, and are therefore moving slowest, the eccentrics are at or near the quarters, and are moving the valves the fastest and the most, thus giving a quick opening at the beginning of the stroke. Now we have seen that the piston moves faster when on the forward half of the stroke, when the pin is nearest the cylinder, than on the back half, when the pin is away from the cylinder, and this difference in piston movement is made while the valve is doing the most work.

In designing valve motion, the position of the link is laid out as it would stand when cutting steam off at half stroke of the pistons, regardless of the position of the pins, as in Fig. 2, where the link numbered 1 shows the position when cutting off at half stroke for one end, and the link numbered 2, the position of same link when cutting off at half stroke for the return stroke of piston. The line *D E* is the center line of the engine, and the line *B C* the center line of the link motion.

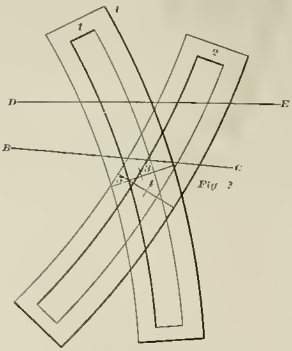
If the link hanger was fixed at *A*, and reached to the center of the link in either position, as at the points 3 or 4, the cut-off could not be even, as the hanger would not allow the link to move from 3 to 4

By selecting a mean point at 5, found at the intersection of the lines drawn across the center of the link, the motion is so modified in each case as to cut off steam at exactly half stroke, regardless of the angularity of the rod. If steam is cut off evenly at half stroke, it will be cut off very nearly even for other points. Links are sometimes suspended out of the center, for other reasons, which will be explained in lesson three.

It is the general rule in the old country to build locomotives without equalizers; each spring has its hangers fixed rigidly to the frame.

Special Breed of Cooking for Workingmen.

We are in receipt of a report from the consuls of the United States, concerning Cookery for Workingmen's Wives and Oatmeal Food, sent out by the Government at Washington. The pamphlet abounds in receipts for cooking various foods especially recommended for workingmen—foods



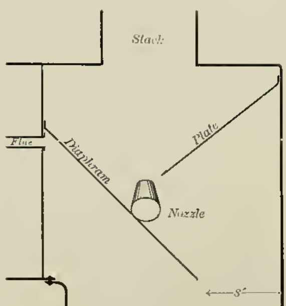
LESSONS ON FIRST PRINCIPLES.

that will presumably enable them to do more work than that on which they now subsist. This idea that there is anything different necessary for workingmen, either in food, clothes, school, church or state, is a bad idea to propagate. The workingmen want an opportunity to earn enough by their labors to buy such food for themselves and families as they like and need. Foreign receipts for cooking are rather cold comfort to the thousands of workingmen now out of employment in America. Some change must come, and that quickly, whereby every human being who desires to toil can find opportunities to do so, and at something like a fair remuneration for the service he gives.

The farther the "workingmen" are isolated and distinguished from the "upper crust," so much the worse for the crust in the final collapse.

An Early Extension Front.

We recently ran across the original drawings for an extension front end, designed in 1850 for one of the 8-foot wheel Camden & Amboy passenger engines, by Mr. Isaac Dripps, then Master Mechanic of the road, and for many years afterward Supt. of Machinery of the Penna. road.



The extension was principally down, and the diaphragms as shown are not far different from present practice The nozzle was high on account of the exhaust pipes entering the sides of arch well up —cylinders were on a line with them, but further back. This is, no doubt, the first.

The Travelling Engineer.

By J. E. PHELAN.

One essential point concerning the supposed duty of traveling engineers will bear considerable comment in relation to different kinds of engineers in service.

We all know that a certain percentage of men in charge of engines master the art thoroughly, so that instruction at any time is unnecessary. An idea imparted to such men to set thought at work is all-sufficient A mere suggestion is ample prompting to cover desirable points in practice.

This class and kind are born engineers, and practically traveling engineers themselves, insuring reliable service by their methods, and benefiting the general service by example shown in daily work.

Another kind of engineer is the one who knows enough to do work right, and care for engines properly; but having been born tired, need continual bracing up. They know when wedges are down; they know when rods need keying up, but from constitutional indisposition to work, they drive engines along in service until the machines resemble rattle-traps.

The mission of such men on earth—after gaining a place on pay-rolls as engineers—seems to be to keep the back shop and roundhouse filled with premature wrecks; keeping the mechanics busy; overcrowding the limit of the management's appropriation for repairs, and compelling good engineers to get excessive mileage out of engines kept in service by necessity, in order to keep up the general average in service.

While we are remarking on this particular point, we can truthfully say that we have known traveling engineers who considered such work fair; but we often find traveling engineers born tired—constitutionally—including both mental and physical forces.

With such men on engines, we claim it is the duty of the traveling engineer to take engine, engineer and firemen in charge, and devote time enough to subject in hand to remedy all accessible defects; and if necessary have particular attention paid to engine at terminal points for equipping with necessary requirements to insure performance of duty to maximum capacity. If the engineer's maximum capacity is of too contracted a standard to suit the requirements of the engine and service in hand, it becomes the duty of the master mechanic to apply a remedy.

But let us not forget the subject of teaching so far as within the duty limits of the traveling engineer.

On railroad systems where it is the rule to promote all engineers from ranks of firemen—and pay is regulated by several grades—more and greater chances, as a usual thing, are taken on class of men promoted, and the field for educating influence enlarged to a great extent. Under such circumstances the task of keeping the men up to the standard is increased, and the chances are that no amount of work will bring the average up to a decent respect for mechanical laws. Of course this portion of our remarks relate to territory where promotion as a rule is rapid, and mind and body denied that slow, deliberate fruition in experience which should be common.

We claim no traveling engineer's position is more desirable, or more to the point of insuring good reliable service, than where all engineers are held equally responsible in matter of keeping engines in proper condition to perform duty to a maximum capacity.

Under such conditions, where firemen are promoted, they should be of character to adopt deliberate methods, and by proper precaution, watchfulness, inquiry and study, be able to successfully manage engines without serious delays or expensive damage to machinery. We claim that every road has such men in employment, and we further claim that, where an intelligent traveling engineer can come in contact with such men, good results are sure to follow.

Where engineers are employed for road service, such employes should be fully up to the times in all matters pertaining to the proper management of locomotives.

There is a class of floating talent, perennially seeking employment as first-class engineers, who do more harm to the cause of good men and competent engineers getting positions than all other influences combined.

This class, as a rule, are graduates fully developed in all that is knowable about locomotives. Being employed on a railroad they start out to learn the road, and at first opportunity seek a soft seat or a bunk in the caboose, instead of remaining on the engine and learning important points about the service.

Should a traveling engineer be required to instruct such men? We simply opine, Not much!

When such men start out, unless the fireman happens to be kind hearted and experienced—experienced firemen usually lay off about such times—the engine managed (?) rests near the brow of every hill after nightfall. A coal famine shows up, and water gets scarce, and if the weather happens to be frosty it gets very interesting. Engineers of this class should be required to learn the road before taking charge of an engine. They should know how to handle air-brakes on freight trains, where such are used, and they should honestly aim to be in every particular what they profess to be—competent engineers.

When competent engineers, only, can get recommended for position, and be insured employment, the general standard of machinery and talent employed in care of same will average high, and the life of a traveling engineer become correspondingly happy

We must pay tribute to the *competent* engineers, who seek and gain employment, and by honest effort improve every opportunity in rendering good service.

The least that can be said is that experience, of the competent kind, is never better understood or more fully appreciated than by the reliable traveling engineer or the master mechanic; while the diligent mechanic in the roundhouse sings praises in his heart, as well as frequently with the mouth.

The traveling engineer who can silently, persistently and effectively sow seeds of understanding that may grow and bring forth fruitful results in insuring, or requiring, all engineers to locate defects about machinery or air-brake appliances, so that a machinist, after looking at the repair book, can go and place hand or tools on parts needing repairs, without having to guess for two hours to locate ten minutes' work—we say such results should warrant an everlasting and honorable reputation.

Simple Lessons in Drawing for the Shop.

By ORVILLE H. REYNOLDS.

FIRST PAPER

The apprentice of A. D. 1889 is in enjoyment of opportunities not dreamed of by his confreres of past generations.

What with well-lighted shops, latest improved machine tools, and an abundance of literature pertaining to his calling, there seems to be little to be desired, and those who thirst can drink their fill, thanks to such men as J. G. A. Meyer, Joshua Rose and others.

Preferment comes to him who is qualified for it, the dullard remains in the rut, and it would seem as though that grim fact ought to be a sufficient incentive to make the thinker burn the midnight oil, which he must do if his educational advantages are limited, or he expects to keep up with the procession.

There is no denying the fact that study after working hours becomes irksome, but when the reward for such exertion is considered, it should be a pleasure, and he who loses no opportunity to improve his mind will have no regrets

Anything which has the least bearing on the occupation should be read, and not only that, it should be studied until the subject is thoroughly understood

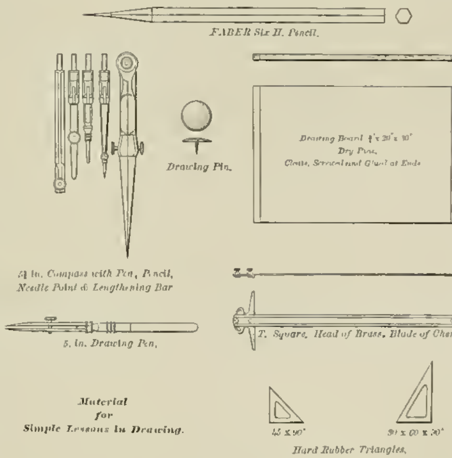
Waiting for six o'clock to come would have a different meaning to those who once found themselves interested in their books.

A fellow-feeling born of walking in their rocky road impels me to write these lines to a class of young workers of whom I had the honor to belong in the misty past, viz., the apprentices.

For him we purpose to give a few simple pointers in a homely way, so that, if he is so inclined, he can make himself understood in the universal language of a sketch, either free-hand or drawn to scale, and apply the lessons so given to the laying out of work with which he is familiar.

It will be necessary to have a few accessories to begin with; we will get them up as cheaply as possible consistent with good work First we require a drawing-board, 20"x30"x⅞" thick, preferably of well-seasoned pine; such a board can be made for $1.50 The only requirement being that the board shall be fairly true and smooth on top, and the edges square.

Next will be needed a **T** square, which, to serve the purpose, should also be made of thoroughly seasoned wood. Cherry is good, and holds its truth well Make the blade 1¾" wide with the two



SIMPLE LESSONS IN DRAWING FOR THE SHOP.

edges parallel, and true the whole length, which should be, in this case, 30". It should be $\frac{5}{16}$" thick, with a chamfer on each upper edge ½" wide, leaving the edges $\frac{1}{16}$" thick Sandpaper and shellac the blade on top, it will keep clean better

The square head can be made of sheet brass $\frac{1}{16}$" thick, having the front edge bent down at right angles to the body for contact with the drawing-board, and secured to the blade by two ¼" brass bolts with milled nuts, one of the bolts to pass through a circular slot in one side of head, making the blade adjustable to any angle within the limit of the slot, which is useful at times. I am aware this would not be called good practice in some quarters; but, as squares of this type are doing good service every day, it will be good enough for us. Such a tool can be made for $1.50, and, if properly built, will be a source of joy to the user.

The one thing necessary to make it a success is to be sure the fits of the thumb-screws are perfect as possible through the blade and head, any lost motion at those points will not cause a smile of gratification to flit over the artist's features.

If it cannot be easily made, then a plain, wooden one can be got up instead; make the head of cherry also, 2" wide and ½" thick. Secure to under side of blade by two nickel-headed screws Squares of this description can be bought of Keuffel & Esser, New York, for $1.20, or can be built by any good wood-worker.

Drawing-pins having German silver heads ⅜" diameter will be next wanted, only those with heads screwed to a shoulder. If there is a delusion and a snare in this beautiful world of ours, it is a drawing pin that insists on coming up through the head, to remind us that it is not, nor never was, a screwed head.

For triangles select two of hard rubber—one of these to be 45°x90°x5" long, the other to be 30°x60°x90°x5" long—the price of these will be 65 cents.

The most important thing of all to be considered now presents itself, *i. e.*, a choice of drawing instruments, which, while they will be cheap enough to come within the reach of all, will also be good enough to do anything like passably good work.

The instruments actually required to do work with are, One drawing pen, one 5½ compass with pen, pencil and needle point, and lengthening bar These are the bare necessaries, and can be obtained for $5 in New York.

These will fill all requirements to start with, but after getting interested in your work it will be discovered that a bow pen, bow pencil and bow dividers would be good to have; indeed, you cannot do without them if you care to do nice work. Their price is $4.45 for the set. The above are furnished with neat morocco case. It is much better to buy the instruments singly without the case, if it can be done, and purchase the case after the instruments are all procured. Remember, a cigar box is not a proper receptable for drawing instruments.

Instruments mentioned are of a cheap grade, as the price would indicate, but, while they are not "Alteneder's," they will do good work when properly handled. A few articles more, and the outfit will be complete. A triangular scale, divided to ⅛, ¼, ⅜, ½, ¾, 1, 1½, 3 and 4 inches to the foot, also one side to sixteenths, can be bought for $3 if metallic and nickel-plated. While these scales are convenient, they may also be regarded as a luxury A 12" steel scale, such as is used for shop work, can be used satisfactorily if it is necessary to dispense with the regulation draftsman's scale.

An ink slab with cover, 1¾"x4¼", will be something we will require when "inking in," which is going over the pencil lines with the drawing pens; the cost of such a slab is 50 cents. If desired, Higgins' prepared ink can be used instead of the cake, it comes in small bottles at 25 cents per bottle. The cake is best to use.

For drawing, a six H. Faber pencil is needed, and for sketching, a number 5 Faber pencil will be about correct.

For erasing construction lines, and cleaning the drawing after completion, it will be necessary to have a piece of soft rubber. Davidson's velvet rubber is the best. A piece ½"x2¼" is one commercial size, and convenient to handle.

A recapitulation will show what the cost of all the articles mentioned will be:

One drawing-board	$1.50
One **T** square	1.20
One doz. drawing-pins . . .	.60
Two hard rubber triangles .	.65
One set of drawing instruments..	5.00
One ink slab....	.50
One six H. pencil	.10
One No. 5 Faber pencil.... .	.10
One Davidson rubber....	.10
	$9.75

Which is certainly not an unreasonable price for the articles described. With such an outfit an effort can be made by him who is so inclined, that may lead in paths both pleasant and profitable.

The humble apprentice may, with the aid of these very humble instruments, become the chief stone of an important corner.

Copy of Circular Sent by the Westinghouse Air-Brake Co. to Locomotive Works.

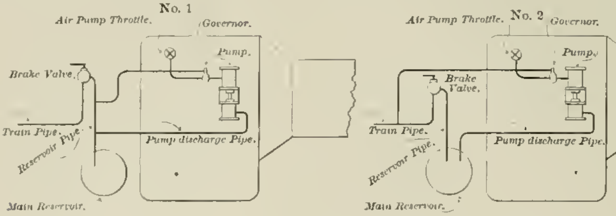
"We are occasionally in receipt of inquiries from railway officials as to causes of some supposed defect in devices employed in our brake system, which, upon investigation, is sometimes found to be due to improper methods of attaching the apparatus to an engine or car.

One of the most prolific sources of trouble arises from improperly arranged pipe connections on the locomotive, where the pump discharge pipe and the pipe leading to the engineer's brake valve are united, instead of which, independent pipes for each purpose connecting with the main reservoir should be used."

The sketches for which we are indebted to the *National Car and Locomotive Builder* will serve to make the reference clear.

"When the improper plan (No. 1) is used, quite an amount of moisture and filth from the pump is carried directly to the engineer's brake valve, and to the brake apparatus on the train vehicles, to such an extent as to sometimes impair their efficiency.

"When the proper method (No. 2) is used, the objectionable matter is deposited in the main reservoir, from which it may be drained at will, by unscrewing the plug, which should be placed in some convenient and readily accessible position. We have also *frequently found the pipe to the air-pump governors connected to the main reservoir.* This should *invariably* be connected to the train pipe, a union connection being provided at the engineer's brake valve which communicates with the train pipe. The sketches will also show proper and improper methods of connecting the air-pump governor, and should be considered illustrative only of the points we wish to convey. Proper union connections are provided at the brake valve for the gauge and governor.



WESTINGHOUSE AIR-BRAKE.

We trust you will co-operate with us in the desired reformation, if not already your custom, and take the necessary steps to inaugurate it at your works. Please acknowledge receipt."

The Union Pacific have just closed the contract for two Jull snow-plows. The Jull plow has a coned fan, with the point of cone supported near one rail, the cone hanging at an angle across the track. The Jull Manufacturing Company can well feel proud of Mr. Cushing's indorsement of their machine, if indorse it he does, after a thorough trial.

Break-Joint for Cylinder Packing Rings.

The break-joint blocks herewith shown are the invention of E. F. Peacock, roundhouse foreman of the P. R. R. at Philadelphia, and are in use on quite a number of locomotives on that road, five of them the famous class "K" 6½ foot wheel passenger locomotives. The block has been fitted to old pistons in badly worn cylinders, and done good service.

Mr. Peacock describes it as follows:

"Figs. 1 *A* and 2 *B* on the sketch show the blocks. Fig. 1 *C* is piston with rings and blocks in position. Fig. 2 *D* is section through piston-head in cylinder, showing position of block at bottom of piston, and showing a solid portion of the ring at the top of piston. The line in this that represents the cylinder bore also represents the outside line of ring, and the next solid line represents the inside line of ring. The dotted line is outside line of piston-head, and the inside solid line is bottom of ring groove. Fig. 3. "*E*" shows open space at *F*, where steam can blow through between the ends of ring, when no break-joint or dowel pins are used. The advantages that I claim in this break-joint are (1st) to obviate loss of steam, setting the rings out too tight, abrasion to cylinder, rings and piston-head. Also setting the rings out too suddenly, and breaking them. (2nd) to create a smooth enameled surface on the cylinder, rings and piston-head, easy reciprocating for piston, good results in train service, and a saving in fuel. (3rd) that the blocks can be used with narrow rings, which are preferred on account of less friction. The blocks can be used with a single ring as well as with two rings."

Snap rings set out by steam are the cheapest device known, but the sudden setting out at the ends, caused by the steam, and the compression, cause the cylinders to be cut at the ends, and when the ring becomes thin and old the sudden slapping of the rings against the cylinder breaks them.

Fig. 2."D"

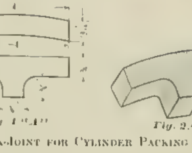


Fig. 1."C"

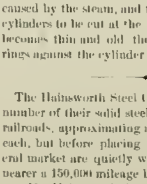

Fig. 1."A"

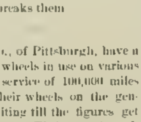

Fig. 2."B"

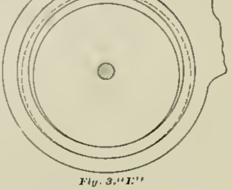

Fig. 3."E"

BREAK-JOINT FOR CYLINDER PACKING RINGS.

The Hainsworth Steel Co., of Pittsburgh, have a number of their solid steel wheels in use on various railroads, approximating a service of 100,000 miles each, but before placing their wheels on the general market are quietly waiting till the figures get nearer a 150,000 mileage basis. Their superintendent, Mr. Hainsworth, is widely known as a successful steel man.

About Correspondence.

We are in receipt of no less than eleven long communications on both sides of the subject touched upon by Grant, Arnold and H. T. R. While they are all good, and each make points, we will have to refrain from publishing any of them—it would be unfair to use one without the others. As a matter of fact, the most of them, on both sides, give too many opinions, leave out too many facts that could be stated, and wander from the real subject. In the first place, we let Arnold accuse the engineers of gross and universal ignorance, and then had to let H. T. R. reply. To carry the dispute further will not benefit anybody; we will gladly publish any reasons developed by experience, either for or against the practice of running with wide-open throttle, etc.; simple opinions prove nothing.

A Roundhouse Kink.

In the City of Brotherly Love the Pennsylvania Railroad Company own a roundhouse in which the locomotives head in. We noticed that in front of each stall there was a hole knocked in the brick work big enough to take in about half the pilots; some of these were arched up and left, others were simply holes just as they came from the punch. A little inquiry developed the information that they were made so as to let the big engines far enough in to close the doors behind the tanks; this done, the mills are backed up under the smoke-jack and cooled down. Why they did not think of swinging the doors out does not appear plain. In case of fire, every dead engine in the house would be in jail; if the doors opened out they could be saved by a switch rope and an engine. Curious conveniences that do not convene and many improvements that do not improve are concocted on railroads, even the great P. R. R.

Mr. H. D. Gordon, the able young master mechanic for some years in charge of the Philadelphia, Wilmington & Baltimore shops at Wilmington, Del., has been selected by the management of the P. R. R. to take charge of the new shops at Altoona, Pa., especially built for the erection of new locomotives. Mr. Gordon has received an enviable distinction in this selection, but the place he will easily fill in a quiet, business-like manner, wearing the same sized hat from first to last.

There are in use around the Pullman (Ill.) car shops over 400 little push cars.

Big Job of Moving Locomotives on Country Roads.

Those of our readers who think it an awful big job to get a locomotive on the track again, when once on the ground, or in the ditch, may be interested in a little account of the biggest job of moving locomotives on the ground that we have ever heard of. In 1862 Stonewall Jackson made a raid into West Virginia and Maryland to capture some railroad equipment; at Martinsburg he found thirty-eight locomotives on the Baltimore & Ohio road, and took possession of them. They could not be run either way on the road, as the Federal troops were in possession of important places each side of Martinsburg, but the army went prepared to take locomotives, they did not ask for rails, all they wanted was a sight of the mills.

This branch of the work was under the care of Mr. Thos. R. Sharp, who became, years afterward, trainmaster of the B. & O. The mechanical work was under the charge of John O'Brien, a young locomotive engineer scarcely twenty-one years of age, and who is now master mechanic of the Atlantic Coast Line, at Manchester, Va. Those engines must be secured and taken thirty-five or forty miles across the country to Strausburgh, on the Manassas Railroad, over the country roads of a hilly section; they must be got ready for their trip with the Yankee batteries shelling the robbers, and they had nothing to load them on except the comparatively light army wagons. Plenty of men, plenty of horses, and plenty of nerve was the principal equipment.

The engines were disconnected, and loose parts put into the tenders, the front trucks were taken out, ropes fastened to their frames, and four horses sent down the road at a gallop with each of them; the front drivers were taken out, hooks made to go over the axles, ropes attached, and a pair of horses to a pair of wheels saw them on the road. The front of boilers was raised up, an army baggage wagon backed under it, made fast, and away they went one at a time, the back pair of wheels trundling along on the ground.

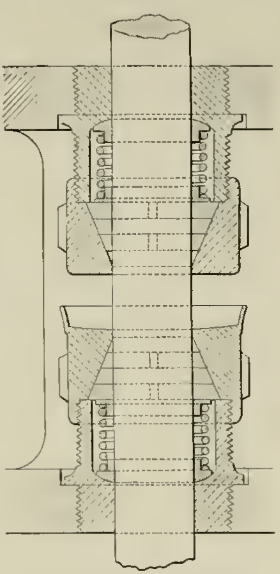
The first one went all right till it came to a down grade, then it got away, killed some horses, and turned on her side down a bank—this engine was placed on the road again and started in twenty-five minutes; this also taught the wreckers a lesson. The next one had a crude brake, across the frame, and fastened in the jaws, where the front axle ran, a huge timber was placed; enough men could get hold of this to help turn the engine, hold her, and prevent her turning over. In this way thirty-eight locomotives were taken nearly forty miles across the country. At one place in the road a turn about a steep bluff was so short it was deemed impossible to get the engines around, and even the commander was disposed to destroy them and go, but the mechanics in charge declared that, if given enough men and horses, they would take them *over* the bluff, and, although the sides were rough and very steep, they successfully got them over and to their destination, set them up, ran them South, and drafted them into the service of the Confederacy.

On another raid several locomotives were captured at Harper's Ferry and Leesburg, but they had only to run over the tracks South.

After the war the B. & O. made numerous efforts to secure the services of Mr. O'Brien in identifying their property, which was pretty thoroughly scattered over the South. Of course nothing but the necessity and excitement of war would induce men to undertake such stupendous jobs in handling locomotives. Mr. O'Brien tells us, however, that very little damage was done the engines, and all of them went to work at once.

Kellogg's Air-Pump Packing.

The metallic air-pump packing which is illustrated on this page consists of a conical nut, and three sectional rings with spring to keep them in place; it is understood that the peripheries of the packing rings are inclined to correspond with the conical opening, and the several packing rings decrease in size. When the several parts of the packing are in place the coil spring is compressed, and exerts an outward pressure against the packing rings; as the several packing rings are made in sections, and are pressed outward in the conical opening, the sections have a tendency to close toward each other, thus pressing firmly around the piston rod. A very secure metallic packing is thus formed around the piston rod, and all leakage is prevented, as the openings in the several packing rings break joints. The advantage of this packing is that it



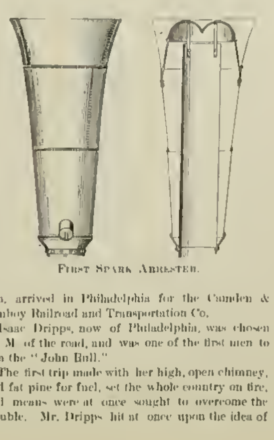
Kellogg's Air-Pump Packing.

can be taken out, and new put in without disconnecting any part of the pump. It will last longer, as it don't take as stiff a spring to keep it to the rod, as the rings are in section.

This packing has been in use on the N. P. R. R. almost a year, and is giving the best of satisfaction. One set, with proper care, will last three years at least. This packing was patented by F. G. Kellogg, a mechanic in the Brainerd shops of the N. P. Ry.

The First Spark Arrester.

In August, 1831, the old locomotive, "John Bull," now in the National Museum at Washing-



First Spark Arrester.

ton, arrived in Philadelphia for the Camden & Amboy Railroad and Transportation Co.

Isaac Dripps, now of Philadelphia, was chosen M. M. of the road, and was one of the first men to run the "John Bull."

The first trip made with her high, open chimney, and fat pine for fuel, set the whole country on fire, and means were at once sought to overcome the trouble. Mr. Dripps hit at once upon the idea of a deflecting cone and inside pipe to hold cinders, that from the very first became the standard spark arrester of the continent—a sound patent on the device would have been worth an immense fortune.

Some five or six years after the device was in use a stranger came along, copied the device, secured a patent upon it, and sued the Camden & Amboy for damages.

One of the company's important witnesses was old Jim Howell, the pattern maker, who originally made the patterns for base, cinder doors and cones. Jim was a good pattern maker, but had a habit of irrigating a little too copiously on all state occasions; so a guard was put on him to keep him level during the trial, but, as usual, he eluded them, and when he was called to the stand he was pretty drunk. The case, it seems, depended upon the prior use of a stack capable of catching cinders on the road, and discharging them when at end of run. Drawings of the device, as in Figs. 1 and 2 were upon the wall.

The lawyer against the company is cross-examining Jim:

Running his pencil down the drawing, he stops it at the cinder door at base of stack, which was marked *K* in the drawing

"Well, sir, what is this *K* here?"

Jim wabbled up to the edge of the box, looked at the drawing, and said

"Oh, h—l! There wan't no *K* there, it was a leetle cast-iron door to get cinders out!"

The very evidence the road wanted.

Correspondence.

The U. P. Examination Questions.

Editor The Locomotive Engineer:

In question 58 of Mr. Cushing's questions and answers for engineers and firemen, he says, "Should a steam chest burst or break, what would you do?" The answer he gives is this: "If the steam chest leaked too badly to run the engine, would break the joint in steam pipe on disabled side by removing bolt, and insert a piece of sheet metal or board between the joints, and screw up the bolts again; take off valve rod, and main rod, and block crosshead." Now, it looks to me, that it would be much better to take off chest casing, take out all studs in chest, take off valve, and lay a piece of sheet rubber or board over steam ports, take valve off from rod, and put back on and fasten there by putting in studs enough to hold it down with blocking between valve and chest cover. If chest cover is so badly broken that it will not hold valve down, take fish-plates or something of that kind. Then take down main rod, and block crosshead. To break steam joint, would make it necessary to go into front end, and to go into an extension front would be a hot job. With the short front a man could get at steam pipe much easier. Then answer to question 58 would be the best, but I can't see it in that light where the extension front is used. What are your ideas on the subject? Mr. Cushing does not answer question 33 in regard to holding valve stems where metallic packing is used, and you have no gland to cramp it with. I have seen valve stems with metallic packing fastened perfectly tight by taking off stuffing-box, and filling full of lamp wicking, and then screwing up tight.

Fireboy.

Fargo, N. D.

The Compound Locomotive on the B. & O.

Editor The Locomotive Engineer:

A departure from the regular American locomotive has just been completed for the B. & O. R. R. in engine No. 848, the departure being a compound or double expansion engine, having four cylinders, with one main rod for each pair of cylinders, one valve also doing the work for both high and low pressure cylinders.

It has the ordinary link motion without any rocker, giving a direct connection of link and valve—a saving of several joints, which is always an improvement. The high-pressure cylinder lies above the low, each having a piston rod that connects to one crosshead, which is made deep enough to admit of such connection, the front end of main rod being coupled to the crosshead in the usual manner, exactly between the two piston rods, which is so designed that the same amount of pressure will be applied to each piston while the engine is at work. The cylinders, high and low-pressure, are 12 and 20 inches respectively, and the amount of steam in the high pressure cylinder will do the same work as the exhaust does in the low-pressure one.

By this means the pressure is equalized on both top and bottom of the crosshead, avoiding any tendency to cramp in the guides, and unequal wear, the same as it would be if only one piston rod was connected to it in the center line of the main rod, with the same force applied to one piston, as here applied to both.

On each pair of cylinders is a plate as follows:

BALDWIN COMPOUND No. 1
Pat. June 25th, 1889, No. 406,011
Pat. June 25th, 1889, No. 406,012

Cylinders 12" and 20" all 24" stroke. Driving wheels 5' 6" with blank tires on front wheels to admit of rounding the sharp curves for which the B. & O. R. R. is noted.

Boiler is very large, 60" in diameter with the usual wagon top. Fire-box 9 feet long, and will burn soft coal.

The engine is fitted with a variable exhaust, thus placing the control of the blast in the hands of the engineer, which should prevent any trouble for want of steam, always having the 150 pounds carried.

As the cylinder plate reads it gives one to understand the building of this type of engines will be no small part of the work to be done by the largest locomotive works in the world.

The operation of this engine will be watched with much more interest than any previous change in design that has been made for many years past. As the question of to-day is, "How cheap can passengers and freight be carried, and what speed can be secured?" every manager and stockholder have the question brought very near their purses. I look at this as a step in the direction of economy. Engineers and master mechanics have been trying to improve the valve-gear of engines by many different schemes, which, while very ingenious have not as yet been able to replace the old link.

Now let them give the man a show who is trying to save something by using exhaust steam, which has been used to make engines burn more coal and throw a lion's share out of the stack or into the extension smoke-boxes. It certainly appears to those unskilled in the arts of locomotive practice, that any heat going out of the cylinders more than was required to burn the fire properly, is a dead loss, so it seems that compounding is a step in the direction of economy. We trust this will not be the only type of compound locomotive that will soon be tried in this country, and we await with interest the appearance of more in the field.

Germantown, Pa. O. H. RIDGWAY.

Don't Believe in the Gas Theory, nor in Going into Front Ends to Repair Broken Cylinders or Chests.

Editor The Locomotive Engineer:

I wish you would say how the answer to question No. 57 in Mr. G. W. Cushing's Union Pacific questions and answers strikes your every-day common sense. I do not think Mr. Cushing ever intended that any such explanation should get into print, as I know him to be a well-informed man.

When everybody knows the reason for a broken steam-chest or bursted dry pipe under such circumstances, why hunt around for a Keeley motor sort of an explanation?

Yet such men as H. T. R. learn that *this* is the kind of "theory" which is dangerous, and leads to "steamboat stops" on the other side of Jordan, after some of this same kind of "gas" has stowed the crown-sheet neatly in the ash-pan, and sent this kind of a "theory engineer" to talk with St. Peter about the "spheroidal state" in locomotive boilers.

Again, in the next question, No. 58. I think if I were a passenger on a delayed train, and went forward and found my man burrowing into his extension front to find that steam-pipe joint, I should class him at once with the young engineer Mr. Sinclair tells about, who was found in a snowbank shoveling snow down the smoke-stack to fill his boiler.

Why not tell the men to carry some sheet rubber with them, and block over steam ports in the chest, using steam chest lid to hold the blocks down—or a piece of plank if the lid were broken?

Detroit, Mich. E. H. MUMFORD.

A Kink for Water Stations.

Editor The Locomotive Engineer:

The sketch accompanying this article is intended to illustrate a condenser I have seen used in connection with a steam pump, with the double purpose of saving fuel and warming the water in the tub, so that service pipes for filling locomotive tenders will not freeze up. It is very effective, in some cases raising the temperature of the water to 70°, depending, of course, on the pressure of the steam, and the amount used.

This device is made by enclosing the suction-pipe, which we will suppose to be 4", with another pipe an inch larger. A tee with a 4" opening in one side, a 5" opening opposite, and a side opening large enough to receive the exhaust pipe, is used on one end, and a reducing coupling 4" and 5" openings at the other. The steam comes in to the tee, and passes along between the pipes where part of it is condensed, and into the stream of water at the opening *C* between the two parts of the suction *A* and *B* at the reducing coupling, where the rest of it will be condensed without any jar or rattling noise. This opening *C* should not be more than ⅜" wide, and should be made as much smaller than

that as will allow the steam and condensed water to enter the suction without any back pressure, by screwing the end *B* of the suction farther through the coupling. The end *D* has a thread on it, and after going through the tee is screwed into an elbow or coupling. This condenser can be made any length above 4', and if set perpendicularly should have the opening *C* at the bottom, to allow the water to drain out. On one railroad where a condensing device has been extensively used for four years, one of the pumps has a 3" exhaust coupled to the 3½" suction with an ordinary tee, and works smoothly and with less pounding than when exhausting into the open air. This pump lifts water 22' and forces 38 high, besides a horizontal distance of 150'. The exhaust pipe in this case enters the suction about 4' from the water in the river, so as to keep the pipes all warm; and I presume it works better when coupled as far as possible from the pump.

Do not understand that this condensing device will work well on all classes of pumps, for it will not. It seems to work best on pumps which have a crank and fly-wheel, and an ordinary *D* valve for admitting steam to the cylinder. Where a piston valve is used for shifting the steam valve, the condenser takes all the steam away from the exhaust, so there is no back-pressure to cushion the valve, and it will pound the end of the steam chest. Close the cylinder cocks tight as soon as possible after starting the pump, as the air will draw in and affect the working of the pump. There is not enough air in the *condensed* steam to make any difference.

The advantage of this style of condenser over a tee coupling in the suction is, that the space *C* can be made small enough so the water will not run up into the exhaust pipe at each stroke of the pump, and cause what is called "water ramming."

Lansing, Mich. C. B. CONGER.

Theory and Practice.

Editor The Locomotive Engineer:

No matter how much practical experience a locomotive engineer may have had, nor how old a runner he is, it is *never* going to do him a bit of harm to read or study some good work on mechanics, or the workings of a steam engine. You know the old maxim—"We are never too old to learn"—every word of it is true. Only some people make too broad a distinction between what we learn "practically" and what we find out by "theory." In order to become a first class man in whatever branch of life we may be in, it is absolutely necessary to gain *some* theoretical knowledge as well as practical experience.

Don't you suppose that a master mechanic would rather have you explain something in regard to your engine in a clear and concise manner, than in a slipshod and "know-nothing" sort of a way? If you want your draught pipe raised or lowered, don't you suppose he would rather have you tell him in a clear way just *why* you want it done, than to say, "Well, she don't steam very well, and I would like to *try* it higher or lower" (as the case may be)? Some may say, "What has theory got to do with that?"

I once had an engine just from the shop with a new style of stack on her, called a "boot-leg." She was a fine steamer when she went in, with her old "diamond" stack, but when she came out I could not do anything with her. She "stalled" three or four times in her run, and would not keep her thermometer more than ninety in the shade. My old engineer was an anti-book man, and on general principles wanted her nozzles made smaller—because she would not burn her fire (which was the whole trouble). Well, she had smaller ones put on her, and was twenty per cent. worse than before. Would not burn her fire at all. So be had still smaller nozzles put in her, and she seemed to be worse off—if that could have been possible. In fact, we were stalling everywhere. Other men tried her, with no better luck. One day a young runner got a hold of her, and said if they would put *larger* nozzles *than she had in the first place* on her, he thought she would be better. Every one laughed at him, but he stuck to his point and got them, and the next trip she was as hot as any could desire all over the division. I then asked him how he had found it out. He said that in reading some railroad work he had found that an engine would not burn the fire unless the exhaust steam *filled* the stack at every exhaust, and he said that in "priming" one day he had noticed that the water had shot out of the center of the stack without touching the sides at all—just as though there had been a 2-inch stream forced straight upwards out of the center. (I had noticed this at the time she "primed," but did not think much of it.) He had told the master mechanic all this at the time he wanted larger nozzles.

Now don't you suppose the M. M. was more pleased than if he had just said, "I want larger nozzles—because I want them"? I do; and if this same young runner had had that engine sooner, he would have found it out just the same, and saved the company lots of coal and expense.

Now I think that it is just those little (?) things that we get from books that are going to boost us in this great big world. Look at Mr. Angus Sinclair. He was once a locomotive fireman and engineer. Do you suppose that he never thought of anything else but to get his train over the road? I will bet that he had to study—and do lots of it—before he was promoted step by step to his present position. There is no use of getting Corliss valves and triple expansion compound condensation—or any other disease—mixed up in your head. I don't mean that these things *are* a "disease," but I say learn the locomotive—if you run one—as *thoroughly* as you can, and you will never have cause to regret it.

About the air-brake I will have to give in partly to H. T. R. You will have to go to the roundhouse and study one, if you want to understand it thoroughly. And yet there are lots of things about it that you cannot learn by watching its workings in the shop. For instance, the triple automatic valve that H. T. R. speaks of between the auxiliary reservoir to train pipe and brake cylinder. Can you see that work by taking it apart? No. You have *got* to learn its action from the descriptions furnished in books, and then it will pay you to go and watch one in operation. Not that you can *see* its operation, but you *can* see and understand the results of its workings. I have lots of respect for theory. There are many things that *cannot* be learned without the help of books; or, if you please, theory. Perhaps these non-theory fellows think that men who lay out valve motions do so with little sticks and strings. But do they? No. They lay it down on paper, and if the *theory* of the thing is correct they are not afraid of putting into *practical* operation, *trusting entirely to this* much abused "theory." This only goes to show the value of a correct theory, where it would not be possible to put a thing in practical operation at first without it. ROBT. B. READING.

New York City.

More Ways Than One—A Simple One.

Editor The Locomotive Engineer:

I notice question 33 in October number has no answer. Now we use metallic packing here in valve stem and piston stuffing-boxes, and the valve stem stuffing-boxes have an oil cup that screws into the gland. In case of a breakdown, cover ports, remove oil cup and insert a brass set-screw made to fit oil-cup hole, screw it down as tight as you wish, as the brass will not mark the stem and you have got your stem fast, you will find by trying that when set-screw is tight you cannot move the lever.

Green Bay, Wis. R. C. BELKNAP.

Rio Grande Air-Brake Car.

The Denver & Rio Grande road have an air-brake instruction car of their own, it is in charge of C. E. Leeman, one of the older engineers, and is taken from place to place, and all employes in train service are required to visit it and listen to the explanations until they understand it.

The car carries an upright boiler at one end, with air-pump attached, and has thirty brakes set up and in operation. These brakes are not all alike; some are the old style triple valve, some the new, quick-action, some are set to travel but a short distance, some full stroke, and the student is shown the cause, effect and remedy. One triple valve has a stem extending through its case and is attached to the stem of another triple valve that has a section of its case cut away, so that it can be seen just what is taking place under actual service.

Air-brake cars are good investments and more of them will be used next year than there were last.

Denver & Rio Grande—The Denver Shops.

(Editorial Correspondence.)

The Denver & Rio Grande Railroad is an interesting line of road for more reasons than one. It is a mountain road, its main line and branches crossing the continental divide of the Rocky Mountain chain no less than five times, it traverses many renowned canons and crosses and recrosses mountain streams until its bridge numbers reach into the four figures; it formerly had 1839.86 miles of track, but the Rio Grande Western—the Utah Line—secured a separate charter and became separated from the parent tree leaving but 1466.86 miles.

There are in use over 250 locomotives varying in size from 16,000 to 110,000 pounds and carrying cylinders from 7x12 to 20x24.

This road can be said to have been the first entirely successful narrow-gauge road; it has for years and is now carrying on its narrow gauge lines the same loads of freight on a 36-inch track as is carried on any of the standard-gauge roads of the country, their narrow gauge freight cars are of 40,000 pounds capacity and the writer has pulled cars of bullion over the road weighing 57,000 above the weight of the car. The road commenced in 1871 and laid a road along the base of the foot hills south 75 miles to Colorado Springs at the foot of Pike's Peak, this road was laid with iron, weighing 37 pounds to the yard, and the first engines were little Baldwin, narrow gauges of very small size. Frank Wilson, an engineer on the old Kansas Pacific, was hired to run the No. 1, and went "down east to Kansas" to bring his family to Denver. While he was there the No. 1 came and the management could not wait for Mr. Wilson and placed the engine in charge of Quimby Lamplaugh, an engineer on the Colorado Central; Lamplaugh was almost as big as the engine he ran. Both these men are still in the employ of the company, Mr. Lamplaugh as M. M. of the first division and Mr. Wilson as general road foreman of engines. The "baby road," as it was called, fared poorly for some years, built to Pueblo, 120 miles south of Denver, from there 40 miles west to Canon City at the Portal of the Grand Canon of the Arkansas and south 86 miles to the coal fields of El Mora and Walsen's, then the Santa Fe leased it for 99 years, but not handling the property to the satisfaction of the Rio Grande stockholders, the latter enlisted the men and took possession of the road in 1878 by force, which act was afterward sustained by the courts.

The discovery of silver at Leadville gave Colorado a boom, and the little road built in less than three years over 600 miles of mountain road, with scarcely a mile of straight track and with grades varying from 75 to 217 feet per mile.

On all grades less than 200 feet per mile the men run 105 miles for a day on passenger—unless the division is less than 105 miles long, in that case they get a day for the division—and 85 on freight, engineers receive $4.00 per day and firemen $2.40, firemen on broad-gauge "hogs," 20x24, receive $2.65. On grades of over 200 feet per mile 44 miles is a day's work, for all delays of over one hour the engineer receives 40 cents per hour, the fireman 24 and 26 5 cents.

Just now the men are running very hard and all making $200 per month and over.

In 1880 a third rail was laid from Denver to Pueblo to accommodate the Sante Fe trains and several broad-gauge locomotives were bought; now there are in service about 50 broad-gauge locomotives and the third rail has been laid on about 300 miles of track and in the case of the El Mora branch the narrow-gauge rail taken up, the broad-gauge road is being extended rapidly and there is little doubt that the entire main line will be standard gauge in two years. This is not done because the narrow gauge was not a success, but because of the delays incident to transfers that cut into the through California business, that has grown wonderfully.

The main shops are located at Denver, with smaller ones at Pueblo, Salida and Alamosa, of which I will write at another time.

The car shops at Denver are large enough to keep up the entire service of 7,000 freight and 218 passenger cars, but the recent purchase of large numbers of new broad-gauge cars, and the evident intention to let the narrow-gauge freight cars wear out, make these shops comparatively dull.

The main shop is a fine brick structure of modern design, having a large number of modern machine tools located in one end and the pits, seven in number, in the other; the boiler shop and blacksmith shop are the same length as the main shop, but not so wide, and are separated from it only by the width of a transfer table capable of handling the largest locomotive.

On the opposite side of the main shop from the transfer table there are three wings, the center one containing the engine and boilers, one the copper shop and the third the tool room, separated from these wings by a supply track is the storehouses, and behind this, and next the main tracks, the offices.

There are two roundhouses, only one being used for engines in service, the other being too small, and as the one used has but 12 stalls and the Rock Island use the same house, more than half the engines stand out. The roundhouse is in the charge of Charles Sisler, and the generally good condition of the engines attests his ability on running repairs.

The back shop is under the supervision of General Foreman John Bryman, the blacksmith shop under W. W. McLellan and the boiler shop under John Mitchell.

The engine room has a large plain slide valve engine and an octagon frame, on each side of which is located a long stroke air-pump, these pumps engineer Ed. Kenna calls his "organ"; they supply air to the system of pipes and drums that cover the entire plant. In the coach shop and car repair yards, long hose connections are located at convenient points and connected to an underground system of pipes to test brakes on cars without the use of a locomotive. An air-pipe comes down between every stall in the roundhouse and a hose connected to a T in the blower pipe is used to hurry fires and prevent smoke when firing up cold engines. In the back shop and the boiler shop small slide valve engines on trucks are run by air to drive boring bars, drills, valve seat planers, etc. Most of the machine tools are of recent build and good quality. The shops are light, well ventilated and well heated.

The narrow-gauge passenger locomotives are mostly ten wheelers, 14x22 with a 47" wheel. All the narrow-gauge freight locomotives are consolidations; the smaller size, mostly used on branches, are 15x18, 36" wheel, and boiler 48" diameter; the second size are 15x20, 36" wheel and 50" boilers, and the larger class, 17x20, 36" wheel, and boilers 52" diameter—a pretty big boiler for a 36" track. The work that these engines do is remarkable, their average train on a grade of 217 feet per mile being 5 loaded cars. One of these little monsters does a regular business on the Calumet branch, eight miles long, with an average grade of 303 feet per mile and several places where it reaches 409 feet per mile.

The passenger locomotives have straight stacks and extension fronts, the freights short fronts and diamond stacks—all the broad gauge equipment have extensions.

The native coal used on the road is of an extraordinary good quality.

Everything on the line has undergone the enlarging process just as the locomotives have, the original 37 pound iron rails grew to 40, 46, 52, 60 and finally to 72 pounds of steel per yard. On a road moving its freight with such small wheels and on such grades the repairs are a matter of great importance, but Mr. Sample, the Supt. of M. P., has kept himself out of lots of trouble and the road out of lots of expense by adhering strictly to one make of locomotives; all the locomotives are Baldwin build excepting 28 Grants, that, since they have been rebuilt, are practically Baldwins.

The older consolidations used have a very short main rod and the wear of crossheads and guides is considerable, while trouble has been experienced with pistons breaking at the crosshead, the new consolidations have the main driver next the back pair instead of next the front, and they give much better service. A curious experiment is being tried on engine 202—a narrow-guage consolidation; the pair of drives next the back pair are close up under the front of the long fire-box, prohibiting the use of eccentrics there, but on this engine they have put the main pins on this pair of wheels and lengthened out the main rod, leaving the eccentrics where they were on the axle ahead, the engine has been running some months now, is square, doing well, and requiring less work on her guides, it is no doubt an improvement.

All the new broad gauge locomotives have the Sample boiler, wagon-top with radial stays, dome on wagon-top ahead of fire box, the passenger engines are 18x24 10-wheelers, the freights consolidation 20x24, weight 115,000 pounds, every locomotive and car owned by this company is equipped with air-brakes.

Many of the older locomotives have had their cylinders bushed when bored out too large, a cast bush is turned and bored and forced into the cylinders; no trouble has ever been experienced from these bushings, many of which have been used for five years.

"They ain't got much the best of us old timers arter all," remarked an old gentleman in a crowd of Jersey Central commuters the other day as they walked from the train in Jersey City to the ferry-boat. "Not so awful much; now look a there!" and he held the end of his umbrella against the Baldwin plate on the side of the smoke arch. "Eighteen-forty-three, sir! 1843, and how much better are they maken 'em now—a little bigger, that's all!" The innocent old gentleman was pointing to the "shop" number on an 8-wheeler about 15 or 16 years old.

Patrick Keys, Green Bay, Wis., writes to the L. E. thusly:—"I get more for my dollar from you than from any other publication I know of. *I only wish your paper was a $4.00 weekly* instead of a monthly."

CONTENTS

An Awful Lesson.

Since the last issue of this paper there has been another railroad disaster of a particularly sad nature. A suburban train on the Rock Island road was run into by a freight engine, killing seven persons. The freight engine was run by a son of General Master Mechanic Twombly, who, it is alleged, was drunk, and running ahead of time in a reckless manner. Twombly and his fireman are both held for manslaughter, and M. M. Twombly was also arrested as an accessory before the act.

That the engineer was drunk on duty there seems little doubt, and final punishment seems just—no excuse a man can make justifies him in going out upon a locomotive drunk.

That the fireman is to be held responsible in the premises seems strange. The fireman has no authority in the movement of a locomotive, any more than a cabin boy has in the movement of a ship; he is there to obey the engineer, and if he undertook to run things, ever so little, he would soon find himself at outs with the engineer, and out of a job The companies employ and put on locomotives as firemen men from every walk in life, without regard to any qualification whatever, and that they should be entirely under the control of the engineer is right under the circumstances. This boy had no choice—he was like a common soldier—there to obey. He should be held blameless

No doubt Mr. Twombly has in his thirty years as master mechanic forgiven many another man for drunkenness, and given him another trial; but this case, the culprit being his own son, makes the case a sad one for him; but his prosecution for crime in this particular case, while it might tend to increase the vigilance of railroad officials in the punishment of drunkenness, would seem like persecution.

If the freight train had been provided with air-brakes the accident would never have occurred; it is claimed if the engine even had a steam-driver brake it would have been stopped. If the line had been provided with block signals—and the accident occurred right in the city of Chicago—the train would have been stopped or derailed. For this lack of proper modern appliances the Rock Island road is to blame.

We do not believe that any man or company of men, railroad or railroad official, has got the right to say to any man, "You shall not drink" But the railroad officials have got the right to say that any man who drinks intoxicating liquors, on or off duty, shall not run a locomotive under them; and this is just what they need to be saying and doing.

The brotherhoods ought to be singling out those who are known to drink, and drop them, instead of making a kick to have men reinstated who have been removed for drinking.

Too many men are daily risking their lives against such men as they know are not safe, and liable to cause a disaster at any time It is time that, in cases of this kind, where it is clearly proven that modern safety appliances are not employed, the railroad companies should be held responsible. That competent employes get along every day without them is no excuse—a competent crew might bring a ship into port many times with a cob driven into a knot-hole; but the cob would be liable to rot out at any time

It is also time that all competent employes arrayed themselves against strong drink, the lives of all quiver in the balance of every engineer's judgment—don't let any man run against you, and see that you run against no man, where there is the slightest fear that whisky may throw the scales out of balance

Butchery for the Want of Modern Appliances.

Last month a terrible rear collision on the N Y Central at Palatine Bridge caused the death of five or six people, and crippled many others. The special car of President Ledyard, of one of the Michigan roads, was on the rear of the first section of the St. Louis express, and at the place mentioned the engine blew out a cylinder head, a stop was necessary, and the second section crashed into the first.

President Ledyard says the brakeman went back with all speed, but was too late

General Supt Toucey says the fault was the engineer of the first section did not stop as soon as he should.

No doubt the officials of the road would be glad to lift the burden and the blame from their own, to the shoulders of the men ; that this can be done at will, and is done every day, is a standing disgrace to the laws of the United States

No railroad doing the business, or one-half the business, that the N Y. Central does, has any right to be operated without the block system of signals.

The block, and that alone, is the only safe way to handle many trains running close together. It has its faults, and costs money, but it requires a blunder from two or more men to cause a wreck

The practice of running fast passenger trains over a road on "ten minutes headway" is simply gambling in human life.

A thousand things may come up to stop or slow down the first train, while there might be nothing to check the pursuing monster in the rear. When it comes down to a matter of who is to blame, no honest court of inquiry, composed of disinterested men, would place it anywhere but upon the New York Central Railroad Company. It is high time the railroad men of this country were agitating for laws to make the killing or maiming of every human being upon our railways the subject of a government inquiry.

Alfred B. Ropes, mechanical engineer of the Southern & Central Pacific road, one of the brightest young men in the service, died suddenly at Sacramento, Cal., on the 8th of Oct. A. B. Ropes graduated from the Stevens Institute of Technology, at Hoboken, N J., about four years ago, and then took service in the Brainerd shops of the N. P. road, where he soon pushed himself to the front, and became the mechanical engineer. When Mr Cushing went to the Reading road he took Mr. Ropes as mechanical engineer, and he left there in 1888, to accept a similar position under A J. Small, on the Central & Southern Pacific. That so promising a mechanic should be thus cut off, at the very threshold of a promising career, is a grievous loss to the mechanical world.

The Twenty-Sixth Annual Convention of the B. L. E.

On the 16th of Oct the 26th annual convention of the B L. E. convened in Denver, Col. The opening exercises at the Tabor Opera House were the best and most interesting we have ever listened to, and great credit is due the general committee of arrangements, Messrs. Rice, Hall and McGill

The speeches of welcome from local and State officers were interesting, and the assemblage entertained by an original poem from the engineer poet, "Shandy Maguire," and the presentation of a gavel of petrified wood, made to Grand Chief Arthur by Rocky Mountain Div 186.

As a general thing, speakers on occasions like this take it upon themselves to tell the engineers how brave they are, how noble their calling, etc.; this is especially true of railroad officials We were particularly interested in the speeches of General Manager C F. Meek, of the D., T & G , and of General Supt. J. K Choate, of the U. P We consider their speeches as fair and manly, without taffy, and as representing the ideas of, and the attitude of the best class of railroad officials toward, not only the B. L. E., but all other orders of organized labor The following speech of J. K Choate has much food for solid reflection.

"Mr. Chairman and Gentlemen : I feel deeply sensible of the honor you have conferred upon me, and appreciate more than I can express the kindly terms in which the letter of your local committee was couched, asking me to be with you to-day. Your meeting being in Denver, and in charge of a local committee so largely represented by men serving with and under me, I felt bound to accept You are assembled here for your annual meeting to discuss methods and plans for your own good and advancement, and naturally expect, when you ask an officer of a railroad company to join with you, to get from him some expression of the feelings of the officers and stockholders towards your organization I feel perfectly safe in saying that the good will of all is towards you and with you, and that they are always willing to join in anything that is for your good or benefit, provided it is consistent with good management, Officers of railroads are as a rule always willing to look into your grievances, and to try and right them when presented with good judgment. Great advancement has been made in the past few years in the methods of railway management, and now it strikes me that the most essential requirements of a railway company in its men, is their character, and their personal character, the character of their attainments and abilities, and the character of their organizations; for organizations have their character to maintain as well as individuals. You have all noticed, I know, how well the engineer gets along whose personal character is good. The man who does not drink or keep bad company, who, when off duty, devotes himself to his household and his family, to an improvement of his mental and social condition by study or in reading good books that tend to elevate, who has not the morbid idea that the success of life is to see how little they can do, and how much they can get for it. I don't like a man who wants to be an engineer, and thinks that his aim in life has been accomplished when he is given the fast express to run. I don't like a man who figures out all there is in being an engineer that he must have the best run on the road by being the oldest man in the employ of the company. I like the man who works for his spurs, who says, 'I will show my master mechanic that my heart is in my work, that I will be careful and carry out the instructions, and live up to the rules of the company or my superior officers That I will show him that I know my machinery, how it is constructed, and why it moves. That I will do my work faithfully, and I want to catch his eye by deserving promotion, and that my kite of ambition is flying for the top position with the company.' Now I know promotion comes slowly, from personal experience, but we must all have patience, and try hard, and in the end we will get there. MacKay's words fit the situation exactly:

'If thou canst plan a noble deed,
And never flag till it succeed,
Though in the strife thy heart should bleed,
Whatever obstacles control,
Thine hour will come, go on, true soul,
Thou'lt win the prize, thou'lt reach the goal.'

Much in the character of an engineer depends on courage. I do not mean physical courage, but moral courage, which characterizes the highest order of manhood, the courage to seek and to speak the truth, the courage to be just, the courage to be honest, the courage to resist temptation and the courage to do our duty. Engineers who do not have this virtue have no security whatever for the preservation of any other.

Now, as to the character of the abilities of engineers. As I said before, modern practice in railway management has advanced and improved very much in the past few years. The character of the abilities of engineers must keep pace, and be of a high order. Are we and you giving this enough attention? I know many of you are, but as a brotherhood are you? Think it over and see. In railway management we all work for the same end, and must all pull on the same end of the rope. If we all improve and advance there will be less friction and less liability to disagreement. I hope what little I have said may be of some interest and a groundwork for your thoughts. Choose for your leaders, thinking men and men of character. Don't choose the man who jumps first and thinks afterwards. Thanking you for your kind attention, may I wish you success, and may the objects of your organization, and the precepts of your constitution be fulfilled, and may it be known as an organization by all as one of character."

At the election held Monday, the 28th, Grand Chief Arthur was re-elected for a term of three years, and the national headquarters established at Cleveland. The great question as we go to press is, "Federation or no Federation"

The Swinerton Locomotive Company have had several experts looking over their engine, the "Onward," of late, with a view to demonstrating the superiority of flat spotted drivers over round ones. Mr. M. N Forney has been up looking her over, but we have as yet failed to see any report of the tests, if tests there were, with Mr. Forney's name attached. Mr. Forney's name is worth something, and when signed to a report carries some weight, and it is but fair to presume that, if he were willing to sign a report favorable to the flat driver machine, the company would only be too glad to send it out, as the report is not forthcoming, it is more than likely that Mr. Forney declines to become a flat driver proselyte

The packing rings in the 30-inch cylinder of the P R. R. compound locomotive, three brass ones, were recently found to be broken into several pieces and some of the pieces nearly worn out. The engine has sounded as if her packing was down for some time; she will now, no doubt, show a better fuel economy than ever.

Books Received.

A TREATISE ON STEAM BOILERS: Their Strength, Construction, and Economical Working By Robert Wilson, C E. Enlarged and Illustrated by J J Flather, Ph B

No work on boiler-making has ever been so deservedly popular as the work of Mr. Wilson. It is descriptive, plain and sufficiently elementary for beginners, but it has always lacked engravings and complete adaptation to American practice. Prof Flather has supplied both these brought the work up to date, and placed before the mechanics of the country a reliable work on steam boilers and their fittings. This work is published by John Wiley & Sons, Astor Place, New York The price is $2 50.

ASKED & ANSWERED.

(46) Apprentice, Baltimore, Md., asks:

Why is the link saddle-pin or stud, in locomotives, always set a little out of line with center of link? *A* —See article in this issue entitled, Elementary Lessons on First Principles

(47) I. G B. Aspen, Col., asks

About how much coal is burned per day or trip on the steamships City of New York and City of Paris? *A* —About 330 tons per day of 24 hours, or from 20 to 21 hundred tons per trip.

(48) G M H, Auburn, N Y., asks.

Will a locomotive go faster when the reverse lever is near the center than it will when it is thrown the full length of the rack or quadrant? *A* —Yes, will run faster when working steam.

(49) H. O. Blanchet, St. Johnsbury, Vt., writes.

Would you kindly tell me if that book of "Questions and Answers" to enginemen, by Mr G W Cushing, could be bought? If so, please tell me Mr. Cushing's address, and the price of book *A* —Mr Cushing's address is, Supt. M P. & M, Union Pacific Ry, Omaha, Neb. The books in question were issued free to the employes of the U. P road, and are, we believe, not for sale Preserve them complete in this and the October number

(50) Subscriber, Detroit, asks

1. Are the engines of Class O on the Pennsylvania Railroad fast? 2 What is the fastest railroad record made in the United States? 3. What was the speed of locomotive 1014 on Atlantic City Railroad on its trial? (1) Class O on the P R R. are 8-wheeled, soft coal burners, cylinders 18x24, 60' wheels, and weigh 91,000; they are fairly fast. (2) We do not know what the fastest authentic speed is (3) We do not know that the Reading engine 1014 had a trial; her regular card speed is 49 miles per hour

(51) S W Stahr, Jr., Phila., asks

Can you tell me whether an engineer can reverse his lever when his locomotive is running at the rate of one-half mile a minute, when there is no steam on; and whether he can when there is steam on? By answering the above you will greatly oblige. *A* —The speed is but thirty miles per hour. An engineer can usually pull the lever over at this speed, if the valves are lubricated and the eccentrics not hot or cutting. With steam on, it is harder to handle the lever, but it can generally be done. On some locomotives with extra reach-rods, long-armed tumbling shafts of other unusual designs, it is often very hard, if not impossible, to handle the lever at high speed

Pullman, the City and the Shops.

(Editorial Correspondence.)

The name Pullman is fixed in the minds of all railroad men in connection with that modern convenience and luxury, the sleeping car, and I thought that a condensed description of the great shops and the place where they are situated might not be without interest to railroad men, as they were to me. Less than 30 years ago, Geo. M Pullman built the "Pioneer," the first regular sleeping car; now there are 1,089 in service upon the railroads of the United States, besides some hundreds of other makes of cars following his general plan.

Prior to 1880, Pullman cars were built at the different shops, at Detroit, St. Louis, etc., but the demand for more cars made the establishment of a large central shop necessary, and it was then that Mr. Pullman conceived the idea not only of building a shop, but a city as well. Probably no other place of its size on earth was conceived and built by one man.

Fourteen miles from Chicago a large tract of level land was secured, it was without a single improvement, never had been used and seemed never likely to be, it was so low Here Mr. Pullman has built a city

COMMENCING RIGHT

The history of most towns of 10,000 inhabitants is much the same, there is always the first settler, he usually comes upon the land and rears himself a little house of sod, logs, slabs or any convenient material, he ties his horse to a stake, builds a pig-pen and a water-closet—conveniently near the house—digs his well between them, and proceeds to raise crops, children and malaria Years afterward, the ground is platted into the village, having a Mayor and water-works, and the first citizen and all his neighbors put bath-rooms in their houses, and dig a temporary cesspool in the back yard, that soaks the soil with the germs of disease till the sewers come.

Pullman built his sewers first, not only one system, but two, one to carry off the waters of the elements, rain and snow, which are clean, and a separate one to carry off the sewage of the houses. In every street running east and west there are sewers, every other street having a brick sewer for roof waters, and emptying into Lake Calumet; the other sewers are made of vitrified pipe, carry foul waters to an immense tank holding 300,000 gallons, and located under a huge water tower in the center of town.

The sewage is pumped from it to a sewage farm three miles away, as fast as received, and before sufficient time elapses for fermentation to take place The ventilation of the reservoir is perfect, eight flues lead from it to the top of the tower above it, and a twenty-inch flue connects it with the large chimney, which takes the smoke from the fires under the boilers of the Corliss engine, this flue creates a downward draught in all the manholes in the vicinity of the water tower and in the floor over the reservoir, thus preventing the possibility of any odor from the sewage Standing over the reservoir the visitor never detects anything unpleasant, the air being just as pure as it is in the Corliss engine-room

Thus, before a house was built, a complete sewerage system was in operation

The following facts were gleaned from a sketch written in Spanish for the information of the South and Central American representatives, now traveling in this country, by Mr Duane Doty, the civil engineer of the city, who kindly furnished us with a copy of the translation.

"Pullman is the most remarkable business enterprise of any age, it is the only city in the world built from the first for a city, and on scientific principles, and marks an era in the history of labor, giving workmen far better homes and surroundings than, by their unaided efforts, they could hope to have. Adapting themselves to these improved conditions, their earnings are larger, and their modes of life bettered by being placed upon higher planes. The characteristic features of our time are mechanical industry, and the consequent massing of men in urban communities. This city plainly shows that comfort, cleanliness and delightful surroundings conduce to the prosperity of all, there are no idlers here; all are busy earning money. There are about 5,000 persons engaged in all the different industries, and the pay-rolls are $10,000 a day

Mr. Pullman began building the city in May, 1880, and the first family moved here January 1st, 1881 The population is now about 11,000, and nearly as many more have made homes in its immediate neighborhood With few exceptions the 1,825 tenements here are built of brick, and have good basements are situated upon twelve kilometers, or seven miles of paved streets. Every home is supplied with gas and water, and provided with perfect drainage and sewerage, in other words, with all the 'modern conveniences'

The storm waters from roofs and streets goes through one system of drains into Lake Calumet The sewage from dwellings and shops goes through another and separate system of pipes to a reservoir under the water tower, whence it is pumped to a sewage farm five kilometers distant

The present industries at Pullman are the Passenger Car Shops, the Freight Car Shops, with a capacity for making forty freight cars a day, or one car for every fifteen minutes of working time, the Street Car Works, The Allen Paper Car Wheel Works, The Union Foundry and Pullman Car Wheel Works, with a capacity for using 250 tons of iron a day, The Pullman Iron and Steel Works, rolling 100 tons of iron a day, The Drop Forge Works, which, in addition to their other work, are now making 700 pairs of shears a day, The Calumet Paint Works, The Illinois Terra Cotta Lumber Company's Works; The Standard Knitting Works, and the Pullman Brick Works. Cars of every kind are built for all portions of North America 2,000 Pullman cars are now running on 125,000 miles (or 202,000 kilometers) of railroad.

There are now 50 kilometers of railroad tracks already built for the use of the town and shops, and seven kilometers of street-car tracks. The Arcade is a building 80 meters long, 50 meters wide and 80 high; it contains all the stores of the place, the bank, in which operatives now have about $300,000 in savings deposits, the post office, a theater which holds an audience of 1,000, and a library of nearly 7,000 carefully chosen volumes, a personal gift of President Pullman to the city The library takes 70 papers and periodicals; every one has access to it on the payment of a nominal fee of twenty-five cents a month; 13,113 books were taken from it during the year ending July 31st, 1889. The Pullman Company has no interest in any mercantile business, but simply leases stores to business men.

The water tower, which is 60 meters high, has an iron water tank at the top, holding 2,000 liters of water, it is kept filled for fire pressure only Meats and vegetables are sold in a public market building There are excellent public schools now taught by 24 teachers The very best facilities are afforded for all kinds of athletic and aquatic sports There are now thirty clubs, societies and lodges for social and insurance purposes.

Half the population is American-born; German-born persons come next, and Swedes third in numbers. The population is composite, all European countries being represented in it The lessons taught by this new industrial center are studied and pondered by scientific men, political economists, municipal authorities, capitalists, and students of social science in every portion of the world, and it is everywhere conceded that they have a suggestive value of the highest importance to the human race."

There are flats in the city renting as low as $5.50 per month, all have running water, closets, etc.; the average rent is about $14

The shops are very large, mostly one story but some of the cabinet shops are four stories, where can be seen the fine woodwork of the parlor cars in all stages

Wood-working machines of all descriptions are in operation everywhere, not the least interesting of which are the

CARVING MACHINES

that do the beautifully carved finishing pieces in the car decorations. These machines are simple, the working part being a jointed frame capable of being moved in any direction; this frame carries two spindles running at a very high rate of speed, each spindle holding a little tool not unlike a round-nosed countersink for wood, these tools are exactly the same length, in the center of the frame is a round-headed bar, that is the guide for the other tools, this guide does not revolve, it is guided over the pattern of carved work by hand, and wherever it goes the tools on the ends of the bar each cut out a piece of wood like the pattern, large tools are used to rough out the work and smaller ones to finish it, the smallest finishing tools being less than 1/4 inch in diameter These machines are not sold by the inventor, but rented at $2,000 per year each. As this shop is using six of them, he has a pretty fair income from them alone.

SIZE OF SHOPS

It would be impossible for me to go on and describe these works, they are too big and the paper too small; I saw in the machine shop—which is made up mostly of axle lathe, wheel-boring machines and presses—men turning up axles who were calipering the holes in wheels to make a fit; a system of measuring gauges would seem to me to be a surety of better work. I am not sure that this is the regular practice, but it was being done during my visit

THE CENTENNIAL CORLISS

The great Corliss engine that made the "wheels go 'round" at the Centennial is handsomely housed and cared for here, it was undergoing repairs during my visit, and separate engines doing the work. This great piece of machinery is, no doubt, a good advertisement for these works, but there is no doubt that separate engines located in each shop do the work better and more economically and do not shut down the entire works in the event of a breakdown.

NEW DESIGN OF CARS.

In the shops were two cars as yet unfinished, that bid fair to do honor to their names, "Superb" and "Ideal." They are sleepers, but are entirely composed of state rooms; these rooms can be thrown open, making a central aisle through the car, or closed and locked, an aisle being provided around them. Each compartment is complete, wash-room, closets, etc., they are finished magnificently and each compartment in a different style and color.

FREIGHT CARS.

The freight car shops are the most interesting, here all the rough material goes into one end of a very long shop and comes the other end painted cars ready for the road. The iron work goes into this shop ready to be put up and is sent in car lots; that is, there are just enough pieces to make a car, and the wheels, rods, bolts and nuts are piled along the tracks in the erecting end of shop ready for use; the timber goes from machine to machine on rollers and the machine end of shop pours a steady stream of completed timbers to the erecting tracks. One of the most interesting tools I noticed was one for

BORING A SQUARE HOLE.

The tool was a square piece of steel the size of hole desired and had in its center a round hole in which was located a common bit running at high speed; back of the wings of the bit there were slots through the square bar that let the chips brought back by the bit escape; the point of the tool was concave, like a rivet set, so that each corner of the square tool would tend to bring the wood from the corners to the center when forced into a timber, the auger taking all out. This tool is used to cut the tenons in car timbers, a slot any length being cut by moving the timber along and striking it a number of times.

While I was there they were at work on a large order of huge coke cars for a Pennsylvania Coke Co., and these 60,000 pound cars were coming out of the hopper painted, numbered, lettered, weighed and ready for service at the rate of 40 per day of 10 hours, or one every 15 minutes; this is the every-day capacity of the shop, but 60 flat cars have been built in 10 hours, which is at the rate of one car every ten minutes.

I visited the hotel where many Chicago people board; the bank having on deposit over $300,000 of the savings of these workmen; the library, which the records show is not patronized by the masses as it should be; the office of the *Arcade Advertiser* a lively little weekly edited by Duane Doty, the civil engineer, and came away from Pullman with altogether a different opinion of it than I went there with.

I had understood that the place was run on the store order system, with all the oppression that that system is capable of, but the stores and all business rooms are rented to independent merchants, and the men are free to buy where they can get the cheapest—and Chicago is only 14 miles away. The people seem contented and the wages paid are fully up to the best, the houses are certainly better than could be otherwise obtained, the streets clean, and all surrounded with trees, grass and flowers, that workingmen do not enjoy elsewhere.

H. O. Canfield, of Bridgeport, Conn., has placed on the market a full line of every size and shape of rubber gaskets for steam engine and water work. He makes a class of gaskets for steam work that it takes a temperature of more than 350 degrees to affect, a special soft gasket for water glasses, and all kinds of packing for all purposes.

The Ashcroft Manufacturing Company, 111 Liberty street, this city, who make the Tabor indicator, have issued a little book of 72 pages on indicators and indicating. It describes the indicator, tells how to attach, use and figure, and is, withal, a useful little volume. It is given free to enginemen interested. Write for it.

Editor Debs, of the *Locomotive Fireman's Magazine*, has our thanks for referring men who are seeking *light* to this paper. We get them all, and we want them.

Questions and Answers for the Examination of Engineers and Firemen.

Conclusion

Ques 71 —What is the effect of a small exhaust pipe?

Ans.—To increase the draught from the fire-box, and the passing of air through the grates and fire.

Ques 75 —Can exhaust pipes be made too small for economical working of the engine?

Ans Yes, if made smaller than necessary the power of the engine is reduced in proportion.

Ques 76 —Is it, therefore, desirable to enlarge exhaust pipes to within practicable limits?

Ans Yes; the larger the pipes are the more tons may be hauled or speed obtained by the engine

Ques 77.—In the case of the breaking of an engine truck or tender wheel do you understand how to proceed?

Ans —I should take means to secure the wheel from turning, and in this way make a slide, if possible to do so, and report to headquarters.

Ques. 78 —Do you consider it the duty of an engineer to examine and care for the engine truck bearings and tender journal boxes?

Ans —

Ques. 79 —Have you ever put in a tender brass on the road? If so, how do you proceed to do it?

Ans.—

Ques 80 —In case the rear draw casting on your tender should become broken, what would you do?

Ans —

Ques. 81.—In case a hole should be knocked in your tender, or a serious leak develop suddenly, what would you do?

Ans.—

COMBUSTION.

Ques 1.—Do you understand the subject of combustion in locomotive fire-boxes?

Ans —(Yes or no)

Ques 2.—What elements perform the most important functions in the act of combustion?

Ans —Oxygen and carbon.

Ques. 3.—What is carbon and oxygen?

Ans.—Carbon is the fuel, oxygen the supporter of combustion. Carbon is the fundamental ingredient of all fuel

Ques. 4 —What is combustion the result of?

Ans —The strong tendency that carbon and oxygen have for each other, and their union freely

Ques. 5 What is the result of this free union of carbon and oxygen?

Ans —A certain high temperature combining them very rapidly, with violent evolution of light and heat.

Ques. 6 What is oxygen?

Ans.—An abundantly diffused element in nature Eight-ninths, by weight, of all water is oxygen. Its presence is necessary to life

Ques 7 Where is air, necessary for furnace combustion, taken from?

Ans —The atmosphere.

Ques 8 —What is it composed of?

Ans —One cubic foot of oxygen to three and three-quarters of nitrogen.

Ques 9.—What is nitrogen?

Ans —An inert and neutral gas which does not promote combustion but passes into furnace with the oxygen, and is heated to the same temperature as the other gases

Ques. 10 —If the supply of air is so liberal that there is an abundance of oxygen for the burning fuel, what is the result?

Ans.—The carbon will unite in the proportion of one atom with two atoms of oxygen, producing carbonic acid, an intensely hot gas, and of great value in steam making.

Ques 11 —If the supply of air is restricted and oxygen scarce, what is the result?

Ans —The one atom of carbon is contented to grasp one atom of oxygen only, instead of two atoms, and the result is carbonic-oxide gas, which is not more than one-third as valuable for steam raising, according to quantity, as carbonic acid gas.

Ques 12 —Is the same quantity of fuel used in both cases?

Ans. Yes; the only difference being in the decreased value for steam raising

Ques 13 —How much air is needed, ordinarily, per each pound of coal for good combustion results?

Ans.—About twenty pounds of air per one pound of coal

Ques 14 How much space does one pound of air occupy ordinarily?

Ans About thirteen cubic feet of space.

Ques. 15.—How much coal per hour is used, working ordinarily hard?

Ans About 2,100 pounds of coal is used per hour working hard.

Ques 16.—How much air per minute is needed in the ordinary furnace, working the engine hard?

Ans —About 600 cubic feet of air per minute must pass through each square foot of grate, or about 11,200 cubic feet of air for the whole grate area, averaging 17 square feet

Ques 17 —What does this result indicate?

Ans —That the best results follow only with a proper admission of air, necessitating a clean ash pan and unobstructed passage for air, and the use in fire-box of sufficient fuel only for the purpose desired, viz: perfect combustion.

Ques 18 —Are the volatile gases of value?

Ans Yes; the combination of hydrogen gas, if it combines with eight pounds of oxygen taken from the air, produces about 50,000 heat units, or enough to raise 294 pounds of water to the boiling point.

Ques 19.—Is it difficult getting the necessary large volume of air needed for combustion to the proper place?

Ans Yes; as the hydro-carbons are released at the top of fire some means of admission of air to the surface of fire is necessary

Ques. 20 —Is there danger of heat losses as result of bad firing?

Ans —Yes; an inferior fireman, who maintains a thick fire, will often use up an enormous quantity of coal without making an engine steam freely.

Ques. 21. —How is this caused?

Ans.—By the air failing to reach the 25 per cent. of the fuel that exists as hydro-carbon, and which, in consequence, are wasted, and because, also part of the carbon is burned to carbonic oxide instead of carbonic acid.

Ques 22.—Is there danger of loss in combustion by reason of use of small nozzles?

Ans Yes, nozzles too small will make blast too sharp, and will tear holes in a thin fire by reason of the fierce rush of air, and the fireman will make a thick bed of fire to prevent this, and it often happens that enlarging nozzles will cause an engine to steam better.

Ques. 23 —How will a fireman act who is desirous to work well, and who knows what good firing means?

Ans —He will keep sufficient fire on the grates to suit the engine's working, and enough to prevent loss of air by passing up so freely as to reduce the temperature of the fire-box. He will keep up the fire by using a shovel full of coal at short intervals, and the result will be that most of the gases are burned and very little or no smoke is passed from the stack.

BRAKES.

Ques. 1.—What is your duty regarding air brakes before coupling engine to a train?

Ans.—The air pump is to be started and lubricated for the trip, maximum pressure pumped up with which to charge the brakes, and those which may be set should be released.

Ques. 2.—What is your duty as soon as engine is attached to train?

Ans.—First, charge the brakes; second, apply brakes at full force and hold them on while brakemen or inspectors go over train to make sure that all brakes are set; upon their signal, brakes are released. Then wait for report regarding number and condition of brakes before starting out.

Ques. 3.—How would you start your pump?

Ans.—Would start slowly and increase speed gradually, and thereby not force out the water of condensation, which would be injurious to the pump.

Ques. 4.—How would you lubricate your air pump?

Ans.—I would lubricate steam cylinder with cylinder oil, and air cylinder sparingly with a small quantity of engine oil; would not use tallow or lard oils in air cylinder.

Ques. 5.—What is meant by "automatic air"?

Ans.—The term "automatic air" is applied to the modern Westinghouse system in which the auxiliary reservoir (air storage on cars) and the triple valve come into operation. The brakes are applied by releasing the pressure of air in brake pipe.

Ques. 6.—What is meant by "straight air"?

Ans.—The term "straight air" is used to designate the original Westinghouse system, which operates the brakes by applying the air pressure from the engine reservoir directly through the pipes to the brake cylinders of cars.

Ques. 7.—Does water accumulate in air reservoir and air pipe? If so, what should be done to remove it?

Ans.—Yes; the moisture in the air will condense and accumulate in the main reservoir, which should be drained off once a week in summer and daily in winter.

Ques. 8.—How would brakes be applied in making ordinary stops for stations?

Ans.—For ordinary stops the brakes should be applied lightly, by opening engineer's valve and closing again slowly until the pressure has been reduced on the gauge from four to eight pounds.

Ques. 9.—When are brakes fully applied?

Ans.—Brakes are fully applied when pressure, as shown on the gauge, is reduced twenty pounds.

Ques. 10.—Should brakes be held fully applied until train comes to a full stop?

Ans.—No.

Ques. 11.—Why?

Ans.—Because it causes a reaction in the motion of the train which is very disagreeable to passengers.

Ques. 12.—How can this be avoided?

Ans.—By releasing brakes gradually before a full stop, so that all the air will be off at the moment stop is made.

Ques. 13.—If some brakes are sticking after the train has started, how may they be released?

Ans.—If all the excess pressure has been exhausted, or the amount is not sufficient to release brakes, the engineer's brake valve is put at "lap" and speed of air pump increased; as soon as 15 or 20 pounds additional pressure has accumulated in main reservoir, brake valve is thrown into releasing position, and kept there from ten to twenty seconds. If this does not release brakes the proper signals (two short blasts of whistle given three times) are used, calling attention of trainmen, and they release brakes by hand.

Ques. 14.—What is the maximum air pressure allowed on passenger trains?

Ans.—Eighty pounds.

Ques. 15.—What is the maximum pressure allowed on freight trains?

Ans.—Sixty-five pounds.

Ques. 16.—With a passenger train of from twelve to fifteen cars, what air pressure would you keep the brake charged with, and how would you handle the brakes in making a stop?

Ans.—Would carry from seventy to eighty pounds pressure. In making a stop, would apply brakes gently, reducing the pressure from four to eight pounds, as might be found necessary, and then gradually increase the pressure on brakes until train is brought nearly to a stop, without releasing the brakes more than once. See questions ten, eleven and twelve.

Ques. 17.—Give the different positions of engineer's brake valve handle.

Ans.—First, releasing position, handle against left hand stop.

Second, running position, handle against middle stop.

Third, at lap, handle one-quarter inch to right of middle stop.

Fourth, applying position, handle still further to right. The suddenness of application of brakes depends on distance to which handle is moved to right of middle stop.

Ques. 18.—How much pressure would you carry on a passenger train of two to four coaches, and why?

Ans.—Would carry same pressure for all passenger trains, regardless of the number of cars. Because, with the automatic air brake, each car carries its own reservoir charged with a pressure to be used for a given stop and is therefore subject to the same braking power, regardless of the number of cars on the train.

Ques. 19.—Given a freight train of thirty to forty cars, from five to fifteen of these in front end of train are equipped with air-brakes and can be used to aid in stopping the train, at what pressure would you keep the brakes charged, and how handle the brakes in making a stop?

Ans.—Would carry from sixty to sixty-five pounds pressure. In making stop would apply the brakes gently by reducing pressure from four to five pounds; this will be sufficient to let the cars run together, with only a slight jar on any of them. As soon as all slack is taken up, would gradually increase the force of brakes as circumstances required, being careful to reduce the pressure on train pipe gradually, so as not to use full braking power until absolutely necessary. The object is to gently bring the slack against the air-brake cars, and to hold the brakes on until the train comes to a full stop.

Ques. 20.—Given a full train of freight cars all connected with air brakes, what air pressure would you carry and how would you handle the brake in making a stop?

Ans.—Would carry the pressure prescribed for freight trains—from sixty to sixty-five pounds. In making stop would reduce pressure slightly, just enough to set brakes over entire train simultaneously, and gradually increase braking power until train is brought to a stop, releasing the brake, after once set, as seldom as possible. If the engineer's brake valve be opened wide, allowing the pressure to escape quickly, the brakes on a long train will set on front end some time before those on rear end, causing the cars to jam together with destructive force, then, if the engineer's brake valve be closed quickly, without giving time for the pressure to become equalized throughout the entire train, the forward brakes will become released, resulting in a severe jerk that will, perhaps, break the train in two. In any case, the use of brakes so released is lost. Failures to observe this rule have been a serious cause of accidents.

Ques. 21.—Give essential points to be observed in holding a train of air-brake cars while descending heavy grades.

Ans.—1. Have train charged with maximum pressure before bringing brake into use.

2. Regulating the force of brakes so as to maintain a regular and steady speed of train, also make as long a distance as possible in each application of the brakes. By doing this the pressure is used economically, and the pump is given more time to accumulate the necessary pressure for recharging.

3. Always keeping brake valve in releasing position while recharging, thereby giving the brakes the greatest advantage in recharging quickly.

4. Making no new application of brakes until the full amount of pressure consumed in previous application has been restored.

5. Reducing the pressure as shown on gauge not more than fifteen to twenty pounds from one recharging to another, as it would be difficult to replenish the full amount in so short a time. Moreover, when the pressure, as shown on gauge, has been reduced twenty pounds, the brakes have been fully applied, and any further reduction is a waste of pressure.

Ques. 22.—What is the object of the pressure-retaining valve?

Ans.—The object of this valve is to hold a portion of the pressure in brake cylinder, while the brake is being recharged when descending heavy grades.

Ques. 23.—What are the two positions for handle of the pressure retaining valve, and what is action of valve in each?

Ans.—1. Perpendicular, handle of valve is turned down; this allows the entire pressure to escape from brake cylinder when brake is released.

2. Horizontal, handle is turned up; this retains a pressure of ten pounds in brake cylinder, but permits all pressure over that amount to escape when brake is released.

Ques. 24.—When "double-headers" are run, by whom and how should air-brakes be used?

Ans.—(a) By head engineer alone; second engineer closes stop-cock in train pipe under his valve, or, in absence of this stop-cock, he places engineer's valve in the "lap" position, in order to give forward engineer complete control of brakes.

(b) Second engineer also keeps his air pump working, and thus has air pressure ready for any emergency, such as failure of air pump on forward engine, in which case forward engineer proceeds as second engineer would in (a) above.

Ques. 25.—Would this apply in cases where "helpers" are used for a short distance only?

Ans.—No.

Ques. 26.—The second engineer having assumed control of the brakes, how long should he retain charge of same?

Ans.—Until the end of the trip, except in a case of necessity, which may again reverse the operation.

Ques. 27.—Is it proper to make any experiment with the brakes when on mountain grades?

Ans.—No; this must be done at other times.

Ques. 28.—What should always be borne in mind when on mountain grades?

Ans.—To keep train well under control.

Ques. 29.—Should descending at high speeds be practiced?

Ans.—No.

Ques. 30.—Why not?

Ans.—Descending at high speed must not be practiced with any train, for there may come a time when some part of the machinery may fail, and, while practicable to control speed by hand brakes at eight to ten miles per hour, it may be impossible at twenty to thirty miles per hour to regain its control.

Ques. 31.—Are you familiar with the use of driver brakes on locomotives?

Ans.—

Ques. 32.—How do you apply them?

Ans.—I apply the brakes gradually in order not to bring a too sudden strain on the brake rods and lever.

Ques. 33.—Would you reverse your engine when driver brakes are set?

Ans.—I would not.

Ques. 34.—What would be the probable result of reversing engine with driver brakes set?

Ans.—The effect would be to lock and slide the wheels, resulting in flat tires.

Ques. 35.—In case of failure to any part of air or driver brakes during the trip, what would you do?

Ans.—Report it promptly to master mechanic or foreman for inspection and repairs.

Ques. 36.—What extra air brake parts should you always carry on your engine?

Ans.—I should always have on engine one extra hose for connection between engine and tank, and one hose for between tank and car.

The *Frog*, of Denver, has enlarged, doubled its size. Seems like a pretty healthy toad.

Talk about railroad men not wanting to keep posted up on the new devices pertaining to their business, which manufacturers are all the time bringing out! Some time ago H. K. Porter & Co., of Pittsburgh, put an advertisement in THE LOCOMOTIVE ENGINEER, and about half a dozen other papers, asking interested readers to send for their new illustrated catalogue containing useful information about light locomotives. A man, who was present at the inquest, tells us more men wrote referring to this paper, than to all the rest put together, and the letters were from the right kind of men, too. The other day the Vance Tube Cutter Co., of Geneva, N. Y., wrote the publishers of this paper: "We are having very good results from our LOCOMOTIVE ENGINEER advertisement, and feel perfectly satisfied with your publications as an advertising medium." Now the Mason Regulator Co., of Boston, come upsmiling, and say they are "hearing from their card in THE LOCOMOTIVE ENGINEER from all over the world." Just wait till we get into long pants!

On a recent visit to the Meadows shops of P. R. R., we noticed that connections had been tapped into the three cylinders of the Webb compound locomotive and "pig-pens" built to keep the men on. They were also making indicator connections on one of the new class "P." A comparison of their work would be very interesting indeed. The indicator connections were, of necessity, tapped into the heads of the low-pressure cylinder, but the practice is not considered the best, unless the pipes are large and without bends, it is followed in the case of high-pressure cylinders as well. The compound begins to look hard, is dirty, and has the general appearance of a tramp without friends.

We have noticed on some roads where air pumps were overhauled, that the pump man has tried to make an improvement by making the top of packing-nut on air cylinder cup-shaped, thus preventing the water and oil from running down over lower end of the pump. The cup is a bad thing, for it collects the water condensed from the steam that leaks past steam piston packing, and holds it around the rod, right in shape to be sucked down into air cylinder when the piston is on the down stroke, we all know the disadvantage of having water collect in the pipes and the drum.

The new shops of the Mason Regulator Co., at Milton, Mass., are completed and occupied. These shops are 34x80, two stories high, and all windows. The shops were designed by Mr. Mason himself, and were especially fitted up for their specialties—pressure regulators, damper regulators, reducing valves, etc., and as the shops and the tools were designed to make a specialty, they are enabled to turn out a large amount of duplicate work. They are especially busy now on reducing valves for car heaters.

During the busy hours, trains on the Brooklyn bridge actually overlap one another. Before the passengers leaving the depot from one train are clear of the platform, they are joined by those of the train following. It is only a matter of a short time before the present crowded accommodations will be inadequate, and the enlargement of the depots and approaches to admit of the arrival of a four-car train every forty-five seconds is now under consideration.—*Safety Valve.*

The Baldwin Locomotive Works are turning out twenty-eight locomotives a week. At this rate they will build 1,456 during the year.

Cylinder Boring and Facing Machine.

Made any size required. Will bore cylinder and face off the ends at same time. Built strong and powerful; has variable feed that feeds either way.

BORING BAR for LATHE.

Has Hardened Steel Centres. Constant Feed of Cut Gears. Steel Feed Screw and Nut. All bars accurately ground, and are first-class. All Sizes Made.

PEDRICK & AYER,
MANUFACTURERS OF
Special Tools for Railway Repair Shops
1001 & 1003 Hamilton St., Phila., Pa.
CIRCULARS ON APPLICATION.

PORTABLE CYLINDER BORING MACHINE.

For boring IN THEIR PRESENT POSITIONS all makes and sizes of Steam Engine Cylinders, Pumps, Steam Hammers, Air Compressors, Mining and Hoisting Engines, Heavy Housings, Large Wheels, etc. Machines made any size required.

Greenwood's Universal Planer Chuck.

For Straight, Curved (Concave or Convex), or Angle Work. Used on any Planer with Cross-Feed for Links, Wedges, Keys, etc. Indispensable for Locomotive Builders and Master Mechanics.

STEEL OPEN • HEARTH • CASTINGS •

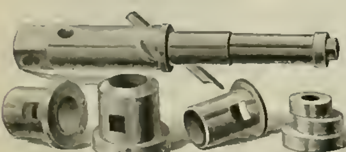
ROSS REGULATOR VALVE
FOR CAR HEATING.

Low in price and always reliable. No complicated parts. Easily understood. Durable. Has no equal.

ROSS VALVE CO.,
TROY, N. Y.

— THE —

Vance Lightning Flue Cutter.



For removing Flues from Locomotive and Stationary Boilers. One man can cut five hundred (one end) in a day. In use in the leading Railroad Shops of the country. Combination Cutter for removing 2", 2¼", 2½" and 3 inch Flues, $50. Sent on approval to Railroad Co.'s. Liberal Discounts to the Trade.

Address,

VANCE TUBE CUTTER CO., GENEVA, N.Y.

WANTED!

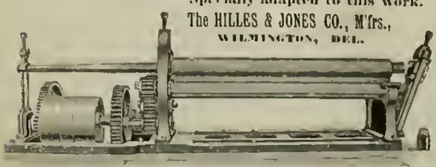
Every Engineer, Fireman, Conductor, Brakeman, and Baggage-Man, to send 6 cts. in stamps for Sample Copy of Eaton's R. R. Time Book, also Terms to Agents. Address,

FRANK EATON,
LYNDONVILLE, VERMONT.

TOOLS FOR LOCOMOTIVE BOILER WORK.

The Cut shows our
PATENT PLATE BENDING ROLLS.
Specially adapted to this work.

The HILLES & JONES CO., M'frs.,
WILMINGTON, DEL.



Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast-iron bed-plate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started, stopped or reversed instantly.

THE GLACE LOCOMOTIVE CHECK VALVE.

Three Separate, Distinct and Independent Valves in One Case, Insuring Freedom from Sticking, and obviating difficulties experienced with old-style single valve.

POPULAR WITH ENGINEERS
Wherever Tried.

LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO XII. NEW YORK, DECEMBER, 1889. 1.00 per Year or 10c. a copy.

A Stylish Locomotive.

When Mr. William Hoffecker became Superintendent of Motive Power of the Central Railroad of New Jersey, about a year ago, he began at once to discard the Russia iron covered and fancy-capped straight stack for a very plain one, jet black, and the veriest excuse for a bead around the top. They were cheaper, easier repaired and just as good, but the engineers did not like them very well—they were not pretty in their eyes.

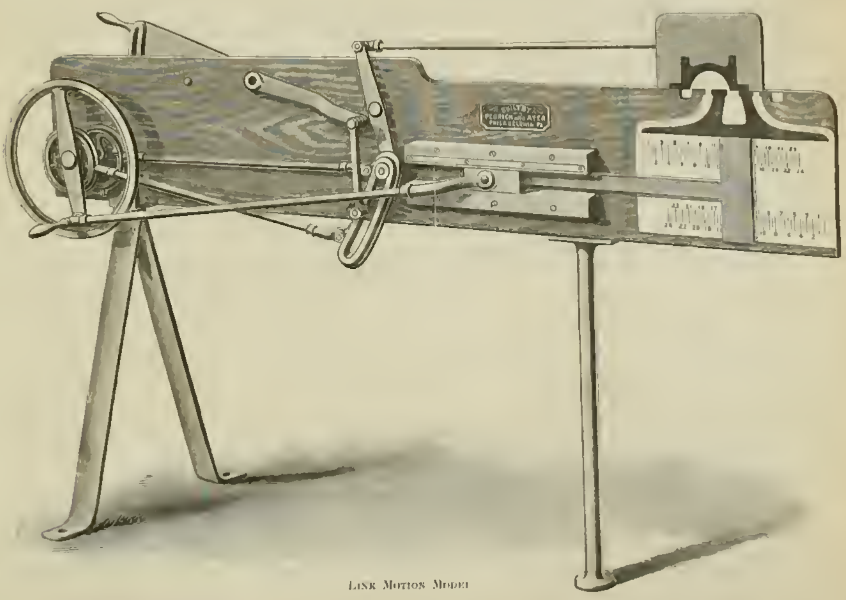
They tell a story over there on one of the engineers, whose engine was about to go into the shop and who hoped that he would not get one of those stacks.

Mr. Hoffecker asked him if he had seen the 147, and how he liked her. He got the following reply:

"First class, she is a mighty nice looking engine. Do you know, she reminds me of a young, handsome, stylish lady, russet leather shoes, striped stockings, satin dress with low neck and short sleeves, pink sash, red corsets, silk suspenders, diamond earrings, and a darned, old, dirty calico sun-bonnet, with pasteboard slats in it."

Locomotive Link Motion Model.

Ever since the establishment of THE LOCOMOTIVE ENGINEER it has been giving voice to a very large class of engineers and firemen, who are attempting to help themselves to a more thorough knowledge of their business, and among the first demands was one for a cheap, yet accurate, model of the valve motion of a locomotive; excellent models were in the market, but they were designed more for the drafting-room than for the lodge-rooms of men on the road, and cost well up in the hundreds of dollars.



LINK MOTION MODEL

After considerable thought on the subject, and the failure of many attempts to get some one to put such a device on the market, the editor of this paper and Mr. Fred J. Miller, associate editor of the *American Machinist*, designed the model illustrated on this page, which is being manufactured and introduced by Pedrick & Ayer, the well-known railway tool builders, of Philadelphia, Pa.

No attempt has been made to get up any improvements or to make the model different or better than the motion under any engine. On the other hand, every effort has been made to make the model as near like an every-day locomotive as possible, each part occupying the same place as on the machine itself. The model is just half size, every measurement, but diameter of the driving wheel, being taken from a standard, 17 x 24, 8-wheeler.

The entire motion, wheel, main rod, valve, cylinder, piston, link, hanger, eccentrics, etc., are arranged on one side of a solid frame that admits of the whole motion being watched from one point and by a lodge room full of men.

The frame, piston and guides are made of wood, all the working parts are of iron or brass, well fitted and stiff for the work they have to do. The main rod, valve stem and eccentric rods are made of polished brass tubing, the eccentric rods having right and left-hand threads, so that they can be easily adjusted to the right length, they are held at any point desired by knurled nuts on each end. The eccentrics are held on by set screws, and can be moved, to practice in setting them. The valve and the ports are painted on the frame, and can be changed by simply tacking cards over them with different dimensions on them.

On the cylinder there are two scales, one number-ing from either end, so that the position of the piston can be noted for the cut-off, exhaust, or any other position of the valve. There is no reverse lever to be out of order or to mislead as to the point of cut-off, the link is raised and lowered by raising or lowering a fan shaped counter weight that is attached to the tumbling shaft, and extends toward the wheel on the back side, if it is desired to set the model to cut off at a certain point, the crank (which is an extension of the main pin) is moved so that the piston uncovers the figure that represents the point of cut-off wanted, the lever behind the board is then moved just so that the valve is closing the port, and then fastened by a thumb screw, this makes the lost motion take care of itself, as every time the lever is set for a point of cut-off it is set by the piston itself, and not by a quadrant that may be "out."

On the back of the valve there is a device—not shown in the cut—that makes an audible snap at the moment of exhaust, this is adjustable, and can be used to denote the port opening, cut-off, or any other position of the valve, but is intended to show the exhaust, as the men are used to hearing that—a student can be watching the position of other parts, the link or eccentrics, and still note the time of exhaust.

The wheel has but two spokes, so that the eccentrics are easier seen. On the back of the axle there is a crank that can be used to turn the model when it is desirable to give an entirely clear view of the whole device in motion. The rim of the wheel is turned up true, so that accurate measurements may be made on it in getting the dead center. On the frame ahead of the wheel is an iron pin with a center in it, so that a correct point to tram from can be had without marking up the machine; there is also one on top of the frame just back of the valve to tram from in setting valves. On the guide there is a strip of brass to scratch on in getting measurements. There is a steel tram furnished with the machine for making these measurements.

Complete directions for setting up the model, measuring to get the extreme of dead center, setting eccentrics, setting valves, etc., will be sent with each machine.

The model is a little over six feet long, stands about four feet high, and will weigh about seventy-five pounds, it is neatly painted or polished, and has the appearance of a machine, and not a toy.

The aim of the designers has been to make this model just as adjustable as a locomotive's motion is—and no more. It will be found to contain all the points of advantage and all the faults to be found in average practice. It was designed to teach the principles of link motion, and will, we think, be found of great value in lodge rooms of enginemen, reading rooms, and in railroad offices where engineers and firemen are examined.

There is a spirit of progress growing in the country, and railroad officials cannot do better than to help their men to such devices as this. The want of a little knowledge of the inside of a steam chest or cylinder by a man in charge has cost many a railroad more than a hundred times the cost of this model, that might have made it plain to him. The price is low enough for the poorest lodge or the average engineman.

On a recent trip over a part of the U. P. Ry. we enjoyed a ride on locomotive 824—an eight wheeler, built by the company. The engineer informed us that she had been in service three years last February. She was pretty lose generally, especially the cab and running boards, but she had balanced valves, and they had not been faced during this time, or the eccentric straps closed. The lever handled easily, and the motion work showed little signs of wear. This alone should be more than inducement enough for a thorough trial of balanced valves where they are not now known.

Don't use emery to grind in brass cocks, it imbeds itself into the soft brass, and keeps on grinding itself out of true after the cock is put in use. Use grindstone grit, this cuts brass well, and will wash off by using water.

None so Blind as Those Who will not See.

It is curious how some men can look at a thing and not see it. A member of the examining board of an important railroad recently told the writer that they found a great number of men, engineers, firemen, and trainmen, who did not know there was a difference in the *shape* of the red and the white signal boards at all telegraph stations.

The white, or safety board, is square, and has a square hole in it, while the red, or stop board, is round and has a round hole in it—if a man is thoroughly familiar with the shape, it is perfectly safe for him to run by the board if it is covered with sleet or snow—the *shape* tells him what it is.

How any man can fail to note a thing of this kind, when he sees one at every station on the road, is obliged to look at it, and his life depends upon every look, is more than we can see.

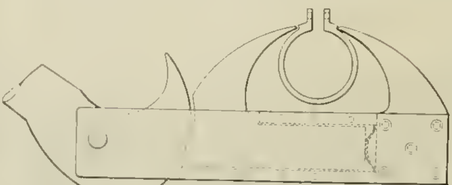
Look about you, notice things, think about them and don't be blind.

A Record for Repairs.

The Pueblo Smelting and Refining Co., Pueblo, Col., own and operate two, six-wheeled, saddle-tank ponies that have done a remarkable amount of work for the repairs they have received. They have been run pretty hard, sometimes double crewed, and one of them ran five straight years without having her valves faced—she has the Richardson balance.

They have solid ends on their main rod fronts, and these ran the same length of time.

Master Mechanic Jones has recently rebuilt these little engines, and found many parts that would naturally be supposed to be badly worn, were not so bad as to need repairs. No running repairs are done on them, except what the engineers do, and they have no machinery or tools, and only a shallow pit under a shed to work in.



HOSE CLAMP HOLDER.

Hose Clamp Holder.

At the Denver shops of the Rio Grande road we noticed a little device for forcing the clamps on air hose together, to enable the operator to insert the bolt and secure it by a nut. The frame, jaws, and lever are made of ½ inch iron, the end jaw being riveted fast, the jaw next the lever being loose and sliding freely between the sides of the frame and the strips riveted between them at top and bottom, a spring at the end will slack this jaw off when lever is released. The end of the lever can be made any length or shape desired, and the device can be held in a vise, or the frame extended to bolt upon a bench.

We are under obligations to Ben Diggory, traveling engineer of the Denver & Rio Grande road, for a copy of the new instruction book, recently issued by N. W. Sample, Supt. of M. P. & M., governing use of air brakes and Baker heaters. The book is in the shape of questions and answers, and is conveniently divided into general instructions to all, instructions to enginemen, instructions to trainmen and to car repairers. The D. & R. G. was one of the first if not the very first, to adopt the air brake for all freight service—they do not own a car not equipped with air—and Mr. Sample ought to know what is needed in the care and handling of air-brakes.

The P. R. R. compound recently broke the piston head in her big cylinder.

The Traveling Engineer.

BY J. E. PHELAN.

LAST PAPER.

Among the most agreeable experiences of the traveling engineer can be named pleasant dealing with master mechanics, who are ever ready to receive reports of defective machinery, and always willing to remedy the same.

The prime element in successful work, for either the traveling engineer or master mechanic, is constant watchfulness and properly locating defects, with an ever present and active determination to remedy fault, while maintaining proper discipline, and keeping machinery and engines in thorough repair for effective service on the road.

We have known master mechanics who always had their engines in first-class shape, on paper, *i. e.*, never failed to report the condition of engines to the general office as first-class, regardless of the miserable condition of the engines in actual service.

Dealing with such talent (?) gives the traveling engineer his most distasteful and most disagreeable experience.

However, under such circumstances, there is but one course to pursue, and that is for the traveling engineer to tell the truth about the condition of the engines, and report the same to general officials, and let the misguided M. M. paddle his own canoe.

After watching the progress of individuals in official position, one can realize that the official who ever stands ready to remedy defects generally gets through his duties with a fair measure of successful results, while the men who are incapable of discerning right from wrong soon sink to proper level, and, though lost to sight, stand as a beneficent example to the errors of false practice.

The traveling engineer who can gain and uniformly command the respect and good will of master mechanics, and engineers and firemen, with whom he associates, can count on a happy pathway through the field of duty.

Such good will can be gained by uniform truthfulness and square dealing—*i.e.*, by treating all men alike, and having no friends to reward, or enemies to punish.

In any event, when consistent, be fair with your friends, and let your enemies take care of themselves.

When you find engineers or firemen not fully competent, and not thoroughly posted regarding their duties, do not be hasty in condemning them. Do not form prejudices in advance of the verdict of intelligent judgment.

Never condemn any one until fully satisfied beyond any measure of doubt that the retention in service of parties at fault may lead to demoralization of the service, or be disastrous to desirable and successful results.

The traveling engineer possessing that happy gift of nature, capable of discerning true merit, wherever found, and giving full measure of credit to the same, regardless of personal prejudice, or bias of association or nationality, can be relied on to attain successful results, and reflect credit and confidence around all with whom he may come in contact.

Our readers must not assume that we are reaching after ideals; for we know such principles are in practice at the present time, and carried out successfully by traveling engineers in active service.

Traveling engineers who do business according to such principles can afford to bear the criticism of a few while being supported by the confident sentiments of the majority.

We have known men to criticise traveling engineers for showing up on the road after night fall. We can hardly recognize the necessity for traveling engineers going to bed at time set by chickens, simply because a few chronics are disposed to growl.

A clear conscience will go a great ways toward warding off effects of criticism, as well as rendering similar criticism scarce.

At the present time, the innovation of a traveling fireman is becoming quite popular on certain railroads, and, from evidence at hand, proving a successful experiment.

For our part, we cannot see why such a practice, honestly and skillfully executed, should not be most beneficial to general service.

A locomotive engineer cannot be considered thoroughly competent, unless fully versed in the art of firing.

Successful and skillful firing means dollars in profit to railroad management, when economy in consumption of fuel and supplies is fully considered.

It stands to reason that an instructed fireman, becoming efficient from competent direction, commences building on a proper foundation, and can more readily comprehend further instruction after becoming an engineer.

However, knowing how an incompetent engineer can render successful results from skillful firing impossible, the query is, "What authority has the traveling fireman over the incompetent engineer?"

We know, however, that the successful traveling fireman of to-day will make the successful traveling engineer at some later period, and we wish to add words of cheerful encouragement to all worthy characters laboring along the path of progress.

In closing our extended and rambling remarks on this subject, we want to say to our associates, whether traveling engineers or traveling fireman: Be ever faithful and diligent in enforcing rules and doing duty. Be uniformly consistent and fair with your associates on the road, and with the management employing you—but don't do any detective business, never sneak or crawl, but always stand out openly and aboveboard; be manly.

All know how much annoyance and expense is caused to them by the breaking off of oil-cup shanks, but few have stopped to consider the total cost from this little thing alone. We have before suggested the use of a steel shank, but this is open to one objection—it can rust fast in the strap. On the Denver & Rio Grande road they screw a steel plug into the rod strap, and put a very large hole in the top of it, and a correspondingly large shank on oil-cups, the cups set up higher, but are stronger and not in the repair shop so often.

Did you observe that this issue is composed of twenty pages instead of sixteen, and the index extra. A steadily growing subscription list, and a list of liberal advertisers make enlargement necessary. It is our aim to give just about three times as much reading matter as we have advertisements. You thus share in our prosperity in receiving more meat for your dollar.

A Pennsylvania Passenger Engine.

Since we published an account of some of the changes in the class "P." engines of the P. R. R., in the October number, we have had many requests to "show them up, and let us see what they are like." The P. R. R. are not willing to let much of anything be shown—did not want to let us show up the compound—but we did all the same. Our readers have called for a cut of the new class "P.," and here it is, taken from a photograph—caught on the fly by Albert E. Bruen.

For part of the details we refer our readers to page 3 of the October number. This engine has the Belpaire boiler—square top. Two hundred and ten flues, two inches in diameter, with the fire-box end swaged down to an inch and a quarter. The pops are incased in the device on the wagon top, into which the whistle is tapped. The dome is ahead of the fire box and contains nothing but the throttle. The sand-box—like all P. R. R. engines—is in the front wheel cover, and out of sight. The engraver has shown the steps on the tender as well as on the engine; they are large and strong.

The Arbell or Belgian wrought-iron wheel is used on the front trucks; they are forged in one piece, with steel tire shrunk on; they appear of very light

A PENNSYLVANIA PASSENGER ENGINE.

section. Just below the stack will be noticed a lever on the smoke arch; this is a muffler to throw over the exhaust nozzle when in depots and around stations. There are two air-drums arranged side and side; this is a good thing, as it provides a large volume of air to draw from and does not rob the drum so much in re-charging, allowing of a more even running of the pump.

These engines are unhandy in the cab, crowded, and uncomfortable, and are therefore not likely to be popular with the men who live on them, but they all say they are pretty good engines, steam well and handle their trains easily. They are 18½ x 24, 68-inch wheel, hard coal burners, weighing about 105,000 pounds ready for the road, and carry 160 pounds of steam. The excellent engraving tells the rest of the story.

Some roads in the country still use the old-fashioned "chair" under the ends of rails. The rail splice, then the angle bar, supplanted them. Now comes a new device, that is a combination of the chair and splice, which reminds us

In 1848, Isaac Dripps made some splices for the old Camden & Amboy, that had a bolt through the splice bars and the end of each rail, and was spread out under and at the sides of the joint, to receive the spikes. The bolted splice did not supplant the chair for fifteen or twenty years after this, however.

A Special Machine for Paper Wheel Work.

At the Allen Paper Car Wheel Works, Pullman, Ill., there is in use a very ingenious machine for removing the nuts and bolts that hold the plates and web of old wheels together, and for putting the bolts into new wheels.

The wheels are swung between two cones entering the bore, these cones are on sliding heads that can be moved in and out to adjust the different rows of bolts in position to be operated upon.

On either side is located a small steam cylinder, the one on the side of wheel where bolt-head is has a hollow head on the piston, and the movement of a small lever throws it solidly against the web of the wheel and over the bolt, the other cylinder piston striking a blow that drives the bolt out.

In putting up new work the operation is reversed, the other piston acting as an anvil to drive against, and the head end piston driving the bolt.

By running the wheel carriage across the frame of the machine, the row of bolts is brought in line with two chucking heads; one holds the head of the bolt, and another, revolving, screws on the nut.

How do you like the appearance of 20 pages at the old price for 16?

Originality.

The editor has to thank the many friends who see that he gets "comps." invitations and tickets to all the brotherhood balls from one end of the country to the other.

There have been no poor ones, but the most original and unique comes from Fargo Lodge, No. 85, B. L. F., at Fargo, North Dakota. The invitation is printed in script, on yellow manifold paper, in the shape and language of a train order. Let it tell its own story.

Brotherhood of Locomotive Firemen, }
Fargo, Thanksgiving Eve, 1889. }

ORDER No. 11.

TO YOURSELF AND LADIES:—Run from your home to Armory wil'; dance between 8.30 P. M. and 3.00 A. M. to music by Rupert's orchestra, meet Ehrman with refreshments at 12.00 A. M. Flag against long trains; approach crossings with caution, and look out for another party following next year. Be particular to enjoy yourself.

Correspondence

Exchanging Kinks—A Piston-Rod Remover.

Editor The Locomotive Engineer:

I have been an interested reader of your paper for the past year, and take great interest in it.

I would be pleased to divide some of our shop experience with readers of your paper, and send you enclosed a blue print of a very practical device for removing the piston-rod from the crosshead.

The tool has been in use for some time, but was improved by A. Bardsley, M. M., and his machine shop foreman, so as to be applied to all classes of engines, especially to moguls, as they are more in use here. The print will give any practical mechanic a clear idea of its use.

The front end of main rod is to be disconnected, remove plugs *B* and *C* from device, take the tool in one hand and put it between crosshead sides, so *D* will point to center of piston rod, screw *B* from the outside of wrist pin hole, *C* from the inside of the same, and apply the power as indicated by *H* and *G*. The large piston to move up quickly, the smaller one for power.

A flue sheet cutter, you referred to in your September issue, I have improved to drill 200 holes in 10 hours, blue prints and description for which I will send you at an early date.

O. G. Burrish.

Brainerd, Minn.

The Trials of an Inventor.

Editor The Locomotive Engineer:

When I was coming home from the convention, traveling, as is my custom, *incog.*, a bilious-looking delegate, who was working his way homeward in the steerage, took a farewell munch, as we approached the Missouri River, of a cold lunch he had got together at the banquet—he threw the last bone out of the window, wiped his mouth on the tail of his Prince Albert, and covered my feet with the paper that had held all that was mortal of the late lamented hen turkey, and sadly left the train at Omaha. When he was gone I picked up the paper and read it. It had been amputated from an alleged railroad paper, and contained advertisements only. Among the rest was one for a wrench that registered how much strain there was being applied to a bolt. I threw the old scrap away, but all the evening I kept thinking that I had seen an old, familiar face, some friend long since gathered to his fathers—I was haunted. Along toward morning, the engineer used the emergency clause on the Westinghouse to stop at a tank, and I changed seats with a Swedish emigrant who was trying to sleep on top of a tin trunk in the aisle, I butted my head against an iron seat—and it all came to me. I am the father of that idiot notion myself.

It was away back in the tail end of the fifties, or the fore and front of the sixties that I—then a boy in knee pants and my teens, first got a job of running—it was from the fire-door to the tank. It was on a New England road that wandered off in an aimless and westerly direction from the good city of Boston, and the general manager was an old friend of the family.

I never knew what put it into my fool head, but that registering wrench racket struck it hard; I thought it a grand idea—remember I was terribly worried least some one should find it out and get ahead of me—I wish they had. After burning the midnight oil and my new and tender mustache, during a whole winter, I at last produced a wrench that was fearfully and wonderfully made; it was one of those combination abominations, and the register was the striking feature about it. It was so arranged that its adjustment to a nut would move a gauge that would admit of only so much pull on the handle—according to the size of the nut. I decided that, say, ten pounds was enough pressure to apply to the nut of a one inch bolt. I set the spring so that is all the pressure that can be applied. I figured out a great saving in not breaking bolts as well as in wrenches by applying the proper pressure. I got the advantages all down fine, and then took it up and laid the whole thing before the "old man," the General Manager.

He looked the whole thing over carefully, and offered to pay for the patent and introduce it on the road for half—I agreed. The patent came along in due time, and we had a couple of the wrenches made in the shop—company expense. The engineer I was firing for got one to try, some machinist the other.

The first time old Paddy O'Wing took that wrench down, he screwed it out to fit the two-inch base of the rod-cups, and twisted two of them off trying to get pressure enough on the wrench to bring the indicator up to the scratch—the fool did not take into consideration the size of the stem on the cup—said the wrench was supposed to figure on that, and that I had made my brags that any numbskull could do as nice work as the best mechanic, if he only used the great and only wrench.

When I got in the G. M. sent for me. I remember now how I wondered if the old skinflint was going to try and buy me out for a song, or was just going to tell me that he had got an order for thirty or forty gross of the great and only, John Alexander, perfection, registering wrench. After I got seated in his office, he turned on me and said:

"How did that wrench go?"

"Well, only middlin'," said I, and then I had to tell him how it fared at the hands of old Pat.

"Your inventive genius has got the whole shop shut down here, Mr. Alexander," said he.

"How's that?" said I.

"Well," said he, "the watchman washed out the shop boiler last night, and put in the wash-out plugs with that measly wrench of yours; the plugs are about three inches at the thread, and are turned in by a square end about three-quarters of an inch in diameter; they turned them in as hard as that wrench would let 'em, and when they got up about twenty pounds pressure, one of them blew out, broke fourteen lights of glass, cleaned out the shop, cooked all the paint off two tanks, the meat off the foreman's leg and burned the boiler to boot."

This sort of staggered me, and the old gentleman wrote a few minutes while I thought.

"You forgot something, Mr. Alexander," said he.

"What is that, sir?" said I.

"To furnish brains to use with that wrench," said he, commencing to write.

"Or use any in its construction," continued he.

"Yes, sir," said I.

"You don't know much about wrenches, sir," said he.

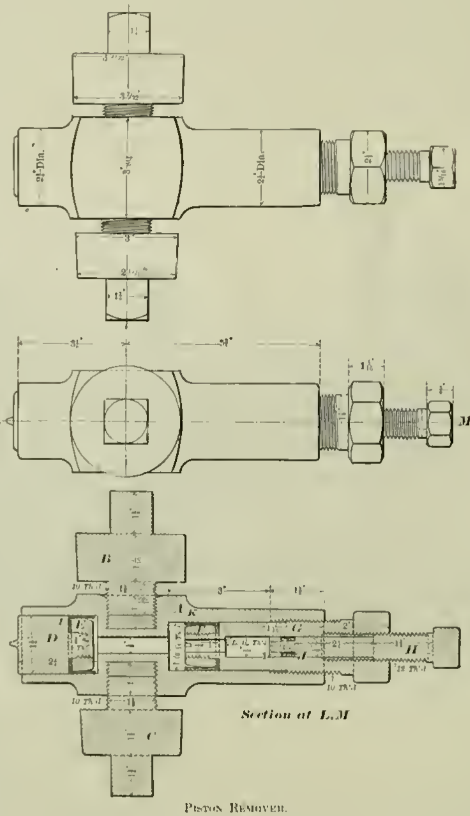
"Not much," said I.

"You may go now, sir," said he, "and don't let me hear any more about your great inventions, sir, you are a fool, sir, a fool!"

I made for the door, and as it closed behind me I heard that old sinner saying: "You are an ass, sir, a dommed idiotic ass."

That wrench was a sore place in my life for a long time, but I lived it down, and I want to say this to the young mechanics who are figuring to invent something: Don't waste any time on anything that is not a simpler and cheaper way of doing things than that in vogue in the practice of your road. Don't try to invent anything that tries to put brains into the head of any one, or that expects to accomplish much by putting skilled work into the hands of those not trained to that skill; they won't work. Again, remember that it is easier for a giraffe to carry a load of umbrella frames through the eye of a needle than it is to invent anything that is really new and useful, anyway.

John Alexander.



Piston Remover.

Beat this Time—According to the Gauge.

Editor The Locomotive Engineer:

In looking over the August number, I notice an account of a fast run for a narrow gauge. now I don't expect you to open up your columns for the competitive liars about fast running, for if you did there would be no end of it, but I want to tell you what a little railroad up in this neck of woods is doing.

I am running on a little two-foot gauge road, the Brighton & Saco River Railroad. We have two locomotives; they weigh but ten tons, and have drivers only thirty inches in diameter. The road is sixteen miles long, has one curve of twenty degrees, and lots of them sixteen to eighteen, and a grade of two hundred feet to the mile. We have made the run over the line, sixteen miles, in twenty-seven minutes, five and a half miles in seven minutes, and three and a half in four minutes.

This is a pretty good sized story—for the wheel—but they can run, and no mistake. Can any of the readers beat us—considering our size?

Brighton, Maine. J. A. M.

[We suppose, of course, that this time was made on the fireman's side of that 200-foot grade—something on the order of a stone falling down a well.]

What is the Difference?

Editor The Locomotive Engineer:

Why is it that, if a back tire on a six-wheeled coupled engine breaks, the side rod should be taken down, while, if a front tire breaks, the rods are left up? as per Mr. Cushing's questions and answers.

I fail to see where there would be any difference. C. H. REYNOLDS.

Cape Girardeau, Mo.

[We fail to see what difference it would make, and have seen eight-wheeled locomotives brought in many times with the back tire broken and side rods up. It is no doubt a safeguard to take down the rod, as, in case the tire comes off, it cannot do the damage it would with the rod on; if by taking down only a *section* of the rod this security can be obtained it is best. To take all side rods down would make the engine unable to handle her train.

Device for Duplicating Irregular Forms on the Engine Lathe.

Editor The Locomotive Engineer:

I see so many valuable labor-saving tools illustrated in your paper that I desire to add another one to the list.

Though not engaged on locomotive work at this time, yet I can see how useful it will be on many things about a locomotive. Many of the lathes now being built have the back taper attachment to them, and a former of any design can be used, but there are many lathes now in use that have not these attachments.

This can be used on any ordinary slide lathe. We use it for turning handles and circular work. A great variety of work can be done by changing the former. The tool holder slides in and out, according to the shape required. It is fastened into the tool-post holder by the piece marked *A*, with two flat head screws.

Think its construction will be plain from the drawings. J. J. BINGLEY.

Watertown, N. Y.

Railroad Shop Management—Good and Bad.

Editor The Locomotive Engineer:

What is good shop management? As "Order is heaven's first law," the first thing is to keep the shop clean and in order, next to keep the machine hands on machines, and see to it that they keep their machines scrupulously clean.

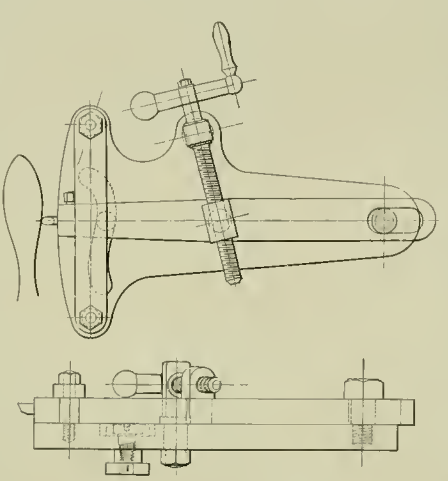
All lathes should have their centers ground in and turned up true to a common gauge, and hardened, so that work can be changed from one machine to another, and have it run true. Throw all square centers into the scrap pile, as they do a lathe more damage than they are worth; have a small drill chuck for your lathe for steel work, use two center punches for wrought iron work; keep all lathe tools well hardened and ground, so they will cut, and not tear off the metal. All lathes and planers should have a water can for wrought-iron work; the writer has used water with good success on mild steel (crank-pins).

Have a hole drilled in all flat or lathe drills, and hang them up, when not in use. Put neatsfoot oil on belts instead of resin; have dirt box and tool shelf on all lathes possible, as described in THE LOCOMOTIVE ENGINEER for September. Keep lathe dogs hanging up where they can be found; put all bolts and clamps belonging to lathes and planers where they can be found when wanted in a hurry. Have all machines painted and varnished, and the numbers of all thread gears painted on them, so there can be no mistake in picking up the wrong wheel; keep a man on drill press, and keep all drills dressed in good shape, and ground to gauge, and allow no alteration in them. Soapsuds or water with washing soda is good for drilling wrought-iron, and is cleaner and cheaper than oil.

Put a drill press and grindstone in boiler shop for use of boiler makers and blacksmiths; put a man in tool room to serve out and repair tools, also put oil tank for use of shop in tool room, and have cans ready filled to exchange for empty ones; discharge the first man that uses a hammer to start a tap—taps that are right will start themselves. Keep a good emery wheel in the shop, and keep it running true; run the grindstone true and fast. Run lathes and drills at a good speed on small work; use coarse feed on planers when possible, and get the work out.

Don't allow vise hands to run the tools, but let each stay where they belong; put self-feeding oil cups on all line shafting and loose pulleys, keep windows clean and let in the daylight—it costs nothing. Have all forgings made close to size; don't have men running about the shop, or to the scrap pile, to find material to work with; have all nuts for finished work tapped to a standard size and thread (not $\frac{1}{64}$ large), and have them on hand when wanted.

Don't allow old clothes, boots and shoes, broken tools and scrap-iron to accumulate on or under the benches; keep the men busy without being overbearing; avoid familiarity with the men under you, treat all with consideration and respect, but hold your own ground. A clean, orderly shop is an advantage to the men, a profit to the employer, and good for all concerned. Shops have been run, and can be again, on the above principles, and the foreman who does it is a live, wide awake man, and up to the times.



DEVICE FOR DUPLICATING IRREGULAR FORMS.

Bad management starts in with a dirty shop, broken drills lathe and planer tools, bolts, nuts and clamps, litter the floor, lathe and planer tools are ground every way but the right way, drills are ground in all shapes and sizes, broken and thrown on the floor; everybody runs the lathes, planers and drills; result, machines in a broken, dirty, filthy condition, nobody cares a continental, so the time is put in. Men go to the tool room, take out tools and throw them down when done, no account taken of anything; break and waste; "the company is rich let them stand it," is the motto, and in a great many cases it serves the company right.

Smith puts a job on the planer, gets a tool ground, lays it down and goes to the roundhouse to work, Brown comes along and throws Smith's work off and puts his on; Jones is on a lathe and is cutting a tap, he is sent to the roundhouse to put in a tender brass or drill a lot of holes with a ratchet; O'Brien throws the tap out of the lathe to turn up a lot of patch bolts, uses Jones' lathe tools, and breaks them, lets the tool catch, and off goes the point of the lathe center; before he gets through he breaks one of the thread gears, and then goes and jumps some other man's vise.

John Doe uses the drill press, the belt breaks, he goes off and leaves it, and the next man comes in a hurry, but must stop and lace the belt.

A boy in the shop wants to be smart, and throws in the back gears while a lathe is running; result, a lot of teeth knocked out, but it is all right, "the company is rich." A lot of follower bolts come in from the blacksmith shop, forged from $1\frac{1}{4}$ iron, to be turned to $\frac{7}{8}$ in., the heads are forged $\frac{5}{8}$ thick to be turned to $\frac{1}{2}$ in.; there is a little taper left on the heads so the follower wrenches will slip off, and as they are not all of a size it will require a number of wrenches to fit them; other forgings, supposed to be bolts, are brought in, they are curiously wrought bolts indeed, but as the heads are neither oblong nor square, and no use can be found for them in or about the engine, they are hove over into the scrap pile.

If it is cold weather, and the oil won't run, set the supply can alongside the stove to thaw out, open the faucet, and go away and forget about it, the stove gets in its work on the oil, if the floor is any criterion to go by.

Brown wants some wedge liners, he goes to the iron rack, takes down a whole sheet, and mangles off what he wants on a pair of old dull shears, throws the rest on the floor, no account kept of it—everything goes—put in all the time you want on a job, and charge it up against some engine.

An engine goes into the back shop for general repairs, fire-box, etc., the ash pan is dropped into the pit, it lies there, a catch-all for bolts, nuts, rivets, boiler scale and what not, and is a delightful thing for men to climb over while the engine is in, and as the pit is a receptacle for waste water, there is lots of joy for the men who do the work; the foreman don't care, *he* don't have to tramp around in it.

The valve on the stationary engine is not right, but so long as it keeps the belts all jerking and whipping about, it will do—"the company is rich."

Machinery is run in an exposed and dangerous condition, the foreman knows it, and he knows the company is liable for damages for injuries to the men; his attention has been called to it, but so long as *he* don't get hurt he don't care. Work turned out of a shop of this description costs over a hundred per cent. too much, and when done is done badly. Show me a shop run this way, and I will show you a foreman that ninety-nine times out of a hundred is a lazy, shiftless nobody, with no record for anything but wire-pulling. W. DE SANNO,

Engineer and Machinist.

Corry, Pa.

Wants to See One.

Editor The Locomotive Engineer.

If you hear of any locomotive engineer or fireman answering "Yes" to Question 1, under head of "Combustion," in Mr. Cushing's questions and answers, please publish his picture. I have no good photograph of a first-class liar in my collection at present. JAMES ARCHIBALD.

St. Louis, Mo.

Not so Sure Now.

Editor The Locomotive Engineer:

Like all engineers who watch their engines carefully I try to locate cause, and have before now thought something was wrong that proved upon investigation to be all right, but I never was quite so badly beat as I am now. I am riding an engine with a 17x24 cylinder, and only a 4-inch dry pipe, and I have been kicking for two years to have that pipe enlarged. The engine does well enough on slow runs, but, come to crowd her, and she seems to choke up with indignation. I swore all the time that it was because she could not get steam through that little pipe fast enough, but the other night I struck a wagon and broke off the hand rail posts on one side; one of the studs in the boiler pulled out, and left a hole less than half an inch in diameter, and, to save my neck, I could not keep that thing from blowing her off, and got less than a mile with my train. Now, if a half inch hole can carry off more steam than the boiler can make, what is the use of steam pipes as big as the cylinders?

Buffalo, N. Y. P. J. DANIAN.

A Guide to Go By.

Editor The Locomotive Engineer.

I think that, when telling young runners and firemen how to set eccentrics, as in Answer 26 U. P. Questions and Answers for the examination of enginemen, that it impresses the student better and makes it easy to remember, that, in setting eccentrics, always move the loose eccentric in the direction it is intended to run when it is in gear. There can be no mistake made then.

Speaking of water grates bursting, Answer 69, I never saw one burst or burn out that did not of its own accord attend to the putting out of the fire.

THOS. SHERIDAN.

Jersey City, N. J.

A Simpler Way.

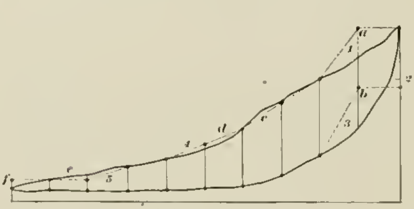
Editor The Locomotive Engineer:

Thinking that the method shown by Fig. 4, October issue LOCOMOTIVE ENGINEER, of laying out indicator cards for measuring ordinates, might not be clear enough to some, I have taken same card, and shown lines more fully, thus giving the complete outline of card as re-arranged.

It will be noticed that the new lines do not alter the length of ordinates shown by Fig. 4, or change the method, but it is hoped that it may be made more clear.

The parts *a* 1 and 2 have been added to take the place of *b* and 3, and *d* and 4 for *c* and 5; the parts *e* and *f* also being equal exchanges.

Harrisburgh, Pa. CYRUS F. RICHMOND.



A SIMPLER WAY

Getting Age Problems on the Road.

Editor The Locomotive Engineer:

All this time that I have been keeping still I have not been dead nor yet asleep—I have been running. I left the Kid about a year ago to try my hand at running, and thought it would be just as well for me to keep still and saw wood for a while as to be telling what I did and some one else did not know. I am soaking myself in experience, and in a year or two more will be able to spit over my shoulder and talk about "us old timers," and refer to the young runners as the "tidbits," the "kids," etc., but every day or so something comes up that shows me that I am not so well posted as I think I am, and I am going to mention a few of them to you.

Here is one: Coming to shop with an old engine from a coal branch; she has pumps, the left one has no lug on the crosshead, no air chamber or hose—I don't see how she got rid of so much at once—but the right-hand pump is all right, that is, it will work. I dropped over a hill, and there is twenty miles of a fall in front of me; I try to shut off that pump for the first time, and find that the lazy cock is in the same position it has always been—is rusted fast and cannot be moved, even with a coal-pick. I try to shut off the tank hose, and find that I cannot do so—it is off the stem and out of the hole. Now I have to get that old tub in, and I found out how I could do it about the time she was too full for utterance, and I did it without getting off my seat. How?

The Kid bet a box of cigars with the roundhouse foreman that he could put a pail of boiler scale dope into his boiler with steam on it, and without putting it into the tank or the feed hose, and without running her a foot. She had one pump and a Little Giant lifting injector. He did it. How?

TEXAS.

Galveston, Tex.

[You could prevent that pump from getting water by putting on the heater wide open, this would blow the water back into the tank.

The "Kid" could put that liquid compound into the boiler by letting the injector drink it. Take out the valve over the overflow nipple, replace the plug, put the injector to work, and you will find a strong suction at the overflow; hold a pail of the "dope" up there, and the instrument will take it up and carry it to the boiler.]

On Examination Questions—A Book Needed.

Editor The Locomotive Engineer:

I have been looking over Mr Cushing's list of questions and answers for engineers and firemen, and on the whole rather like them, not that I think they are *all* right, and can be followed implicitly, but they are the seed of something better—the idea will grow.

I don't believe you can lay down a set of cast-iron laws, that can be followed implicitly; it would be impossible; the circumstances of every case differ.

What is wanted in laying down or in living up to rules in a case of emergency, is to teach the runner to follow his own best judgment in accomplishing a certain number of things that *are* laid down in the rules, with the means and under the circumstances in the case.

First, to protect his train, insure it against being run into.

Second, to clear the line in the shortest possible time, and let trains by, delaying inferior class trains, if needs be, in order to let passenger trains make their time. Here comes in a chance for the engineer to show his judgment, and tell by his acts just what kind of a railroad man he is. Sometimes he will find it the best to disconnect his engine, and get half his train to the nearest side track, and proceeding with rest, or he may find that he is so near to shops or a side track, and another train so near due, that any attempt to disconnect would cause unnecessary delay, it might pay to do nothing until the train came and pushed him into a siding where he could do his disconnecting without disturbing the other trains on the road.

It is considered a disgrace to be towed in; well, it is more of a disgrace in my eyes to hold several important trains while a fix-up is made to run a few miles that might have been almost entirely averted by letting your disabled engine be towed in.

The railroad company earn their money by hauling freight and passengers over the road, every minute is of value, and the reputation of the line depends on the trains making time. Every effort should be made to further these ends.

I know it is a difficult thing to explain, but no one has yet hit the nail on the head, in giving the subject of combustion a practical explanation. Mr. Sinclair did very well in his little book, but it failed to convey the proper information into the heads of average engineers and firemen, and Mr. Cushing's book leaves us in the same fix. Don't you know some one who will be able to tell us something about the subject that we can absorb, not how much beltiric acid gas there is in four miles of air, and how much oxygen it takes to burn it, or burn itself, but what to do under different conditions, not by the name of the gas, but by the appearance of the fire? We want to know something about heat, what it is, and how much of it we can use, and how much we cannot use. I am hunting for a work that will tell me the scientific facts of the case, and then just take me into its confidence and say, "Now, look-a here, old man, it's like this," and then compare the case to something I know about, and can see the comparison. I want that book to pull the fire-door open, and say, "Now do you see that the fire seems to have a shell on it, a little mantle of blue flame; now that is because there is not enough of this blank gas to combine with that blank acid, and you see how I make her hustle by doing so-and-so," then tell me how to do it.

I would like that book to tell me how in the name of old combustion herself I am going to pull fourteen cars three miles through a certain city with soft coal, and obey the city ordinance, not to throw any smoke, or put in coal, or stir the fire, and follow the superintendent's order to run with the door on the latch. I have to keep up over a hundred pounds to pull the train, I have to keep some water in the boiler, but must have it boiled up ahead, as I am prevented from heating it after I start.

When some genius combines theory and practice, enough to get out a work on combustion on these general lines, I want a copy, if it costs me $10.

Albany, N. Y. W. E. ANDROS.

Federation, Almost.

The engineers adopted a plan at their late convention, that admits of the men on any road to federate with other trainmen, if they feel so disposed, to the amount of the necessary two-thirds majority. We were always disposed to be a home-ruler, let each locality take care of itself. We are a little afraid that in case the firemen got into trouble first, the federation scheme would be inactive, but if there was a chance for war on the engineers' side there would be great scrambling to get federated at once. Either federation is right or wrong, and should be so agreed upon. We are inclined to think that it would be a mighty good thing for the engineers and firemen to be under one general head in times when trouble is imminent, but have always thought the amalgamation of all trainmen and enginemen would be a top-heavy organization; but that is not proving that it would.

Bound to Work.

It is a very convenient thing, after inventing a device, to be able to create a demand for it—have the authority to adopt it. Many a railroad device, that is now the "standard" of some system, would have died a bornin', if it hadn't been for the fatherly or motherly relations that some official of the aforesaid system bore to it.

Once in a while an inventor invents something and finds at the eleventh hour that there is no place for it; the long-felt want that it was especially designed to fill does not exist. To be able to make a place for it is a privilege worth something—it saves the invention. The older railroaders of New England will perhaps remember the following circumstance, recently related to the philosopher of this paper by an old-timer from the backest county in the land of hard cider and granite.

"On the old Norwich & Worcester road some twenty or five and twenty years agone, I think it was when Richard Colburn was the master mechanic," relates our informant, "there was a valve invented that was designed to go into a pipe between the cylinder cocks; this valve was made to open at a given low pressure, and remain open until closed by a sudden high pressure. The idea was to prevent back pressure on the pistons; the large valve was supposed to stay open and prevent the compression from doing too much work on the wrong side of the piston, and then automatically close at the moment of admission. Well, the first one was made with great care, and presented an imposing appearance with its O. G. dados, and fluted columns, and it was placed on the old Hinckley, insider, War Eagle, but it seemed to have missed connections altogether, wouldn't work, and after much tinkering and experiment the cause was discovered—there wasn't enough back pressure to close the pesky valve.

"Now you or me would a tho't that we had jest simply slipped up, made a thing to prevent something that wan't there, but they didn't, you bet; no sir, they jest took out the old War Eagle's valves and give 'em more lap on the inside, a plenty too, $\frac{1}{16}$, or $\frac{1}{8}$—there had to be back pressure enough to shet them valves—and every engine on the whole pesky line was fitted up with them, and they had to work—'cause if they didn't have back pressure they was fixed so as they hadn't no trouble to find it. Didn't run long? you bet, they was runnin' that way the last time I was up in them parts, and that is, well, lemme see, long about eighteen years ago, I reckon."

We recently heard an ex-master mechanic say that he railroaded at least four times as long, before he got to be an M. M., as any superintendent did, before promotion, that he had worked with, always had at least four times as much to do, more men to handle, and never got more than half as much pay, and the only way he could see to get a living salary, was to own a patent on the standard stack, ash-pan or valve-gear. The officials of our motive power departments are not paid anywhere near what they are worth or earn. Perhaps if they were they could afford to give some of their standard inventions to the poor.

Accomplished the Objects Sought.

In a private letter to the editor, George W. Cushing, superintendent of M. P. of the U. P. Railroad, says:

"I notice the criticisms of Mr. Mumford and others, who review the questions and answers published in the Engineer.

"The matter was not, as you know, intended for publication, nor was it originally intended to be placed as a whole in the hands of the men. The questions only were so intended to be used. When it was concluded to put the questions and answers together, it was thought best to so frame a few answers as to elicit discussion and criticism. This was particularly the design in the answer referred to by our young friend Mumford. By careful reading of the Answer 57, it will be noticed it does not say that explosion of gas *is cause of failure*. As a matter of fact Mr. Mumford is right, and his criticism was expected on the point referred to.

"The writer has been favored by letters from numbers of engineers and firemen in relation to several points referred to in the little book. To reply would consume more time than is available, but the fact that interest is excited and discussion is going on, is perhaps enough to ask or expect, and I feel gratified at the result."

We were fully aware of Mr. Cushing's intention in leaving some of the answers open to criticism; it was to stir up discussion and argument. The many letters we have received on the subject have shown an interest that we do not believe existed a year ago, and this is encouraging, men are thinking, they are trying to keep up with the procession. Mr. Cushing's book will be the forerunner of other and more elaborate ones, and thus little by little the standard of efficiency is raised.

A Difference.

When the English driver was over here giving the P. R. R. boys pointers on the compound, he told the writer, during a pleasant visit, about some of the differences met with here and there.

"You hengineers are thought more of 'ere than we har," said he, "now hi go up town with some of the lads an' they meets a lawyer, hor a doctor, hor han h'officer, han they says: ''Ow do do, Mr. Jones, 'Ow do do, Mr. Smith,' han-so-hon; now 'hover in the hold country, them fellows don't look at you, they says: 'The driver—'im to 'ell!'"

Elementary Lessons on First Principles.

Third Lesson.

In Fig. 1 will be found the commonest arrangement of hanging links on our locomotives. As the raising of the link slightly affects the position of the pin at top of hanger, forward and back, the best results would be obtained by making the tumbling shaft arm as long, at least, as the eccentric blade, but this is impractical. To prevent the raising and lowering of the link at each end of its stroke, the hanger should be long. In this form the arc a b, through which the lower end of the rocker arm and the link block travels, coincides considerably with the arc c d, through which the hanger carries the link; the difference between these two arcs is provided for by the link sliding up and down on the block, familiarly known as the

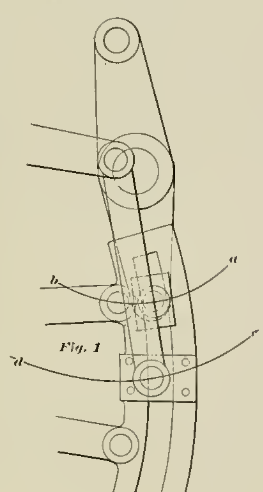
SLIP OF THE BLOCK.

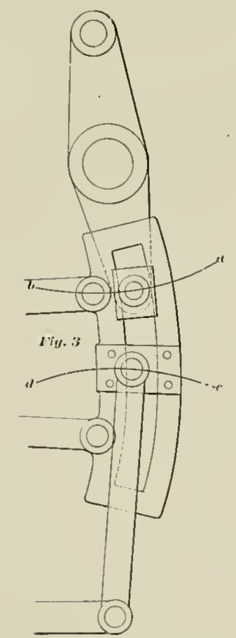
This was a great bugbear to early builders, and many devices were gotten up to avoid it, the best known device of this kind being the one used by Wm. Mason and other builders of his time.

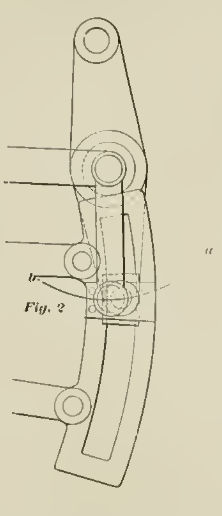
This is shown in Fig. 2. He suspended the link from

ABOVE THE CENTER,

and fixed the length of the hanger so that, when the engine was working in eight or ten inches the upper end of the hanger would stand on a line with the center of the rocker, and the suspension stud on the link would stand on a line with the link block, then the link and the lower end of rocker swing through the same arc, and the slip of the block was reduced to a minimum.







Lessons on First Principles

Of course, when the link is in full gear, or in backing, there is a difference in the slip, but it was reduced the most in the position most used. The object in reducing the slip was to prevent wear of the parts, but it was impossible to *entirely* prevent slip, as the angle of the link would cause some movement, and the consequence was that the links were worn more, all load coming upon a part of the link little larger than the die block, and a shoulder was soon worn.

Again it was found that locomotives with links hung in this manner were not so smart as those of the same style, but having the then common

UNDERHUNG LINK,

as in Fig. 3, and its value was a matter of considerable speculation and dispute among engineers and designers of a decade or two back. Old runners will, we believe, bear us out in the assertion that these engines with underhung links were really smarter than those with overhung links.

The cause is plain when we examine the arcs a b and c d, in Fig. 3. It will be seen that, when the link swings away from the center, carrying the block with it, that the two arcs leave one another, causing excessive slip. This was greater in full throw than when hooked up, as the centre of the link travels a shorter distance back and forth than the ends do. With this motion the valve was delayed at the ends, which kept the exhaust port full open longer, as well as the steam port on the other end. When the link approached its central position it was hurried in the same proportion that it had been delayed in its outward trip, thus giving a quick opening of the valve and closure of the exhaust.

About Russian Railroads

We received a very pleasant call last month from Mr. W. A. Abegg, a gentleman who has spent the past thirty years in Russia, and is now a large dealer in railway supplies at St. Petersburg. Mr. Abegg says that the railroads now being built in Finland are receiving the attention of the imperial government, and are well built and profitable lines. They use 65 pound rails and wooden sleepers. He says there is a good opportunity in that country for the establishment of locomotive works, there being but one in the country, with a capacity of but eight or ten a month. Just now the government stands in need of a large number of locomotives, but the excessively high duty prevents their being built abroad. A good 35 ton engine is worth there about 22,000 rubles, or 11,000 dollars. Iron is plenty and cheap, and coal is worth about three and a half dollars per ton. America can produce locomotives and other machinery at about half the price that Russia can, and Russia can produce any quantity of raw material at about half what America can—there is more crude oil running to waste upon the ground every day in Russia than is produced in these United States—what a nice little dicker it would be, all around, if we could trade—if it wasn't for the fence.

Car Heating.

The harvest time of the car heater men is at hand. There are now over fifty "systems," all having their own peculiar advantages, and—dare we say it?—"disadvantages." Most any of the systems are all right on five or six cars; it is the fifteen and eighteen car trains that make the sweetness—and the heat—long drawn out, and exceedingly chilly. The direct steam heats up quicker, but the hot water holds the heat longer when the engine is detached. And most any of them are cold enough when the engine dies in a snow bank.

Taking everything as it stands now, there is little doubt that the hot-water rig is the best. All will have to make some provision to keep up the heat by fires after the locomotive is cold in death—a sort of an emergency clause.

The greatest problem is to get a universal coupler that all can use, so that the interchange of cars will not kill off the heating arrangements.

LOCOMOTIVE ENGINEER. DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN LOCOMOTIVE MAINTENANCE AND REPAIRS

NEW YORK, DECEMBER, 1889.

CONTENTS.

Our Birthday.

With this issue THE LOCOMOTIVE ENGINEER completes its second year. What it has done we leave to the individual reader to judge for himself, for, after all, it is what good a paper does to individual subscribers that determines its value. Judging from the letters received on the subject, we feel very well pleased with the results so far. The circulation has gone steadily forward from the first, and is now ten thousand copies.

Manufacturing concerns have patronized the advertising columns liberally, and found, as we contended they would from the first, that what was of interest to the men in the ranks was of interest to the officials over them, and that all had a certain amount of influence in the purchase and use of tools and supplies.

We are indebted to many friends for the raising of large clubs, a considerable number of which had more than a hundred names.

The paper may now be said to be fairly on its feet. The avenues of information have been paved and improved, and connections and acquaintances formed that make the road, if not easier, at least surer for the future. We are going to try to make a better paper next year, than we have this, and, with your help, we are sure we can.

Compression—Its Advantages and Disadvantages.

There have always been those who have contended that the ordinary Stephenson link motion, such as applied to locomotives, was a wasteful device, and much inferior to other forms of valve gear; yet it seems to fill the requirements of the service very well, its popularity, it has always been maintained, has been because of its simplicity as a reversing gear.

A writer in the *Railroad Gazette* has recently been pointing out its shortcomings, on account of the high compression at fast speeds, claiming that some form of gear that would reduce the compression would be a great advantage—producing a card of greater area.

The advantages would not be all on one side in this case. In locomotive practice long ports and large clearance spaces are necessary for high speeds, in a valve motion that held the exhaust open until the piston had completed its stroke, the loss in steam necessary to fill the clearance space and port would be great; the cooling of the walls of the cylinder and ports would call for the expenditure of more live steam to re-heat them, and the time it took to fill the clearance space with steam would materially reduce the mean effective pressure.

With a compression great enough to fill the clearance space with a pressure nearly, if not quite, as great as the initial pressure, there is a saving of the amount of steam that it would take to fill the clearance, the time it would take to fill it, and an important saving in heat in the walls of the cylinder and ports.

Locomotives need their large cylinders to start their trains, not to pull them when once under way, and it would, no doubt, result in a saving if smaller cylinders were available to use when once under way, and the link motion does, in effect, make smaller cylinders of the ones we have, by taking back in the shape of compression some of the work put into them. Compression is necessary to smooth running at high speeds; were it not for the pressure that commences to gradually check the momentum of the piston and its attachments, and increases until that momentum is stopped, no locomotive would run cool at high speeds, and broken pins would be a frequent occurrence. The momentum of the piston and other parts depend upon their own weight and the speed at which they are moving, "*increasing directly as the square of the speed;*" therefore, compression should increase, being greatest for the fastest speed. As the link motion is hooked up the port is closed earlier, and compression is increased—just exactly what the condition of things calls for.

Were there no compression an earlier cut-off would be necessary, and an earlier cut-off would be ruinous, on account of the condensation. Careful experiments that are now accepted by the engineering world as correct have proven this, and shown that, with a cut-off of but five per cent. of the stroke, the consumption of water due to cylinder condensation was 42 per cent. of the total water used, and with a cut-off at 50 per cent. of the stroke, or half stroke, the loss by condensation was but 14 per cent.

Sir Daniel Gooch.

There has recently died in England a man who has not only seen a revolution in the railway and telegraph business, but himself contributed largely to the successes obtained by them.

Mr. Gooch was born in 1816, his brother and cousin were the first apprentices of the elder Stephenson, and he knew him intimately, he served his time in an iron works in Wales, and then went into the Vulcan Foundry, Robert Stevenson's new locomotive works, two years later he helped start a locomotive works, but it failed.

At the early age of 21 years he was appointed locomotive superintendent of the Great Western Railroad, the 7-foot gauge, a position he held for twenty-seven years. He here invented the fixed link, since called the Gooch link, this link was hung to the frame, the block and valve rod being moved through the slot by the reversing gear. This device is yet much used in Europe, but comparatively unknown in America. Mr. Gooch was chairman of the Great Eastern Steamship Company, and attempted to lay the Atlantic cable after the first project had failed; his first attempt, with the Great Eastern in 1865, was made under his personal supervision, and 4,000 tons of cable were laid—and lost. The next year he sailed on the same great ship, and on the 27th of July, 1866, sent the following message to Lord Stanley:

"Mr. Gooch has the pleasure to inform Lord Stanley that the Newfoundland shore end of the Atlantic cable was laid to-day, and the most perfect communication established between England and America. God grant it may be a lasting source of benefit to our country."

For this service he was made a baronet.

He next took charge of the almost bankrupt Great Western, as chairman, and raised its stock from 38 cents to par, in twenty-three years he doubled its length, its earnings, and its mileage.

Mr. Gooch was the first chief officer of an English railroad that gave to the employes the right of access to the board of directors, the humblest boy in the service could present his grievance, and tell his story at the head office, before judgment was passed in his case.

Sir Daniel Gooch passed away from earth just as the hammers of the wreckers tore asunder the last timbers of the Great Eastern upon the beach of his native land. Like her, he was a humble but important means to a great end, and like her his history should be known and remembered by those who stand upon the foundations he helped to lay, and enjoy the privileges and advantages he helped to establish.

An Elevated Breakdown.

The daily papers of this city have so persistently croaked on the subject of what is going to happen on the elevated roads, that some of them actually believe that something is going to happen, and they never let a chance slip to magnify every little thing.

One morning last month an engine on the Ninth Avenue line, broke a piston and blew out a head on the high part of the line, near 110th street, and the blood-curdling accounts of the "accident" were dished up in almost all the papers. From actual experience on the road, the writer knows that this accident, under ordinary circumstances, means considerable delay, and took a notion to find out exactly how much delay occurred in this case. The accident happened in the busy rush of the morning down trains, when they are running about two minutes apart, the following are the actual facts:

The engine behind left her own train and shoved the cripple into the center track, this took three minutes, the engine then began to push the train ahead of it, arriving at the next station only five minutes late. As fast as one train stopped behind another, the engine was cut off, and the train ahead pushed until a station where a relay engine is kept was reached; this engine got onto the main line and coupled onto the train, and the one behind cut off and took her place at the head of her own train as quick as it stopped. In this way the trains were kept moving, and the latest one at South Ferry, the end of the line, was eight minutes, and all on their own trains except the cripple. No attempt was made to disconnect the cripple; she was taken to the shop by another engine.

Of course this could not be done on a trunk line road, but it goes to show that the management of the "L" roads have the thing down fine enough to keep their passengers on the move, when other roads would have them waiting.

Running 3,500 trains a day, on 32½ miles of road, for hours at a time only one minute and five seconds apart, stopping every five blocks, averaging fifteen miles per hour, and carrying between five and six hundred thousand passengers daily, is no fool job.

Two Good Men to the Front.

On November 1st J. E. Phelan was appointed superintendent of the Missouri division of the Northern Pacific road, with headquarters at Dickinson, North Dakota.

We are not going to waste any taffy on J. E.—he is getting there first-rate; we dislike to see men trained in the motive power department get switched off upon the transportation siding; but the transportation pays best, and, after all, will be better in the hands of a man that knows all about the details himself.

On leaving Mandan, where they have been for less than a year, Mr. and Mrs. Phelan were tendered a banquet by the railway employes, which goes to show the kindly feeling all around, and will, no doubt, always be a bright spot in the memory of those who participated.

T. W. Macfarlane, who has been general foreman of the Mandan shops under Mr. Phelan, takes his place as master mechanic, a well-deserved promotion. Mr. Macfarlane is a thorough mechanic, a reading, thinking man, and will be heard from, from this out.

The Embargo Raised.

At last the engineers have raised the embargo, and will take in members of the Firemen's Brotherhood without obliging them to withdraw from their order. THE LOCOMOTIVE ENGINEER feels as though all the talk it has made in the past two years had done some good in this field, and as the law was repealed on a reconsideration, and by a bare majority, all the helps were worth something. It was a disgrace to the B. of L. E. as long as it stood on the pages of the by-laws of the order, because it was unjust. The demands of the more progressive delegates must have been yielded with a bad grace, as no sooner was the anti-fireman law repealed, when another was made, obliging new members to take out an insurance policy in the Engineers', this, in itself, is a good thing, and should have been done a long time ago for the benefit of the engineers' insurance, but the obvious object was to make the new men drop the fireman's insurance in order to keep up the other. But when a man, or a body of men, does a good thing or undoes a bad one, it is unfair to question the motives, and we don't. The 26th Annual Convention of the B. of L. E. did themselves proud in repealing a law that did them honor in the breach rather than in the observance, and they are to be complimented therefor.

Monument to A. J. Stevens.

We note in an account in the daily papers of the raising of funds by popular subscription, for a monument to the late A. J. Stevens, who was for years Superintendent of M. P. on the Southern Pacific Railroad, that the statement is made that this will be the first monument ever erected in this way to the memory of a workingman. This is a mistake; in 1887, David Shaw, an engineer on the Denver & Rio Grande, was killed in the discharge of his duty, and a very handsome monument was erected by popular subscription, no small part of which was given by the passengers on the train that was saved by his last act.

The fireman on a train that was taking the delegates of the engineers' convention on an excursion, a couple of years ago, was killed, and the engineers of the country raised a handsome monument over him. No doubt there are a good many other similar instances that are only remembered locally. The monument in California is probably the first one raised in that way to a man occupying the position that A. J. Stevens did, but the cases we have cited show that there have been other workingmen remembered.

ASKED & ANSWERED

(52) Ignoramus, Lawrence, Mass., asks:

What governs the adhesion of a locomotive driving wheel on the rail? A.—The weight that is pressing the wheel upon the rail.

(53) W. T. H., Galion, O., asks:

How many passenger trains does the Manhattan Elevated roads run in 24 hours? A.—About 3,500. During the busy hours night and morning, the trains are but one minute and five seconds apart.

(54) Fireman, Denver, Col., asks:

Is it possible, with the present triple valve used on the Westinghouse air-brake, to set the brake, hold it on, and at the same time re-charge the auxiliary drum? A.—No. What controls the movement of the triple valve? A.—The pressure in the train pipe.

(55) Subscriber, Spokane Falls, Wash. T., writes:

We have trouble with our extension front ends scaling the paint, can you recommend some compound that will stand the heat, and not scale off? A.—Where the fronts burn off at the bottom and not the top, it is evidence that the cinders collected there are getting air and burning, this should be looked into first. Boiled oil and lampblack are the commonest kind of blacking used, put on with a sponge; it is almost too thin to scale. For a prepared paint to stand heat, probably the boiler front and smoke-stack paint made by the Jos. Dixon, Crucible Co., of Jersey City, N. J., is as good as the best.

(56) M. M., Pittsburgh, Pa., asks:

What is saturated steam? A.—Steam generated in free contact with water, where the steam could not be increased in temperature without heating the water, or cooled without cooling the water. If steam is in contact with water, and we know its temperature, we can tell its pressure, or if we know its pressure, we can tell its temperature. If we can evaporate all the steam in a boiler, or isolate a portion of the steam, and then heat it to a higher temperature, its pressure and temperature can be increased without increasing its density or its weight. It is then called superheated steam, and by some authorities, gaseous steam. In superheated steam you can increase its elasticity without evaporating more water; with saturated steam you can not. Steam generated in a locomotive boiler is always saturated steam.

(57) K. & W. R'y Employe, Centerville, Iowa, writes:

A short time ago I heard an argument between the roundhouse foreman and an engineer. The engineer had reported his "piston packing" examined, and, the engine not having metallic packing in her stuffing-boxes, the round house foreman took the cylinder packing out. When the engineer came around he said that he thought his report right and that the piston rod packing should have been looked at. Now the foreman claimed that it should have read "cylinder packing" in the report, and there was quite an argument over it. Now for my benefit, and also for students here and elsewhere, I want you to give us your opinion of this case. A.—Broadly speaking, "piston" should include both head and rod, to distinguish it from either the head or rod. It is customary to use both the terms "piston packing" and "cylinder packing" to designate the packing on the piston head, and, while either may do, we believe that "cylinder packing" is the best, as it would leave no room for doubt or argument.

Obituary—Albert B. Ropes.

A. B. Ropes, Engineer of Tests for Southern Pacific Company, died at Sacramento, Cal., Oct. 8th, 1889, aged 27 years.

His active life was devoted to the advancement of principles advocated by THE LOCOMOTIVE ENGINEER, and a more fitting place for a tribute to his memory cannot be found.

Born in Orange, New Jersey, July 7th, 1862, he advanced in life and education, and entered Stevens Polytechnic Institute, of Hoboken, when in his 17th year. He graduated from Stevens Institute in 1883.

After graduating he came West, and entered the employ of Northern Pacific Railroad Co., in machinery department, directed by G. W. Cushing.

Albert first located at Brainerd, Minn., and was employed in the drawing office under management of H. J. Small, Assistant Superintendent of Machinery.

Seeking practical knowledge at all times, he left the drawing office and donned his overalls for practical service in machine shop soon after arrival at Brainerd.

His pronounced ability was soon recognized by his superiors, and he was not allowed to remain in the shop.

Seeking further practical knowledge, he was given position as locomotive fireman in freight service on Minnesota division, and worked successfully at such duties for six months, when he was returned to the drawing office, when of his own option he would have remained on the road.

Albert Ropes may have been considered a boy by many, but to those who knew him best he displayed the wisdom of a seer and the judgment of a philosopher.

He was remarkably bright in knowledge of mechanical principles, and particularly efficient in mathematics.

His knowledge of natural law and conditions was faithful to truth and correct announcement.

Coming West fresh from the East, and a graduate from an institute, it was natural that he should be the object of critical observation and remark, that often begets prejudice and enmity.

Yet Albert Ropes advanced through this experience, at all times knowing his own business and attending to it strictly, without reason for adverse judgment.

Returning to drawing office from position as fireman, he soon branched out into an active field on the road in conducting indicator and fuel tests, coupled with other duties assigned to him by the management.

Albert Ropes possessed one remarkable trait of character that endeared him to all his associates. Personally he was always seeking practical information, but his generous, broad and kind nature was ever willing to return golden information tenfold for that which he received.

He would take especial pains to inculcate the principles thoroughly known to him into the minds of associates seeking knowledge.

Kind and obliging, and at all times accommodating, he made friends on the line of the Northwestern Pacific who sincerely mourn his loss.

His death removes a bright star from the path of his associates, who gained pleasure and profit in daily life from association with him.

G. W. Cushing and H. J. Small having severed connection with the Northern Pacific, and assumed charge of the motive power department of the Philadelphia & Reading Railroad, Albert Ropes was offered and accepted position of engineer of tests for the Philadelphia & Reading Railroad under Mr. Cushing, and entered this new field of labor in July, 1887.

Several months later, H. J. Small taking charge of machinery department for Southern Pacific Co., Albert Ropes was made engineer of tests for same company, with headquarters at Sacramento, Cal., where he remained in active service until death removed him from earthly care.

A natural organizer, with knowledge of the requirements of this progressive age, and ever active in simplifying scientific facts and formulæ, so that such knowledge could be easily comprehended by the average practical mind, the loss of this bright mind from the mechanical field can best be appreciated and mourned by his immediate associates.

For one I sorrowfully pay tribute to his memory, and feel that I but voice the sentiments of all his associates in doing so. J. E. PHELAN.

A first-class fireman or engineer seldom has to go around defending his ability, his associates and his superior officers generally know about his real value. A gentleman does not have to announce himself as such in every gathering; people know it by what he does and says. A firm resolve, fairly lived up to, to be a man and treat all as you want all to treat you, will generally give a man a standing on a road or in a shop, without any other effort.

Denver & Rio Grande—Pueblo & Salida Shops.

(Editorial Correspondence)

Pueblo was the point originally designed for the general shops of the Rio Grande, and a start was made early in the 80s in the erection of a thirty two stall roundhouse, one of the best ones in the western country; but a city council, who were thoroughly impressed with the idea that railroads are grasping monopolies, and must be sat upon, delayed the work until shops became necessary, and they were built elsewhere. Four stalls of the new roundhouse were partitioned off, an engine and boiler put in, four or five lathes, a couple of drill presses, a shaper, bolt cutter and a few smaller tools set up, and, with these few facilities, eight or ten men have been keeping up the running repairs of upward of 50 locomotives in hard service, and rebuilt six to eight consolidation locomotives per year. The divisions south and west of Pueblo are under Master Mechanic Kelker, and this shop is under general foreman W. H. Hubbard, with Eli Tyler in the roundhouse.

Over the large lathe there is an

INGENIOUS CRANE

of home manufacture. The upright is a piece of 4" gas-pipe set on a step on the floor, back of the head-stock of the lathe; about 3 feet from the floor, there is bolted to the upright, one of the largest sized air-brake cylinders into the bottom of which there are tapped two three-quarter pipes, connected to the main through the medium of a common three-way cock; these pipes have two-foot lengths of hose under the cylinder, to allow of its being turned with the post. Above the cylinder the piston-rod is connected to the second joint of a lazy tongs containing four sections, or squares, the top section of which is pivoted to the arm of the crane, the arms of the tongs are made of iron, about a half-inch by three inches, the arm of the crane being about three-fourths by three or four inches, and six feet long, this arm is forked at the post, and carries a roller that supports it against the post, from the outer end there is a brace running up to the post with a roller behind it, this roller runs over a strip that is riveted to the post, this serves to make the whole device turn together with the post. In using the crane water is admitted to the cylinder by turning a small lever, placed about as high as the lathe-bed, and where it can be easily reached from either side of it. The lazy tongs multiply the lift about four to one of the piston travel; it moves steadily, will stand at any position, and lowers quickly; it is a very efficient device for one made almost entirely of such repairs or extras as are always on hand around every shop.

A WATER MOTOR

This shop is now supplied with air all about the shops and roundhouse, just as the other shops of the system are, but it was a long time after the air was in the other shops before it was introduced here, and in the interim, H. R. Jones, who was then general foreman, and who built the crane, was in need of power to drive the cylinder boring-bar and other tools, and he then built a water motor for this purpose, the base of this little motor is about two feet square, the water-wheel being a disk about ten inches in diameter, with buckets about the size of a penny; this wheel makes about 1,800 turns per minute with a three sixteenth jet of water, backed by a hydrant pressure of 60 pounds, this speed is belted and geared down to that required for the work in hand. Two men can carry the motor, it requires no attention, and has given about six years of service without repairs.

DEEP PITS

One thing that strikes the man used to standard gauge roads is the depth of the pits; they are about twice the depth usually found, which is easily explained by the narrow gauge locomotives, with only a 36-inch wheel, that have to be got under.

During my visit they were putting new flues in the stationary boiler, and the steam for the engine was being supplied by the boiler of a locomotive undergoing repairs. It was rather an unusual sight to see men boring out cylinders, putting up driving boxes, etc., while the boiler was being fired from an elevated staging.

In a place of so much importance, it is wonderful how the management here have kept up their running repairs with such poor facilities as they have here.

THE SALIDA SHOPS.

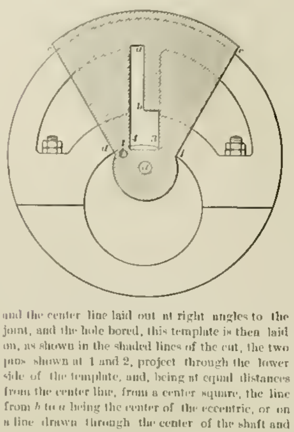
This shop is located 97 miles west of Pueblo, and at the foot of the great range; here the traveler goes north to Leadville and Aspen, and by another route west, over Marshall Pass, to Salt Lake and Ogden. At Salida there is a 16-stalled roundhouse under the care of Ben. De Remer, and a very neat shop under Owen Owen. Giving the size of a shop on the ground, does not in any way convey reliable information as to its capacity. This shop has three stalls, on which, in a pinch, 6 engines might be crowded; they rebuild about 30 locomotives a year. The stalls are in one end of the shop, and stand in the direction of its length. As the shops are new, the tools are new, and all of a pretty fair build. The shop has a disadvantage in standing north and south, the sun pouring in strong enough to make it necessary to put up shades.

The office building, which contains, beside the offices, a large storehouse and the blacksmith shop, stands parallel to the shop, and is nearly as large.

General Foreman Owen has taken great pains to preserve the original measurements of the engines, and has devised numerous jigs and templates to carry out this idea. All shoes and wedges are fitted up to templates, measurements made from the frame, and no liners allowed on new work.

LAYING OUT ECCENTRICS

In making new eccentrics the template shown in the engraving is used to insure uniform work, the pieces are planed at the joint and bolted together,



and the center line laid out at right angles to the joint, and the hole bored, this template is then laid on, as shown in the shaded lines of the cut, the two pins shown at 1 and 2, project through the lower side of the template, and, being at equal distances from the center line, from a center square, the line from *b* to *a* being the center of the eccentric, or on a line drawn through the center of the shaft and the center of the eccentric, then the lower opening at 3 and 4 are guides to scribe the keyway by, and the outsides of the template at *e f* and *c d* becomes guides to scribe the lines to drill the set-screw holes by. This plan secures uniformity of the work and precludes the possibility of mistakes in laying it out. Eccentrics are kept in stock, and it is a great convenience to be able to put on a new one without the usual delays in cutting the key way by hand after finding out where you want it by the cut-and-try plan.

PISTON-ROD REMOVED.

For removing piston-rods from the crosshead, they have a plug of steel just big enough to slip into the bore for the pin; through this, and at right angles to its length, there is a steel screw, about one inch in diameter, and long enough to reach from the end of the piston back of the crosshead far enough to take a wrench; this device is found all-sufficient in removing the most obstinate rod.

ROCKER-BOX JIG.

For boring out rocker-boxes, they have a frame to which the box is bolted in the same position it occupies on the engine, and which has provision to keep the bore of the box at right angles to the frame and in line across it. When this jig is placed on the carriage of a lathe and the boring-bar run through a pair of boxes there is a reasonable surety that their centers are the same distance from the frame in every direction as when they were new.

Great attention is paid to the case-hardening of link motion, and a new furnace for this work has just been erected in the blacksmith shop. This shop has modern closets, and a wash-room, where twenty basins are provided with hot and cold water. The entire plant is kept much cleaner than the average, Master Mechanic Jones taking special pride in a little plat of grass and a fountain in front of the office.

J. A. H.

Union Pacific—Omaha Shops.

(Editorial Correspondence)

With regard to my western trip over the U. P. and the Rio Grande roads, I am in about the same fix as the boy who attended the Centennial Exposition; said he "saw the whole business in two days—but that it would take him six months to remember it."

The Union Pacific is one of the monster roads of the country, and its history is as interesting as a novel.

The Union Pacific Railroad Company was chartered on the 1st of July, 1862, by the Congress of the United States, which granted to it the right of way over the public domain, 12,800 acres of the public lands per mile of road, and a subsidy in Government bonds, at the rate of $16,000, $32,000 and $48,000 per mile of line, the object being to apportion the subsidy in ratio to the cost of the several sections. The amount of the subsidy for 1,033 miles was $27,226,512. By the act of incorporation, the subsidy bonds were to be a first mortgage on the road. By a subsequent act, July 2, 1864, the company was allowed to issue an equal amount of its own bonds, which were to be a first lien on the road, the subsidy bonds being thereafter a second mortgage. For the repayment of the subsidy bonds the company was required to pay annually to the Government 5 per cent. of its net earnings, and to allow the former to retain one-half of the charges for transportation on its account. The time fixed for the opening of the road was July 1, 1876. It was opened May 10, 1869.

The Kansas Pacific also had a similar grant of land and subsidies from the Government. The system is now composed of over twenty distinct lines, containing in all 6,288.40 miles of road, and 414 miles of side tracks.

There are in use upwards of 800 locomotives—143 of which are narrow guage—and more than 16,000 cars.

This road earned in 1888 the neat little sum of $19,898,816.93, and expended $11,779,348 77.

For a system having so many locomotives the road is poorly provided with shops—there are plenty of them, but they are all more or less make-shifts, that have long since become too small for the work, or the work too large for them. All the shops on the line, especially the Union Pacific proper, have built locomotives in the past, that have added to the already complete assortment of locomotives from all American manufacturers, making the stock of repairs to be kept on hand twice what it should be, and making it necessary to make and keep in stock patterns enough to bankrupt a private concern of the same capital. It also produced a lot of fatherless and motherless locomotives, some good, some bad, and many indifferent.

THE WAY TO REBUILD.

George W. Cushing has recently become Supt. of Motive Power here, and has prescribed some heroic treatment that has already had good effect; he has condemned all engines, regardless of present condition, with a cylinder 16 inches or less in diameter. This will at once do away with making up small trains for small engines and reduce the percentage of operating expense—as the same crew, for the same money, will move more tons of freight if provided with engines of modern size. But the greatest gain will be in running repairs, cleaning up with one wipe, tons of castings and forgings now carried in stock, and allow about twenty cords of wood, now treasured as patterns, to be turned to use as kindling. The older and smaller of the condemned engines will be cut up, and those in good condition will be sold or given away. The nicest thing about this change is that

Mr. Cushing gets 47 new locomotives charged, as they should be, to repairs. The new locomotives are mostly consolidations, and are being built at Rome, N. Y.

The Omaha shops are located in the river bottom, were built a good many years ago, are not well arranged or adequate for the needs of the road, and it is not likely that they will ever be enlarged, as they are now building, at Cheyenne, the largest and finest railroad shops in the West; the Omaha shops will then become simply repair shops for a division, with special facilities for repairing cars—a duty they are well fitted for both in size and arrangement.

A FIXTURE.

John Wilson, Asst. Supt. M. P., is one of those men found about all railroad shops, who seem a part of the works, and not an unimportant part either. Mr. Wilson has been on the road some 15 years, and is thoroughly posted on the past, present and future of the shops, the locomotives, and the service. Mr Wilson dropped his work and devoted the day to showing me what they had, and I have no doubt thought me the most inquisitive individual he had met in many a day, that is the general impression I leave, anyway.

From the offices, in a large, two-story brick building, we stepped across a hall into

THE MUSEUM,

named in honor of the relics of every conceivable form that railroad material can get into by being in wrecks, through fires, floods, or long and honorable service. Here are the ends of an axle that has broken in service, here a piece of boiler plate that has broken in the testing department, a brass that has melted itself onto an axle, templates of worn tire, with their mileage noted thereon, pieces of plates and tubes pitted, seamed or burned, scale of all kinds, and a thousand and one things of this nature, all telling some story of experience, and each conveying a lesson. There is here a valve motion model, full size; it is of home build, adjustable every way, the radius of the link being provided for by changing a bar that represents the slot in a link.

Here are stored the painted panels of a car with a history—the car in which the body of Abraham Lincoln was transported from Washington, to lay in State at New York, Albany and other cities of the North, after the closing tragedy of the civil war.

Above the museum is the

DRAFTING-ROOM.

Here all the drawings are made for the road; they are numbered by the sheet, as well as the drawer where they are kept, certain classes of work being kept together; this makes the filing and finding of drawings easy, as all orders and correspondence about drawings refer to the numbers alone; the arrangements for photographing and blue printing are complete.

THE MACHINE SHOP

occupies two stories, part of the lighter tools being up-stairs; the heavy tools are middle-aged, but there are some new ones, a new 24" slotter being especially noticeable. The shop is only fairly well lighted. They lead, or rather babbitt line, truck brasses here, and then place them on a planer, and, at one cut, dress off the face of a whole row of them by using a tool something in the shape of a gouge. After an extended trial they have given up the use of driving boxes with brass bearing strips let into them, and gone back to the half shell bushing. Solid piston heads are used, and both the Richardson and the Morse balanced valves give good satisfaction. They are lengthening out their six-wheeled switchers, making a heavier and more effective engine of them. There was a large passenger locomotive coming out of the shop the day I was there; she had the new extension front, designed by Mr. Cushing, brick arch, steam jets to prevent smoke, and the U. P. standard solid rod. This rod has been in use some ten years, and has given excellent results; it is shown in Figs. 1, 2 and 3, the bushing *a* is forced in from the back, and held by four ⅞th bolts, it is then placed on the pin, which is made in the shape shown in Fig. 3; the retaining collar *b*, which is made in halves, is then placed on the bolts and into the groove in the pin, the cap *c* put in place and the whole bolted together; the bolts hold the bush from turning, keep the rod on the pin, and the whole incased in a sand-proof box. This does away with retaining collars, drilling the pin for keys or bolts, and admits of easy getting down where it is necessary to disconnect on the road; the covering of the collar must also be a good thing in a country where the sand blows, as it does on the plains.

They have on engines with draught pipes a very neat device for raising and lowering the petticoat without opening the front end; to the top of the pipe there is riveted two rods that come up each side of the stack through castings that carry set-screws; the top of the rods terminate in handles, such as used in the cab for the sand lever, by loosening the set-screws the pipe can be raised or lowered at will.

THE BOILER AND BLACKSMITH SHOPS

are much like the other parts of the shop, except that the boiler shop is very small and poorly provided with tools for the large amount of excellent work they turn out, there is, however, a new punch, shear and drill going in there.

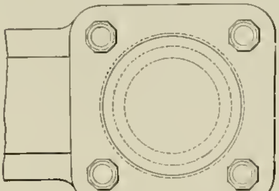


Fig. 1

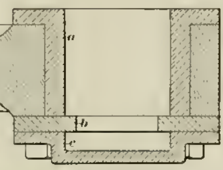

Fig. 2

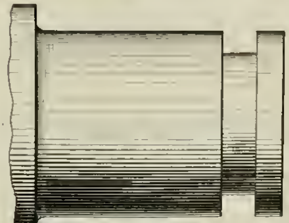

Fig. 3

U. P. Solid Rod.

TESTING DEPARTMENT

This is an important and interesting part of the shops; it is in a building by itself, under the charge of an experienced mechanic, and no doubt is a money saving institution. All material bought has a fixed test to stand before it is accepted. There are several machines to test metals for every service, machines for testing oils, gauge testers and pressure arrangements to test hose, pipe, flues, etc.; some materials are simply to be weighed, some to be measured, but all are tested. There is in this department a sample of all standard supplies, with the test on it—everything has to come up to the standard. Outside the building there are drop tests for car wheels and axles, and such material too heavy to handle in the house. As the purchasing of inferior supplies has always been a cause for complaint, it would seem as though a test department, in the hands of an honest man, was a pretty good investment.

THE CAR SHOPS

are the best and lightest shops in the plant, the machinery of fairly modern construction and in good condition. The shop was half full of fruit cars, or that class of express cars that are run over the road one way in freight, and the other in passenger trains. I believe the experience of all roads is the same in this matter—the repairs to draught gear is simply enormous. The cars have the Miller or the Miller-Cowell coupler to use in passenger service, and they are all right there, as the draw-head does the drawing, and the buffer does the pushing, but coupled into a freight train where the draw-bar does all the work and takes all the grief, they want to see the car repairer every trip. They are equipping a lot of stock cars with an ingenious arrangement, recently patented by Mr. Cushing, for feeding and watering stock, *en route*. The arrangement is not expensive and does not call for radical changes to adapt it to the cars in service.

All cars are being fitted with a new draw-bar stop, also of Mr. Cushing's design, that is much heavier and more effective than any older device, the two sides of the stop are tied together, and double springs take the shocks.

A KINK.

I noticed on an engine out on the road, a device for keeping crossheads on beam, or single bar guides, in line. When the guide is new, they plane a line on its side exactly in the center, this line they true up by a line through the cylinder; then when the crosshead is up and lined with the cylinder, they mark the side at each end fair with the mark on the guide. When the gibs wear, the position of the marks tell where the wear is, and how much, and in lining up it is not necessary to measure between the piston-rod and the guide at all; the scratch on the guide and the marks on the crosshead do not change by wear; the first simply indicates the true line of the cylinder, and the second the distance above the center of the piston-rod that the marks on the crosshead ought to run; this not only allows shop men to line up with more accuracy, but points out at once any blunder made.

TEACHERS

What is going on on this road in the way of educating the men, may be taken as an indication of what is being contemplated on most roads, if not already begun. There are employed here not only traveling engineers, but traveling firemen as well, the duties of the traveling fireman are to instruct new men, and look out for old ones, who are simply throwing coal at a hole, and waiting for their turn for promotion. A few pointers on the prevention of smoke, or correct pointers on correct methods of boiling water are often needed as well on the right as on the left side. Instruction books have been issued, books on the air brakes, on combustion and other kindred subjects, not so much with the idea that the book matter was to be learned like a catechism, but to get them men to think, to argue, and thus to post themselves.

I must say to the readers of the paper that it is never my purpose to give descriptions of shops visited, but to point out such practices, devices and modes of doing work as are different than the usual run, and likely to be instructive, as showing an improvement over, or inferiority to those systems of work with which you are familiar. J. A. H.

Mr. A. J. Allen, a locomotive engineer, lately employed as Inspector of the Nitrate Ry Co., at Iquique, Chili, S. A., has recently come to the United States to introduce a boiler compound invented by him, that has made a remarkable showing in the bad waters of the South American deserts. Mr. Allen has been some fifteen years on the different roads of South America and on the Isthmus of Panama.

The printers of the Engineers' Souvenir of the Denver Convention performed a wonderful feat in showing the pictures of two different men, and designating each as "Governor of Colorado." But the book is a daisy just the same.

The great storm in the Southwest was a grand opportunity for the patent snow plow people to give some illustrations of how their devices work. Every winter the snow king advances his standard a little further South.

Consolidated Shops of the Union Pacific at Denver

The Union Pacific road has acquired, by purchase and otherwise, several lines of road besides its own, that center in Denver—the Denver Pacific, Kansas Pacific, Colorado Central, and the Denver, South Park & Pacific; all of these had shops of their own, so that the consolidated roads have had to maintain shops at all the points of the compass around the city as well as in the middle.

It has now been decided to abandon all the little shops and do the work in one good one; ground has been secured on the site of the old Colorado Iron Works, and the new shops will be commenced at once.

This shop was designed by Geo. W. Cushing, Supt. M. P., and is as convenient an arrangement for an ordinary shop as we can call to mind. The main shop will contain ten stalls, the car shop twelve; the location of the material yards is good, and the plan for getting incoming and outgoing engines around one another is excellent. The ash-pit is arranged to hold cinder cars on a track depressed below the level of the yard, and has a cleaning pit under the tracks each side of it; the supplies of coal, sand and water are convenient to the incoming tracks, while the oil-house is isolated from the other buildings, and is still convenient to the roundhouse, the incoming and the outgoing tracks.

The transfer table tracks are long enough to deliver engines or cars to all the shops, and the scrap heap is limited to one, located in the center, convenient to all the shops. A fifty-foot turn-table will serve the fifty stalls of the immense round-house.

This consolidation of the shops will enable the management of the motive power department to get along with a smaller stock of repairs, and will release to more desirable uses ground now encumbered with poor shops in a very desirable part of the city.

The sizes being given on the plan, the general arrangement can be thoroughly understood from it.

A Careful Engineer.

For quite a distance going into Leadville, Col., the tracks of the D. & R. G., narrow gauge, and the Midland, standard gauge, are side and side, and the boys have a tilt on speed once in a while, the little narrow gauge fellows being surprising climbers on a heavy grade. The boys tell a story on Bill Kreitly, that is not bad; he was running a losing race with a Rio Grande train, and just as they passed him Bill said to the fireman, "Shut your dampers," after they were by the boy was instructed to open them. "What did ye do that for?" asked the smoke shoveler. "To keep from suckin' 'em into the ash-pan," said Bill.

The activity in the steam snow shovel business seems to be all on paper—there are very few actually building.

Simple Lessons in Drawing for the Shop.

By ORVILLE H. REYNOLDS.

SECOND PAPER.

Assuming the drawing-board to be ready, we will discuss the method of handling the instruments which were recommended in a former paper.

Place on the drawing-board a piece of manila paper, 18"x28", and secure it to the board by three drawing-pins at each upper and lower edge, being careful to have it smooth and drawn as tight as possible.

Lay the T square on the board with the head at the left side, placing the left hand on square head with four fingers on the underside, the thumb resting gently but firmly on the blade; in this way the square can be pushed from or drawn toward the operator with ease, leaving the right hand free to handle the pencil, which should be held between the thumb and two first fingers (as in writing) in a nearly vertical position, the top inclining slightly to the right.

There are differences of opinion among draftsmen as to the proper shape of the pencil point, some favoring a chisel point, others preferring a round point, the writer uses the round point for the reason that dimensions can be set off with such a point with greater facility than with the other, although the chisel point will stand fatigue somewhat the best.

Place the pencil lead against the square blade at its junction with the head, and pressing softly to the blade and lightly on the paper, draw the first line the whole length of the paper, keeping the pencil, from start to finish, in as near the same vertical plane as possible, for the reason that, if the top of pencil moves to or from you while drawing the line, the point will also move to or from you in a lesser degree, but still enough to make the line untrue.

After drawing the line, move the T square toward you slightly, and then return it to the position occupied while drawing the line, if the line shows equally plain and is of the same width the whole length, it may be pronounced good; a light line only is permissible.

Draw several lines near and parallel to this, and compare them for truth; this will be a good test, and, if not found satisfactory, can be rubbed out and another trial made. This is why it was remarked above that light lines were the proper thing, for, if the pencil is forced into the paper, the line may come out for the rubber, but the pencil will have left its mark in the form of a crease, more or less deep, which will not come out.

The matter of handling the pencil with a gentle touch is emphasized, because the writer has a faint conception of the difficulties involved above for the beginner, who has done a hard day's work in the shop. Perseverance in this direction will bring happy results, the most important of which is the smooth and artistic appearance of the drawing when completed. Persistent rubbing with the pencil eraser destroys the surface of the paper, and gives the drawing a shabby appearance, no matter how nicely it may be otherwise finished.

To draw vertical lines, or lines perpendicular to those already made, leave the T square in the same position as before, and place the 30°x60° triangle on the paper, bringing the base or short leg against the T square with the 90° side at the left. Now adjust the square truly against the edge of the drawing-board, and slide the left hand along the blade to the right, until the triangle is reached, leaving the thumb on the blade, and applying the fingers to top of triangle, pressing it firmly to the paper, and at the same time making a true contact with the T square blade.

The pencil should be held in all cases as described, and, beginning at the bottom of the triangle, draw towards the top, making a line in all respects like those made horizontally.

Some practice will be required to handle the square and triangle at one time, but this is only another case where practice will make perfect.

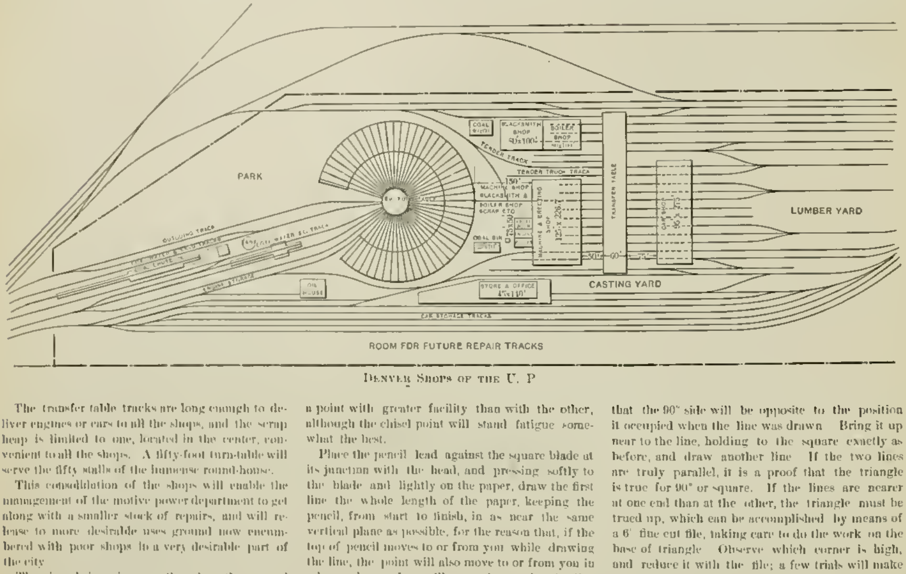
In order to test the perpendicular lines, to know if they are truly perpendicular or "square" with the horizontal lines, move the triangle to a clean place on the paper, and, placing it in position as before, draw a line, and then turn the triangle so that the 90° side will be opposite to the position it occupied when the line was drawn. Bring it up near to the line, holding to the square exactly as before, and draw another line. If the two lines are truly parallel, it is a proof that the triangle is true for 90° or square. If the lines are nearer at one end than at the other, the triangle must be trued up, which can be accomplished by means of a 6" fine cut file, taking care to do the work on the base of triangle. Observe which corner is high, and reduce it with the file; a few trials will make it true.

To test the 30°x60° side, or hypothenuse, make a circle with about an 8" radius, and, with the dividers set to the radius, step off six points on the circle. If the work is carefully done, the dividers go around the circle exactly six times.

Two of these divisions are all that are needed, but, to insure accuracy, step off all the points and draw from two of the points to the center, making an angle of 60°; placing the triangle between the lines so found, its truth, or want of it, is at once shown. If the 60° angle shows correct, no trouble will be experienced with the 30° side; if not right, make it so by the process explained above.

The 90° sides of 45°x90° triangle should be tested by the same method as given for the square sides of the 30°x60° triangle.

To test the 45° side, make a circle of same size as before, and step off eight points; drawing from two of these points to the center, we have a 45° angle. Placing the triangle between the lines, its



DENVER SHOPS OF THE U. P.

truth will also be demonstrated. If found untrue, apply the remedy as before.

The fact that these triangles are bought don't prove that they are true, and, on the principle that they can't be too good for accurate work, see to it that they are all they should be at the outset.

And this is not all; they should be watched, so as to detect any symptoms of change after having been trued up. They are quite human in the respect of going into devious ways when surveillance ceases.

When necessary to draw parallel lines at any angle to the lines drawn by the T square, the triangles will be found to do the work nicely.

Draw first line of required angle, and place the long side of one triangle against the line, then place the second triangle against the first, holding the second rigidly to the paper by the thumb and little finger of the left hand, and the first by the remaining fingers. After drawing a line relax the pressure of the fingers on first triangle, and slide it down the edge of its mate, far enough to make the next line, keeping the edges of the triangles in contact, and being careful not to force them together hard enough to move the second triangle from the position first taken. When angles 30°, 45° or 60° are to be taken, of course the triangles will be used against the T square instead of as above.

As progress is made, the combinations which can be formed with the triangles will readily present themselves to the student.

The dividers, having the pencil leg and needle point adjusted, should be held in a vertical position by the right hand, the thumb and two first fingers taking the instrument at the top, lightly, yet with a grip sure and steady. The legs should be parallel one to the other, from the first joint down, allowing the needle point to gently pierce the paper in a true perpendicular line. If the needle is not square with the paper, the effect is shown by an unsightly hole in the paper for the point to work in, which is an objectionable feature for two reasons: First, the pencil point will not travel in the same path twice. Second, the artistic appearance is injured.

The pencil should be sharpened to a chisel point in this case, because that kind of a point will stand up to its work better than a conical point, when used in a divider.

The pencil should be pressed to the paper just enough to make a clean, fine line, and no more. Once over the path is sufficient if the line is visible and true.

The foregoing remarks apply to the manipulation of the pencils only. The pens will be considered in their proper place.

Humorous and Otherwise.

The young man who is "doing" the European railways for the *Railroad Gazette* is evidently a novice in the railroad business, and a perusal of his notes are almost as good as *Puck*, for a railroader. Those awful printers will make bulls occasionally, but they can hardly be blamed for so many in one issue. He tells of a ride on a German compound, in which all the stock expressions of the young reporter who has just completed his first locomotive ride are used. "The glare of the fire blinds him," in Germany—just like at home. "Rushing along over a strange country without a headlight is exciting"—heard that before. "The steam-gauge is small and registers differences in pressure of about ten pounds—it is graduated in atmospheres"—wonder where the Germans got all that light air? always thought the atmosphere weighed over 14 pounds per square inch. But the most remarkable things are the springs. Listen. "The springs upon which the compound locomotive are mounted are *flexible*, and the engines may be termed easy riding"—wonders will never cease. Listen to him fix out that Dutch stoker.

"The fires burn brightly under the long, slow discharges of steam from the low-pressure cylinder, and there is little smoke *when the furnace is fired properly*. However, in Germany, with all their principles of economy, there exists the same fault that is common in the United States with regard to firing locomotives. There, as in many cases here, the locomotives are run without brick arches, and the coal is shoveled in with as little apparent purpose or mental exercise as would be used if the object was merely to get rid of the coal. Occasionally the fireman stirs up the fire with a long poker, but at other times he devotes his attention to experimenting with the injector, and shoveling coal in a hap-hazard manner into the fire-box and closing the door immediately, thus causing the black smoke to roll in huge volumes from the top of the stack."

That fellow ought to come home; or, if he prefers it, to try a trip at firing there; it is so much different to fire a locomotive theoretically right—with the lip—than to fire them for steam—with a shovel, that he will just simply be surprised.

For the lucid explanation of the English milling machines that are "guided by taper formers," and the driving-wheel that is but "7½ *inches*" outside diameter, we forgive him, and lay it to the printers; but that glare of the fire and those flexible springs are all his.

Perhaps the same young man wrote that description of the New Haven engines in the Nov. 8 issue—they are wonderful machines. The axle journals are 7 inches in diameter and 8 *feet* long—they won't run hot. Slide valves with ⅞ of a *foot* outside lap are hummers, if the rest of the mill is in the proper proportion—may be this is the engine the boys tell about that had a three months lead. The engines are too light on the drivers, in fact lighter than any other engines of their size in the country, but, "In any case, it is evident that the steam used in such cylinders as these, with so little weight upon the drivers, will be well expanded, and if there is any advantage in using greater expansion in locomotive engines without compounding, than that which is commonly used, such advantage ought to become evident from the results of actual service with these locomotives."

What is the matter with taking the drivers out from under the engine altogether, and expanding the steam right down from a hundred and enough to Revelations? We anxiously await a reasonable explanation of how the above law was arrived at.

Speech of General Manager Meeks to the Engineers.

The following speech, by General Manager C. F. Meeks, of the D. T. & G. Railway, to the engineers at the opening of the Twenty-sixth Annual Convention in Denver, contains much that is good and worthy of the attention of every railroad man:

The subject with which I wish briefly to engage your attention relates to conditions, present and prospective in part of railroad transportation, and the importance of the locomotive engineer as a factor in fixing certain standards which must govern in the practical groundwork. We have to-day in the United States about 155,000 miles of railroad which has been built rapidly, and which has in a few years distributed the growing population, so that the country has been settled throughout with an industrious and thriving people, bent upon outdoing their neighbors, and each community ambitious to become a business and jobbing center. Roads have been built in all directions; some of them by the longest possible route between two given points; often with more zeal than foresight, several too many have been built between the same points, all competing for every pound of freight that offers for shipment. The line having the longer distance cannot compete with the short line in quickness of time and service, so that other methods of controlling the business by the long line are resorted to, which the short and direct road resents. Rate wars and competition follow, which can only result disastrously to both. The effect of this strife often involves the rail system of a large section of the country. Associations are formed for the purpose of settling these difficulties by mutual agreement instead of by rate wars, but these associations are founded upon the principle of good faith, and the faith is so often broken that the entire structures are kept in a weak and tottering condition, and answer but partially the purpose of conservative action, the tendency of the times is to reduce the compensation of public carriers to the lowest possible point, without regard to consequences. Congress and State legislatures have been taking a hand until a condition of almost endless complication and increasing hardship has befallen these enterprises. The trouble is organic, and can only be relieved by the work of time and intelligent comprehension of the situation by the people; meantime, the roads are put to the necessity of most rigid economy.

The expense of operating railroads and meeting their obligations must come within the bounds of their income, else the most skillful manager cannot keep clear the shoals of bankruptcy. The locomotive engineer must bear his part of the burden. He must establish the highest standard of efficiency at the lowest expense; he must haul more tonnage with less fuel and other supplies; and he must, by careful work, reduce the destruction of life and property to the lowest minimum.

The time has come when, under existing conditions, it is necessary for every man in the employ of railroads to give his cordial and intelligent support to the work of maintaining a safe degree of service. If the thousands of men now engaged in the operation of railroads would save to themselves the high rate of compensation, as compared with that received by men in other pursuits, they must justify it by the results of their work. A large share of this falls upon the locomotive engineer, and it needs no word from me to suggest to engineers the wisdom of joining hands with the owners and managers of railroad property, for the conservation of their mutual interests and the continuance of the present status of compensation.

Your brotherhood, embracing as it does a large majority of the locomotive engineers of the United States and Canada, is charged henceforth with a grave responsibility. Aside from the benefits and the good fellowship of the organization, there must be a united and systematic effort to establish the highest standard of mechanical skill. The engineer of the future must be not only a man of iron nerve, but a man of the highest intelligence, good judgment, and good faith, and I believe that this brotherhood can do more than all else in aiding locomotive engineers to reach the acme of efficient and economic service.

This is the great work before you, and I hope this convention will inaugurate a systematic co-operation with owners and managers of railroad property to the end that, in the face of all adversities, the locomotive engineer may still continue, as he should, to lead the mechanical world in the rate of his compensation.

You are called upon to share your part in the work of a great people adjusting themselves to rapidly changing conditions, created by unprecedented progress, for which the institutions, of which you gentlemen form a most important part, are in the main responsible. It has all been done in a few brief years, and the people have not yet had time to get down to a solid working basis.

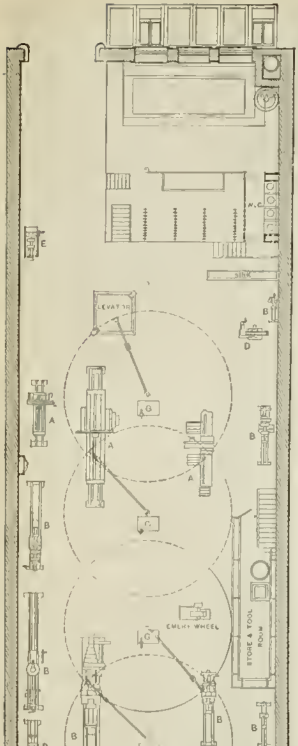
All the ages of man had achieved nothing compared to what has been wrought in the fifty four years since George Stephenson built the little road from Stockton to Darlington. In this brief time the child of that great man's brain has conquered and civilized worlds, has extinguished the savage and reclaimed the desert, has wedded the seas and given to the people of the nineteenth century the distinction of having been the first to discover the true motor of civilization, and the first to enjoy the real luxuries of prosperous lives.

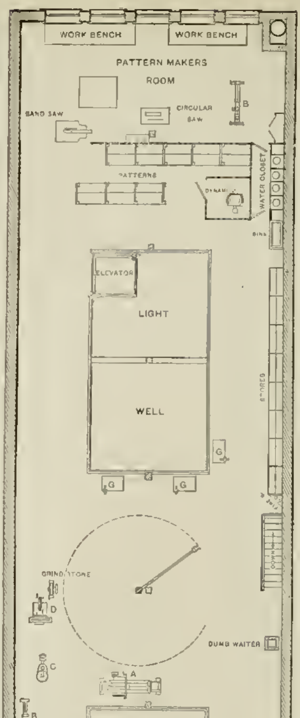
While we are striving to adjust ourselves to those conditions of prosperity, and congratulating ourselves that, in a span of fifty years, we have outstripped all the past, let us not forget to honor the name of George Stephenson, whose spirit sits on the right hand of every locomotive that runs.

Now, I want to say a few words in regard to your brotherhood, and the men who compose its membership. I regard your organization as one of the broadest, the strongest and best with which this, or any country, is honored. You have been conservative, discreet and far sighted, and have achieved splendid results for your individual membership. I have a very great affection for the engineer, and a great admiration for his courage, his nerve, and the good judgment he must exercise to brave the dangers of the rail. Soldiers facing the enemy's guns on the field of battle do not show half the courage the engineer is called upon to have in the discharge of his duty.

And what of your great chieftain? No word from me can add a tithe to his honor. His genius, his qualities of mind, his great abilities, entitle him to a place among the great statesmen of his time. For fifteen years he has led your brotherhood, and led you safely through every difficulty. No general ever led an army to victory with more valor, more courage, more discretion, than your great chief has led you to victory after victory in the long time which he has served you, and with such broad policy that your individual and collective interests have been conserved at the same time as those of the men who have built and controlled these great institutions, and when the history of this, the greatest era of prosperity known to the world, is written, his name will have an important place in its pages. [Great cheering.]

The Strong engine has started on a trip west, and is now in Ohio. She has recently been overhauled, and some alterations made at the Elizabethport shops of the C. R. of N. J. The engine has been for some months on the Erie and the Central, burning hard coal, it is claimed that as she was designed to burn soft coal, and will do better in the West on that account; probably she will, though it would seem as though a fire-box having fifty-four feet of grate ought to burn anthracite coal all right.





A Planers. B Lathes C.—Boring Mills. D—Universal Milling Machines E.—Screw-Cutting Machines G.—Vise

A Model Manufacturing Shop.

We illustrate on this page the general plan of the only shop in the world devoted exclusively to the building of tools for locomotive repairs—that of Pedrick & Ayer, Philadelphia, Pa.

The first floor plan shows the Hamilton street end to the right, Buttonwood street is on the left; the building is 40x160. On the Hamilton street side is the main entrance, with a stair leading to the office; the lower floor is entirely occupied by machinery, the location being plainly shown in the plan so plain it needs no explanation. On five of the supporting columns are hung cranes that serve all the machines and cover pretty much all the floor space. The Buttonwood end of the shop has a large entrance for teams, and a load of castings can be loaded or unloaded on the elevator, without lifting them up or lowering, as the elevator can be set to the right height. The square space shown in the lower left corner, and near the door, is a raised floor on which the tool dresser's forge is located, and the stock of iron and steel kept; this floor is about as high as a wagon, which makes it handy about handling heavy stock. The nicest part of the plant is not shown, and is the part located under this raised platform—the engine-room, boiler-room and casting store-room—the coal-pits are located under the sidewalk. The shop is heated by an improved exhaust system and lighted by electricity. Wash-sinks and closets are located on both floors.

In the front of the second story are the offices and drawing-room, as shown in the excellent engraving. The large light wells through this floor lessen the floor room, but all over the shop the light is excellent. On this floor are some of the lighter tools, and many of the benches used by those erecting machines, much of this work being done here. One crane covers a large floor space on the erecting floor. In the back is the pattern-room, fitted with the usual woodworking tools used by pattern makers. On this floor is the dynamo-room; this is kept locked to prevent accidents. There is an incandescent light over every tool, at every vise, and everywhere there is need of the least ray of light. The office and drawing room are finished in natural wood, and are as neat as can be found anywhere. There seems to be material and tools on hand to do anything that needs doing in the best manner possible; there is no excuse for poor work, and, no doubt, the special tools turned out by this firm in the future will excel the already excellent work they have long been noted for.

The 24-O'Clock System.

J. A. Kammerer, president of the Railway Station Agents' Association, and a train dispatcher on the Canadian Pacific, prepared an interesting paper on the above subject, to be read before the association at Kansas City. It has just appeared in the *Northwestern Railroader*, from which we make the following selections:

". . . On the Western Division of the Canadian Pacific system, for a distance of nearly 3,000 miles, the 24-o'clock time has been in use since May, 1886, covering an experience with me of one year as agent and two years as train dispatcher. Shortly before the change from the old to the new system, all employes were furnished by the management with paper dials for clocks and watches, on which appeared the figures from 13 to 24, these were of such a size as to fit the dial plate within the Roman numerals from I to XII., and were arranged with a hole to fit the post carrying the hands. These paper dials were coated with gum, and, to apply them, it was only necessary to wet them evenly, and when the hands of the time-piece came together slip the hands through the hole left for the hand-post, get the figure 24 straight beneath the numeral XII., and press it evenly onto the dial plate; this brought the figure 13 under numeral I, and others in rotation to 24.

"This arrangement was so simple and effective that, when the new time went into effect, all employes were perfectly familiar with it, and I have yet to hear of an instance where the new time was not rightly understood or interpreted . . .

"Of course, the paper dials were not so ornamental as useful, and watchmakers set themselves the task of arraying dials in conformity with the new time. We have now the 24-o'clock time-piece, which has the figures from one to 24 on the outer edge of the dial, similar to the old numeral dials. The minute hand moves with the same speed as before the change, but the hour hand travels just one-half slower, thus, at 12 o'clock the hour hand is in the same position it would be at 6 A. M. in the old time-pieces.

"We have also the 'jumping dial' furnished by the railway company. This is a two-dial arrangement—an inner and an outer one—the outer dial is stationary and has no figures on it, but has twelve holes in it at the exact spot where the numerals should be in an old-style dial, the inner dial has the figures 1 to 12, and immediately to the right appear the figures 13 to 24. At one o'clock in the morning the figures 1 to 12 appear in the apertures of the stationary dial. At precisely 12.59 a small spring on the movable dial is released, and the figures 13 to 24 'jump' into view. At 24.59 the spring again causes the movable dial to 'jump,' bringing the figures from 1 to 12 in view. This dial is in use at all division terminals and the most important stations, and gives good satisfaction.

"I do not think that it is the best, but that, as the system comes into general use, something more simple and effective will be invented.

"On a long line like the Canadian Pacific Railway, which has its own time card from Halifax on the Atlantic to Vancouver on the Pacific, a real trans-continental railway under one management, an agent must answer questions of travel covering a continuous ride from one to eight days in passenger service, and from one to twenty days with freight. In running passenger trains from one division over six, eight or ten others, with the old A. M. and P. M. time, we were very apt to miss an A. M. or P. M. on the card, and the printer as apt to make a misprint or omission. As a result we would, in most cases, be from 12 to 24 hours out of the way in our figures. . . .

"In train dispatching, the practicability of the system at once presents itself to an experienced man. Of course there are dispatchers who are old fogies and do not move with the times, who still claim the A. M. and P. M. system to be the best, but the introduction and use of the new system, and the benefits derived from it, will soon make the crankiest of them acknowledge its usefulness, and cause them to wonder why they had not thought of it before."

Some Grievances in Australia.

In New South Wales, Australia, the two thousand miles of road belong to the government and are under the charge of a commission. We have been reading in the *Railway and Tramway Review*, of Sydney, the official organ of the Amalgamated Society of Railway employes, an account of a visit of a committee of the men to present grievances to the commissioners. Some of the grievances were small, but the commissioners seemed to argue against lots of them, just like American superintendents.

Under the head of "What's Being Said," the same paper gives some interesting items as follows:

That it is very hard that up-country employes' washing parcels, etc., cannot reach their destination without half their contents being abstracted on the road.

That a certain Northern Station Master appears to be paid to "booze" rather than work.

That it is nice for him to be able to smoke and chat all day as well, while his clerk does both their duties.

That he might also be a little more civil to some of the traveling public.

That men are now sometimes fined without ever being charged with any offense or being asked for any explanation.

That surely this is not "fair play."

That an officer who smokes cigars all day on the tramway premises threatens to suspend any man whom he sees with a pipe, even if he is off duty at the time. Rough, this!

That a Southern Station Master was lately seen crawling around a sick shunter's [switchman] house at night to try and catch him.

That men who take tickets for socials or banquets should be manly enough to pay for them.

That the Passenger Guards have petitioned for frock coats.

That certainly some improvement should be made in their uniforms.

That B van 8 wants serving the same as No. 4, by reversing the hinges of the doors.

That the Signalmen ought to have had the new kind of uniform—blue with white mountings.

That a small clique of officers protested against it. Such miserable jealousy is simply contemptible.

That one Platform Inspector has resigned and gone back on his train.

That there must be a screw loose somewhere when men throw promotion over like this.

That there are two Station Masters on from 7 A. M. till 12 midnight, and from the latter hour until 7 A. M. a porter is left in charge of Redfern station.

That this is rather a curious arrangement.

That a certain public servant, lately detected traveling without a ticket, has hushed the affair up, although he was served with a police court summons.

That departmental correspondence travels at an enormous speed.

That a simple application to the manager goes through three offices, and a man may possibly get an answer in three or four weeks' time.

That the busy season is approaching. This means long hours for Drivers and Guards.

That the work can increase but the staff must not.

That the Audit Department is still working hard to gain that premium.

That the Guards' overcoats are a very poor sample. Also, why are not the Foremen, who have to be out in all weathers, similarly supplied?

That if brake van 9 had the iron steps taken off and a continuous footboard put on, it might be the means of saving some unfortunate Guard's life.

That when two sleeping cars are put on the train at Albury two conductors are sent with them; but when two are put on in Sydney, only one conductor is sent.

In Ye Olden Time.

When the "Best Friend," which was the first locomotive used in the South and the first built in this country, was put on the track of the South Carolina Railroad its performances excited great curiosity. For a time its driver did quite a profitable business carrying the curious in small parties a few miles out on the line from Charleston and return, for a consideration.

An old schedule and freight tariff of the South Carolina road, now in the possession of an officer of that company, provided among other things that no dogs should be admitted to cars without the consent of the passengers; that conductors must require all guns or pistols in the possession of passengers to be discharged before the persons carrying them should enter the cars, and that no package should be entered on the conductor's freight list for less than 6¼ cents.

After the explosion of the boiler of the "Best Friend," through the stupidity of its negro fireman, who held the valve down a little too long, to avoid the annoyance of escaping steam, a special platform car was placed between the engine and the first car of the train, and loaded with bales of cotton as a means of protecting the passengers.

In the early days of the South Carolina Railroad, before the telegraph came to be the handmaid of the railway, and when hours of delay in the arrival of trains were of less importance than are minutes now, the good people of Charleston were notified of the approach of a train by a flag displayed from the steeple of the railway station. It was the duty of an employe to keep a lookout from this steeple, and hoist the flag when he should catch the first glimpse of the smoke and steam of the locomotive.—*Railway Age.*

A piece of concave sheet metal, half an inch wide, and as long as the water glass, held behind it, with strips around the glass at the ends, is made good use of to see the water. Paint the side next the glass white, and then paint up the center of the strip a bright red stripe an eighth of an inch wide; this strip scarcely shows through the steam, but it makes all the water in the glass appear as red as blood. It costs nothing and makes the water-level plain and sure in the uncertain light. Try it, you will be surprised.

On some of the big hogs on the D. & R. G. the engineer's brake valve has been taken from behind the engineer and placed on the side of the cab ahead of him or on the boiler, but in front instead of behind. The position a man must get into to handle the air-brake is positively horrible, on some of the engines built now. A man takes chances enough of getting bunged up in the regular list of mishaps on the road, without driving his left shoulder blade through the off lobe of his liver in trying to reach the brake.

It is funny how men will kick against an imposition after it has once been pointed out to them. Since the quiet "roast" we gave the ball ticket and souvenir racket in the July number, we have received letters from several manufacturers, and our advertisers, thanking the paper for the article, and often enclosing circulars of people who want such advertising. Boys, it don't pay—don't do it.

A fireman on an Ohio road asks us to say, without giving him away, that it is not necessary to strike a torpedo signal cap with a coal pick to see if it will go off; in some recent experiments made by him, he found that not only would the torpedo go off, but in his case a part of one thumb went with it.

In deep fire-boxes, where deep fires are carried, it is almost necessary to admit air over the fire to complete combustion; where the fire-box is shallow, and a shallow fire is carried, it is not necessary, as the fire can be carried thin enough to let enough air through the grate and the fire, which is the better way.

We want a man in every railroad town to get up clubs, and pay very liberally for the work. If none of the boys in your place are asking for subscriptions, send for club rates; it will pay you.

A New and Important Book on Steam Engineering.

Le Van's Great Work on

THE STEAM ENGINE

— AND —

THE INDICATOR.

JUST READY.

THE STEAM ENGINE AND THE INDICATOR: Their origin and Progressive Development, including the Most Recent Examples of Steam and Gas Motors, together with the Indicator, its Principles, its Utility, and its Application. By WILLIAM BARNET LE VAN. Illustrated by 205 engravings, chiefly of Indicator-Cards. 469 pp., 8vo.

Price $4.00, by mail, free of postage to any address in the World.

CONTENTS.—I. Introduction. II. Who Invented the Steam Engine? III. Heat and Work. IV. Expansion. V. The Indicator. VI. The Action of Steam in the Cylinder of an Engine. VII. Horse Power. VIII. Diagrams showing the Action of Steam in Steam Engine Cylinder. IX. Correct Indicator Diagrams. X. Steam Expansion Curves or Pressure of Steam in Cylinder. XI. Comparative Indicator Diagrams. XII. Steam Jackets. XIII. Varieties of Steam Engines. XIV. Gas Engines. XV. Automatic Cut-Off vs Positive Cut Off. XVI. Miscellaneous. Appendix. Index.

☞ *An Illustrated Circular of 6 pages quarto, giving the full table of contents, with specimens of the engravings of this valuable book, will be sent free of postage to any one in any part of the world who will send us his address.*

☞ *Our new revised Descriptive Catalogue of Practical and Scientific Books, 86 pages 8vo., and our Catalogue of Books on Steam and the Steam Engine, Mechanics, Machinery, and Dynamical Engineering, and other Catalogues the whole covering every branch of Science applied to the Arts, as well as a circular of "Van Cleve's English and American Mechanic," sent free and free of postage to any one in any part of the world who will furnish his address.*

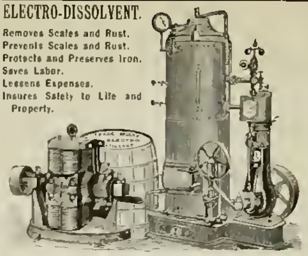
ELECTRO-DISSOLVENT.

Removes Scales and Rust.
Prevents Scales and Rust.
Protects and Preserves Iron.
Saves Labor.
Lessens Expenses.
Insures Safety to Life and Property.



THE ONLY SPECIFIC AGAINST SCALE IN STEAM BOILERS.

Removes Scale and Rust. Prevents Foaming and Pitting.

The Electro-Dissolvent supersedes Compounds. It is a *Metallic Solution.* Works *Equally in all Waters.* Mechanical in its action. Regulates the Electric Currents, thus preventing pitting. Fully endorsed by the best Engineers. Catalogue of price and instructions sent free on application. Beware of Imitations. None Genuine but those bearing this trade mark "MARTIN'S ELECTRO-DISSOLVENT." Address

Electro-Dissolvent Co., 368 & 370 Sixth St., Jersey City, N. J.

THE SHACKLETON SYSTEM

— OF —

HEATING PASSENGER CARS.

THIS SYSTEM utilizes the live or exhaust steam from the locomotive. Steam is conducted through the cars by pipes placed under the roof. Vertical pipes connect the overhead steam pipe with branch pipes that extend through the large water pipes at the floor level, and heat the water in these floor level pipes.

These large pipes are connected at either end of the car diagonally with radiators. Vertical steam pipes also connect the radiators with the overhead pipes.

The surplus water being drawn up into a reservoir that is exhausted by steam is utilized in the closets.

Under the car, or at one end, is placed a boiler for use in heating the water when the car is detached. With this system there is no drip. Pipes are quickly drained; perfect ventilation; uniform heating of all the cars in a train; entire safety.

The Shackleton Car Heating and Ventilating Co.,

JOS. SHACKLETON, M. E., Gen. Mgr.

BOUND BROOK, N. J.

Bound Volumes and Back Numbers of THE LOCOMOTIVE ENGINEER—Vols. 1 and 2.

Bound Volumes for 1889 will be ready about December 15, 1889. Price, $2.00 postage prepaid. Bound Volumes for 1888 still on hand, at same price.

Unbound Volumes of either year now ready, and mailed to any address in the United States, Canada and Mexico at regular subscription rate of $1.00 a year. Single Copies, 10 cents each.

Address, THE LOCOMOTIVE ENGINEER, 96 Fulton St., New York.

Boiler Cleansing Compound

(LORD'S PATENT)

For Preventing and Removing Incrustation In Steam Boilers.

Saves Fuel, Labor and Time.
Is a Safeguard Against Explosions.
Will Not Pass Over with the Steam.
Preserves the Plates of the Boilers.

Neutralizes any Corrosive Acids in Feed Water.
Its Action upon Old Scale is Gradual, but Certain.

Prevents the Formation of Scale, also Grooving, Pitting and Wasting of Iron.

P. O. BOX 1262. PHILADELPHIA, PA.

Steam Mill, cor. Putnam & Mascher Sts. Main Office, 11 S. Ninth St.

☞ SPECIAL NOTICE TO ENGINEERS.—A member of this firm, holding a first class Engineer's Certificate, will gladly assist our friends to qualify for higher positions, by answering questions free of charge.

THE RICHARDSON AND THE ALLEN-RICHARDSON

BALANCED SLIDE VALVES.

Used by 140 Railroads. 4,000 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

Estate of F. W. RICHARDSON, Troy, N. Y.

MY MOULDED BOILER GASKETS ARE ELASTIC, TOUGH AND PLIABLE.

The qualities recommended by Boiler Insurance Companies.

A TIGHT JOINT EVERY TIME. NO STRAINED MANHOLE FRAMES. NO UNTRIED EXPERIMENT.

Have been in use in this Section for past Fifteen Years.

Pump Valves, Air Brake Washers, Crossing Gate Gaskets, Rings, Pipe and Flange Unions, Tips, Feeders, Etc.

No Broken Glasses with Moulded Glass Gauge Gaskets.

Correspondence solicited. Mention this paper. H. O. CANFIELD, Bridgeport, Ct.

CORRUGATED COPPER GASKETS

For all Pipe Fittings and Unions, whether for Steam, Water or Air. Can be used wherever any gasket can be applied, with better satisfaction and greater durability than any other. Will not leak, rust, stick, burn or melt. All sizes and shapes, ½ to 42 inches. In use on N. Y. & N. E. R. R. and others. *Write for particulars.*

U. S. MINERAL WOOL CO., { 2 CORTLANDT ST., NEW YORK.

DANGER PREVENTED!

Your Boiler is the life of your establishment, therefore protect it!

We will remove and prevent Scale in any Steam Boiler, and ask no money until you find our remedy to work to your entire satisfaction.

WE USE NO ACID!

The Chemicals we use will neutralize Acid, Sulphur, and Mineral Waters and will not only protect you from Boiler Scale and Oxidation of Iron, but from corrosion in every form, such as GROOVING, PITTING, and WASTING OF IRON, which causes so many explosions. If you will protect your Boilers from the above-named destructive agents, then with a reliable engineer there will be no occasion for a boiler explosion, and the money saved by the use of our Compound will more than pay the cost of it in every case.

This article has worked its way into favor entirely upon its merits, without sending out a single man to solicit orders, and we can refer to our customers in every steam-using locality from Maine to the Pacific Coast. More than thirty thousand manufacturing establishments, in the United States and Canada alone, are now using our Compound, many of whom, using a number of boilers, order it by the ton.

Authors of the best works on Steam Engineering now recommend Lord's Compound as the only reliable article to prevent corrosion in boilers, and as a safe remedy for incrustation; and as a proof of this fact, we will send any of these books by mail, free of postage, at publishers' price, or free of cost with a barrel of Compound.

A VERY USEFUL BOOK ON CARE OF BOILERS FREE.

Also our circular, with full particulars of the Compound, on request.

Address, GEO. W. LORD,

318 UNION STREET, PHILAD'A, PA.

AGENTS WANTED EVERYWHERE.

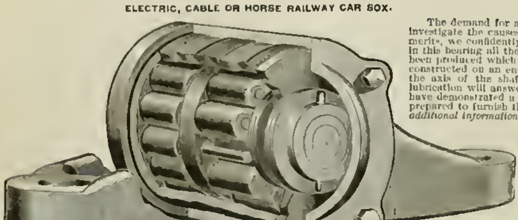
Full Particulars Furnished on Application as above.

The Tripp Anti-Friction Journal Bearing.

ELECTRIC, CABLE OR HORSE RAILWAY CAR BOX.



The demand for a practical and durable ANTI-FRICTION ROLL JOURNAL BEARING has induced us to investigate the causes that have led to failures in the past, and as a result after careful tests of its merits, we confidently present the Tripp Anti-Friction Journal Bearing to the public. We claim that in this bearing all the elements of self-destruction have been carefully avoided, and that a bearing has been produced which is more durable than any of the ordinary bearings now in use. This bearing is constructed on an entirely new principle, by which the axes of the rolls are always kept in line with the axis of the shaft. The Journal boxes are absolutely dust-proof, and we guarantee that one lubrication will answer for one year's constant service. By recent tests with the Dynamometer we have demonstrated a saving in power over the ordinary journals of from 30 to 70 per cent. We are prepared to furnish these bearings for trial, and invite correspondence. ☞ *For prices, terms and additional information, apply to*

For Broad or Narrow Gauge Roads.

From standard designs, or according to specifications, to suit purchasers.

TANKS, LOCOMOTIVE OR STATIONARY BOILERS

Furnished at Short Notice.

WILSON MILLER, Pres. and Treas. D. A. WIGHTMAN, Supt.

NARROW GUAGE LOCOMOTIVES,

—AND—

WIRE ROPE HAULAGES,

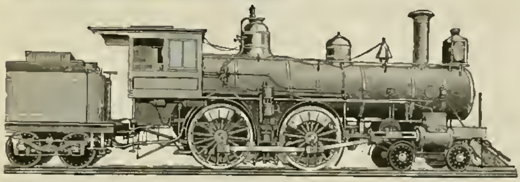
J. & J. B. MILHOLLAND, EXPERT ENGINEERS AND DESIGNERS,

And Builders of HAULAGES for Coal Mines and Tramways.

75 Complete WIRE ROPE HAULAGE Plants in successful operation.

Plans and Estimates Given on Application.

Steam Engines and Machinery Generally. 240 Fifth Ave., Pittsburgh, Pa.



DICKSON MANUFACTURING CO.,

SCRANTON, PENN.

Locomotives of every style and size, Standard and Narrow Gauge, made to Standard Gauges and Templets. Also for Plantations, Mines and Logging.

SPECIFICATIONS ON APPLICATION.

JAS. P. DICKSON, Pres. WM. H. PERKINS, Sec. & Treas.
E. W. WESTON, V. Pres. JOHN DEVINE, Supt.

RICHMOND LOCOMOTIVE & MACHINE WORKS, RICHMOND, VA.

BUILDERS OF

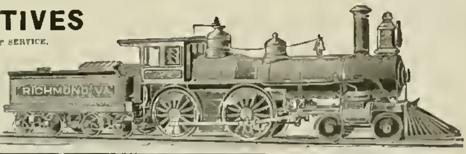
LOCOMOTIVES

FOR EVERY VARIETY OF SERVICE.

MOTORS

for Street Railways, Tram Roads and Mines.

Also manufacturers for the Polo Road Locomotive Company of their efficient logging engines and cars.



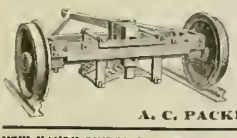
H. K. PORTER & CO., Pittsburgh, Pa.

BUILDERS OF

Light Locomotives & Noiseless Steam Motors.

Send for new Illustrated Catalogue of 1889, containing much valuable information including working record of over 500 locomotives. Mention this Paper.

PACKER'S EASY MOTION ROLLING TRUCK FOR LOCOMOTIVES.



Allows engine to go *around curves* of much *shorter radius* than is possible with *any other* arrangement. Has no springs over boxes or heavy cradles. Can be used under any engine without distorting the frame.

THE SIMPLEST, CHEAPEST AND STRONGEST TRUCK MADE WITH A SINGLE PAIR OF WHEELS.

Illustrated and described in THE LOCOMOTIVE ENGINEER for October, 1888

IN SUCCESSFUL USE ON 50 LOCOMOTIVES.

A. C. PACKER, Patentee, *118 FORTY-FIFTH STREET, PITTSBURGH, PA.*

TIRES

THE STANDARD STEEL WORKS

PHILADA., PA.

NEW HANDY BINDER FOR THE LOCOMOTIVE ENGINEER. In Stiff Covers 50c. at this Office, or 75c. postage paid, to any address. WILL HOLD TWO YEARS' NUMBERS. THE LOCOMOTIVE ENGINEER, 96 Fulton St., N. Y.

—THE—

Smith Triple Expansion Exhaust Pipe

TAKES PLACE OF NOZZLE STAND AND DRAFT PIPE.

OPENING LARGER THAN PORTS.

Produces almost continuous blast without back pressure, which also reduces noise and sparks to a minimum.

Testimonials of Prominent Master Mechanics who are using it, on application. Pipes furnished for trial, free of cost.

SMITH EXHAUST PIPE CO., Doylestown, Penn.

JOHN J. BROCK, Pres't. JOHN Y. SMITH, Gen. Manager. HENRY LEAR, Sec'y and Treas.

WINTERTON METAL POLISH.

BEST POLISH AND QUICKEST CLEANER KNOWN

Class A for Hot Brass, Copper, Nickel, etc. Class AA, for Cold Brass, Copper, Nickel, etc. Class B, for Finished Iron and Steel.

Send 12 cts. for Samples. Try it.

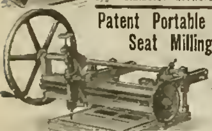
SPECIALLY ADAPTED FOR LOCOMOTIVE WORK.

W. W. CALLERY & CO., 36th & Butler St., PITTSBURGH, PA.

Universal Grinding Machine

For general use in tool-room. Bed raises and lowers. Table swivels and will travel in any position. Has very complete arrangement for grinding tapers, and will grind parallel also. Table will take in 18" long by 6¼" diameter between centres.

Patent Portable Steam Chest Seat Milling Machine.



For milling out corroded steam chest joint surfaces for strips; facing off whole surfaces and milling out ports. Easily attached. Works rapidly. Designed especially for Locomotives.

PEDRICK & AYER,

MANUFACTURERS OF

Special Tools for Railway Repair Shops

1001 & 1003 HAMILTON STREET,

PHILADELPHIA, PA.

Planer Tool for Locomotive Driving Boxes

Applied to an ordinary planing machine. It is forged heavy and strong and will not spring. Will plane a number of boxes at one time with accuracy, making boxes interchangeable—much superior to slotting.

PATENT PORTABLE DRILLING MACHINE

For fitting cylinders to locomotive boilers. It will drill all the holes in smoke boxes and cylinder flanges necessary to hang one pair of cylinders at one setting of machine. Quickly set and operated. Driven by hand or belt power.

STEEL — OPEN • HEARTH • CASTINGS •

STANDARD STEEL CASTING CO.,
THURLOW, PA.

HYDRAULIC TOOLS FOR RAILROAD WORK

VREELAND'S

TRANSFER

JACK

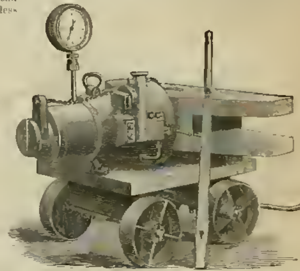
Will Remove and Replace

Drivers or Trucks without Jacking Up.

No Floor Space required for the Vreeland Transfer Jack. No Overhead Tackle. No Blocking. No Danger. Drivers and Trucks taken out in less time than it takes to jack Engine up.

IN USE ON 10 RAILROADS.

Hydraulic Press for forcing pins into Locomotive Drivers, either under the engine or out. Also useful about Railroad Shops, for forcing on and off Balance Wheels, Cranks, Gears, Pulleys, etc. Inclosed Piston Cannot Clog. Valves are large and fall to their seats, no rush of water being required to seat them. Parts easily examined or repaired. Pump is independent of cylinder casting. Movement of ram, 12 inches. 60 to 150 tons pressure.



WATSON & STILLMAN, Mfrs.,

210 E. 43d St., New York.

The Original Unvulcanized Packing.

CALLED THE STANDARD—As it is the Packing by which all others are compared.

Accept no Packing as JENKINS PACKING, unless stamped with our "Trade-Mark."

JENKINS BROS.
71 John Street, N. Y.
105 Milk Street, Boston.
21 North Fifth Street, Phila.
54 Dearborn Street, Chicago.

SELDEN'S PATENT PACKING.

With Rubber Core for Steam.
With Canvas Core for Water.

Try it on your Hydraulic Work.
Try it on your Westinghouse Air Pumps.

RANDOLPH BRANDT,
SOLE MANUFACTURER,
38 Cortlandt Street, New York.

STEEL CASTINGS

FROM 1-4 TO 15,000 LBS. WEIGHT.

True to pattern, sound, solid, free from blow-holes and of unequaled strength.

Stronger and more durable than iron forgings in any position or for any service whatever.

60,000 CRANK SHAFTS and 50,000 GEAR WHEELS of this steel now running prove this.

Crossheads, Rockers, Piston-Heads, etc., for Locomotives.

STEEL CASTINGS of every description.

Send for Circulars and prices to

CHESTER STEEL CASTINGS CO.,

Works, Chester, Pa. Office, 407 Library St., Philadelphia, Pa.

Punishment by Proxy.

"Years and years ago," remarked the old timer, as he put his feet on our desk and borrowed a light for his briar-root pipe, "years and years ago, when William B. Gage was master mechanic of the old Rensselaer & Saratoga, we had a runner there of the name of Noer Prince, who, aside from bein' one of the best-hearted fellers you ever sot eyes on, was the carlessest runner you ever see; if there was anything to get into or off on, that hadn't ort to be got off on or into, jest rest yer mind it was Noer.

"Onc't up around Rutland some'r's he was lookin' at somethin' else and run off a switch in shiftin', and ditched his engine and half a dozen cars, and Gage went up with the wrecking train more for a good chance to dam Noer off than for the little help he'd be. In them days Gage had a dog, the orneriest lookin', bleary-eyed, stumpy-tailed pup you ever sot eyes on. Nobody but Gage would have give him his dinner for him, but he was always at the old man's heels, never so happy as when he could wag his stumpy tail in answer to Gage's call for 'Jack.' Jack follered the old man up to the wreck; there was a crowd around, among them Noer—smilin' and happy, and trying to drive out a bolt in the main rod and look for Gage at the same time. Gage stepped up on the side of the boiler, getting madder and madder every minit; Jack stepped up too.

"'Jack!' demanded Gage, 'do ye see that switch?' Jack whined and wagged his stumpy rudder.

"'Jack, susposen' you was a running of this ingin'—an' you could do it better'n them as has run her—and you come along here, shiftin', and see a switch wrong, what would you do, Jack? Would you act as if you had any sense at all and reverse your ingin' and open your sand lever? or would you go goppin' around like a dumb-headed ijit and run off the switch, and tip over your ingin'? You'd know more'n that, wouldn't ye, Jack? If you didn't, do you know what I'd do, Jack?' and the old man glared at the dog fiercely as he walked up to him, 'Damme if I wouldn't kick the fool liver right out of ye!' and that old sinner kicked the poor dog far out into the crowd of spectators and marched back to the station, cussin' at every step.

"After that, if any of us boys wanted a drink, all we had ter say around where Noer was, would be, 'Jack, what would you do?' Noer allus answered by walkin' up to the bar and reachin' for his shinplasters."

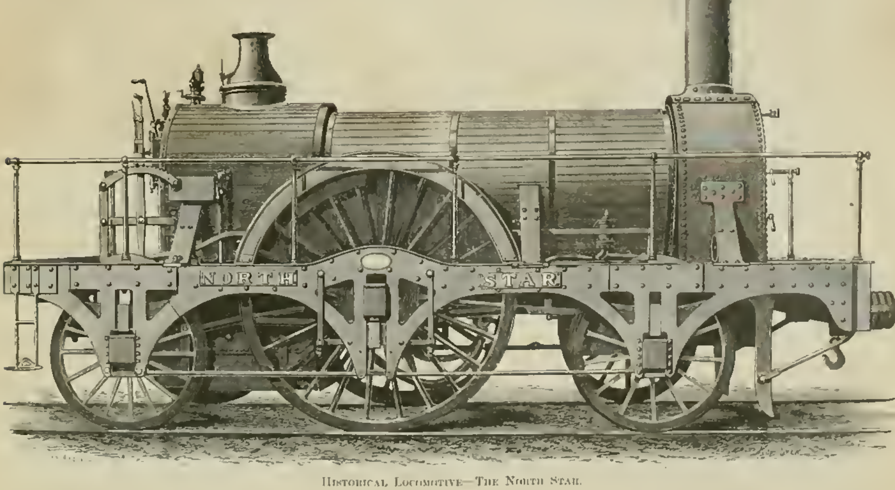
Mr L. W. Rogers, lately editor of the *Railroad Patriot*, has become editor of the *Brakeman's Journal*, in place of Ed. F. O'Shea, who has retired, to enter private business. Mr. Rogers is a man of ability, and a fit successor for O'Shea.

Historical Locomotives—An Early Gooch Engine.

On this page we reproduce from *The Engineer* (London, Eng.) a picture of the "North Star," a locomotive built in 1837 to the designs of the late Sir Daniel Gooch, and one that was long in service on the great broad gauge line. This locomotive was not so far different from the present English practice as were American locomotives of that time different from our present power. This locomotive was built at the works of Messrs Robert Stephenson & Co.; was one of the first used by the Great Western road; commenced work January, 1838, and ran continuously till December, 1870, having been in service thirty two years, making a mileage of 429,000 miles. The engine is now carefully preserved at Swindon, the headquarters of the company

The driving-wheels of this engine were of wrought iron, with round, tapering spokes, being 2¼" in diameter at the hub, and 1⅞" at the rim, and set "staggering" on the hub

The engraving is so plain that all points of interest are easily seen and made plain. The principal dimensions were as follows.



HISTORICAL LOCOMOTIVE—THE NORTH STAR.

Driving-wheel, diameter..	7 ft.
Leading and trailing wheel, diameter	4 ft
Cylinder, diameter	18 in.
" stroke	18 in.
Boiler—length of barrel....	9 ft. 5 in.
Diameter....	3 ft. 11 in.
Number of tubes	167
Length	9 ft 10⅝ in.
Diameter (outside	1⅝ in.
Copper fire-box, length	8 ft. 5¼ in.
Width	3 ft. 10⅞ in.
Height....	4 ft 4½ in.
Heating surface—fire-box. .	94 sq ft.
Tubes	756 sq. ft.
Total.	850 sq. ft.
Fire grate, area... .	11.70 sq. ft.

Simple Lesson in Drawing for the Shop.

By Orville H. Reynolds

THIRD PAPER.

If it were possible to make a drawing with all its lines ending at the proper place at the first trial, there would be no necessity for using the pencil, for in that case the pens would be called into use to the exclusion of the pencil, therefore, being obliged to use the pencil in construction, all lines should pass beyond actual ending place, making a distinct point for the drawing pen to stop at. The function of the pencil, then, is to make a path for the pen to follow, and it is essential that the construction is accurate before any attempt is made to use the pen.

With all reasonable care the student will find erasing to do, but as little of it as possible should be done.

To sharpen the pencils, use a fine file after taking off enough of the wood with the knife, making a conical point for the drawing pencil, and a chisel point for the divider leg.

The drawing pens are handled similarly to the pencils, with the exception that care must be taken not to crowd the ruling pen too hard against the T-square or triangles; any excessive pressure there will tend to close the pen points and obstruct the flow of ink, so that if a line of correct width is started it is likely to be too thin or narrow at the ending, or while satisfactory at certain points, may be so untrue at others as to seriously hurt the looks of the drawing. Aldermanic proportions in the one case, and a consumptive appearance in the other, are the results.

Drawing pens after use show wear on the points, the amount of which depending on their use and hardness, one or both points having a flat spot, which also makes a line that is not a "thing of beauty."

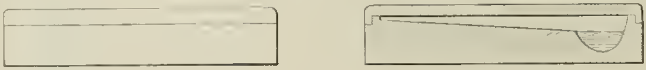
To true the points and bring to proper working order, take an oil-stone slip like the Washita stone used in the shop, close the points by means of the adjusting screw, pass the oil-stone evenly around the edge of the pen points (Fig. 1) until the edges are truly circular and of an equal profile, being sure that the flat places have disappeared. The blades are then ready for the thinning process, which is done by separating the points slightly by the screw, and laying the blades flat on the stone (Fig. 2), moving the pen with a rotary motion, the while making an examination to be certain that the point is not too thin; a true sharp edge is what is sought; one that just fails to cut the paper is right. Bring both points to this condition, and, after cleaning them, draw them over a piece of clean pine with the grain, to take off the wire edge from the inside of the points; close the points together, and taking up some ink on a writing pen, deposit it between the blades of the drawing pen, and draw a line, using the T-square or triangle. A few trials may be necessary the first time this operation is attempted, when a true line is made as fine as the pen will make, open the points a trifle and make another line a little wider, and so on until you have the widest line the pen can make (Fig. 4). If there are no signs of a ragged line in any of the trials, and if the pen feels smooth in the handling, it is all that could be required. If it is necessary to incline the pen either to or from you to make a full clear line, it is evidence of one point being longer than the other, and in that case the process of truing the points must be gone over again until both points are equal in length.

In this honing operation do not use the oil-stone between the blades if possible to avoid it; by doing so the blades soon acquire a bearing above the points on the inside, which is ruinous to the pen; care should be exercised in this particular.

In case there is a wire edge on the inside of the pen points, that refuses to disappear by the mild process given, lay the oil-stone on a table, remove the adjusting screw, and, after opening the blades, place the inside face on the stone and move the pen gently a few times, being sure the pen has a bearing on the stone back of the points.

Triangular Scale.

Fig. 3



Side View Ink Slab *Section of Ink Slab.*

Fig. 5

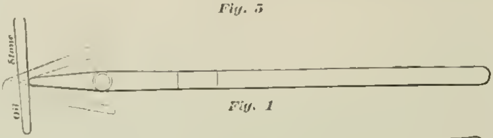


Fig. 1

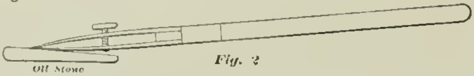

Fig. 2

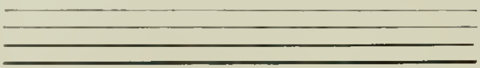

Fig. 4

Keeping the pens in working order is conceded by all to be an exasperating job, one making bulky calls on the draftsman's patience. It is certainly not conducive to an unruffled mind for one to find the pen working badly after a half hour's struggle to put it in shape.

It is difficult to convey a clear idea of "how to do it" on paper. It will be found largely a matter of cut and try.

The pens while in use will need frequent cleaning in order to have them in working condition, and more particularly as the ink dries rapidly when between the blades; fine lining is an impossibility when this occurs. To avoid trouble from this source, use any soft linen, or, better, a piece of chamois skin.

The pen should not be laid down with ink between the blades; when done with for the time always clean carefully, this prevents rust, and the pen is ready for use when wanted.

The triangular scale being graduated differently than the steel scales used in shop practice, makes necessary a description of the same. The scale for our use should read on its different edges as follows: Three inches and 1½" to one foot, 1 and ½' to one foot, ¾ and ⅜' to one foot, ¼ and ⅛ to one foot, $\frac{3}{16}$' and $\frac{3}{32}$ to one foot; and one edge read sixteenths the whole 12" of its length. Fig. 3 shows such a scale broken. An explanation of the 1" and ½' side will suffice for all. Where it is used as a scale of 1' to one foot, each large space, as from 0 to 12 or 0 to 1, represents a foot, and is a foot at that scale. There being 12 in one foot, the twelve long divisions at the left represent inches; each inch is divided into two equal parts, so from 0 to one division at the left of 9 is 9½" and so on. The 1 and ½' scales being at opposite ends of the same edge, it is obvious that one foot on the 1' scale is equal to two feet on the ½ scale, and conversely, one foot on ½" scale is equal to six inches on the 1" scale; and 1" being equal to one foot, the total feet in length of scale will be 12; at ½" to one foot the total feet will be 24.

In all the scales mentioned, one foot at each end is divided into 12 or more equal parts. Applying this description to all of the other scales, it is believed no trouble will be experienced in their reading.

If it is necessary to use a 12" steel scale, the description of above scale will assist the student in its use, as at 1" to the foot, one-twelfth of an inch on the steel scale represents 1", at ¾" to one foot, $\frac{1}{16}$ on the steel scale represents one inch. At 3" to one foot, ¼" represents one inch; so it is apparent that the steel scale will do all the triangular scale will do, but may not be as satisfactory to use, because the lines on the triangular scale go directly to the paper, making it easier to lay off dimensions.

In the first of these papers an ink slab was mentioned as one of the accessories to be provided.

It was stated at that time that stick or cake ink was the best as compared to Higgins liquid ink in bottles. Having used both, the writer sees no reason to modify his language, but it must not be understood that the liquid ink is worthless; on the contrary, it is good. When a rush is on, and every minute is worth gold coin, its value is recognized at its full by the poor but honest draftsman who has been known to rise up and call blessed the architect of the useful little compound. For our purpose perhaps it will do as well as the more expensive India ink, and make another saving in the price of the slab.

A description of the ink slab, and of the process of grinding ink will not be out of place in any event. The slab (Fig. 5) is made of earthenware, porcelain, marble or glass, and has one or more ink wells at the bottom of an inclined plane.

To prepare the ink, fill the well with clean water, take the cake of ink and rub it back and forth with moderate pressure on the inclined plane, taking up enough water at each stroke to keep the rubbing surface wet; when the contents of the well appear to be opaque enough, take a writing pen and make a few lines; if the ink is pale, rub again on the slab, and try once more, when it is black enough it will show a deep black line with more or less luster, depending on the quality of the ink. There is a golden mean to be found in preparing ink, if it is too thin it will not be black, if too thick it will be black enough, but will not run freely from the drawing pen.

To have the ink preserve its fluidity and to keep out all dirt and dust, keep the cover on the ink slab.

The mistake is often made of putting too liberal a supply of water in ink well, which causes a waste of both time and ink—time to get it to the correct degree of blackness, and ink, for the reason that what ink is left unused will dry and scale up before it can be used.

No more should be prepared than to meet immediate requirements. Fresh ink is always satisfactory when rightly prepared—stale ink, never.

A Brief History of Some Modern Locomotive Appliances.

THE "POP" SAFETY VALVE.

While the American locomotive itself has not undergone very many radical changes in the past twenty-five years, its safety, scope and utility have been increased by the developments of modern appliances attached to it.

Among the inventions especially entitled to credit in this direction is the modern safety valve, now almost universally used on our locomotive, as well as most other forms of steam boilers, and familiarly known as the "pop."

Men who ran locomotives before the invention of the "pop" will remember the trouble with the old safety valves. Younger men are, no doubt, but slightly familiar with their construction or peculiarities. The ordinary weighted valve could not be well used on locomotives, the constant jarring, and the friction of the many joints seriously affecting their proper working, so the weight upon the lever was replaced with a spring.

When an ordinary spring safety valve commences to open from the pressure of steam under it, it at once compresses the spring, bringing a greater load upon the valve, and causing it to close before the boiler had been relieved of sufficient pressure. A surplus of pressure in the boiler, above the load of the spring, is the result. If the boiler is supplying steam fast, as in the case of a hard-worked locomotive being suddenly shut off, the ordinary valve is not able to care for the surplus steam, and provisions were made on most locomotives to partially unload the valve by hand.

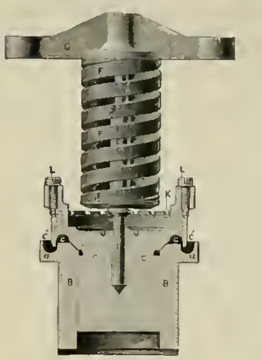

Fig. 3.

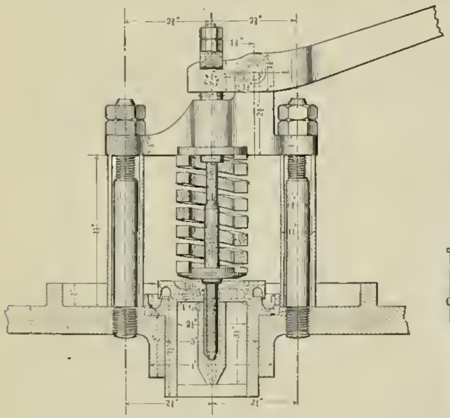

Fig. 1.

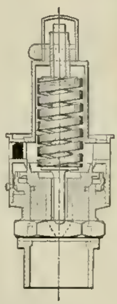

Fig. 4.

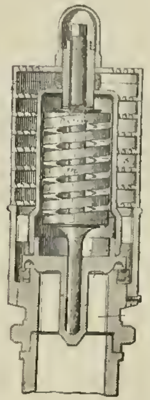

Fig. 6.

Fig. 5.

At first thought it would seem as if the way to overcome this difficulty would be to make the valves larger, but this made the matter worse instead of better; this arises from the fact that the load, the spring or weight, to hold a valve down must increase as its area, or as the square of its diameter—plainly put, to double the diameter increases the area four times, and your valve must be loaded for this area, while the area for the discharge of steam only increases as its circumference, or directly as the diameter. So the large valves had to carry a much greater load, and had a comparatively smaller opening to relieve the boiler.

These defects were well known early in the history of steam engineering, and attempts to improve the valve were many, both here and abroad.

The first attempts were made in England, early in the '50's, and were followed both there and here in the same general line.

The idea was to get a valve whose area increased when it opened, just as the tension on the spring increased.

Valves were invented with all kinds of caps and hoods on them with this idea in view, but most of them merely turned the current of the escaping steam down, without increasing the pressure against the spring.

After this followed valves in which the steam escaped from the boiler into a chamber, and there acted upon a larger valve before escaping to the atmosphere, these valves would blow at the required pressure, but would not close until they had relieved the boiler of enough pressure to allow the spring—which had been set to hold down a valve of small area—to close the large top valve against the pressure, and actually reduced the pressure from 20 to 50 per cent. Obviously this would not do for locomotive practice. What was needed was a valve that would open at a certain pressure, relieve the boiler quickly and close at a certain *lower* pressure than that at which the spring was set to open—this seemed like a mechanical paradox not likely to be accomplished.

At this time—early in the '60's—there was a locomotive engineer running on the old Troy & Boston Railroad, now a part of the Fitchburg, who got to thinking and experimenting on the safety valve problem, as he thought and experimented on almost every other problem that came up in his daily work—this was George Richardson.

Richardson figured that if he could make a valve, that had a ring around it larger than the joint, or seat, he would have an increased area, but that if he let the steam blow from under this freely that it would have no tendency to help lift the increased load caused by compressing the spring.

Then he figured that if he had another place below this cap, with an open space or cavity between them, the steam would "huddle up" there, as he expressed it, and if it could not get to the air too easily it would gain pressure and lift.

All this thought and experiment called for a great deal of patience and application, until by actual trial Richardson found that there existed a certain relative proportion between the area of the valve, the increased area and the amount of opening that could be permitted to the atmosphere.

This opening, or stricture, was discovered to be a very delicate subject, the slightest change causing a wide range of action of the valve.

On the 25th of Sept., 1866, Richardson obtained a patent on this device. The engraving on this page, Fig. 1, shows the valve as it was then made, this engraving as well as Fig. 2, which shows the valve as used with relieving lever, was made from the original drawing made at Altoona, Pa., the next year, for the valves on the P. R. R. road, where they were immediately adopted. In making these valves great care had to be exercised, and the wear of the seat or grinding in of the valve changed its range. In 1869, Richardson patented the adjustable lip, this made his invention as perfect as it is possible to make a mechanical contrivance.

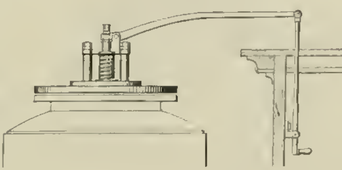

Fig. 2.

Many engineers who have attempted to adjust the amount of steam pressure reduced by the Richardson valve, have met with failure, and blamed the valve for it, because they did not understand the extreme delicacy of this adjusting ring, one notch under the screw usually being enough to make all the change desirable in service.

To reduce the stricture will make the valve lift stronger against the spring, blow longer, and reduce the pressure more before closing; increase the opening of the stricture under the outside lip will cause the valve to close quickly, without reducing the pressure so much, the best results being found when the valve closes at a boiler pressure of from three to five pounds less than that at which it opens.

The friction and wear of the old lever arrangement, and the proof that the valve was perfectly automatic, and needed no hand manipulation whatever, soon caused the levers to be substituted by the top spring, as in Fig. 3, a form of valve that has been adopted and used, the world over.

Richardson followed his early patents by many others, having taken out some almost every year since.

The commonest kind of locomotive "pop" now is the incased valve, as Figs. 4 and 5, and the latest, the "muffled pop," as in Fig. 6, this is a common valve with a series of rings around its case; these rings are drilled full of holes, the holes in one ring not matching the holes in any other ring; the escaping steam impinges from one surface to another, and is broken up into so many small jets, that it finally escapes to the air noiselessly.

Richardson soon left the road, built a little shop back of his house in Troy, and made valves. His invention was a success from the first, and met with a large sale, and wide imitation and infringement; the latter Richardson fought in the courts for years, and spent in this way a good sized fortune, but he finally came out ahead. Business crowded him, and he went to Boston, and soon after defeating Ashcroft in the courts, consolidated interests with him, and formed the Consolidated Safety Valve Co., of Bridgeport, Conn., where he is now Supt. of the works. Richardson valves are now made in all sizes and shapes, from a half inch in diameter up to a nest of five six inch valves on one base, and controlling pressures all the way from five to five hundred pounds.

The new company was very vigorously opposed in the courts, but in 1883, the Supreme Court finally decided that the usefulness of the pop valve depended entirely upon the size of the stricture, and its relation and adjustment to the valve, and that Richardson was the first to accomplish what others had failed to do before.

When Richardson first built his little shop in the back yard at Troy, the railroad boys dubbed it "Richardson's play-house," but in that little play-house, not only was the pop perfected, but the Richardson balanced slide valve invented, as well as several other devices of merit, but not so well known, and the little "play-house," has been extended, until it now covers the entire lot, and a score of planers are making balanced valves there.

This sketch would be incomplete without the introduction of another person, who was not only the inventor's friend, but his adviser and assistant—Frank Hemenway. Hemenway was a machinist in the shop, and helped Richardson work out his ideas in brass and iron, and helped make the first "pop" valve. Here was an engineer getting a friendly machinist to help him out in some "scheme," that might or might not amount to something, just as many another engineer and machinist are doing to-day.

Richardson was an inventor, and carried his inventions to something approaching mechanical perfection and a business success, saw them adopted the world over, and now rests on his oars, with a well deserved reputation, a comfortable income, and growing business. Hemenway was a student, a thinker and an experimenter; he paid little attention to making money out of inventions; he wanted to know *why* a thing did so and so, and if it did not do so and so, to make it.

Without a technical education, he soon became recognized locally as a first-class mechanic, and a good man to put up machinery, soon became Supt. of a large works, commenced to write on mechanics—especially steam engineering—for the press, and soon became attached to the staff of the leading mechanical paper in the country, and is now its editor-in-chief. His writings on steam engineering, though written in plain language for practical men, are used by the best polytechnic and mechanical colleges of the country, as text books, and in the profession of steam engineering he stands modestly in the foreground, ever ready to help those who are trying to learn, illustrating all propositions and explaining all theories by reminiscences of bits of practical experience gathered in long years in the shop.

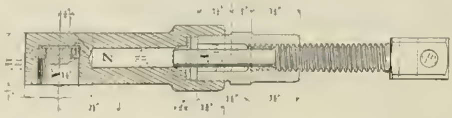
Both these men came up from the ranks, worked out their own destinies, each in a different way, yet each starting from the experiments with the "pop," both have enriched the profession of steam engineering, and both have made the world better for their having lived in it—and we don't propose to wait till they are dead, to say so.

A Piston Rod Remover.

The piston rod remover shown on this page has recently been placed on the market by Watson & Stillman, of this city. The device is extremely simple, as will be seen, the ram *X* has a leather packing at its base, and can be taken out of the head without disconnecting any of the parts, the forcing in of the screw drives the plunger *Y* into the liquid in the space *Z*, and forces the larger ram out with great power. The device is intended to be used in the space generally found between the pin of the front of main rod and the end of the piston rod.

Improved Fibrous Packing.

While metallic packing is fast gaining headway for locomotive use, fibrous packing has not remained the simple wad of hemp that it originally was.



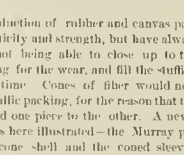
PISTON ROD REMOVER.

The introduction of rubber and canvas packings gave us elasticity and strength, but have always had a fault in not being able to close up to the rod, compensating for the wear, and fill the stuffing-box at the same time. Cones of fiber would not close up like metallic packing, for the reason that the rubber cemented one piece to the other. A new thing in this line is here illustrated—the Murray packing—here the cone shell and the coned sleeve, that comes in contact with the rod, are separated by a thin ring of brass, that prevents their sticking together, and allows the rings to retain their shape and perform their functions much the same as the same form of rings do in metallic packing.

Unlike the metallic, this form of packing can be applied to any ordinary stuffing-box without disconnecting any of the parts, and will work on scored rods. It is made by The John P. Murray Co., Jersey City, N. J.

A Factory for Steam Engine Appliances.

On a recent jaunt in New England, the writer visited the works of the Ashcroft Manufacturing Co. and the Consolidated Safety Valve Co., at Bridgeport, Conn. The Ashcroft Co. manufacture steam gauges, indicators and other fine instruments of that class, one, the Coffin averaging instrument, is an improved planimeter for measuring the areas of irregular forms, like indicator cards. These instruments are very delicately made.



IMPROVED FIBROUS PACKING.

The Tabor indicator, for measuring the power of steam engines, is an instrument of such delicacy, yet strength and symmetry, as to be of interest to any mechanic as a piece of mechanical work, aside from the results it accomplishes, which, of course, are like those accomplished by other indicators. The stock that enters into the manufacture of these instruments is so small that many thousands of dollars worth can be stored in a little space and makes little show.

The advantage of manufacturing in duplicate parts is here shown, where a very few men turn out a large amount of work in money value, through the use of special machines and jigs.

The gauge department makes more of a show. We noticed that most of the gauges built are now made on the plan of the locomotive gauge illustrated in the first issue of this paper, the entire working parts being supported on a central stand, with no connection to the back of the case.

The great care taken here to keep the test gauges right by the mercury column would make engineers suspicious of the accuracy of steam gauges in general; as carefully made as are the test gauges it is found necessary to change them very often—they are tested as often as once per week.

In the shop of the Consolidated Safety Valve Co. there is an immense stock in hand, benches and floors being piled full of safety valve cases of all sizes, from an inch to a pair of 6" pops on one stand. A description of this pop will be found in another column.

Some very ingenious tools are used here for the special work.

Expanding taps of large size, that stand up solid to the work on a huge turret head, automatically close up when the thread is cut, and allow the tool to be withdrawn without backing off.

This company occupy a portion of the Ashcroft building, using two floors, one for a store-room, the other for shop.

One department of the Ashcroft works makes adjustable pipe tongs.

The testing department of the valve works is most interesting. Every safety valve is tested under steam to the exact pressure wanted, and the amount of reduction and popping point are noted. They make pops for pressures of as high as 500 pounds.

The "Neversink."

We have to thank John F. Proctor, of St. Augustine, Florida, for two old daguerreotypes taken of the engine "Neversink" after she exploded. The pictures show both sides of the engine, the driving wheels being crowded together almost under the cylinders, and the back one on the left side gone.

The whole top of the boiler is gone, leaving the dry pipe and the flues bare.

The pictures are so dim that our engravers cannot make anything out of them.

Mr. Proctor knows nothing of the history of the "Neversink," more than that she was built at Cambridgeport, Mass. Who knows her history?

At Mobile, on the 4th inst., Mr. J. C. Clarke, president and general manager of the Mobile & Ohio road, was presented by divisions 140 and 231 of the Brotherhood of Locomotive Engineers with a unique and valuable clock. The address of presentation was made by Mr. E. L. Russell, Mr. Clarke replying in a very happy manner and presenting the engineers in return with a picture of the first locomotive which he ever handled. Of this engine Mr. Clarke said: "It is a crude affair when compared with the mechanism of the machine in use to-day. When I was first charged with the running of that engine I thought that I would not have changed places with the President of these United States. I ran an engine similar to that in 1836 between Baltimore and Washington, and distributed with it the poles for the experimental line of telegraph then being erected by Prof. Morse."—*Mobile Register.*

On the P. W. & B. they still have a good many locomotives with red wheels and gold leaf. We know it is out of style and all that, but somehow our heart warms up at the sight of red wheels. Our first love had wheels of the warmest red—she also had the coolest and calmest fire-box we ever saw.

Wm. Rymer, of Detroit, Mich., has patented the use of an air valve, placed so that when a side rod or tire breaks it will open the valve and apply the brake.

The new Suburban locomotives for the C., B.& Q. have the M. C. B. standard coupler.

The R. I. Locomotive Works.

During a recent call at the above works, our attention was directed to some splendid 10-wheelers in process of erection, these engines have but 16,000 pounds on their trucks—most 10-wheelers carry twice that load.

The practice here of using but one sheet for the wagon-top shell over the fire-box on all boilers of 78 inches or less in diameter would seem to be a practice worthy of imitation; the side seams are usually the ones to give trouble.

All seams are double-riveted, the longitudinal ones having a lap welt.

A pneumatic calking tool used here is very handy and efficient; it is in the shape of a dental hammer, the head being about 3" in diameter, and a foot long; to one end is fixed the calking tool, to the other the air-hose. The tool makes a very short stroke, but runs very fast, working something on the plan of the rock drill. The seams calked by it are very smooth, as the blows are all alike, but the noise is deafening.

Flexible shafts on each side of a boiler are used to tap out the stay-bolt holes, and then to screw in the stay itself.

A new sheet-punching machine has recently been put in, that has some new features; the punch pulls out of the work and then returns to within about a sixteenth of an inch of the sheet and stops, the feeder has his sheet suspended by a crane, with just enough upward tendency to keep it against the punch in this position, then the feeder can feed the center punch, mark with the center on the punch, and starts the punch with a foot lever, by this arrangement the punch has no opportunity to get away from the mark and spoil a sheet.

In putting in stays for the boiler heads, the front head stays come back past the center of the boiler, and are riveted to the shell, and those from the back head are fast to the boiler ahead of those from the front, so that there is no tendency of the stays to pull against each other on any certain part of the shell.

There is not much new in the machine shop, except some nut-finishing machinery. There is one machine that takes rough nuts, faces off the front and back, rounds off the corners, and chamfres out both ends of the threads. This little machine has a double head, and while the machine is doing the work on one nut the operator is putting on another above it, a trip of the head and the rough nut is being operated upon, and the finished one removed. The sides of nuts are finished by a punch that forces them through a hole, in which are arranged a series of cutters that plane off the sides. After case-hardening, no attempt is made to brighten the nuts, they are left the natural color.

In the erecting shop there were a couple of handsome little Forney engines going to some suburban railroad at Los Angeles, Cal. They were very neat, and well-proportioned, excepting the enormous bullers, front and back, made high enough to reach standard cars.

Some engines being built for the Ft. Scott & Gulf have a high nozzle with a large cavity under the tip, this to allow the steam to escape in a more regular stream, rather than by fierce pulsations.

Moulding machines are being put up and one was at work, it was turning out bodies for screw-jacks at the rate of 100 per day—a moulder formerly made ten per day

One thing about machine-moulded iron that we believe is universally recognized now, is that it is better iron to work, as the mould is rammed by pressure and is always even, an unevenly rammed mould will make an uneven casting.

In taking the flasks from the machine, a trolley runs down a track the length of the floor, and every few feet there is a cross track; an ingenious switch allows the trolley to go to any of these tracks or pass any of them.

These works have always made their main pins without a collar between the main rod and the side rod, giving full length of pin for bearing. They have recently commenced to make the bearing next to the wheel, slightly larger than the outside bearing, especially where solid-ended rods are used, as it makes it easier to disconnect on the road

Recognizing the value of balanced valves, they now put them into all locomotives built, whether ordered or not—unless ordered without balanced valves.

"Strange, Passing Strange."

"The Big Four is testing a large double-boiler locomotive, built by Hinckley & Co., of Boston, on the Indianapolis division. The locomotive, including tender, is 85 feet in length and weighs 130,000 pounds. There are two large boilers, between which the cab is situated. Two engineers and a fireman are required to run the locomotive. It is claimed the locomotive has made a speed of 93 miles an hour."—*Ry. World.*

Our 'steemed contemporary don't seem to recognize the Strong engine—suppose the extra boiler and engineers threw them off the scent.

Melting Metals with Oil Fuel and Natural Draught.

At the works of the Deoxidized Bronze Co., at Bridgeport Conn, they melt their metal with oil, using it in a manner altogether different from anything we have ever before heard of. They melt their copper in a Siemens furnace, which is simply a shallow dish with a cover on it. This furnace is large enough to hold 8 tons of molten metal, it stands up from the floor, and is probably twice as long as it is broad, at one end there are two fire-doors, at the other a flue to the stack. In each door of the furnace is located a metal dish about six inches wide, and a foot long, not over an inch deep, there is another dish inverted over this, that has a slot in its top; in charging the furnace no fuel is placed with the metal, but enough wood is placed under this little dish (which projects in from the door) to heat it pretty hot, when the pans are hot the crude oil is turned on and simply *drips* into this hot dish; it is never allowed to run in a stream, yet the blue flame from it is a steady blaze at the stack, ten feet beyond the furnace. The air is admitted right on to the pan, the door being arranged to leave a slot in the center. With this simple and inexpensive arrangement they are enabled to melt a full furnace of bronze in an hour and a half.

Perhaps the oil burners tried on locomotives have been too elaborate. Still, we do not expect to see oil used in place of coal to any great extent on locomotives, even if it was a success and easy to handle. It would soon become scarce, and the Standard Oil Co. would boost the price too high

Activity in Locomotive Building.

Some indication of the condition of the locomotive manufacturing business may be learned from the results of calls for bids for locomotives for the Lake street elevated road, Chicago. It seems that some difficulty was found in obtaining locomotives on the desired dates. It was found that of six locomotive works, two were too full of work to make bids; two could not furnish locomotives until May, 1890, one could furnish some in April, and only one could furnish two in January, two in February, and six in March.—*Railroad Gazette.*

This holds good only of those concerns who are up and doing. There are one or two concerns that have no work on hand at all, and with their present facilities cannot afford to take any

Thirty years ago, on the old Troy & Boston road, they had extension fronts. Wood burners were used, with the old balloon stacks having an inside pipe and a cone over it, the cinders being caught in the large part of the stack. The extension was made of thin iron, and was bolted on ahead of the arch, there being about a two-foot opening into the original front. From the bottom of the large part of the stack, a pipe led into the extension, to allow cinders to run into the front. This early extension was named by the men, the "sub treasury."

On the N. Y., P. & B., we recently observed some engines where a pair of Sellers re-starting injectors were set side and side just above the running board and outside of the cab, both branch pipes being arranged side and side. The cab was wide enough so that the engineer had a stool to sit on beside the boiler

He Ran on the Signals.

In some of the southwestern territories there was, if there is not yet, a law requiring a report to be made to the county officials of all stock killed, together with a description and the "brand" the animal bore.

A great deal of delay was caused by trains having to stop to allow trainmen to look at the brands of stock killed, as it was a grazing country and the roads unfenced. Naturally the officials of the road fought against the law in every trial, but kept up the order to obey it, at the same time pulling men off if they failed to make time—stock or no stock.

One of the superintendents on a certain line had some blooded stock of his own, of which he was very proud, and it was pretty well understood that it would go hard with the man who hashed up any of the short-horned herd.

One old runner, who had enough of a record as a stock killer to have the wipers dub his engine "the slaughter house," was coming down the hill one day, right through the superintendent's ranch, and there on the track stood the prize bull of the whole herd

This engineer was given to the habit of talking to himself. On sighting the bull he put on the air and slowed down his train, remarking, half to himself half to the bull

"Look out there, old man, I'll make a muley of yer."

At this, Mr. Bull lowered his head and pawed up a scoop of gravel from between the ties.

The locomotive was hauled right down to three miles per hour, as the engineer remarked "Oh, no! I don't mind fightin' you, but you and the old man (the superintendent) both are too much of a good thing"

Here the bull turned and ran ahead of the locomotive and beside the track.

"I knowed you'd think better of it," remarked the runner, as he released his brake and commenced to work steam.

The train had almost stopped, and by the time it was going six miles per hour the bull had got some distance the start, but, as the engine neared him, he got onto the track again.

The engineer shut off, remarking, "Yer monkeying with the loaded end, Mr. Bull."

The bull stepped off

"Changed yer mind, hey?" and the throttle was opened easily.

Again the bull took the main line

"So ye've changed yer mind agin, have ye? Well, so have I!" announced the engineer, as the throttle made a jump for the tank, and the sand lever came back with a snap.

In four minutes the old Pittsburgh hog was "all mussed up", there was hair on the pilot, and short horned bull beef in the ditch.

The engineer expected to get sixty days off, if not his final discharge, and so made no report. A trip afterward he was called up on "the green carpet," to face the maddest superintendent in America.

"So you couldn't content yourself a killing eight or ten mavericks a trip, but you must kill my short-horn bull, hey!" roared he, "cost me a clean six hundred dollars, sir! six hundred dollars—and you have the brazen impudence to come up here and ask me what I wanted to see you about"

"Look-a here, Captain," coolly remarked the plug puller, "what bull are you talking about, and who's killed any of your bulls?"

"Oh! you can't come any of that talk, you, sir, you, killed my six hundred dollar bull, and you know it."

"Don't know nothing of the kind."

"Don't know nothing of the kind, hey? ain't satisfied with killin' my bull, then violating the rules of the road by not reportin' it, and disobeying the laws of the government by not reportin' the brand, but ye must lie about it, too! Now sir, do you dare to tell me you didn't strike my bull?"

"Now, that's more like it," remarks the runner, "striking and killing is two teetotally different words. I did meet your bull on my time, but he turned over so easy I was surprised, and was going to stop and go back to get his brand, but I got a signal to go ahead and went."

"But the conductor and brakeman say they were in the caboose and knew nothing of it, there wasn't any signal to go ahead."

"What's that?" asked the runner, as he stood up and waved his hands violently, as if he was trying to fly.

"Go ahead, all right signal," nodded the superintendent, "but who give it to you?"

"Well, when I hit the bull, I looked back and put on the brake, was going to get his brand, but the bull was laying on his back givin' me signals with all fore feet to 'go ahead, all right,' and I reckoned he was all right and went. I run by the rules, I do, and you can't blame any man for that."

Know Your Business.

Mr. Vanderbilt pays his cook $10,000 a year, my boy, which is a great deal more than we get—*because he can cook*, that is all. Presumably because he can cook better than any other man in America, that is all. If Monsieur Saucegravi could cook tolerably well, and shoot a little, and speak three languages tolerably well, and keep books fairly, and sing some, and understand gardening pretty well, and could preach a fair sort of sermon, and know something about horses, and could telegraph a little, and could do light porter's work, and could read proof tolerably well, and could do plain house and sign painting, and could help on a threshing machine, and knew enough law to practice in justice's court of Kickapoo township, and had once run for the legislature, and knew how to weigh hay, he wouldn't get $10,000 a year for it, he gets that just because he knows how to cook. It wouldn't make a cent's difference in his salary if he thought the world was flat, and that it went around its orbit on wheels. *There's nothing like knowing your business through*, my boy, from withers to hock, whether you know anything else or not. What's the good of knowing everything?—ROBERT J. BURDETTE *in Pathfinder.*

[This was written especially for railroaders.]

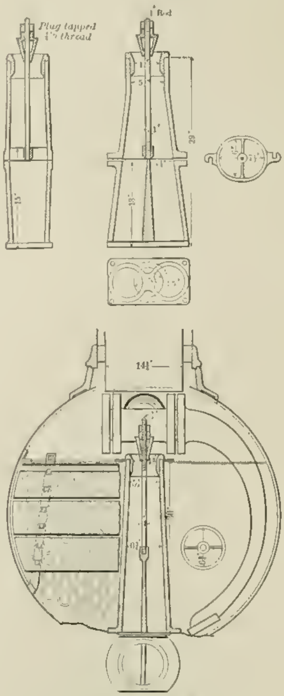
The engineer, fireman and head brakeman on a coal train on the N. Y. S. & W. were killed by their engine and twenty coal cars going into the drawbridge over the Hackensack river during a blinding snowstorm on the 14th of last month. If the road had been blocked, or the train been provided with brakes, or the usual precaution of coming to a dead stop for draws been used, the accident could not have occurred. The way heavy coal trains are turned loose on some of the eastern roads, without adequate brakes, and on lines crowded with traffic, is reckless, to put it mildly. Automatic brakes and automatic couplers would do much to make life a little bit safe around them—which is more than can be said now. When a herd of cattle get the distemper the whole district is quarantined until the disease is cured. Some day the people will quarantine against those roads that are more than half a century or so behind the world in life saving improvements—then the roads will yell, "Granger."

The New York Railroad Club has been thoroughly reorganized with Ross Kells, Supt. M. P. of the Erie, as president, and L. R. Pomeroy, secretary and treasurer of the Suburban Rapid Transit, as secretary. The headquarters will be moved up town, and with the January meeting will be commenced the discussion of live railroad topics. That this club has a large field, practically untilled, goes without saying, and with the present officers in charge, and a goodly company of volunteers, the club ought to become the source of much valuable railroad information.

Thos. Paxton, who was roundhouse foreman at Nickerson, Kan., last year and took a great interest in getting the railroad men to read THE LOCOMOTIVE ENGINEER, has since been appointed master mechanic of several divisions, having more than a thousand miles of road to keep mills in shape on. He is just as enthusiastic a LOCOMOTIVE ENGINEER man as ever.

We are in receipt of a neat little pamphlet of 84 pages, that is being given free to the men on the Pittsburgh division of the P. R. R., by the P. R. R. Dept. of the Young Men's Christian Association, at Pittsburgh. The book contains many rules in case of accidental injury, drowning or poison, the rates of postage, specifications of several classes of P. R. R. locomotives and cars, a list of the block stations, and other information of a like character, that cannot fail to be of interest to the men for whom the book is intended. M. W. Callender, gen'l sec'y, has charge of the distributing of the work.

At the new roundhouse of the N. Y. & N. E. road at South Boston, we observed that the bottom of the pits was made crowning, so that water would naturally run to the sides instead of the middle, as usual. No doubt the men who have to do work in the pits appreciate this—they ought to.



EXHAUST NOZZLE EXPERIMENTS

Correspondence

Some Exhaust Nozzle Experience.

Editor The Locomotive Engineer:

I enclose you blue prints of an exhaust pipe with the cone in the pipe. We use two patterns of exhaust pipes to suit the different types of engines.

We have one pattern we make in two parts, which makes it very easy to put in, and also to take out to clean out the pipe and nozzles when they become stopped up. This is a matter that is often neglected when it is difficult to remove the pipes, they being only cleaned out at the top, and the lower part left closed up.

In this pattern the partition between the two openings is run up 2" above the joint, giving an opportunity to drill and tap out the holes in the bar for the rod which holds the cone. While the openings or passages may seem made for large engines, they are all considerably in excess of the port area and the passages through the cylinder and saddles, giving easy and free passage for the steam to the nozzle opening. The area of the bushing being almost equal to the port opening, reducing the possibility of back pressure. As to there being any special merit or value in this device in the operating of our engines having it in, we have not determined by any comparative tests, by getting at the actual consumption of coal or evaporation of water. But by practical observation, and the experience of the engineers running their engines before and since the cone was put in, and pipes changed, we are satisfied they burn less coal, run much freer, and steam better, burning an even fire. We have put them in some engines burning anthracite and bituminous coal; so far they work very satisfactorily.

I think this is an interesting and an important part in the matter of economically and efficiently running locomotives, and one in which the details of the draught plate, size of stack and grate area are important factors; and then adjustments are not always properly looked after to suit the requirements of the condition or class of engines to which they are applied when the form of boilers is different. On this subject the point was well illustrated by some remarks in your paper some time ago, where it was noted a boiler maker's helper was engaged in or left to adjust the petticoat pipe, while a machinist's foreman was splitting hair setting the valve. As a result, a good working engine was being stalled for steam, because proper attention was neglected in attending to an important matter. In such cases, smaller nozzles are often resorted to as a remedy to make steam, at a detriment to the working of the engine.

While it is not always possible to arrange the apparatus or parts of a front end, so engines will always steam free, investigation and experimenting will often show that improvements can be made in the proper direction.

The idea in making this device was to spread the exhaust so that it will fill the stack at the base.

WM. MONTGOMERY.

Manchester, N. J.

[We have received a number of letters asking for details of arrangement of the coned exhaust, and Master Mechanic Montgomery, of the Central Ry. of N. J. has kindly furnished the drawings of device in use on that road. The nozzle-stand that has a joint in it would seem to be an improvement in any long pipe to facilitate cleaning.]

Little, but Lively.

Editor The Locomotive Engineer:

In the last number J. A. M. tells of some fast runs made on a two-foot gauge road—the Bridgton and Saco River—and asks if any of the readers can beat the time, considering the gauge. How is this: Weight of engine, 12,000 pounds, size of cylinders, 6"x10"; diameter of driving-wheels, 24 inches; gauge of road, 2 feet. Engine built by H. K. Porter, Pittsburgh, Pa. Started from a state of rest and run light 5,700 feet in fifty (50) seconds.

Jamesburg, N. J. J. D. B.

A Licensed Engineer's Ideas.

Editor The Locomotive Engineer:

In Mr. Cushing's questions about breaking side rods on a six-wheeled engine, he says if you break a back connection you take down both back sections of the side rods and leave up the front sections.

C. H. Reynolds says that Mr. Cushing's answer is, when you break a back connection you take down both back rods, and when you break a forward connection the rods are left up. Mr. Cushing does not say that, he says if you break the back connections, take down both back parallel rods, and if you break the forward connections, why, take down the whole line of parallel rods on both sides and run in without train, and when you break a back connection, take down both back parallel rods and leave up both front parallels, and run in with about two-thirds of your train. Mr. Reynolds must look over the questions again and put on his glasses. I have been running a six-wheel connected engine for the last two years, and I know better than that myself. I hope he will look over the questions more carefully next time, and see what Mr. Cushing says before he makes a break. I do not find any fault with Mr. Cushing's questions; they are only for young engineers and firemen, but old engineers can learn a great deal from them. Mr. Cushing's new rules are not new to us down South, for we have been examined and have our licenses. We are all licensed engineers down here, that is where we are ahead of the engineers, in the Northern and Western States. A man has to be a first-class engineer before he can ride an engine, down here. We have a book of rules to study on railroading, and have to run a train and to protect it. They are strict on us. D. W. COWAN.

Wallace, Ala.

[Mr. Reynolds and Mr. Cushing were both talking about what to do with side rods in case of broken *tire*, not rods. Our Alabama friend got his specs on wrong. What kind of an examination do they give you when you apply for a license in Alabama? Cannot our correspondent give us the list of questions?]

Color, not Shape.

Editor The Locomotive Engineer:

In the December issue I noticed some remarks under the head, "None so blind as those who will not see." I don't see where the curious part comes in; it was not the *shape* of the board, the man was to look to, but the *color*. Suppose the management saw fit to put up a *square red* board. Would that be any reason the men should not stop, when that square red board should become sleeted? Suppose that round red board with a round hole should get its shape from that same sleet and snow, and should become the form of the white board—what then?

I know a man who had run an engine over one year, and was asked, one day, if the guide was tapered on the 248; he didn't know; he was also asked if the guide-bolts were put *up* through the guide or *down*—if the nut was on top or bottom—he could not tell, hesitating, stopped, and tried to think. Now don't condemn the man as an engineer, for he was one of the first class. I took the matter up and interviewed several engineers about different parts of their engines with the same result.

There was nothing said about shape, in the rules directing the men's attention to the boards, it was color all the time. If the *color* was not there, they were to *stop*, and that settled it. I am an engineer and a reader of THE LOCOMOTIVE ENGINEER. WM. LANSING.

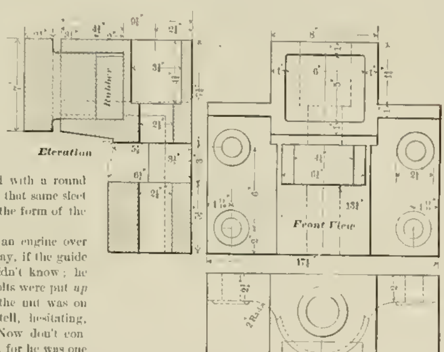
Clinton, Iowa.

[According to this, an engineer would be entitled to go, if the danger signal was against him, but *white* with snow. Of course the rules should mention the shape of the board, but the shape is a help and a safeguard to those who notice it—helps to *make sure*. We should sooner expect men to be unfamiliar with parts of their engine—they do not build or repair them—they *handle* them, every one of those men could tell whether the reverse lever handled easily or not, whether the sand lever was close to a steam pipe or the injector or break valves reachable. These are the parts vital to their work. The signal board is also vital to their work, and on its proper handling *and observance* not only their success, but their lives depend. We were surprised that they did not note the shape, and are surprised yet.]

Improved Draft Castings Between Engine and Tank.

Editor The Locomotive Engineer:

I send you a print of a front draw-head casting and buffer for tenders, which has proved to be of great value on our engines. The strain on the draw-bar of an engine coupled in the common way with solid buffers is very great, especially on crooked roads and short curves, in some cases almost sufficient to shear the pins partially, or else throw the trucks from the rails. And when we think of the very great leverage which the tender exerts on curves—on the draw bar and pins—we don't wonder that they so often have to be taken up or wedges placed on engines for the purpose of taking up the slack between the engine and tender. With this draw casting and buffer, as represented in this drawing, all this trouble is obviated. The draw-bar always remains right and the pins are never sheared. You will observe that the draw casting on the tender has a pocket or recess into which the buffer is placed, behind the buffer is placed a large piece of rubber. When we couple an engine and tender together, we compress this rubber behind the buffer about ⅝ of an inch, which we have found to be about right for our work. We have no trouble with our draw-bars, and there is never any slack between the engine and tender, and in going around curves the rubber relieves the great strain from the pins and bar. We took out a draw-bar after running 18 months, and found it in so good condition that we put it up again and run it until the engine came in for general repairs. That is our usual custom now. We never (except in case of an accident) trouble the draw bar between engine and tender. I ought to say, however, that the buffer castings on both engines and tenders have chilled faces. Sometimes the chill is not



IMPROVED DRAFT CASTING.

very good and they wear off, but they can easily be replaced with the buffer casting represented, which is another thing in its favor. But the draw-bar and pins are never interfered with, except, as I said before, in case of an accident. This draw-casting is the invention of the foreman of our shop, Mr. Russell Hawkes. All our engines on the Worcester Division, N. Y., P. & B. R. R., are equipped with them, with the above results, and some of the Boston & Albany engines have them on. Mr. Hawkes did not take out any patent on it, and has generously allowed it to become public property.

Providence, R. I. W. FOSTER.

A Kink on Disconnecting.

Editor The Locomotive Engineer:

We all know that it must be very unpleasant to have a valve or valve yoke break, especially when the throttle leaks, and steam chest casings solid cast iron, and in one piece, quite a job to take off casing and cover, and replace valve over ports; don't do it. Open smoke-box door, loosen tip on broken side, and slip in a saw blade, screw down bolts, disconnect as usual, and go on.

This is for short front ends, for the extension front end, with double exhaust, take all of the bolts out of base of stack, but one, slew the stack and put in a plug. This plug should be made beforehand, about 10″ long, larger than the pipe at one end, and 2″ at the other, sawed in two in the middle, then by dropping the large end down the exhaust you can then slip the other half down and pull up hard, and it will stay when the steam is on, you can have a hole and a pin through them to hold in place.

Saratoga, N. Y. C. F. G.

How is This, Old-Timer?

Editor The Locomotive Engineer:

Having read an article in the December number of your esteemed paper, entitled "Bound to Work," by your "Philosopher," suggested by information purporting to come from "An old-timer from the luckiest county in the land of hard cider and granite" (which last, by the way, I should judge might be so, especially the "hard cider" part), I would crave permission to correct some of the statements therein contained:

Firstly—There never was a valve made "to go into a pipe between the cylinder cocks" of any engine on the Norwich & Worcester R. R.

Secondly—The old Hinckley insider "War Eagle" never existed on the N. & W. R. R. during the 28 years Mr. Colburn was M. M.

The locomotive "Wauregan" (the only name on the road which by any possibility could be "twisted" into "War Eagle") was built by the N. & W. R. R. Co. at their shops, while Mr. Colburn was M. M., but was an outside connected engine, and had no valves of the kind mentioned by "Old-Timer." A valve was invented by Mr. Colburn, which accomplished the work for which it was intended, and was abandoned in a few years for another of his valves, which cost less to make. These valves were intended to save fuel, and the records of that time, compared with those of other railroads, show they performed their duty well. Being well acquainted with the N. & W. R. R., its motive power, and the man mentioned, and that, too, for many years, I beg the privilege of correcting the misapprehension under which your "Philosopher" seems to be laboring.

It is always fair to hear both sides of a question, and as the "truth" is always desirable, I have taken the liberty of sending this communication, hoping it will be kindly received. I run a locomotive on the N. & W. road for twenty-five years, and am therefore entitled to be called an "Old-Timer" from the

Norwich, Conn. "NUTMEG STATE."

On Studying Indicator Practice.

Editor The Locomotive Engineer:

I admire that fireman who has Pray's second volume, but don't like his wholesale charges of ignorance of locomotive engineers; there are exceptions to all cases. He is, no doubt, trying to learn something besides firing, which every fireman should do. All of us employed in steam engine service of any kind should appreciate the fact that we have the experience of such men as Thomas Pray, Jr., to draw knowledge of practical experience from, let their light shine. I get all such books I can afford, and value them highly—they have done me some good, they can do no harm.

The indicator has come to stay, and valve adjustment will be more governed by the indicator cards in the future than punch-marks and trams.

"Twenty Years with the Indicator" nor any of the books of its class contain any Latin or anything too deep for a practical man to study out, and nowhere furnishes an excuse for a locomotive engineer to run into a switch, or any other engine, but does show the real action of the steam in the cylinder, and that is something we all want to know about. A locomotive engineer who is running a fast express train over a first-class road carries his water so high in the boiler that he has to throttle his engine to prevent it from coming out the stack. Now if a card was taken from his engine running that way, and was shown him, and he could read the card, do you think he would continue to run that way and wonder why he could not make the time?

Of what use is all this knowledge to a locomotive fireman, you ask. Well, the firemen are the future engineers, and the more he knows about his business the better. We should all strive for something higher, and while all of us will not get there, knowledge will be no detriment to any one.

Philadelphia, Pa. PROGRESS.

The Oldest Man.

Editor The Locomotive Engineer:

In a late number of a mechanical paper, under the head of "Wanted," was a call from a Cincinnati establishment for two men for a certain class of work They were to be *live* men and *readers*, who keep themselves posted and abreast of the times. Now if these particular points are essential, together with mechanical ability, in our manufacturing establishments, why does not the same rule hold good on our railroads? Boys, just stop and do a little thinking, for just as sure as the sun shines, the day is coming, and is not far off, when the question will not be asked, Who is the *oldest man?* but Who is the best posted, other things being equal? It is going to be the reading, thinking, practical locomotive engineer, who will handle our fast express and mail trains, and a civil service examination is going to find out what you know, and what you do not know. The oldest man humbug is going to be one of the things of the past. I have nothing to say against the veteran engineers as a class, the most of them are good enough for the present, but things and ideas are advancing. Are you, the oldest man, keeping step with the times? You may think your "Post" or "Kelly" headlight is good enough (and they are good), but they must step down and out, and make room for the electric light; it is the coming light, and will not need to be assisted by any of the lesser lights. There will be a little dynamo put on your engine, perhaps right in your seat-box, and you will have to run the thing, you will begin to have trouble with it; your headlight flickers and don't show a steady light, you will have an incandescent light in front of the steam and air-gauge, and it gives trouble, you look all over the wires but discover nothing; your fireman makes an examination and finds the wires have been chafing, and the insulation is gone in places, allowing the wire to come in contact with a bolt or nut, or some parts of the engine, thereby weakening the current, or the filament in the gauge light is fractured, making that light refuse duty. Do you see the point? your fireman is "abreast of the times," and is going to step over on the right hand side in the near future.

Men are going to get the best runs not only for what they can do, but for what they know in addition. What with sight-feed lubricators, air brakes, steam heating, extension fronts, signal codes, electric lights, injectors, etc., men must be up and doing. You young runners don't waste your spare time sitting in the roundhouse talking railroad; leave that to the fossils; rather get some good book or paper pertaining to your business. Read up, or you will be left behind in the race; you must step in and take the place of the "oldest man." But you say you cannot content yourself reading, but you must acquire the habit, if you ever intend to make your mark, try Jules Verne's "Twenty Thousand Leagues Under the Sea", if that book don't amuse and instruct you scientifically, and give you a taste for scientific reading and a desire to be further posted on compressed air and electricity, then you are cut out for a switch or work train engine, and will have to give up the good things to the boys who have outstripped you. But don't forget to let whisky alone

W. DE SANNO,

Corry, Pa. Engineer and Machinist.

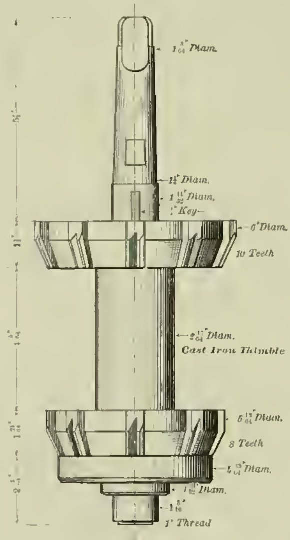
[This is far different advice than that usually given by men whose experience dates back to the time when Baldwin's "Old Ironsides' was one of the finest express engines in the country.]

A Throttle Reamer.

Editor The Locomotive Engineer:

I enclose a print of a throttle valve reamer which we made. The cutters are inserted in soft steel disks, in the usual way, but you will observe that there are two teeth in every piece. This makes the reamer work steadier and smoother than one cut would do; it has been thoroughly tried and works well. Inserting teeth in this way is very much better in large cutters than making them the old way of tool steel and cutting the teeth. I find there is great risk in the hardening of large cutters, very often they are spoiled by fire-cracking. You know the tool maker may take all the pains possible in making tools, which may by improper working or heating be almost useless, to the great disappointment of the tool maker, and great expense of the owners. I remember several such cases in my experience, but in this case there is very little risk, and the work can be done fully as cheap; the cutters can be driven out, hardened, then driven in and ground, and good work done without any doubt. WM. FOSTER.

Providence, R. I.



THROTTLE REAMER

Only One Bright Spot—Tired of Rawhiding.

Editor The Locomotive Engineer:

Have just been looking over some back numbers of your valuable paper with pleasure and disgust—pleasure, when some article would refresh my memory of some good points forgotten; disgust, when I would read of indicators, air-brake practice, performance of new engines, fly runs, etc., because I am denied all these.

I deplore the system here, because it is "chain-gang" and tough, twenty-five or thirty men running sixteen or eighteen consolidators. Being short of engines we usually leave late, then "hit 'er" to get somewhere. Had we regular engines am sure I could look with some pride on the coal and oil report. Can't do it now. Only for THE LOCOMOTIVE ENGINEER I would know nothing of the new engineer's brake-valve, quick-acting brakes, indicators, and many other new inventions. None of our freight engines have air, some have steam brakes, but on account of neglect are not of much use. I am not getting too large for my clothes, or too nice to pull freight, but I often sigh for something different, new and progressive. Reading of them is good, but that isn't satisfaction. I would like to see, feel and have experience with new inventions, and keep up with the times. How can the efficiency of men be got at where the only thought and desire is to "get there"—no thought being given to fireman or self, coal, oil, or engine? What use for me or others to aspire to something better or higher? If a man comes and goes without breakdowns or other mishaps, others call him lucky instead of giving him credit for vigilance or carefulness. I fired up north five years, and had to pass a rigid examination before promotion, but much I learned there is laid aside here for "rawhiding." I wish more M. M.'s, foremen and engineers read THE LOCOMOTIVE ENGINEER YOUNG RUNNER.

Nashville, Tenn.

[Don't give up hoping for improvements; they will come and those "lucky" men who "get there" without mishap will come out on top in the end. Managers have a liking for lucky men—no matter what causes the luck. Try to be lucky.]

Testing the Compound Principle for Locomotives.

Editor The Locomotive Engineer:

The B. & O. compound is still running between Philadelphia and Baltimore, but is now running freight, and has not, I understand, equaled the sanguine expectations of its many friends; the "why and wherefore" of its failure to do so is "what no feller can find out." But from the fact, or rumor, that the "Baldwin Locomotive Works" are making a new pair of cylinders, it would appear that there was still room for improvement. What the change will be is a mystery to the uninitiated. Why do they always saddle a new type engine with so many "improvements" of untried value, and thereby increase the risk of failure? Why not try this type of compounding with the old D slide valve in place of the "improved" piston valve now used, and at the same time apply a piston valve to a standard engine, and ascertain beyond doubt whether the trouble was in the "compound principle" or some of the details, the piston valve among the number? It is not giving a new thing a fair show when it is tried with several others at the same time, as in this case—a sliding bar to connect the link to valve rod, in place of the rocker arm of almost universal practice, being among the number, and this bar has given more or less trouble up to date. It has also a variable exhaust of what is known as the "solid plug" type, which has been in use ever since way back in the fifties, and was in all cases laid aside for the pipes with openings to suit each cylinder, and the piston valve seems, to the many who have seen them tried and condemned, a very doubtful expedient.

This is too much to saddle on the principle of compound locomotives, which has a hard battle to fight with prejudice in this country, and will have a hard road to travel in making itself popular, without being handicapped by any doubtful improvements.

The Webb compound on the P. R. R. has many objectionable features attached, but it would be well to find out why they are used before changing to something untried It may be possible that their use has been well considered, and their objectionable features more than overbalanced by their advantages.

Before trying to improve upon anything it is well to understand the subject fully, so we can see why things are "thusly."

The "Webb" has beyond all doubt shown a saving of fuel over the ordinary engine, and the B. & O. has not. Is it the principle or the improvements that are responsible for this, or can it be that there is something about the Webb besides the compound that does the saving?

Conshohocken, Pa. O. B SERVER.

A Radical View of the Traveling Engineer.

Editor The Locomotive Engineer:

From the article in your paper on the Traveling Engineer, it seems to me that some fellow must be traveling for a job, or else some road must be employing an incompetent M. M., and at Mr. Phelan's idea of letting a M. M. paddle his own canoe I am surprised. A practical engineer ought to know that any M. M. who allows a traveling engineer is not held in position on account of his good qualities as a mechanic or engineer. Did you ever know of a good practical engineer, as M. M., who would employ a traveling engineer? Well, I guess not, unless a friend of his come along and he has all the engineers that he can employ, then he picks up the idea he can employ him for traveling engineer; but as soon as he can give him a regular engine, good-by traveling engineer, until some other friend comes along. No master mechanic who knows the duty of an engineer will employ a traveling engineer. I am surprised that any superintendent would admit anything of the kind to be paid for on transportation rolls; but as long as companies will employ incompetent men for superintendents and master mechanics, such ignorance may be expected as employing traveling engineers. I do think, in my own opinion, that money paid out to a traveling engineer is worse than that of paying out money for cylinder oil that makes 5,000 miles and requires new valves and false valve seats for the engines, also new packing for cylinders. A master mechanic should know the duties of an engineer before he accepts the position of M. M.; then a part of his duty is to know the condition of all his engines in his charge. His next duty is to keep those engines up in good repair, keep their valves square and packing from blowing. The engineer's record as to how he pulls a train, and handles his engine, will soon tell on him, then the M. M. can handle him without any go-between—called a traveling engineer. When a M. M. does not know the duties of an engineer, I would advise him to employ a fireman that does.

Now, Mr. Editor, this will hit some M. M.'s pretty hard, but you just tell them to take my advice as to employing a fireman.

I have been a traveling engineer in pay of the company, and I have also been a traveling engineer without any pay, and I think in my own mind that railroad companies were making more money when I was traveling without any pay, and common engineers were happy.

I am very much pleased with your valuable paper, and I hope you will continue in the good work and swell your subscription to what it ought to be. Every engineer, every railroad official, and every employe of motive power and car departments ought to subscribe for it.

E. A. CAMPBELL,
Supt. M. P. & Mach'y H. E. & W. T. and S. & H. Railway.
Houston, Tex.

A Flue-Hole Cutter.

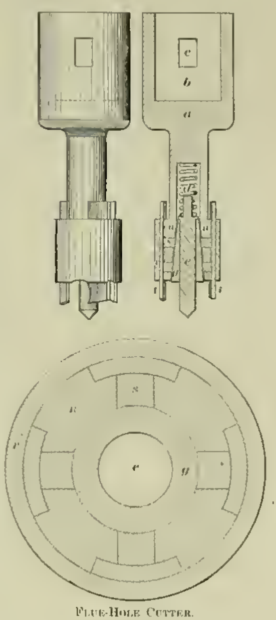
Editor The Locomotive Engineer:

Enclosed I send you blue print and description of a very practical device for cutting all sizes of flue sheet holes.

Consisting of a shell *a* keyed to the outside of drill spindle, so as to make it more durable, and prevent it falling to the floor after every hole, which would damage the tool and cause unnecessary repair, and also to keep drill master in good humor.

The cutter holder *n* is turned the size required, being in this case $2\frac{1}{16}$" scant, the bearing of cutters, four in number, are $\frac{11}{16}$x$\frac{5}{16}$" deep, and the cutters scant of $\frac{5}{16}$" accurately fitted in the slots. The cutters are secured by means of steel pins *s*, two for each cutter, and taper bushing *g* pressing against the inside of bushing *r*, which is shrunk to the body *n*. The center *e* is the guide of cutters adjusted by spring *d*. For grinding the cutters, remove *e g* by means of a slot provided, similar to a drill socket, which is not shown, and the cutters can be taken out and be replaced or refitted when necessary. The cutting edges of cutters should not be ground straight, the follower or second cutter should be about 2° taper to the first one, the third like the first, and the fourth like the second, thus relieving the cutting and making a smooth hole. A case of weak feeding attachment on drill press, where the cutter would not do work required, caused by the additional friction of the same or spring *d*, remove *e g* and put a common reamer corresponding with the same taper as *g*, drill the small holes first and operate the cutter in the same manner. For enlarging the size of holes use the same shell and make offset cutters. With this cutter we have been able to cut 200 holes in 10 hours.

C. G. BRETTING.
Brainerd, Minn.



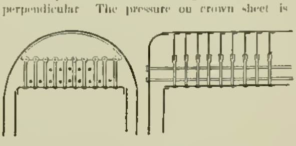
FLUE-HOLE CUTTER.

A Suggestion on Crown Sheet Stays.

Editor The Locomotive Engineer:

In thinking over the different methods of staying the crown sheet, the following idea presented itself. Instead of using the double crown bars fastened to the crown sheet, with stays to outside shell, I suggest single flange plates riveted to the shell, as shown in sketch, with stays to crown sheet.

The stays being of the same length and hanging perpendicular. The pressure on crown sheet is



carried through the stays and distributed over the plates to outside shell. Longitudinal braces could be used with more advantage, and the crown sheet can be cleaned as easily as in the Belpaire fire-box. The shape of boilers with flat sides above the crown would be better preserved.

New York City. MANHATTAN.

About the Air-brake Puzzle.

Editor The Locomotive Engineer:

SIR: I have waited to see if some expert would not explain the "Air-brake Puzzle" of Mr. C. A. Smith in the September issue of your paper. I did certainly think the "air brake" would draw attention fully as much as some other subjects that have been discussed.

Now by your permission I will endeavor to explain to Mr. Smith the "reason why." With eighty pounds pressure and stop-cock closed, we open stop-cock; this lets the air from train pipe into pipes leading to left auxiliary, and by way of extra pipe to tender brake cylinders, setting tender-brake in opening the stop-cock, you reduced pressure in train pipe; this caused triple valve to open port from tender auxiliary to brake cylinder. So you had first the air from auxiliary into brake cylinder, as the air had a longer distance to travel by way of stop-cock and extra pipes. Now we have the pipes, tender-brake cylinder and both auxiliary filled with pressure a few pounds below what it was when we opened stop-cock. As soon as pump has furnished the eighty pounds again the triple valve of tender will be pushed in position it is at release. This will cause a blow of air from exhaust port of triple valve. This will continue as long as everything remains as it now is. Right here probably is where Mr. Smith changed position of four-way cock under tender. Changing it stopped the leak of air, but made no other perceptible difference. Changing four-way cock from automatic to straight air closes port leading from auxiliary to brake cylinder, and opens port direct from train-line pipe to brake cylinder. So we will place four-way to automatic, and we have the leak of air. Now close stop-cock and the supply of air is cut off, so as soon as air stops blowing through exhaust the tender-brake will be released. This is taking air from pipe leading to left auxiliary, and the driver-brakes are set. You can release driver-brake either by bleeding auxiliary or turning four-way cock to straight air, but we will let it remain as it is—automatic. Now we will apply brakes by reducing through engineer's valve, say twenty-five pounds. This will allow air to equalize from tender auxiliary to brake cylinder, through extra pipe to left auxiliary and release driver-brakes and set tender brake. Now turn four-way cock of left auxiliary to straight air, and release brake by re-charging train line pipe from reservoir. Now all the brakes are released. This is the only way the brake can be used with this extra pipe connected, the driver straight air and tender automatic. This I would not advise to be done, as you have the three brake cylinders and extra pipe to fill from one auxiliary, as the left one is cut off. With eighty pounds initial pressure you would not have over thirty pounds on each piston.

This pipe was meant for a release pipe, connected, as it is, with brake cylinder and running along tender to gangway, with stop-cocks in the end, to be reached while train is in motion. So, should triple valve refuse to act promptly, let the air out of brake cylinder through this pipe—about a ½-pipe. If your triple valve is in good order and kept so there is no use of this pipe, as it is very seldom used, although most engines equipped with air have them. Take the pipe off and plug up the hole. Can't see where it will be of advantage by connecting it at *C* as suggested by you. I don't understand why he says "driver-brake" should receive air from tender auxiliary only in case of emergency. The suggestion to put stop-cock in pipe at "*C*" is where it should be, as then you have auxiliary charged for drivers without bothering with stop-cock.

In regard to excess pressure on engineer's valve there may be several reasons for it. The valve may be stuck or the tension in spring may be too light, or rotary valve may leak—"they are apt to warp," or the gauge may be wrong. Reduce pressure and then re-charge train-pipe by putting handle of valve on feed where it is to be carried while running. If valve and spring is O. K. it will make a singing noise by spring vibrating. The excess valve may be put in wrong. The spring should be enclosed out of sight.

BILLY WILSON.
Clinton, Iowa.

W. H. Thomas, Sup't M. P. of the East Tennessee, Virginia & Georgia system, has taken hold of the circulation of THE LOCOMOTIVE ENGINEER on his system, and has interested most of the officers and men in his department. He writes us that he intends to again make it the banner system in THE LOCOMOTIVE ENGINEER'S circulation, as it was the first year. In 1889, the Michigan Central and the Canadian Pacific got away with them in point of circulation.

W. G. Allen, chief of Div. 207, B. of L. E., Atlanta, Ga., dropped dead on his engine on the Georgia Pacific, on the 12th of December.

CONTENTS.

Economy in the Use of Oil.

The man who uses the least oil on a locomotive is not always the most economical. Between the journal and the bearing there must always be more or less friction; this can be more or less reduced by introducing between the moving surfaces some unguent that prevents in a measure the bearing parts from coming in actual contact, or the molecules from interlocking with each other and allows the load to ride more or less upon the film of oil.

This film of oil will be governed greatly by the pressure there may be between the bearings, the speed at which the journal runs, and its temperature. It is never desirable to be so economical (?) of oil as to take from the bearing so much oil that there will not be at all times as much in position to be used as the revolving journal can possibly draw in between it and the bearing. Every bit of lubricant that is used there reduces the resistance and allows more work to be done, with the expenditure of a given power.

True economy in the use of lubricating oils is in so using it that all, as near as possible, shall be used on the bearing and none *around* it. Locomotive engineers are practicing false economy when they try to run light on oil by not putting enough on, and they are practicing economy in the use of oil when they keep the bearings flooded in it—providing they take pains to keep it from getting away.

It is well-nigh impossible to oil a locomotive in a hurry and not use some oil around the holes, but this should be as carefully done as is possible, and the easiest way to do that is to have your feeders and box packing so arranged that it can be depended upon to feed reasonably well and require little or no oiling on the road. When a man has time to oil deliberately before he starts out, is the time to be careful.

When the packing in a driving-box will keep oil-soaked waste up against a journal, all that is necessary is to see that the waste does not get dry—not to pour oil on the box till it runs all over the box, wheel, frame and township. All the oil that you see around the collar of a pin is doing hurt, not good—it catches dirt and grit.

It is good practice to oil all spring bearings once a week or so, a drop on each hanger and equalizer pin and on the expansion hangers will cause the engine to ride easier and adjust herself to uneven track better.

Oil, if kept clean, can be used over many times, so do all you can to keep dirt out of your cellars and packed boxes, the cup-fed oil can only be used once, as there is no way to get it back to the cup after once being used, but you will be surprised to see how little oil a pin needs if it gets it regularly. Heavy oil wears best on such work, but it is a question if the lighter mineral oils are not better, or at least cheaper, as more can be used and less dependence placed upon its staying on the bearing.

To look at many of our engines on a cold morning, one would think that they had been oiled with a sprinkling pot, and the oil in sight is wasted oil, and what runs the amount up so high; but every drop of oil that has passed between the bearings has done good and its use was economical—provided it was used as much as it could be.

Use as much oil as you possibly can on the bearings of your engine, and as little as you possibly can on the frame, rods, outside of guides and on the ends of the ties.

Some people think that there is a certain fixed quantity of oil that a bearing should have; we believe that for locomotive practice this quantity is all the bearing can carry between the moving parts by being at some part of each revolution in free contact with oil, and on a locomotive this is always possible.

A Wrong Idea.

Every time we find a man that knows something about a certain thing; say he is a machinist with a wide experience on running repairs, or an engineer who has had experience on everything from hook motions right down to date, and want him to write up some of the stories, descriptions of tools, or kinks, or accounts of breakdowns; they all say that they can't.

Perhaps they have just told all about a thing, but say: "Oh, I couldn't write anything on it. I'm only a machinist, or an engineer; it wouldn't do for me to express it on paper as I do to you."

Now that is just what would do the very best, there is now, and always has been, a dearth of railroad and mechanical writers from the ranks of railroad men and mechanics.

Don't be afraid you will fail; try. The mechanics of the country are hungry to hear from you.

A Good Railroad Map.

The Official Railway Guide furnishes this year a large revised railroad map of the United States. As the Official Guide has no particular interest in distorting the features, and changing the boundaries of States to make this or that line the "shortest by four hours," we feel sure, when looking at it, that the State of Ohio in no place reaches as far west as Chicago, and that Pennsylvania is in no place four times as long as New York.

A Timely Suggestion.

The regular slaughter of railroad men has at last attracted the attention of no less a person than the President of the United States, and in his recent message to Congress he makes the following statement.

The attention of the Interstate Commerce Commission has been called to the urgent need of congressional legislation for the better protection of the lives and limbs of those engaged in operating the great interstate freight lines of the country, and especially of the yardmen and brakemen. A petition, signed by nearly ten thousand railway brakemen, was presented to the commission, asking that steps might be taken to bring about the use of automatic brakes and couplers on freight cars. At a meeting of State railroad commissioners and their accredited representatives, held at Washington in March last, upon the invitation of the Interstate Commerce Commission, a resolution was unanimously adopted urging the commission "to consider what can be done to prevent the loss of life and limb in coupling and uncoupling freight cars and in handling the brakes of such cars." During the year ending June 30, 1888, over 2,000 railroad employes were killed in the service and more than 20,000 were injured. It is competent, I think, for Congress to require uniformity in construction of cars used in interstate commerce and the use of improved safety appliances upon such trains. Time will be necessary to make the needed changes, but an earnest and intelligent beginning should be made at once. It is a reproach to our civilization that any class of American workmen should, in the pursuit of a necessary and useful vocation, be subjected to a peril of life and limb as great as that of a soldier in time of war.

It is more than time something was done, and Mr. Harrison has not put the case any too strong. Automatic couplers must come, and then the block system must come. These modern appliances cost money, and it is cheaper, at the present price that human lives are held at, to pay for the wrecks. Human life ought to be held higher.

Some official of the Erie road recently went outside of his legitimate business and interfered with that of the Creator, in trying to make the Erie "employes" honest by posting an order that all must pay their debts promptly. A road that has been stolen back and forth bodily two or three times, and never really knew how big its debt was, is hardly the sort of an oculist to pick specks of debt out of the eyes of its employes. But such orders should not be charged against the road, nor do they represent the brains of a road. Every scientific official that is *born* for the place and gets no practical training for it, has to slop over in some way—we used to work for one who imagined he was Joshua, and thought that the sun and moon would stand still if he said so, and sealed the order with his rubber stamp. But they never did.

We cannot undertake to thank all the lodges of engineers and firemen in the country, who have sent us "comps" to their annual balls and banquets—we haven't room for the directory it would make. Thanks, gents, one and all; sorry we can't reach you all; we're slow freight on the dance, but lightning express on the eat.

ASKED & ANSWERED

(1) Student, Meadville, Pa., asks.

What would be the results, as far as operating railroads, if there were no such thing as friction? *A.*—There would be no railroads. Without friction nothing could exist on the earth in its present shape. When friction is eliminated chaos will commence.

(2) C. S. Aldrich, Pascoag, R. I., asks:

Will you please tell me, in seconds, how long it will take a passenger train, going at the rate of forty miles per hour, on a down grade of forty-five feet, to stop with air brakes; and also the distance in feet, using Smith's vacuum brake? *A.*—Your question could not be answered with anything approaching correctness without knowing the entire weight of engine and train, and the weight of the braked portion of the train. Without this data all answers would be simply guesses.

(3) Janesville, Wis., asks.

Are there any reliable rules about the size, weight and depth of locomotive driving springs? I want to know about what proportion of the total carrying capacity of the springs can be safely used. *A.*—Driving springs are usually made so that when loaded there will be as much set in the springs (usually from 2" to 2¼") as to just let them come straight when the driving-box is thrown to its highest possible position. No better rules for determining the size, weight or number of leaves have been found than those of D. K. Clark (1855). In the chapters on running gear in Forney's Catechism of the Locomotive, these rules are given and well explained. We know of no rules in use where the load is determined by the total carrying capacity or breaking strain.

(4) G. A. M., Albany, N. Y., writes:

I am running an engine, and find that her exhaust takes place on one side on the centers, while with the exhaust on the other side one occurs when the pin is on the eighth, the other when it is between the quarter and the back center. Please tell me how I am to make her beat square, as I make the necessary changes myself. *A.*—It would appear from your diagnosis of the case that it was about time that some changes were made. If your eccentrics are keyed on, and are in place, run the valves over; if you are not sure as to the proper methods, see page 2 of THE LOCOMOTIVE ENGINEER of August, 1888. If the eccentrics are slipped you can get them back by placing the engine on the forward center (for the forward motion eccentric), place the lever in the corner ahead, and pinch the eccentric around on the shaft, in the direction it is to run, until the valve slightly opens the front port; this gives the lead opening; fasten the eccentric and bar the engine over to the back center; if the lead opening is the same for the back port as for the forward one the eccentric blades are of the proper length; if they are not of the same length, run the valves over and get them so.

IN THE ROUNDHOUSE AND Repair Shop.

A Connecticut Railroad Shop.

(Editorial Correspondence.)

Somehow or other the railroad shops of New England are not so easy to write up as those of the West; there are different things to see, but somehow they do not exactly seem the things that you want to describe at length. I started out this month, as usual, to find something of interest for the readers of THE LOCOMOTIVE ENGINEER, and steered in a northerly and easterly direction, more because it was just about opposite to the direction of my last tramp than for any other reason. A train of the New York, New Haven & Hartford Railroad was standing at the Grand Central depot, and I stepped aboard.

The first thing I do nowadays on boarding a railroad train is to

CONCEAL MY IDENTITY

by putting my hard-boiled hat in the rack, and getting on one of those little good-for-nothing skull-caps, then I conceal my Brotherhood pin in the lining of my vest, and commence to ask the train men such questions as, "When the 11 o'clock train goes?" so as to effectually throw them off the scent, if they might have thought I was a railroad man—not that I am ashamed of the crowd or the occupation, but it hurts my proud spirit to claim to be a railroader, and yet have in my possession a real, made-a-purpose ticket. In the past I confess to being instrumental in the free transportation of a large quantity of railroad meat, and try as I may to be independent and pay my fare, it seems as though I ought to ride free to get even. I don't think I shall ever get over this feeling—perhaps I rode free too long.

The first thing of interest was a hat-rack that was actually made to hold things; this is a brass frame about two feet wide, the bottom of which is composed of a coarse web of brass wire; there is no attempt to make sides to it; the whole thing is inclined toward the outside, and it runs from end to end of the car. The largest valise can be held there securely, it will take in umbrellas, fish poles, or anything else likely to get in at the door. Where such a device is provided, there ought to be a heavy penalty for the swine that wants a seat for his grips, one for his feet and another for himself.

ENCOURAGING DRINKING.

A few miles out of the city, some one touched my arm, and asked me to "have a drink?" and a colored man held a silver-mounted tea-kettle, with a beer-glass receptacle in front of it, invitingly in my face—nothing but ice water—but it was pretty good, and I thought it must be a pretty nice thing for women with children, or aged or ill people, it might also keep from suffering, the man who is always afraid some one will get his seat, if he risks getting a drink of water. I am told that the passing of water on all passenger trains in the State of Connecticut is required by the laws, and was enacted for the benefit of the soldiers, during the late unpleasantness.

THE NEW HAVEN SHOP.

I don't know how big the New Haven shops are, and I don't think there is a reader of the paper that cares to know; they are built of brick, are old enough to vote, without a doubt; there is nowhere an attempt at ornamentation—they are business all the way through.

The roundhouse is a complete circle, and the office and the main shop are located back of it, so that in going to them you have to go through the roundhouse or around it.

HANDLING THE COAL.

The coal used here is of two qualities, the best being the famous Pocahontas, the other being a fine, dirty coal from Pennsylvania, that the men have named "Philadelphia mud." This coal is brought here in vessels, and these tie up to the coal-bin at the shop, the latter being right on the shore. The coal is hoisted out of the schooners in a special bucket, and is elevated by steam to a track running out over the coal chute; here the coal is dumped into a car on this track, and after that it takes care of itself—the track being inclined, the loaded car runs down the track by gravity, in doing so it winds up a weight attached to a cable on the upper end of the car; at the end of the track the car strikes a trip that dumps it, and then the weight, being heavier than the empty car, returns it to the upper end of the track for another load. Pocahontas or Virginia coal is good, and the engines do well with it, but the other coal is rather poor stuff. They tell a story there on one of the engineers. He went by the coal dock on his way home, and seeing the captain of a schooner, whom he knew, just tieing up, asked him if he had a load of Pocahontas. "No, Philadelphia mud," was the reply. "I wish to thunder, you had sunk in the Sound," was the cheerful retort. This reminded me of the story of the old Scotch dominie, in the days when dominies lived on faith and donations, one brother donated a load of green poplar wood, and was surprised the next Sunday morning to hear the good dominie pray that brother so and so be prevailed upon to cut some of that wood, and donate it to the use of Satan, as he, the dominie, was sure that about four cords of it would put out the fires of sheol.

AGE AND SIZE.

The present New Haven road is a consolidation of several smaller roads, most of which were started or built well back into the 40's. The line is known locally as the Consolidated Road, it operates 863.65 miles of road, including sidings, and has in use over 200 locomotives. Most of the divisions are short, and the men do considerable dodging around for a day, but make big money for an eastern road. One feature not usually seen is the

WEEKLY PAY CAR.

Another law in the "Nutmeg State," all corporations have to pay their men weekly. This road, short as it is, keeps two pay cars in service. The engines are backed into the roundhouse, which is a low-roofed one, with an open center. There are no improved methods specially worthy of imitation in this roundhouse; it is a fair sample of a house on a busy road, not as good as the best, and far from being the worst.

THE ENGINES

would be noticed anywhere; the majority of them were built by the road, and are peculiar to it. While they have a few Moguls and 10 wheelers for freight that have come to them as prizes with the little roads that they have got hold of, the great majority are 8-wheelers, straight stack and extension fronts. They are a nicely modeled engine, and do good work, ride well and steam fair. The first thing remarked by the observing engineman is that there are

NO RUNNING BOARDS.

The board ends at the wagon top, just ahead of the cab, this makes the cleaning of the lower part of the boiler easier, and provisions are made for agile firemen to get around over the upper works—we observed several standing on the copper injector pipes. The guide yokes do not reach across the frame, but are strongly braced to the side of boiler, all have an expansion hanger just ahead of forward driving-box. A great many of these engines have underhung links, something not usually seen now.

A DUST PREVENTER.

The extensions are lagged and covered by jacket; the front cinder slide is the common one of a piece of flat iron in a slot across the pipe, with coal-pick marks on the slide, to tell how it is opened. They have one good thing about them, and that is a hole in the front of the cinder pipe into which a stream of water is introduced when sparking engines at division terminals, this is a simple safeguard against clouds of dust.

WATER TABLES

are used in most of the fire boxes, though there are some brick arches; and movable diaphragms operated from the cab. The bands on the jackets are Russia iron, but are made to look better and stronger by a row of neat, round-headed brass rivets in the center. The cylinder castings have a single admission port into the chest, this is at the back, or cab, side of the other ports.

The Bristol

ROLLER VALVE

is used, this is a plain slide valve riding at each end on a series of steel rollers running in a frame on a track at each end of the ports. The success of this device depends so much upon the nicety of the fits that it is very difficult to keep the valves tight—one man will be kicking about his valves blowing on a new engine, and the next one will swear he has run two years without a simmer. The main trouble with the device seems to lie with the tracks—the least wear or displacement of the track lifts the valve off the seat or drops it down on the seat, and takes the load off the rollers, either of which defeats the objects of the invention.

THE LINK BLOCKS

have no sides, but are held in the link by ribs on the die block that fits into slots in the center of each link face. I fail to see any advantage in this plan, but perhaps it has some; probably it is retained to prevent making changes. On most of the 8-wheelers the forward tire has no flange; this, it is claimed, enables the engines to go around the heavy curves into Springfield—the engines all have rigid trucks—there are Y's on the road where these engines are not allowed to go, because of the bald tire—curious thing it don't work both ways. Iron pilots are used.

CAB LAMPS

are hung from the roof of the cab, and seem to make a neat, cool and handy arrangement. The gauge-cocks are of that class we used to call "automatic" in the West—leak so bad, as a usual thing, that it is unnecessary to open them. I never saw a babbitt seated valve I would trust at all to keep tight. There are no automatic cylinder lubricators used, and there is no limit to the oil a man may use. A bulletin is posted monthly, but no credit is given for the best records on coal or oil. I noticed that some of the men ran only two miles to a pint of engine oil, some—principally construction engines—ran 19 to 21 miles for a pint, while the average is but six or seven miles. The engines are kept clean and show good care. This road at one time owned the finest painted engine in America, gold leaf and oil paintings were everywhere, and some of the scenery painted on the tenders was worth lots of money; this has all gone now, and while the engines are neat, there is nothing of the circus poster about them.

There are men to

CLEAN FLUES

and spark the engines, and the firemen are not required to polish the bright work on the cylinder heads and chests, most of which are polished iron. In cleaning flues they have a little device worth imitating, a piece of air hose with a coupling head is coupled to the front end air hose, and by using a piece of pipe on the other end, each flue is blown out thoroughly, if a flue is stopped up solid, an auger is used to loosen the cinders, then the air-jet does the removing.

NEW ENGINES.

There are six very large Baldwin 8-wheelers here on freight, they are very heavy, and have a cylinder 20x22; it is claimed that they are so heavy they break rails, their short stroke does not help them out for freight service. The Sellers restarting injectors used on these engines were originally placed close to the roof of the cab, some forty inches above the top of tender; these have all been lowered to a line with the top of the seat box, the air pump has also been placed below the cab and between the drivers.

Some new 8-wheelers just sent here were built at the R. I. Locomotive Works, at Providence, and are the standard engine of the road exactly, they have 54,000 pounds on their drivers, and cylinders 18x24, and are the engines that were to expand steam more on account of the light weight—a feat promised by one of our railroad papers.

Back of the roundhouse there is a store-house and the offices in one building, and another building where all the wheel work is done. Here are located the big wheel lathes, the presses, etc., in fact, all the wheel and axle machinery. We noticed on a pair of wheels having the tires turned, that the tire was set on blocks of hard wood arranged around the wheel center, a plan originally used by Mr. Griggs, Sr., one of the oldest master mechanics in the New England States.

NEAT TOOLS.

All the machine tools are painted a wine color and striped with red, and are kept clean and neat, we noticed no ancient tools, and the back shop presents a busy appearance, there being several engines getting general overhaulings.

FRATERNAL FEELING.

There appears to be no red tape between the men and the officials, all being approachable. We found a couple of young men hustling around the roundhouse taking subscriptions for THE LOCOMOTIVE ENGINEER, and Master Mechanic Henney advised all the men to take the paper—said it was in the right line.

The Fireman's Brotherhood lodge at this point, having over a hundred members, have recently inaugurated the locomotive discussion movement and there is a great interest taken. They took Mr Cushing's questions in THE LOCOMOTIVE ENGINEER, and discussed every one of them, from preface to finis, and called my attention to the fact that the large club recently sent in all commenced with the papers containing these questions.

This party of progressive young men are going to take up the discussion of the train rules of their own road, and then a general line of mechanics. To show with what interest such things are watched by officials, I have but to mention that Master Mechanic Henney is having a valve motion model built for this lodge, and General Superintendent Shepard has asked to address the club, and help them in any way in his power.

AVERAGES WELL.

Taking it all around, the New Haven shops are above the average of eastern shops, the engines are good, and the men are intelligent. If I was going to offer any suggestion at all, I would want the inverted dish-pan taken off of the top of those straight stacks—it is far from pretty.

J. A. H.

Fig. 1.

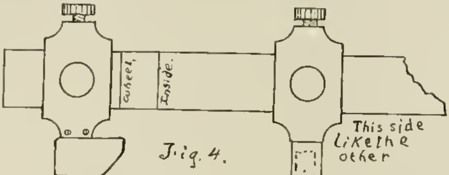

Fig. 4.

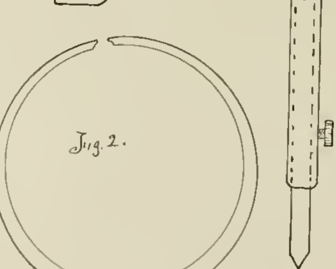

Fig. 2.

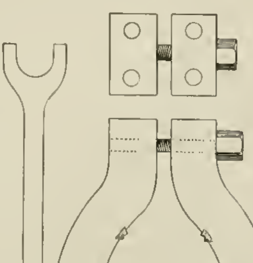

FIG 3

The Schenectady Locomotive Works have completed a compound locomotive for the Michigan Central. It is built on the Mallett system, with an automatic equalizing valve between the high and low pressure cylinder, something like the valve of the Worsdale-Van Borries system.

A Rhode Island Railroad Shop.

One of the neatest little shops that it has been our good fortune to visit, is the shops at Valley Falls, in the suburbs of Providence, of the Providence & Worcester road—now a part of the N. Y., P. & B. system. The old P. & W. road had fifty miles of track, and used thirty eight locomotives, doing a large passenger business—especially suburban business.

The shops at Valley Falls were built five or six years ago, and, for the size of the plant, are as elaborate as the best. The buildings are neat, part of wood, the rest of brick, but all complete, painted and in repair, no old sheds or eyesores anywhere.

The paint shop, drawing office, store-room and master mechanic's office are separated from the main shop by a steam-actuated transfer table.

In the main shop there are three stalls, and the machinery is located at the opposite end of the shop. The machine tools are about the same age as the shop. There seems to be a sample tool from most of the first-class makers. All the lathes have different tapers for their centers, and are in every other way about as different as they well can be.

The heavier tools are covered by cranes, and facilities are had for handling easily all heavy work. All the tools are clean and well kept, and every wrench, chuck and gear has its place.

Just off the main shop is the tool-room—probably 14x30—the most interesting part of the shops. There are here a small engine lathe, a milling machine, twist drill grinder, etc. Along one end of the room there is a cabinet of drawers, in which fine test gauges, taps, dies, and such work as is used to measure cutting tools, are kept. On the side next the street is a bench the entire length of the shop; at the other end a stairway leading to the stock-room above, and on the other side, next the shop, a series of inclined shelves about 18" wide and extending from the floor some ten feet high.

The manner of classifying the tools is different from the plan used in any other tool-room we ever visited.

All the special tools intended for work on any certain part of a locomotive are assembled together, regardless of what they are. For instance, here is a section of a shelf a couple of feet long, on which is painted "Crosshead tools." There are the gauges as to size, drills to drill holes, reamers to follow the drills, and taps to follow the reamers if needs be; there will be a taper plug gauge to fit the piston rod hole to, and all jigs used in making and repairing crossheads.

Every tool is branded, in plain letters, its use, and it would seem that mistakes caused by men using the wrong sized tools could not occur.

The plan for caring for crosshead tools is followed with all other parts, such as valves, pistons, boxes, etc. Some of the kinks and short-cuts are extremely ingenious, and the readers of THE LOCOMOTIVE ENGINEER have by no means heard the last of them at the end of this article.

Wm. Foster, who has charge of this department, is a well-known "kink" man to our readers, and he has an able assistant in Frank Pond.

For putting studs into boilers, cylinders or other work, they have a series of forcing nuts—simply nuts in which the hole does not go through. These are double, having a different size or different thread at each end. The thread is made a loose fit on the studs, and the end of the stud is allowed to "bottom" on a copper disk in the center of the nut. These are very handy, as any stud can be put in with a common wrench without marring the stud, as is the case with the use of pipe wrenches.

For removing studs they use a very ingenious tool, as shown in Fig. 1. This is a long nut having a swinging disk of steel with a milled edge, that engages with the side of the stud and binds. It has a wide range for sizes that it will hold, can be used right or left, and ought to be a popular tool. It was invented by John Bowman, a mechanic in the Altoona shops of the P. R. R.

Great care is taken here to keep the trucks square, and there are in use many gauges for wheel and axle use that our friend Foster will no doubt let us know about. They mark all axles on the center, exactly between the centers of the bearings, and use a gauge like Fig. 4 to find out if the wheels are in their proper places

Some makers shove the wheels upon the axles to a shoulder or to a gauge measuring only from one flange to the other, and it often happens that the wheels are not the same distance each from the center of the journal, and a "slewed" truck is the result, but by measuring from the center to each flange, and also to the inside of wheel flange, it can be seen at once whether or no the wheels are right upon the axles. This gauge has two wheel tread gauges and one center pointer; this is so arranged as to be lengthened or shortened to meet the requirements of service for all sized wheels.

It may be well for us to explain right here that these cuts are from pencil sketches from memory, and are not intended as specifications to build to, but to show how results are accomplished.

Crossheads where the main-rod pin is cast solid, generally require quite an elaborate machine to turn them up. Mr. Foster has a clamp made in the shape of Fig. 3, that does this work very nicely. Each side carries five steel cutters, each cutter having two teeth; the clamp is forced against the pin by the top bolts, and the whole device turned by using the wrench shown by inserting its forked end in holes drilled into the end of the clamps, as shown. This device does good and true work in a short time, and can be used on a crosshead without taking it off the guides

Above the tool-room there is kept a large stock of repairs, mostly finished parts—valves, packing, brass work, etc. We noticed that the packing rings used were heavier at the bottom, as in Fig. 2. These last as long as the engine stays out, as a usual thing. They are turned considerably larger than the cylinder, a piece cut out, and the ring sprung together and turned up in the shape shown.

The interior of this shop is finished in hard pine, and the interior of the offices and tool-room is finished in oil. Such tools as boring bars, valve seat planers, etc., have a cabinet of their own, where they are kept out of the dirt and dust.

An overhead system of steam heating was put into this plant, but in the shops, especially the car shop, where the roof was high, it failed to keep the men comfortable while making the pitch fry on the roof, and has been put below the benches.

Albert Griggs is master mechanic here, Russell Hawks general foreman, and Wm. Foster master of tools and kinks.

The engines are of several classes, mostly eight-wheelers, some Forneys being used on suburban work.

They have good water, and little trouble with flues or fire-boxes leaking.

We found here, as on most New England roads, that brass pipe is used for most of the work—feed pipes and branch pipes; it does not rust, looks better, and is easier kept clean than copper, and will "let go" when you try to take it down.

Elementary Lessons in First Principles.

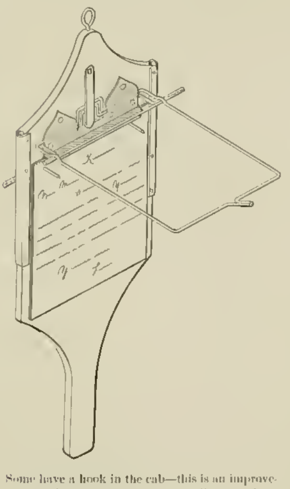
FOURTH LESSON.

In England it is customary to connect the eccentric blades to the ends of the link instead of back of the slot, and to hang the link from one of these pins, sometimes the top and as often the bottom. In this case the angularity of the rod is partially compensated for by placing the upper end of the hanger "out"; when this is done it is necessary to place it farther out than when the lower end is hung out of the center line; it may not be out of place here to remark that the "limp" is the first thing an American engineer notices on English engines. On some classes of engines the eccentrics are located on an axle, other than the main axle, and ahead of it, like the elevated engines in New York and Brooklyn, when this is done it is necessary to put up the motion so that the link will be *up* when the engine is running ahead. If the link is down when the engine is running ahead, the lead will *decrease* as the link is worked nearer the center, whereas it ought to increase; this is explained when we learn that, to increase the lead on an ordinary link engine, we would *advance* the eccentric on the shaft *in the direction in which it is to run*. So, when we hook up the link on an ordinary link motion engine, we do not move the eccentric on the shaft; but we do move the entire motion *back* on the eccentrics, which amounts to the same thing.

In the class of locomotives mentioned, if the link was down when the engine was in forward gear, when we raised the link we should move the entire motion *ahead* on the eccentrics, and in the direction in which they will run, instead of back, which would delay all the functions of the valve—opening, cut-off, and compression, and decrease the lead.

A Handy Order-File for the Cab.

On this page will be found an illustration of one of those handy little things that most railroad men appreciate. Every man who has ever run an engine knows that the matter of keeping the train orders received in service is not attended to with the care its importance deserves; nine runners out of ten simply read them, crimp them up and put them in the first pocket they can reach; if it is necessary to consult them a second time, they have to sort over a miscellaneous collection of old orders of uncertain age, and select the last one; this style of order hook is the one that prevents the fireman from seeing them also.



Some have a hook in the cab—this is an improvement, but do the best we can, they will get too dirty to read, are liable to blow away or get too much wear to be legible.

The little device shown herewith is the invention of Mr. H. C. Cunningham, of Topeka, Kan. Its construction is so plain that any one can understand it; the board body has a wire frame on each side, that is held against it, and keeps the orders stretched out and on the file in the order received, and by using both sides two orders can be consulted without lifting the wire holder. Thus the points can be filled with orders before any are lost, and disputes that come up can be settled by referring to the file, but the adaptability of the device to locomotives lies in the frame and the handle; the runner can find his order with his gloves on, it is all stretched out ready to read, and he can take it by the handle and hold it up to the cab light or in the glare from the fire-door, and read it while the engine is in motion. There are loops of metal on each side that stiffen the whole device and serve to hold pencils or a stylus. It can be hung up or carried in the seat-box, costs but a few cents, and will save orders, finger marks and delays.

An Engineer's Christmas Story.

BY JOHN ALEXANDER.

Mr. Editor, there has no right fresh pointers come to the top of my mental soup-kettle of late, so I have not skimmed one off for you, but I was just paying my month's salary over to Mrs. A., to get me a Christmas present with, and it brought up to my mind a Christmas story of another engineer, and I thought I would tell it to the boys—with your permit. It is not so very much mechanical—neither is the other stuff I write to you.

In the summer, fall and early winter of 1863, I was tossing chips into an old Hinckley insider up in New England, for an engineer by the name of James Dillon. Dillon was considered as good a man as there was on the road, careful, yet fearless, kind-hearted, yet impulsive, and a man whose friends would fight for him, and whose enemies hated him right royally.

Dillon took a great notion to me, and I loved him as a father; fact of the matter was, he was more a father to me than I had at home, for my father refused to be comforted when I took to railroading, and I could not see him more than two or three times a year at the most, so when I wanted advice I went to Jim

I was a young fellow then, and, being without a home at either end of the run, was liable to drop into pitfalls. Dillon saw this long before I did. Before I had been with him three months, he told me one day coming in that it was against his principles to teach locomotive running to a young man who was liable to turn out a drunkard or a gambler, and disgrace the profession, and told me I had better pack up my duds and come up to his house, and let "mother" take care of me—and I went

I was not a guest there; I paid my room-rent and board just as I should have done anywhere else, but I had all the comforts of a home, and enjoyed a thousand advantages that money could not buy. I told Mrs. Dillon all my troubles, and found kindly sympathy and advice, she encouraged me in all my ambitions, mended my shirts, and went with me when I bought my clothes. Inside of a month I felt like one of the family, called Mrs. Dillon "mother," and blessed my lucky stars that I had found them.

Dillon had run a good many years, and was heartily tired of it, and seldom passed a nice farm but he would call my attention to it, often saying,

"Jack, now there's comfort; you just wait a couple of years, I've got my eye on the slickest little place, just on the edge of M——, that I am saving up my pile to. I'll give you the Roger William one of these days, Jack, say good evening to grief, and me and mother will take comfort. Think of sleeping till eight o'clock, and no poor steamers, Jack, no poor steamers." And he would reach over and give my head a gentle "duck," as I tried to pitch a curve to a front corner with a knot. Those Hinckleys were powerful on cold water.

At Dillon's home there was a "system" of financial management. He always gave his wife just half what he earned, took ten dollars for his own expenses during the month, out of which he clothed himself, and put the remainder in the bank. That was before the days of very high wages, so that, even with this frugal management, the bank account did not grow surprisingly.

They owned their own home, and out of her half "mother" had to pay all the household expenses and taxes, clothe herself and two children, and send them to school. The oldest, a girl of some sixteen years, was away to normal school, the boy, about thirteen or fourteen, was at home, going to public school, and wearing out more clothes than all the rest of the family.

Dillon told me that they had agreed on the financial plan used in the family before their marriage, and often used to say to me that for the life of him he did not see how "mother" got along so well on the allowance.

When he drew a small month's pay he would say to me, as we walked home:

"No cream in the coffee this month, Jack." If it was unusually large, he would say "Plumb duff and fried chicken for a Sunday dinner."

He insisted he could notice the rate of pay in the eatables, but there was none—it was his kind of fun, "Mother" and I were fast friends; she became my banker, and when I wanted an extra dollar I had to ask her for it, and tell what I wanted it for, and all that. Along late in November, Jim had to make an extra one night on another engine, which left me alone at home with "mother" and the boy—I had never seen the girl—and after swearing me to be both deaf, dumb and blind, "mother" took me into a *secret*.

For ten years she had been saving money out of her allowance, until the amount now reached nearly $2,000. She knew of Jim's life ambition to own a farm, and she had the matter in hand if I would help her. Of course I was head over heels in the scheme at once.

She wanted to buy the farm near M——, and give Jim the deed for a Christmas present—and Jim mustn't even suspect.

Jim never did.

The next trip I had to buy some underclothes—would "mother" tell me how to pick out pure wool? Why, bless your heart, no, she wouldn't, but she'd just put on her things and go down with me.

Jim smoked and read at home.

We went straight to the bank where Jim kept his money, asked for the president, and let him into the whole plan. Would he take $2,100 of Jim's money, unbeknown to Jim, and pay the rest of the amount above what "mother" had?

No, he would not, but he would advance the money for the purpose—have the deeds sent to him, and he would pay the price—that was fixed.

Then I hatched up an excuse, and changed off with the fireman on the M—— branch, and spent the best part of two lay-overs fixing up things with the owner, and holding back the records of the deeds till after Christmas.

But every evening there was some part of the scheme to be talked over, and "mother" and I held many whispered conversations. Once Jim, smiling, observed that, if I had any hair on my face, he would be jealous.

I remember it was on the fourteenth day of December, 1863, that pay day came. I banked my money with "mother," and Jim, as usual, counted out his half to that dear old financier.

"Uncle Sam 'd better put that un in the hospital," observes Jim, as he comes to a ragged bill.

"Goddess of Liberty pretty near got her throat cut there, guess some reb. has had hold of her," said Jim, as he held up a ten dollar bill, then laying it down, he took out his pocket book and cut off a little three-cornered strip of pink court plaster, and made repairs on the bill.

"Mother" pocketed her money greedily, and before an hour I had that very bill in my pocket to pay the recording fees in the court house at M——.

The next day Jim wanted to use more money than he had in his pocket, and asked me to lend him a dollar. As I opened my wallet to oblige him, that patched bill showed up. Jim put his finger on it, then turning me around toward him, said:

"How in the h——l came you by that?"

I turned red—I know I did—but I said, cool enough, "'mother' gave it to me in change."

"That's a lie," he said, and turned away.

The next day we were more than two thirds of the way home before he spoke, then, as I straightened up after a fire, he said:

"John Alexander, when we get in you go to Aleck (the foreman), and get changed to some other engine." There was a queer look on his face; it was not anger, it was not sorrow—it was more like pain.

I looked the man straight in the eye, and said:

"All right, Jim, it shall be as you say; but, so help me God, I don't know what for. If you will tell me what I have done that is wrong, I will not make the same mistake with the next man I fire for."

He looked away from me, reached over and started the pump, and said:

"Don't you know?"

"No, sir, I have not the slightest idea."

"Then you stay, and I'll change," said he, with a determined look, leaned out of the window, and said no more all the way in.

I did not go home that day; I cleaned the Roger William from the top of that mountain of sheet-iron known as a wood-burner stack to the back casting on the tank, and tried to think what I had done wrong or not done at all, to incur such displeasure from Dillon. He was in bed when I went to the house that evening, and I did not see him until breakfast. He was in his usual spirits there, but on the way to the station and all day long he did not speak to me.

He noticed the extra cleaning, and carefully avoided tarnishing any of the cab fittings, but that awful quiet, I could hardly bear it, and was half sick at the trouble, the cause of which I could not understand. I thought that if the patched bill had anything to do with it Christmas morning would clear it up.

Our return trip was the night express, leaving the western terminus at 9.30. As usual, that night I got the engine out, oiled, switched out the cars, and took the train to the station, trimmed my signals and headlight, and was all ready for Jim to pull out. 9 o'clock came and no Jim; at 9.10 I sent to his boarding house—he had not been there. He did not come at leaving time—he did not come at all.

At 10 o'clock the conductor sent to the shop for another engineer, and at 10.45 a fireman came in his stead, with orders for John Alexander to run the Roger William until further orders.—I never fired a locomotive again. I went over that road the saddest-hearted man that ever made a maiden trip. I hoped there would be some tidings of him at home—there was none. I can never forget the blow it was to "mother," how she braced up on account of her children; but oh, that sad face. Christmas came, and with it the daughter, and then there were two instead of one—the boy was frantic the first day, and playing marbles the next.

Christmas day there came a letter—it was from Jim. Brief and cold enough, but such a comfort to "mother." It was directed to Mary J. Dillon, and bore the New York post-mark. It read: "Uncle Sam is in need of men, and those who lose with Venus may win with Mars. Enclosed papers you will know best what to do with. Be a mother to the children—you have *three* of them. James Dillon."

He underscored the three—he was a mystery to to me. Poor "mother," she declared that no doubt "poor James' head was affected." The papers with the letter were a will, leaving her all, and a power of attorney allowing her to dispose of or use the money in the bank. Not a line of endearment or love for that faithful heart that lived on love, asked only for love, and cared for little else.

That Christmas was a day of fasting and prayer with us.

Many letters did we send, many advertisements were printed, but we never got a word from Jas. Dillon, and Uncle Sam's army was too big to hunt in. We were a changed family, quieter and tender of one another's feelings, but changed.

In the fall of '64 they changed the runs around, and I was booked to run into M——. Ed, the boy, was firing for me. There was no reason why "mother" should stay in Boston, and we moved out onto the little farm. That daughter, who was a second "mother" all over, used to come down to meet us at the station with the horse, and I talked sweet to her, you bet.

Along in May, '65, "mother" got a package from Washington; it contained a tin-type of herself, a card with a hole in it, evidently having been forced over a button, on which was her name and the old address in town, then there was a ring and a saber; on the blade of the saber was etched "Presented to Lieutenant Jas. Dillon, for bravery on the field of battle." In the bottom a note in a strange hand, simply saying:

"Found on the body of Lieut. Dillon after the battle of Five Forks."

Poor "mother," her heart was wrung again, and again the scalding tears fell. She never told her suffering, and no one ever knew what she bore. Her face was a little sadder and sweeter, her hair a little whiter, that's all.

I am not a bit superstitious, don't believe in signs or presentiments, or pre-nothing, but when I went to get my pay on the fourteenth day of December, 1866, it gave me a little start to find that bill with the chromo of the Goddess of Liberty with the little three-cornered court-plaster on her windpipe, and I got rid of it at once, and said nothing to "mother" about it, but I kept thinking about it and seeing it all the next day and night.

On the night of the seventeenth I was oiling around my Black Mariar to take out the local, leaving our western terminus just after dark, when a tall, slim old gentleman stepped up to me and asked if I was the engineer—don't suppose I looked like a president.

I confessed, and held my torch up so I could see his face—a pretty tough looking face. The white mustache was one of those military kind, with reinforcements of whiskers on the right and left flank of the mustache proper. He wore glasses, and one of the lights was ground glass. The right cheek bone was crushed in, and a livid red scar extended across the eye and cheek, the scar looked blue around the red line because of the cold.

"I used to be an engineer before the war," said he. "Do you go to Boston?"

"No, to M——."

"M——! I thought that was on a branch?"

"It is, but is now an important manufacturing point, with regular trains from there to each end of the main line."

"When can I get to Boston?"

"Not till Monday, now, we run no through Sunday trains. You can go to M—— with me to-night, and catch a local to Boston in the morning."

He thought a minute, then said: "Well, yes, guess I had better. How is it for a ride?"

"Good; just tell the conductor I told you to get on."

"Thanks, that's clever. I used to know a soldier who used to run up in this country," said the stranger, musing—"Dillon, that's it, Dillon."

"I knew him well," said I; "I want to hear about him."

"Queer man," said he, and I noticed he was eyeing me pretty sharp.

"A good engineer."

"Perhaps," said he.

I coaxed the old veteran to ride on the engine—the first coal burner I had had. I wanted to pump him.

He seemed more than glad to comply. Ed was as black as a negro, and swearing about coal burners in general, and this one in particular, and made so much noise with his fire tools after we started, that the old man came over and sat behind me, so as to be able to talk.

The first time I looked around after getting out of the yard I noticed his long slim hand on the top of the reverse lever. Mr. Editor, did you ever notice how it seems to make an ex-engineer feel better and act more satisfied to get his hand on a reverse lever, and feel the life throbs of the mighty giant under him? Why, his hand goes there by instinct—just the same as an ambulance surgeon will feel for the heart of the boy with a broken leg.

I asked the stranger to "give her a whirl," and noticed with what eager joy he took hold of her. I also observed with surprise that he seemed to know all about "four-mile hill," where most new men get stuck. He caught me looking at his face, and, touching the scar, remarked:

"A little love pat, with the compliments of Wade Hampton's men."

We talked on a good many subjects and got pretty well acquainted before we were over the division, but at last seemed talked out.

"Where does Dillon's folks live now?" asked the stranger slowly, after a time.

"M——," said I.

He nearly jumped off the box. "M——? I thought it was Boston."

"Moved to M——."

"What for?"

"Own a farm there."

"Oh, I see; married again?"

"No."

"No!"

"Widow thought too much of Jim for that."

"No!"

"Yes."

"Er—what became of the young man that they—er—adopted?"

"Lives with 'em yet."

"So?"

Just then we struck the suburbs of M———, and, as we passed the cemetery, I pointed to a high shaft, and said:

"Dillon's monument."

"Why, how's that?"

"Killed at Five Forks; widow put up monument."

He shaded his eye with his hand and peered through the moonlight for a minute.

"That's clever," was all he said.

I insisted that he go home with me. Ed. took the Black Maria to the house, and we took the street cars for it to the end of the line, and then walked.

As we cleaned our feet at the door, I said:

"Let me see, I did not hear your name?"

"James," said he. "Mr. James."

I opened the sitting-room door, and ushered the stranger in.

"Well, boys," said "mother," slowly getting up from the fire, and hurriedly taking a few extra stitches in her knitting before laying it down to look at us, "you're early."

She looked up, not ten feet from the stranger, as he took off his slouched hat and brushed back the white hair. In another minute her arms were around his neck, and she was murmuring "James" in his ear, and I, like a dumb fool, wondered who told her his name.

Well, to make a long story short, it was James Dillon himself, and the daughter came in and Ed came, and between the three they like to have smothered the old fellow.

You may think it funny he didn't know me, but don't forget that I had been running for three years—that takes the *fresh* off a fellow—then, when I had the typhoid, my hair laid off, and was never reinstated, and when I got well the whiskers, that had always refused to grow, came on with a rush—and they were red. And again, I had tried to switch with an old hook-motion in the night, and forgot to take out the startin' bar, and she threw it at me, knocking out some teeth, and, taking it altogether, I was a changed man.

"Where's John," said he, finally.

"Here," said I.

"No!"

"Yes."

He took my hand, and said, "John, I left all that was dear to me once, because I was jealous of you, I never knew how you came to have that money, or why, and don't want to. Forgive me."

"That is the first time I ever heard of that," said mother.

"I had it to buy this farm for you—a Christmas present—if you had waited to have got it," said I.

"That is the first time I ever heard of that," said he.

"And you might have been shot," said mother, getting up close.

"I tried my darndest to be, that's why I got promoted so fast."

"Oh, James," and her arms were around his neck again.

"And I sent that saber home myself, never intending to come back."

"Oh, James, how could you?"

"Mother, how can you forgive me?"

"Mother" was still for a moment, looking at the fire in the grate.

"James, it is late in life to apply such tests, but love is like gold, ours will be better now, the dross has been burned away in the fire. I did what I did for love of you, you did what you did for love of me; let us all commence to live again in the old way, just as if there had been no mishap at all," said she, and those arms of hers could not keep away from his neck.

Ed. went out with tears in his eyes, and I beckoned the daughter to follow me. We passed into the parlor, drew the curtain over the archway—and there was nothing but that rag between us and heaven.

And where are they now? Why, probably sitting on that same old sofa, the lovingest old lovers that ever loved.

And where is Ed? Married to the homeliest woman in the State of Massachusetts, and pulling passengers on the main line.

And where is the girl? Mr. Editor, did you notice that there was hummixes in the lines of this copy, and that there were some letters that ought to have tails that were bobtailed, and some that should be tailless that are all tail? You did? Well, it looks as if that might have been caused by the table being *jiggled*, don't it? Well, now, if you had a plan of our kitchen taken at this present moment, you would see a horny-handed son of toil that ought to be in better business, trying to write a Christmas story on one end of a kitchen table, while that daughter irons on the other, and kicks about the size of the air-holes in my socks.

Mr. E. N. Dickinson, one of the best known patent attorneys in the world, died in this city on the 22d of December, in his sixty-fifth year. Mr. Dickinson took up the case of Sickles, the inventor of the cut-off known by his name, and, in the long trials to establish the inventor's rights, became himself a well-posted engineer. Mr. Dickinson was a great advocate of the expansive use of steam at high pressure. He fitted up the steamship "Idaho," and made some trials in competition with other vessels of the day. He had a locomotive built at Cooke's some years ago, that, while using the ordinary link motion, if we remember right, had four valves, one for each admission port and each exhaust. The engine run a short time, and met with an accident that broke her cylinders, and they were never rebuilt. At the time of his death he had a new design of a locomotive well under way, and the boiler had already been built at the Cooke Locomotive Works.

The Erie officials are entertaining a general grievance of their employes, and we hope will be able to settle with them in a manner honorable to both sides. There was a new book of rules gotten out that the men were required to sign, among other rules was one wherein the signer agreed not to claim damages from the company in case of injury in the line of duty. It is not at all likely that this would stand in a trial, but it would have resulted in much annoyance and delay to injured men, and the men objected to it on general principles—and they were right. The Erie has suffered for some time from a scientific management that has frozen out some of their best men in the motive power department, and has economized on the head end, as usual.

Grading is being done on the cog-wheel railroad up the barren side of Pike's Peak, and the *Rocky Mountain News* describes the whole line, even going so far as to show a picture of the locomotive; they say it will be built on the Abt system, but show a picture of a locomotive of the Riggenbach system. The line may be completed next year.

Pedrick & Ayer, of Philadelphia have given this office a pen wiper on the general plan of the new green and gold flag of Bazil. In thus inferring that we use pens here, they charge us with being behind the age. We do not need a pen wiper—we want a better looking type writer, and a law preventing boys from learning the trade.

There is a division of the L. & N. that the old timers have dubbed the "kid division," because most of the men employed there are young. Supt. Dickson being less than 35. It has as good a reputation as the best, however.

Last month two sections of a delayed passenger train on the Northwestern road made some remarkable time West in order to make the connections with the "Overland flyer." The second section, with the baggage only, made 78 miles per hour during parts of the run.

It is a common practice in Great Britain to set the front ends of locomotive flues about 2" higher than the back end.

A New and Important Book on Steam Engineering.

Le Van's Great Work on

THE STEAM ENGINE

— AND —

THE INDICATOR.

JUST READY.

THE STEAM ENGINE AND THE INDICATOR: Their origin and Progressive Development, including the Most Recent Examples of Steam and Gas Motors, together with the Indicator, its Principles, its Utility, and its Application. By WILLIAM BARNET LE VAN. Illustrated by 305 engravings, chiefly of Indicator-Cards. 469 pp., 8vo.

Price $4.00, by mail, free of postage to any address in the World.

CONTENTS.—I. Introduction. II. Who Invented the Steam Engine? III. Heat and Work. IV. Expansion. V. The Indicator. VI. The Action of Steam in the Cylinder of an Engine. VII. Horse-Power. VIII. Diagrams showing the Action of Steam in Steam Engine Cylinder. IX. Correct Indicator Diagrams. X. Steam Expansion Curves or Pressure of Steam in Cylinder. XI. Comparative Indicator Diagrams. XII. Steam Jackets. XIII. Varieties of Steam Engines. XIV. Gas Engines. XV. Automatic Cut-Off vs. Positive Cut Off. XVI. Miscellaneous. Appendix. Index.

☞ *An Illustrated Circular of 4 pages quarto, giving the full table of contents with specimens of the engravings of this valuable book, will be sent free of postage to any one in any part of the world who will send us his address.*

☞ *Our new revised Descriptive Catalogue of Practical and Scientific Books, 86 pages 8vo., and our Catalogue of Books on Steam and the Steam Engine, Mechanics, Machinery, and Dynamical Engineering, and other Catalogues the whole covering every branch of Science applied to the Arts, as well as a circular of "Van Cleve's English and American Mechanic," sent free and free of postage to any one in any part of the world who will furnish his address.*

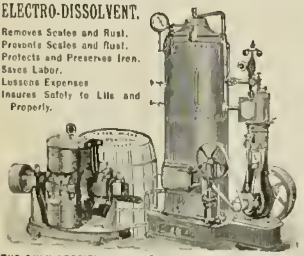
ELECTRO-DISSOLVENT.

Removes Scales and Rust.
Prevents Scales and Rust.
Protects and Preserves Iron.
Saves Labor.
Lessens Expenses
Insures Safety to Life and Property.



THE ONLY SPECIFIC AGAINST SCALE IN STEAM BOILERS.

Removes Scale and Rust. Prevents Foaming and Pitting.

The Electro-Dissolvent supersedes Compounds. It is a Metallic Solution. Works Equally in all Waters. Mechanical in its action. Regulates the Electric Currents, thus preventing pitting. Fully endorsed by the best Engineers. Catalogue of price and testimonials free on application. Beware of Imitations. None Genuine but those bearing this trade mark "MARTIN'S ELECTRO-DISSOLVENT." Address

Electro-Dissolvent Co., 368 & 370 Sixth St., Jersey City, N. J.

THE SHACKLETON SYSTEM

— OF —

HEATING PASSENGER CARS.

THIS SYSTEM utilizes the live or exhaust steam from the locomotive. Steam is conducted through the cars by pipes placed under the roof. Vertical pipes connect the overhead steam pipe with branch pipes that extend through the large water pipes at the floor level, and heat the water in these floor level pipes.

These large pipes are connected at either end of the car diagonally with radiators. Vertical steam pipes also connect the radiators with the overhead pipe.

The surplus water being drawn up into a reservoir that is exhausted by steam is utilized in the closets.

Under the car, or at one end, is placed a boiler for use in heating the water when the car is detached. With this system there is no drip. Pipes are quickly drained; perfect ventilation; uniform heating of all the cars in a train; entire safety.

The Shackleton Car Heating and Ventilating Co.,

JOS. SHACKLETON, M. E., Gen. Mgr.

BOUND BROOK, N. J.

THE RICHARDSON AND THE ALLEN-RICHARDSON

BALANCED SLIDE VALVES.

Used by 140 Railroads. 4,000 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

MURRAY'S

PATENTED

PISTON ROD PACKING.

It consists of two Sectional Fibrous Rings with a Brass Ring between the Sectional Rings, that prevents friction. It is adapted for Hydraulic work, Steam Hammers, and where Piston or Valve Rods are out of line.

MANUFACTURED BY

THE JOHN P. MURRAY CO., 123 RAILROAD AVE., JERSEY CITY, N. J.

Bound Volumes and Back Numbers of THE LOCOMOTIVE ENGINEER—Vols. 1 and 2.

Bound Volumes for 1889 are now ready for delivery. Price $2.00 postage prepaid. Bound Volumes for 1888 still on hand, at same price.

Unbound Volumes of either year now ready, and mailed to any address in the United States, Canada and Mexico at regular subscription rate of $1.00 a year. Single Copies, 10 cents each.

Address, THE LOCOMOTIVE ENGINEER, 96 Fulton St., New York.

DANGER PREVENTED!

Your Boiler is the life of your establishment, therefore protect it!

We will remove and prevent Scale in any Steam Boiler, and ask no money until you find our remedy to work to your entire satisfaction.

WE USE NO ACID!

The Chemicals we use will neutralize Acid, Sulphur, and Mineral Waters, and will not only protect you from Boiler Scale and Oxidation of Iron, but from corrosion in every form, such as GROOVING, PITTING, and WASTING OF IRON, which causes so many explosions. If you will protect your Boilers from the above-named destructive agents, then with a reliable engineer there will be no occasion for a boiler explosion, and the money saved by the use of our Compound will more than pay the cost of it in every case.

This article has worked its way into favor entirely upon its merits, without sending out a single man to solicit orders, and we can refer to our customers in every steam-using locality from Maine to the Pacific Coast. More than thirty thousand manufacturing establishments, in the United States and Canada alone, are now using our Compound, many of whom, using a number of boilers, order it by the ton.

Authors of the best works on Steam Engineering now recommend Lord's Compound as the only reliable article to prevent corrosion in boilers, and as a safe remedy for incrustation; and as a proof of this fact, we will send any of these books by mail, free of postage, at publishers' price, or free of cost with a barrel of Compound.

A VERY USEFUL BOOK ON CARE OF BOILERS FREE.

Also our circular, with full particulars of the Compound, on request.

Address, GEO. W. LORD,

316 UNION STREET, PHILAD'A, PA.

AGENTS WANTED EVERYWHERE.

MY MOULDED BOILER GASKETS ARE ELASTIC, TOUGH AND PLIABLE.

The qualities recommended by Boiler Insurance Companies.

A TIGHT JOINT EVERY TIME. NO STRAINED MANHOLE FRAMES. NO UNTRIED EXPERIMENT.

Have been in use in this Section for past Fifteen Years.

Pump Valves, Air Brake Washers, Crossing Gate Gaskets, Rings, Pipe and Flange Unions, Tips, Fenders, Etc.

No Broken Glasses with Moulded Glass Gauge Gaskets.

Correspondence solicited. Mention this paper. H. O. CANFIELD, Bridgeport, Ct.

CORRUGATED COPPER GASKETS

For all Pipe Fittings and Unions, whether for Steam, Water or Air. Can be used wherever any gasket can be applied, with better satisfaction and greater durability than any other. Will not leak, rust, stick, burn or melt. All sizes and shapes, ½ to 42 inches. In use on N. Y. & N. E. R. R. and others. *Write for particulars.*

VOL. III, NO 2. NEW YORK, FEBRUARY, 1890. $1.00 per Year or 10c. a copy.

Historical Locomotives—The Monster.

There are very few of the 75,000 enginemen in this country who ever saw one of the four locomotives that were known as the "Monsters." The picture on this page was made from a tintype taken in the later days of the "Monsters," after they came into possession of the Pennsylvania Railway, and after they had gone through many changes, and is only used here to show how they looked in their old age, just before they were broken up.

The tintype was a dark one, and many of the parts obscured, but the picture shows the general complication—a sort of link motion having taken the place of the hook and cut-off, a pair of drivers been traded for a truck, and many minor changes made, but with all the modernizing it shows a strange looking "Monster" to be prowling around our railroads at as late a day as 1875.

The original "Monster" was built by the Camden & Amboy Railroad Co. in 1834 She was commenced at Hoboken in 1333, and the partially finished pieces were moved with the shops to Bordentown, N. J., where she was put into service the following year.

In 1838 the "Monster," with all the other motive power of the Camden & Amboy road, including all their steam vessels, came under the hand of Mr. Isaac Dripps, now of Philadelphia, as Superintendent of Machinery, he having had charge of repairs for some years before this, and Mr. Dripps was one of the first, if not the first man, to bear the title of Superintendent of Machinery on the American continent. Mr. Dripps soon had the "Monster" to rebuild, and, in doing so, made some changes—especially in her boiler

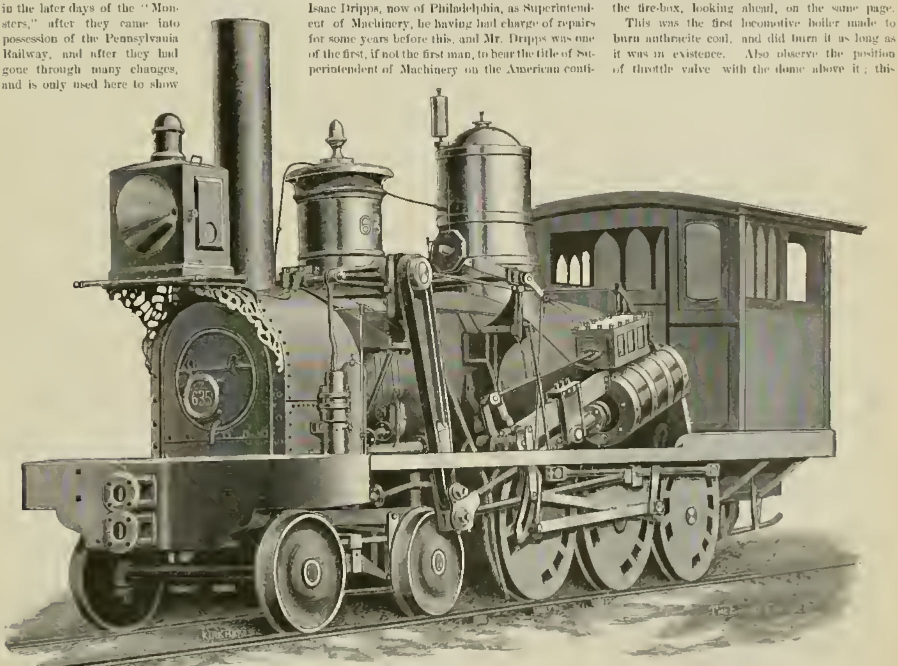
On page 22 will be found an outline drawing of this engine, taken from the old shop drawings, on tough paper, made at that time by Mr Dripps. The lettering and all on the card is reproduced. It will be seen that the plan was considerably different from that used in the final one, shown on the first page

On page 21 will be found drawings, as then made, of the original boiler, and the changes made in it by Mr. Dripps.

Looking at the old boiler, you will see that it has a combustion chamber ahead of the fire-box, there was a partition, or water-leg, ahead of the grates, and then the chamber. In the center of this bridge, or partition, there was a large, flanged pipe up to the crown sheet, to promote circulation. This is plainly seen in the small end view through the fire-box, looking ahead, on the same page.

This was the first locomotive boiler made to burn anthracite coal, and did burn it as long as it was in existence. Also observe the position of throttle valve with the dome above it; this dome blew off, and Mr. Dripps recalls the incident. The engine had just returned from a wreck, and a crowd of men were standing around her, Mr. Dripps among the rest, the light, cast, flange gave way and the dome went skyward to a great height; the rush of steam *up* produced a partial vacuum, and the air rushing in to fill it threw all the men down *toward* the engine, their hats being especially lively. Afterward there was great discussion among the laborers about how a boiler could blow up and blow people *toward* it.

This dome and throttle were replaced by the arrangement shown in the top cut.



"The Monster."

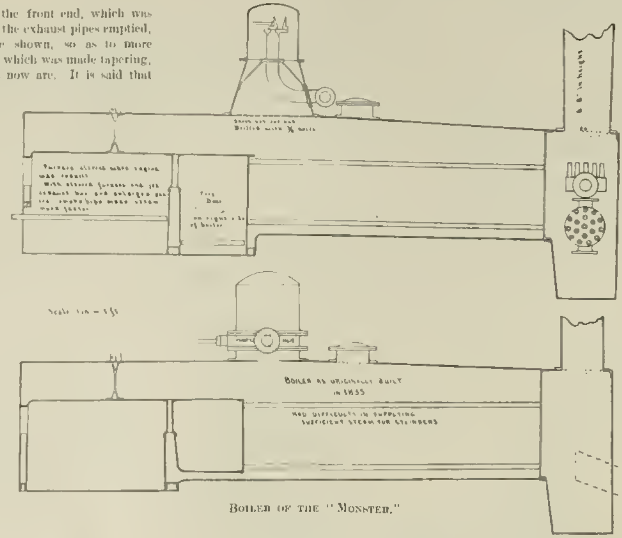
Mr. Dripps was convinced that there was not grate surface enough, and got more in a novel way—he put grates in the combustion chamber and a fire-door on the right side, and run two fire-boxes, and says that, whatever else the engine was, she was a very satisfactory one as far as steaming was concerned after that.

The nozzle stand in the front end, which was merely a box into which the exhaust pipes emptied, was made in the shape shown, so as to more effectually fill the stack, which was made tapering, as many straight stacks now are. It is said that the engineers used to plug up some of these little nozzles with pine plugs, so that the modern nozzle fiend is not the first and original. The crown stays of these boilers were of the crow-foot pattern—a style almost unused now, but one that gave little trouble. Now look at the outline of the old "Monster" on page 23, and get the idea into your head. The vibrating beam, or "horse neck," as the boys called it, was ahead of the stack, and the whole engine further ahead than those afterward built, but the plan was much the same. There was a rod from crosshead to the knuckle on end of "horse-neck," that gave it its pendulum motion, then a main rod back to the third pair of wheels—all wheels under these engines were drivers—the two back pair were coupled together by side rods, as were also the two front pair by side rods of their own; between the second and third pair of wheels was an idle shaft, in the center of which was a huge gear wheel, meshing into corresponding gears on the second and third axle, as shown. The engine drove the third pair of wheels, the back side rods the back pair, the gear driving the second pair, and the front side rods the first pair. If the gear broke—and we are told it often did—half the tractive power of the engine was gone. It will be noticed that the side rods on one pair of wheels were set opposite the other pair—one was above the center, while the other was below.

The valve motion was driven from a return crank on the main pin, as shown in the rear view on page 23; it will be seen that this return crank carries an eccentric as well as a pin—the eccentric moved one of the drop hooks, the pin the other, being the first time this arrangement was ever used. The reversing gear is not shown.

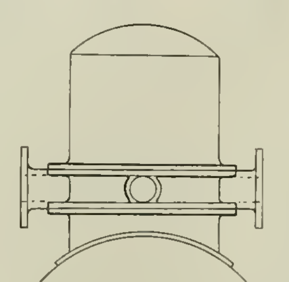
The cut-off was effected by a valve riding on the back of the main valve, like other cut-off engines of the day. This cut-off was driven from a pin on the "horse neck," and was handled from the cab by the levers shown, one on each side, and the tumbling shaft and arms just back of the stack; it was in detail very similar, if not just like, the cut-off shown in The Locomotive Engineer in February last. This cut-off mechanism was designed by Mr. Dripps, and the first one applied to the "Monster." This same motion was afterward used on the eight foot wheeled Norris engines, which were designed by Mr. Dripps. It was afterward applied to many locomotives, especially by Norris, and became known as the Norris cut-off. The pump in the original engine was driven from the horse-neck and was located near the fire-box. On the later engines it was located and driven as shown on title page cut.

In 1858 the Trenton Locomotive Works were established, and Mr. Dripps, who was one of the firm, was made superintendent, and these works built three more "Monsters," though much better ones than the first. We have before us, as we write, part of the original drawings used in these works. They were once very fine drawings, on parchment paper, different materials represented by different colors, brush-shaded, and every detail complete; but they have lain in cellars and garrets for nearly forty years, and they are mildewed and broken, many important parts being gone, so that our engravers could do nothing with them—a fact we regret.



Boiler of the "Monster."

These engravings show that the guides were V shaped top and bottom, that the four back driving-boxes had wedges, but the four forward ones none; that a well-made and well-proportioned cab was used on the "Monsters"; that the large copper exhaust pipes on each side had the feed pipe running through them to heat the feed water; there was no frame, the jaws or pedestal for each box was riveted to the boiler itself, the driving-box jaws were of the slab type, two plates with shoes on their edges, and the main rod was trussed like a beam engine rod. All the rods were of round section.



"Monster's" Boiler, Looking Ahead, through Fire-Box.

The "Monster" was not a successful experiment, but did fairly good work, and would have done better on a good track—she was too heavy for the tracks then used. But the "Monster" is not one whit further from being a good locomotive than some of the later day experiments, and by turning the cylinders around, and putting some of the surplus drivers on top of one another, one of them could be sold in the dusk for a Fontaine engine—and that was going to revolutionize the world only a few years back.

There were 1,860 locomotives built by regular locomotive works in this country last year. It is impossible to get data of the number built by the different roads, but the number would certainly bring the total number built up to 2,000. Baldwins lead with over 900.

Some New Engines on the Old Colony.

Some new 8-wheeled locomotives, turned out of the Boston shops of the Old Colony road, are very handsome and substantial looking pieces of machinery. All the motion is extra heavy and plain; the Dean guide, a solid cast-iron box, is used; they are 18x24, with all modern improvements. The guide yoke is fast to side of boiler, and does not reach across frame. The tender has two flanges around the top, one outside and another around the coal space; this allows the top of tank to be kept clean, and tools thrown there are not lost or covered up. Trucks are very heavy, with roller bearings. Shoes are large and fit solid top and bottom at each side of the box, a thin wedge is fitted behind the back shoe, there is no possibility of the wedge moving with the box, and thus sticking itself. A great deal of the cab fittings are, like the checks, left square—a shape we should think very easy to mar up and hard to clean. These engines are running with a single nozzle 4¼" in diameter. The tenders have heavy wrought-iron frames, and the whole engine presents a neat appearance. On this road there is a small, square iron bar across the center of the headlight glass outside, on which tin numbers are hung, to denote the number of the train the engine is pulling. Coal used is poor, but engines steam well. Plain paint with a light gold leaf stripe sets them off well; the motion work and interior of cab are painted green.

The trouble on the Erie has been settled by the company withdrawing the book of rules with the cast-iron death warrant. Another abuse that is tolerated there will soon cause the Erie officials trouble, and that is the plan of suspending men "pending investigation." Any measures the men may have to take to stop this abuse will be justified. When a man is reported to have violated a rule, he is supposed to be innocent until proven guilty, and it is despotism, pure and simple, that allows him to be punished in advance by suspension "pending investigation."

Hereafter the pages of this paper will number continuously through the year, so as to make the bound volumes and files more like a book.

"Great Locomotive Competition."

Under the above head, *Engineering*, of London, England, publishes the following communication:

To the Editor of Engineering:

SIR: Referring to the paragraph under this heading in your last week's Notes from the North, it will no doubt be of interest to your readers to learn that the invitations addressed to the seven chief locomotive builders in the United States, by the Engineering Committee of the Edinburgh International Exhibition, 1890, to send a representative American express engine for exhibition and practical trial, have all been declined, on the ground that the expense would exceed any benefits likely to accrue. Since the success of an American engine in competition with those of the British build would constitute a world-wide advertisement for its makers, the accuracy of this conclusion may be doubted. Even the famous Baldwin Company decline, on the score of expense. The invitations provided for the American engines being worked throughout by American engineers, and stated that fair play in every respect would be guaranteed.

There can be no doubt that trials of an American engine over some of the British railways would be most interesting and improving to those concerned in railway working on both sides of the Atlantic, it being calculated to bring out the good and bad points of each type, and so lead to mutual improvement, and the Engineering Committee consider that, if expense is the only obstacle, it may still be possible to bring the trials about. A letter is now in the post, inquiring of the Baldwin Company whether they would send an engine if all expenses were paid. It would not be possible for the Executive Council of the Exhibition to guarantee all the expenses, but it is expected that one of the great steamship lines trading to New York would undertake the transport to and from Great Britain free. This would be the chief item, and it is suggested that the balance might be made up by subscription amongst those interested in railway machinery on both sides of the Atlantic. When the idea was first mooted, Americans in this country hailed it enthusiastically, and expressed confidence that an engine would not only be sent, but that it would be backed to beat the British ones to the tune of hundreds of thousands of dollars. It would seem that a change has since come over these views; but still it might reasonably be imagined that a sufficient number of public-spirited Americans could be found to provide the necessary funds to recoup the Baldwin Company for the outlay. Even should freight have to be paid on the engine, the total expense could not well exceed $5,000—a mere bagatelle to set against the loss of prestige to American builders which the declining of such an invitation must involve.

I am, sir, yours, etc.,

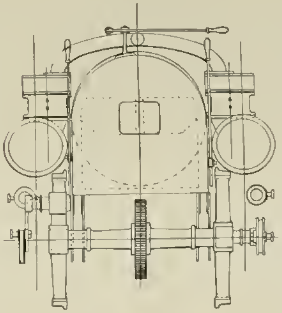
GEORGE E. WATSON, Sec

40 *Frederick Street, Edinburgh, Dec.* 31, 1889.

This is putting it pretty strong, and we hope some of our builders will take the matter up and build a winner—which we think they easily could

Of course there is no field open in Europe for the sale of American-built locomotives, but English, Scotch and German locomotives are largely sold in South American and other countries in competition with American locomotives, and to beat them on their own roads would be worth thousands of dollars to the winner, in advertising alone.

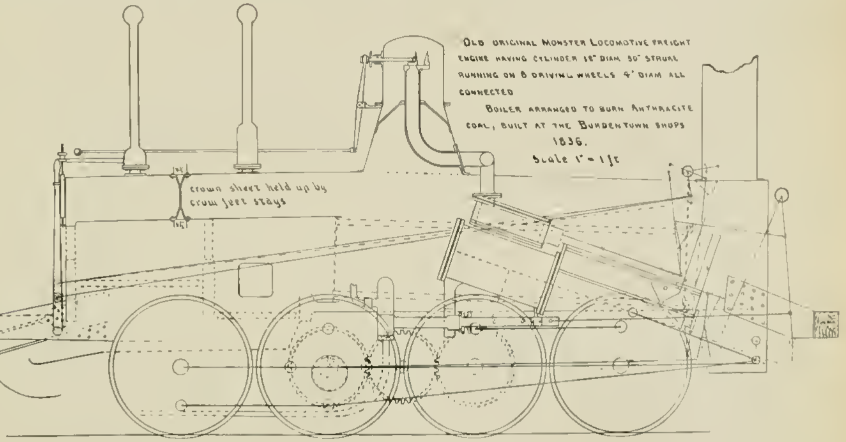
In comparison with European locomotives, our



THE "MONSTER," LOOKING AHEAD, THROUGH MAIN AXLE.

build are far superior in handiness and accessibility for repairs, as well as being cheaper; but the plain, honest fact of the matter is that American railroad men have been making lots of fun of English-built engines without any grounds except their appearance and our prejudice. Such of their machines as have come here have been, in the main, experiments, and failures here as well as at home. Their standard locomotives do a good deal of work, and "get there," but whether or no our locomotives would not do their work cheaper for a term of years is an open question.

The thing now is that cousin John has a chip on his shoulder, and swelling around daring any Yankee locomotive builder to knock it off and whip him on his own ground. When a man thinks he can't be licked, the easiest way to argue with him is to do the licking. Nobody afraid of the English engine, is there?



ORIGINAL "MONSTER"

We desire to say to the many who have inquired about price and time it will take to furnish the valve motion model shown in the December number, that Pedrick & Ayer, of Philadelphia, have complete control of the building and selling of the machines. Please apply direct to them.

The Swinerton Polygonal Driving Wheels.

About two years ago a Boston syndicate brought out the invention of Mr. C. E. Swinerton in locomotive driving wheels, and had the locomotive "Onward" built at the Hinkley works in that city.

The invention consists in the making of the face of the tire in flat facets instead of turning them round. The "Onward's" wheels have, or had, 105 flat spots about one inch long on them.

The claim is made that this arrangement allows more surface of the wheel to be in contact with the rail, and thus produces more adhesion.

This is directly against the established laws of friction. The surface in contact does not affect the adhesion unless one piece be so sharp as to cut into the other—a brick can be drawn over a board just as easy on its side as on its edge or end—weight governs the adhesion. Mr. Swinerton claims that this law holds good up to a certain point, then it is wrong.

This paper or its editor have no hobbies to ride or axe to grind in this or any other matter. We want to know the truth, and publish it for the entertainment and instruction of our readers, and propose to tell it as we find it, regardless of consequences. We shall be glad to make a favorable report of the polygonal wheel if we are convinced that it has any merits whatever. At present we are not so convinced. The comparison of the "Onward" with other engines is no test at all; she is altogether different, and there is no doubt that a locomotive with a single pair of wheels will do better under many circumstances than one with coupled wheels, except, perhaps, on the start

The Manhattan Elevated road have received a set of these tires for one of their engines, and the tests of merit need not take a day. By fastening the engine to a buffer-post with a dynamometer between it and the post, carefully noting the pressure, water line, etc., and letting her pull on the dynamometer in competition with another engine just like her, with plain wheels, the difference in adhesion will show up, if there is any.

Prominent men who have had opportunities to test the matter have endorsed the invention, however, and a friend of this paper who witnessed the tests and rode on the "Onward," calls our attention to the following notice from the Boston *Evening Traveler*:

Mr. George W. Tilton, superintendent of motive power and machinery of the Chicago & Northwestern Railroad, by the invitation of the directors of the Swinerton Locomotive Driving Wheel Co., was present at a meeting of the board at the Revere House lately.

Mr. Tilton stated that he was familiar to some extent with the practical working of the polygonal wheels, having witnessed their operation under the locomotive "Onward," and also that he had critically reviewed the detailed report of the recent trial tests of the polygonal and smooth driving wheels in comparison under locomotive "Onward," on the Boston & Maine Railroad, as well as the deductions made by Mr. John E. Clarke, Ph. D., of Boston. From data obtained from these tests, and in view of the above, he gave it as his opinion that the ordinary eight-wheel coupled locomotive could draw on an average from 10 to 15 per cent. additional tonnage if equipped with the polygonal wheels

A new machine will be built at once by order of the directors, and will be used by Mr. Tilton in cutting driving wheels on the Chicago & N W It would appear that the use of the wheels thus cut will very soon become general on the principal railroads.

The same gentleman has kindly furnished us with copies of the following letters, which tell their own story

Despite all this, we cannot help but think that something about the "Onward" beside the tire is responsible for the results apparently obtained

Boston, Nov. 13th, 1889.

I ran the engine "Onward" in the recent tests made on the B & M. R. R., both with the Swinerton polygonal wheels, and after the wheels were turned smooth. It did good work, both freight and passenger, with the polygonal wheels, but after the wheels were turned smooth or round I found the engine practically useless, on account of drivers slipping so badly I also ran the freight engine "Beach Bluff" equipped with the polygonal wheels in the worst weather last winter, and had no occasion to use sand

L. C TODD,
Engineer B. & M. R. R.

Boston, Nov. 13th

I am running the engine "Beach Bluff" equipped with the Swinerton polygonal wheels, and I know that the device adds largely to the traction of the engine. My run, one way, is a night run with a heavy freight, and I have a good chance to know the value of these wheels

W E DUNLAP
Engineer B. & M R. R.

Boston & Maine Railroad, Office of Supt M. P. & M.

MR C E. SWINERTON, Prest. Swinerton L. D. W. Co.:

MY DEAR SIR: Replying to your inquiry of recent date, the locomotive "Onward" commenced her regular trips on our Portland express January 7th, 1889, and was taken off July 6th, 1889, after running just six months.

Her performance on this train gave good satisfaction, and she made her time The train is a four (4) hour train, distance 115 miles with 15 stops; number of cars 6 to 8.

Yours truly,
WM SMITH, Supt. M P & M

Chicago, July 29th, 1889.

MR C E. SWINERTON, Boston, Mass.,

DEAR SIR: Your favor of the 26th duly received, and I thank you very much for sending me a full and complete report of the performance of the "Onward" in the thorough, severe, and I will also add conclusive tests the engine has been subjected to. It is all you could ask or expect, and I presume more than many expected. The performance of the engine is simply wonderful, and I am sure no one is more pleased and satisfied with the results than I am with the manner in which the tests have been conducted in every detail.

If your improvement had but increased the hauling capacity of locomotives fifty tons of revenue freight per train, the saving would be enormous in that item alone, saying nothing about the saving in fuel, rail wear, and wear and tear to machinery incidental to slipping, and many other factors that have an important bearing in the matter, but it seems to me that the results of this test must disarm all adverse criticism, and at least impress upon the minds of the critics that, in the language of the Rev. Jasper (the colored preacher of Richmond), "the world do move, if the sun don't."

I think I can realize something of the feeling of satisfaction you and those connected with you have over the results of the test

Hoping to have the pleasure of seeing you in the near future, I am yours truly,

G W TILTON,
S. M P. & M., Chicago & N W R. R.

The polygonal wheel is too close to a practical test right before our eyes to condemn or commend it until that test is over. We have no interest in the matter except to state the facts.

Some Experience with the Belpaire Boiler.

BY AN EX-RAILROADER.

Some years since, I was connected, in an official capacity, with the motive power department of one of our trunk lines, and one of the first to use the Belpaire form of boiler in this country.

The square shell around a square fire-box, with straight and direct stays, seemed at once a good thing to me. I was tired of the crown bar, and the endless trouble with mud, the expense of the device, and the weight, but I was not then prepared to trust the radial stay. The latter, I am free to confess, are giving remarkable service in some sections of the country, but the many angles at which the different rows of stays must be riveted to the sheets, to say nothing of the difficulty of properly tapping the sheets to receive them, still kept me fearful of results

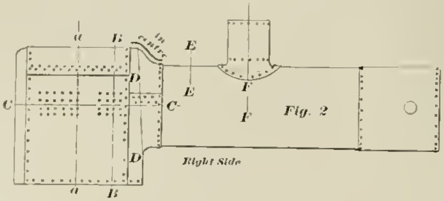
I had charge of the boiler work, and kept very close watch of the new form of fire-box—or rather outside shell—for the fire-box is like any other.

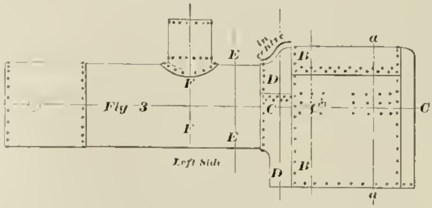
They were in passenger service, but only carrying 140—now considered rather low pressure.

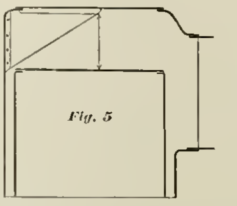
Some of the rivets in seams on top of boiler leaked after a time, and there soon developed a slight leak on top seam, where wagon-top sheet joins first course in the barrel of the boiler.

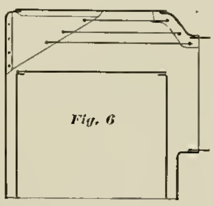
After a year or more of service, one of these engines came in for repairs, and a thorough inspection was made, and I commenced to experiment.

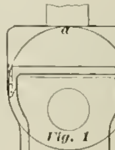
Hydraulic pressure at once showed that there was a decided "bulge" over this spot—just where the flat top of boiler and barrel come together. The boiler was "straight"—no wagon-top—and, looking endwise, the sheets would appear like Fig 1 at *a*.

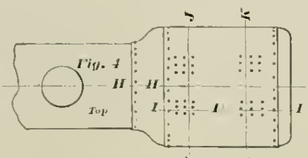












Why the "bulge" there? It was not hard to reason that out. We all know that when pressure is applied to the interior of a closed vessel—like a boiler—the pressure, being alike in all directions, tends to force the vessel into a spherical form. The round part of a boiler is braced against itself in every way, but flat places in a boiler must be strongly stayed, to prevent them from being distorted by the pressure.

Now, from the front row of stay bolts from the shell to the crown sheet, there is fully ten inches to the point where the throat sheet joins the barrel, or rounded part of the boiler; and this flat, or partly flat surface is entirely unstayed. At the corners, the throat sheet drops abruptly, and have a stay from the central point to the back head; but the flat place at the top is unprovided for.

We found this trouble in all the Belpaire boilers with the straight top, and cured it by riveting a piece of heavy **T** iron 6 inches wide and 24 long, on the underside of shell—resolved to buy no more Belpaire boilers with a straight top. As an experiment, we built one boiler with a high wagon-top, and I resolved to test it thoroughly, before it was put into service, to this end, I set it up as it would be in service.

When the boiler was ready templates or straight edges were fitted to it, at the points shown by the lettered lines on the engravings, Figs. 2, 3 and 4.

Two up the sides on flat part, one fitted to the throat sheet up the side, one down the top, two on rounded part of boiler, and one across wagon-top sheet lengthwise; this was not exactly in the center, because the throttle stand was in the way, but it was near enough for my purpose. (See top view of boiler, Fig. 4.)

The boiler was then filled with water and steam turned on, and temperature raised to about 212, when the templates were again refitted to the boiler at that temperature. At that time the hydraulic pressure was put on the boiler, and every change between the sheets, on the lines mentioned, and the templates was noted carefully until the pressure had reached 200 pounds.

On the right side, along the lettered lines, there was no change whatever. On the left side, no change, except on lines *B*, *B*, and *C*, *C*, there was a bulge of $\frac{1}{16}$ of an inch at the intersection of these lines at *C* 1. Here the sheet commenced to bulge at 130 pounds. On top, the line in center of throat sheet *H H* was the only one that did not suffer On the line *I I* at *I* 1, the sheet went *down* $\frac{1}{8}$ of an inch, on the line *J J*, sheet dropped $\frac{1}{16}$ in the center, as it also did at *K K*. I sent a man into the fire-box—the crown sheet was *down* there $\frac{1}{8}$ of an inch—what caused it?

If you will note the construction of the boiler, the back head is stayed by gusset stays, riveted to the outer top shell (see Fig 5). Any pressure on the back head must exert through the gusset sheet stays on the top sheet. The pressure on the top sheet and top of crown sheet being equal, there is nothing to counter balance the pull through the gusset sheets from the back head. The natural assumption would be, then, that the only resistance to any outward movement to the back head would be its own stiffness, and that due to the gusset stays riveted to it, and to the resistance through the gusset stays from the top, outer shell of the fire-box This resistance was not quite equal to the pressure on the back head, and the result was, in my opinion, that this pressure pulled down through the gusset stays on the outer top sheet, and through the stay bolts on to the crown sheet of the fire-box, which is proven by the depression in the fire-box being equal to that in the top sheet. The crown and wagon-top sheets had no power to move both sheets the same way; one pressure was equalized by the other.

What caused the left side-sheet to bulge, is not easily answered; it was very slight, and was, no doubt, caused by some slight tension on the sheets or other structural cause.

We riveted several heavy angle irons to the inside of throat sheet—as at *H H*—and ran the two rows of stays from gussets on the back head across to them, in almost a direct line.

There is a flat spot, not stayed, at each side of such a boiler, as well as at the top, and we provided for it by riveting to each side a heavy angle iron, and putting a brace between them, as shown in Fig. 1; this brace was just high enough to escape the top row of flues.

After these changes, the boiler stood 200 pounds pressure without a quiver, and, so far as this form of boiler is concerned, in comparison with other forms in our service, it has done fully as well as the best.

The *World* had a reporter in the recent snow blockade on the C. P., he is a mechanic (?) or has an eye for mechanics—a blind eye. He describes the rotary snow plow as said to be able to make 60 miles per hour through 10 feet of snow, and tells how it started out, with several big locomotives behind it, "and your reporter on the pilot!" and —was stuck before it got 600 feet. Then the engines got out of water, and "a gang of shovelers were sent to fill the boilers with snow." Oh, dear! Oh, dear! No wonder they are stuck fast, with "prospects of staying several days."

Extension Front Used by the Union Pacific.

The accompanying cut shows the U. P. adaptation of the Barnes extension front. The arrangement has some interesting features, notably the large area of netting, all arranged ahead of the nozzle, which is lower than those generally used on extensions. As will be seen, the diaphragm drops from above the flues to a line just below the top of the nozzle, and then, at a less angle, to a point only 17 inches from the bottom of the front at the center; this plate is fastened to angle irons by bolts. A solid plate extends from the front side of the diaphragm to a point just ahead of the nozzle, where the perforated sheet, that takes the place of a wire netting, commences, and extends well toward the front, where it is fastened to a solid cross-piece and from the top of which another perforated sheet extends back at an angle just sufficient to bring it to the top short of the stack; this gives a very large area of screen, as the main sheet is almost in the center of the arch, at the widest point.

The nozzle stands only 4⅜ths of an inch above the netting and 2 inches above the center line of the boiler, above it is a short draught pipe as shown, 24 inches wide at the base and tapering down to 10 inches at the top in a length of but 20 inches. This petticoat pipe is raised and lowered by the handles extending up through the arch each side of the stack, and held by screws. The success of working of this device, discharging the exhaust from a ten-inch draught pipe right at the base of an 18 inch stack, rather knocks the argument of those who advocate some scheme to make the exhaust fill the stack at the base, to pieces.

A great deal of care is exercised in putting these front ends together, every precaution to prevent the plates warping in such a way as to open a seam, or any place where cinders could escape, is taken, angle irons stiffen the whole arrangement, and it is fastened to the nozzle and extra cross-braces. The cinder slide is that known as the Barnes, being simply a flat iron piece, held against the mouth of the hopper by a half elliptic spring; the mouth of the hopper is double, simply two round holes side and side; the bolt that holds the cover being between the holes; when this piece is pushed in either direction it uncovers the holes. This slide cannot stick, get lost, or work open on the road.

Fig. 3 on page 32 shows a section of the perforated plate, full size; this is always arranged in the front, so that the slots are across the boiler; as will be seen, the slots are a quarter of an inch by an inch and a quarter.

As the sizes are given on the engraving, it is not necessary to describe the front at any great length. They are giving good satisfaction on the road.

We are in receipt of the Annual Report of the Railway Commissioner of Michigan, for which we have to thank our correspondent, Clinton B. Conger, mechanical engineer on the board.

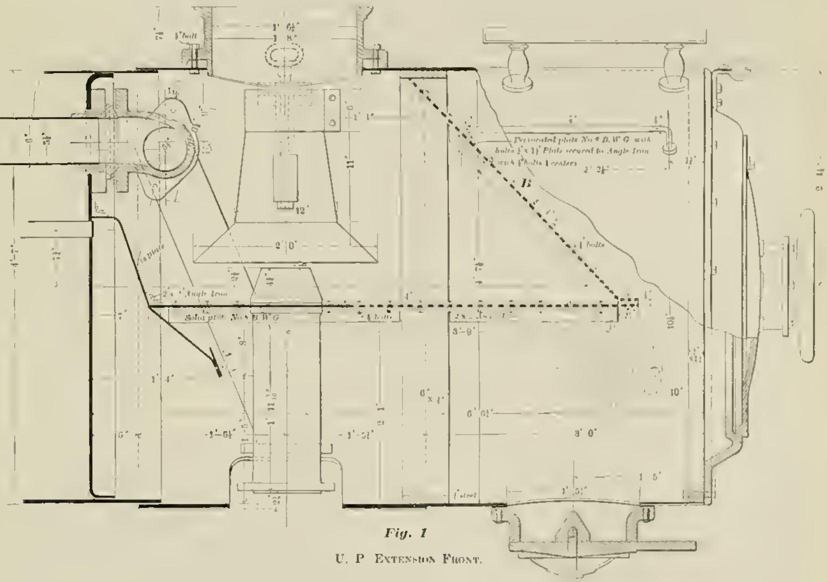


Fig. 1

U. P. EXTENSION FRONT.

We had some trouble with domes, on all classes of boilers, and in a future paper I will tell you how we went at it to find out what the matter was, and how we treated the disease after we found out.

Big Enough.

The mileage of the St. Paul system, now aggregates 566,905 miles.—*Journal of Railway Appliances.*

One road, that has over three times as many miles of track as there are in the United States, and much more than there is on the face of the earth, ought to be counted as large—exceedingly large.

On the New York, New Haven & Hartford road the engines are provided with a handle on right side of tank-head to open and close the cock in back end of air-brake pipe on tender. Men on the engines can close the cock themselves, and see at a glance whether it is open or not. They are also provided with a cock to bleed the auxiliary drum on the tender. Men who have tried to make a run of cars, and found that the "gafter" had only closed the cock on the car, and when the hose was cut the tank brake went on with a slam, will appreciate the usefulness of this arrangement.

Simple Lessons in Drawing for the Shop.

By ORVILLE H. REYNOLDS.

FOURTH PAPER.

In practical drawing, several kinds of lines are used, among which are full lines, broken lines, dotted lines, and broken and dotted lines. A full line, however wide or narrow, is made by the instrument without removing it from the drawing until the line is finished, as *A B*, Fig. 6.

A broken line is made up of a series of short lines, say from an eighth to three-eighths inch long, having a space between about equal to the length of the line, as *C D*, Fig. 6. Much care is required to produce a creditable broken line. The broken line is used principally to connect like parts of different views on drawings.

The dotted line is what its name implies, and is made by raising and lowering the instrument in quick succession, producing a line as *E F*, Fig. 6. This line is used to show a hidden portion of a drawing, and makes a fine finish when skillfully done.

Broken and dotted lines are a series of short lines or dashes, followed by one or more dots, like *G H*, Fig. 6. This style of line is recognized almost universally as the correct thing for a center line, both on account of its singular form and beauty, and ease with which it can be made after a little practice.

Sections of materials used in construction are represented by diagonal lines drawn with the 45° triangle about $\frac{1}{16}$ inch apart (Fig. 7).

This figure represents three pieces in section. Some practice is necessary, by the way, to make a neat-looking section, owing to the difficulty of making the spaces equal; if there is any inequality in the spaces the eye catches it at once.

There seems to be no standard for showing *what* the different materials are, unless we except sections of wood, Fig. 8, each draftsman being a law unto himself.

The foregoing kinds of lines are embodied in the different sections shown, as wrought-iron, Fig. 9, steel, Fig. 10; cast-iron, Fig. 11 brass, Fig. 12. These sections are mades up from average modern practice, and are perhaps as close an approximation to general use as can be given; but it makes not much difference what method for showing sections is chosen in the absence of any recognized standard, for the material represented must be named before it can be admitted to the family of parts which go to make the perfect whole.

A cylindrical surface is shown by lines drawn close together at the edges, gradually widening the distance as the center is approached, receding portions being the darkest, Fig. 14.

The shading of a plane surface will not be covered here, for it is our purpose to make the lessons in outline only, with the exception noted above.

With these remarks on lines, this portion of the subject should be clear, and we leave it, to adopt a standard size sheet of paper to be used.

Our board is 20"x30". If now we cut a sheet of paper 14"x24", and pin it to the board centrally, we have a space of 3" between the edges of the board at sides and ends. With a due appreciation of high art, the paper should have a border line placed one inch from each edge, leaving a working space of 12" x22".

One of the principal beauties of a nicely executed drawing is the manner in which the views are arranged on the sheet; now here is an opportunity to exercise a little taste. The symmetry of the whole, when finished, pays for all trouble in this direction.

In the adoption of this standard size of sheet there must be no haphazard arrangement of the exercises, for the size is such that care must be used, or they will contain too few lessons.

The arrangement of the views in this lesson will convey a clear idea of what is intended in the above.

The drawing should be so disposed on the sheet as to leave not less than one inch between it and the border line, arranging so as to leave a space at the lower right-hand corner for the inscription, the scale at which the drawing was made, and the date of completion.

The inscription should state in clear terms what the drawing represents. The style of the inscription is a matter which can be left to the individual taste, but it will not be out of place to say that the less ambitious attempts that are made to that end, will give more time for good work on the drawing. Nothing ornate is required. The finest inscriptions are those which are severely plain, where no embellishment whatever is attempted. It is often the case that, when a drawing has a title rivaling a circus poster in splendor, that there is something wanting either in execution or accuracy in the make-up of the drawing.

A plain title is made by drawing two parallel lines with the T square about ¼" apart, and making the block letters free-hand, *i. e.*, without the aid of the instruments, in pencil first, and using a 303 Gillott steel pen with the ink.

The scale used, and the date below it, should be made in plain script, also free-hand, after making three parallel lines—the two outer ones about $\frac{3}{16}$" apart, to designate the height of letter, and the middle one slightly nearest the top. An example of above is shown in Fig 15.

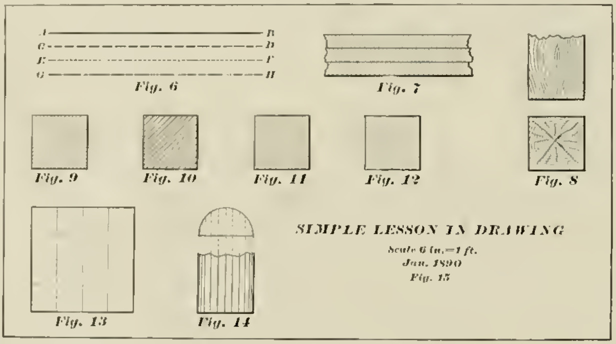
The necessary preliminaries are now arranged for the first lesson, which, to familiarize the student with the handling of a few plain figures, will embrace the exercises shown.

To draw Fig. 6, erect two perpendiculars with the triangle—in this case about 4" apart—which makes a point to start and stop the lines, following the description given in first mention of the figure.

To draw Fig. 7, produce three parallel lines any distance, as 3 inches, connect the ends by an irregular line, and alternate the direction of diagonal lines drawn with 45° triangle.

Fig. 8 is made by drawing two parallel lines about one inch apart, and erecting two perpendiculars, also about about one inch apart. In representing the grain, use the 303 pen to make the concentric circles, and from the center make radial lines. This is a transverse section of wood.

To draw the longitudinal section of this figure, make two parallel lines with the T square as before, showing one end square and the other broken, using the writing pen again, to represent the grain in wavy lines.



Figs. 9, 10, 11 and 12 are drawn in outline similar to Fig. 8, after which the diagonal lines are made with the 45° triangle.

To construct Fig. 14, mark off any number of points equally on a semi-circle, and through the points draw perpendiculars to the diameter.

The spacing is mentioned to show the principle; it can be omitted in practice.

To construct Fig. 13, draw with the T square two parallel lines, about two inches apart; erect two perpendiculars, also two inches apart, and cutting the parallels; divide two adjacent sides into any number of equal parts; through these points draw lines.

Let the student make an earnest endeavor to follow this lesson and give his attention to placing the figures as close to the arrangement shown as possible, and not be discouraged if the first attempt is crude, but place another sheet on the board, and go at it manfully, with a determination to succeed. Victory will surely perch on his banner in the exercises to come.

On the N. Y. & N. E., many of the solid-ended side rods have the eye at each end separate from the rod, having straps that are bolted to the rod. Probably put on rods having the old strap and half brass.

An English syndicate have been making some pretty big bids for American locomotive works. This is no joke; we know whereof we speak.

Correspondence

A Kink for Keeping Cab Windows Clear of Snow.

Editor The Locomotive Engineer:

In looking over THE LOCOMOTIVE ENGINEER for January, I noticed an article headed, "A Wrong Idea." Now I am not a machinist, nor yet an engineer, but a fireman who tries to keep track of a few of the kinks the article speaks of.

I make it a point to keep the furnace door shut whenever we approach switches, railroad crossings, highways, etc., on night runs. I like to see ahead as well as any engineer running. We have a device in use here, on the Detroit, Lansing & Northern Railroad, to keep snow off the front windows, which, though not new, may be of use to some of the boys. Take a piece of ¼-inch round iron eight inches long, heat and flatten two and a half inches of one end, bend square across, and punch through two holes, fasten on with screws a narrow strip of wood eight inches long with a strip of rubber nailed to the edge full length. Now bore a hole through window-sash close to the edge of glass, and about middle of window; run the rod through and bend down the end on inside, and you will have a device to keep window clear, that any one who ever rode on a locomotive in a snowstorm will fully appreciate. By moving the end of rod inside the cab a clear place can be kept on the outside of glass, as the rubber cleans off the snow. In cold weather we keep a piece of canvas nailed to coal gate on top, and weighted at bottom, which keeps out a lot of coal-dust and cold, and well pays in comfort for the little trouble it makes.

A FIREMAN

Howard City, Mich.

[Here is a simple little kink worth trying. The writer has opened the front door and wiped a clean space on the glass milli—well, hundreds of times, anyway.]

About Testing Locomotives.

Editor The Locomotive Engineer:

While reading in the *Railway Review* a description and account of the performances of the compound engine built for the Michigan Central Ry., at the Schenectady Locomotive Works, my thoughts wandered back several months, and the description and accounts of a certain remarkable run made by the *late* Strong locomotive (I say late Strong locomotive, because it was generally behind time), as published by the same paper, came to mind.

I wondered if the final outcome of this engine, would fall as far below the published accounts as the Strong has done.

There is no better way of judging the future than by the past, and the value of reports is governed by the source from which they come. Should this be the case with the Michigan Central compound, it would be pitiful indeed, and better things are hoped and expected of it.

There is much credit due the officers of the M C. Ry., as well as the Schenectady Locomotive Works, for making an effort to solve the much disputed problem of compounding the locomotive.

There may be, and no doubt are many changes to be made, before a decision can be reached in the matter, and if it were possible to have accurate statements of what the engines perform in the different trials, it would be very useful to every one interested in railways and railway machinery, and any mechanical paper, that furnishes the public with reliable news, will be putting itself in a position to *look down* when it tries to see its many competitors.

An ounce of information is of far greater value than pounds of misstatements, which are so common amongst the news furnished.

Anxiously waiting for further reports, I am

Cherry Hill, Pa. C. RITIC.

Which is Which?

Editor The Locomotive Engineer:

I quote from your issue of January, 1889, in reply to a correspondent's question as to the proper position in which to stand an engine when keying the back-end of main rod: "On the engine center, because the main pin is flat where it receives thrust and pull of piston, and is largest where least work is put upon it at the center." I have always held this opinion of the wear of a main pin; but, in a conversation recently with an old machinist here on the "Erie," a man who has the reputation of being one of the best on the road, I was informed that my line of reasoning was wrong. He said that in trying main pins with the calipers, he had found that they wore more on the center than at any other point. The reason of this was that the slap or pound of main rod, when passing the centers, caused a greater wear of the pin than was caused by the greater power exerted by the piston at the quarters.

"When doctors disagree who is to decide?" I shall look in your February number for the light which shall dispel the atmosphere of "comfuddleness" which at present envelops us. H. M.,

Fireman N. Y., L. E. & W.

Paterson, N. J.

[With a fast engine, generally cutting off at six or eight inches, there is little doubt that there is more pressure on the pin at or near the center than on a freight or switching engine that works most of the time at from a half to full stroke, wearing the pin more at or near the quarters. And on engines working between these extremes the pins will wear differently; at the point where the least strain is on the pin it will be found the largest, and may vary in different engines, but the great majority will be found largest on a horizontal line when they are at the centers. Perhaps some of our machinists can give us pointers on this; let us hear from you.]

The Good Old Times.

Editor The Locomotive Engineer:

The other day I got up on an engine that was coupled to a big passenger train, while the passengers were eating dinner, and had a talk with an old friend whom I knew when we were both firemen in 1870. We got to talking over old times, and my friend, who I will call "Doc," for short—although that is not his name—told me a doleful tale of the trouble he is having with the new-fangled machinery an engine has on at present.

"You need not tell me about the improvements in engines nowadays, for I can't see it. In the first place, look at those solid-end side rods, they are the biggest nuisance I ever struck. The little McQueen engine I had so long, after I was set up, had a regular built rod with straps and keys, and I used to go around them every trip, try the keys and set-screws to see if they were all tight, key them up as fast as the brasses got to working in the strap, and about once in six months have them reduced. Look at those solid rods, how are you going to key them up? And the worst of it is I will have to put up with them while I run this mill, for the bushings ain't a going to wear out in my time. I have had them a straight year, they have not got hot so far, and I guess they will never wear out. The rattle of them is enough to drive a man crazy; you can hear them farther than you can the bell, and it makes me tired to think they are going to last forever. There is the air-brake, it is getting so complicated, it takes a smart mechanic to understand what it is all for. I was examined by the travelling engineer the other day, and he took a triple valve all apart to show how it was made, and how it worked; there was a plumb twenty-nine pieces in it, besides two or three gaskets. After he got through asking me questions, he said I would pass all right, even if I could not explain *all* the ins and outs. When a fellow wants to stop awful bad, the air is the thing to have, and beats the Armstrong brake all hollow. My air gave out the other night, because the flange broke off the air-pipe where it joins the pump; that let the air out, and you can bet we soon stopped. The boys had to do the crank act from there in. My heart was in my mouth most of the way in, for fear something would happen, and we lost time at every stop. In the good old times we did not worry about that, because the 'shacks' then would stop us all right; but the fellows on passenger trains nowadays don't know anything about braking, they are only good for poking up stoves and helping the women off the cars. Then there is the driver brake, it works at the same time the train brake does; my hair stands up straight—N. B., Doc. is baldheaded—when I see the fire flying out of the driving wheels, but I can't help it. It ought to be a separate brake worked with steam or air, so a fellow could use it when he thought it necessary. You can bet I would not use it any oftener than I had to, for I don't go much on a driver brake. Some of these days she will strip herself on one side, and then where will the driver brake business go to? The steam heat business is a corker, if you look out now you can't see the hind end of the train for steam leaking out around the couplings. The conductor has to get up towards the engine to give a signal, because you can't always see him. That don't matter much, for the dispatcher has us held for orders about every time we stop, so he has to come over to the engine with the yellow paper. Time card rights don't amount to much nowadays. But about the steam heat. Last winter it was a holy terror, this season it ain't so bad. We did not have that to bother with in the good old times. This traveling engineer business beats me, though; the other day he came around and said I was using too much oil and coal. I asked him if the company was getting poor, but he did not mind that, and went on, saying that her nozzle was too small, he thought. That made me hot, and I told him it was too big, it ought to be made smaller, so she would bark right out sharp every time. He allowed that the day for barking out sharp had gone by, and there I ran up against another one of your modern improvements, for he had it made bigger the next trip. She steams pretty fair, and don't use quite so much coal and water, but the first cold night she will lay down. She is a bully steamer for a straight stack engine, and I suppose he will fool around with her nozzle and stack, trying to save a little coal, till he spoils her. But there is one of your modern improvements that is pretty fine, that is the electric crossing. It used to be a big job to stop at a railroad crossing, and we did not always do it, till three or four years ago. When they began to give a man his red ticket for not stopping at a railroad crossing it made it pretty binding. Now they are getting the interlocking switches in everywhere, I don't have to stop with a varnished car train once a week, and the beauty of it is, the other fellow can't run into you. Just the same, I feel nervous when I am crossing one, and keep my eye on the home signal and split rail. Most of the engines now have to haul too many cars for the size of their boilers. When you get a signal to go, you have to work them as hard as you can to make the time to the next stop; if you lose any time, the old man wants to know mighty quick what is the matter. Well, I must be going, so good-by till I see you again."

While my friend has an idea that, because anything is new and different from the old machinery, it is not so good, most of his objections arise from some other reason. Some of us have been traveling along in the same old rut so long that we hate to get out of it. While we see new ways of doing work to make it quicker and safer coming into use all around us, yet we sigh for the old crosshead pumps, diamond stacks, oil cups on the steam chests, etc., because it was lots of trouble to learn how to use the new equipment. My friend "Doc," while complaining about a good many devices that have come into use in the last ten years, did not give a single good reason against the fact that they could be successfully operated. He did not like to get out of his old rut. But it is a fact that the number of engineers who object to keeping up with the times is growing less each year, they are not dying off, *they are learning how*. Most of them welcome any new machinery that will make things any safer, even if it looks more complicated. "Let well enough alone" is a pretty good motto, but "Do the best you can, and look for better," is a sentiment more in keeping with railroad operations of to-day. The demand of to-day is for heavier trains and greater speed with trains closer together on a single track; if this demand is complied with, and *safety* made the first consideration, the old ways will have to be abandoned whenever they are not up to the standard. First cost is not looked at as closely as endurance and amount of service. Some methods look complicated when new, but after we study them up they are simple enough. Let us study up. C. B. CONGER.

Lansing, Mich.

Here Too, Mr. Campbell.

Editor The Locomotive Engineer:

Why is it that railroad companies imagine they must have a man in the locomotive department whose duty it shall be to ride back and forth over the road, to see how their engines are working, their general condition, and to instruct firemen in their duties? At the same time they keep a man, under pay, called division master mechanic, whose duties are identical with those of the traveling engineer. Ninety-nine times out of a hundred these two men are cut out of the same piece of cloth, namely, old runners, and neither of them practical mechanics, sometimes both doing duty on the same division, both bucking, both at swords' points the one with the other. I have seen a division master mechanic seclude himself, go off and pout, when the T. E. was making his "grand rounds."

The division master mechanic represents the general master mechanic; the T. E. does the same on the road, only a little more so. The T. E. rides on an engine and berates the poor fireman for burning so much coal; the T. E. jumps down, grabs the shovel, and says: "Let *me* show you how to fire", he opens the door, gives the shovel a circular motion, which brings the mouth of the shovel on a line with the top of the arch, the engine is working hard; result—if the coal is fine the exhaust picks it up and distributes the coal *on top* of the arch, and it is not long before the steam gauge begins to weaken, the engine gets tired, and wants to lie down and rest. The fireman was putting the coal on the fire, the T. E. put it on the arch; in his frantic efforts to instruct the fireman he loses sight of the fact that the engine is blowing badly, and that she has a three-cornered exhaust. If he notices these things at all, he thinks the division master mechanic should attend to them, but he don't tell him so; at the same time that is just what he was created for; but he thinks it is the master mechanic's business, and says, "Damficare."

The master mechanic sits in his office, and hears an engine go wheezing and limping along, but he says "Damficare; the T. E. is paid to get onto these things," although he was made master mechanic not only to sign the pay-rolls of his division, but to keep his engines up; but if he don't know and don't care, what can be expected?

There is one thing the T. E. can do—he can take advantage of his position to bulldoze some poor devil against whom he may have some private grudge. The man for a division master mechanic should be a good, practical machinist-runner, other things being equal. They would then know when an engine is in the right condition to go out of the back shop, so that the man who runs her can take a little comfort—their life is hard enough at best.

Putting up a locomotive according to the ideas of the back shop men, and what the real requirements of the road are, are two different things, and it is right here that the machinist-runner master mechanic can get in his work to advantage. But where the master mechanic is not a practical mechanic, and the foreman is not a practical engineer, and you mix in a few parts of traveling engineer, it makes a bitter pill for the boys to swallow.

The traveling engineer as a man I have nothing to say against, but I claim they are a useless appendage, so far as my own observations go.

The writer was pulling a late passenger train one night, and having to stop for orders, when I got ready to pull out, lo, and behold there was the traveling engineer on the engine—in itself bad enough—but, to make matters worse, he had jumped my seat, with the intention of piloting me over the last twenty miles of the road. I knew the road, had been there before with same train and engine, and at night; I asked myself the question, Will Ben never get up and let me have my place? but, like Poe's "Raven," echo answered, "Nevermore," and the animal sat there, and I had to run and look ahead as best I could.

Do I like the T. E.? not by a good deal.

W. DE SANNO, Engineer and Machinist.

Corry, Pa.

[Now this will probably stir up a discussion. please remember that in that case *facts* and *points*, not *opinions* and *assertions*, are what is wanted. Arguments educate, scolding degrades.]

The "Neversink" on the P. & R.

Editor The Locomotive Engineer:

The locomotive Neversink blew up on the Philadelphia & Reading Railroad early in the 50's, perhaps before that time. I recollect the circumstance very well, but forget particulars; think it happened at or near what is called Neversink curve, on the P. & R. W. DE SANNO.

Corry, Pa.

[Perhaps some of the older Reading men will remember about the Neversink.]

The Michigan Central Compound.

Editor The Locomotive Engineer:

Much has been written of the compound locomotive, of its fuel economy and the like. Many, no doubt, suppose it is an easy matter to get out such an engine that will do the work of the standard 8-wheeler, besides showing a considerable fuel economy. Enclosed I send you a report, from the *Detroit Free Press*, of the compound built by the Schenectady Locomotive Works for the Michigan Central Railroad. It will be seen that the engine consumed a little over seven tons of coal between Detroit and Michigan City, a distance of 228 miles, while standard engines use but little less from Jackson to Michigan City, a distance of 152. Surely this is the most successful compound yet built in the United States, so far as fuel economy is concerned.

Could not a considerable fuel economy be effected by using pressed coal on our engines, as is common in Europe. Among the locomotives at the Paris Exposition was a four cylinder engine exhibited by the Paris, Lyons & Mediterranean Railroad. Two of the cylinders were inside connected, and the other two were placed outside. The engine resembled an American locomotive, minus bell, pilot, etc. Size of cylinders 17x24 inches, diameter of boiler about 58 inches, drivers 72 inches in diameter. Total weight perhaps 80,000 pounds. Mr. Editor, do you think this engine was a compound? If so, does it not resemble the B. & O. engine? I believe in the compound, but it must not have any elaborate gearing, and be able to attain a good rate of speed. The M. C. engine has showed good fuel economy, but I have not heard of any very fast runs. These are my observations of the compound, and, as I am probably the youngest subscriber to your excellent paper, they don't amount to anything.

Detroit, Mich. GEORGE L. FLEITZ.

[Facts and observations are what we want, and are therefore glad to hear from this correspondent, and as it is the fact or the observation that we want, and not the recorder of the fact of observation, it makes no difference about the youth of the writer. Youth, age, sex, shape, size, hue, or previous condition of servitude makes no difference with the fact, be it told by one or all.]

Some Pointers from Jersey.

Editor The Locomotive Engineer:

One day last summer, while watching the arrival and departure of trains at Matawan, N. J., I was approached by a ministerial looking old gentleman, who asked me this question: "Why is it that, upon stopping here, some of the locomotives blow off steam at one end of the boiler, while others blow off at the opposite end? I have noticed particularly," he continued, "that the engines belonging to the Pennsylvania Co., while blowing off, emit a very subdued sound, and that it invariably proceeds from the chimney or smoke-stack, whilst the engines of the Central of N. J. do all their blowing from the top of the cupola like structure at the other end of the boiler. Can you explain this to me?" I said I could, and straightway proceeded to enlighten the old gentleman.

I pointed out the difference between a pop safety-valve and a blower, and how necessary they both were to a locomotive.

I said a P. R. R. engine depended on the blower to get its train over the road in time for the final resurrection, and, if he doubted my word, to get on the next train and ride as far as the mouth of Cheesequake Creek (Morgans), and watch the fireman claw for that blower valve as soon as the engineer shut off for the station.

The old gentleman seemed interested, and I gave him more food for thought. He admitted that he knew the difference between the sound produced by an epileptic man sawing wood, and the clean cut, well-timed roll of a drum. Then I likened the former to the sound of the exhaust of a Penna. R. R. engine, and the latter to one of the Central of N. J.

This ended our talk, as my train arrived, and I was compelled to bid my friend good-by.

Speaking of locomotives, it is a fact that there is one—that, when not undergoing repairs, pulls the early train through my native town; that, when hooked up to the fourth notch, has one less exhaust than the Webb compound on the Penna. R. R. In conversation with the engineer he said: "What can you expect, when valves are set on the piecework plan, and no one to see or care whether they are square or otherwise"; but he evidently derived some consolation from the fact that the engine was "standard."

An engineer told me, recently, that he one day had orders to relieve a certain young runner at M——, that, while oiling around, he discovered the crosshead pin on the engineer's side ready to drop out, the split-pin and nuts having fallen off somewhere up the line. He called the young runner's attention to it, when the latter exclaimed, "Yes, I know it. I've been watching it, and, if the pin had dropped out, was ready to catch her before she struck the cylinder head." BAY.

Matawan, N. J.

[Evidently the lightning engineers are not all dead yet.]

The Dimensions of a Radical.

Editor The Locomotive Engineer:

In January issue of THE LOCOMOTIVE ENGINEER, we find among correspondence, a contribution under heading: "A Radical View of the Traveling Engineer."

Has the true significance and imposing grandeur of a title ever dawned upon the observing readers of THE LOCOMOTIVE ENGINEER?

If not, we wish to give an example of the overpowering elegance of authority, and *assumed* wisdom of a titled individual down in Texas.

This individual signs himself E. A. Campbell, Superintendent of Motive Power and Machinery of the Houston, Eastern & Western Texas, and Shreveport & Houston Railroads.

This indeed makes a grand combination, but its grandeur becomes woefully modified when we find that this immense railway system is even smaller in length than the title which covers it, rivaled in turn by Mr. Campbell's overpowering wisdom.

This great railway system is an ordinary 3-feet narrow gauge railroad, embracing about one hundred and ninety miles, and with sixteen locomotives and 570 cars credited to its entire service.

Now let our kind readers again note the following, evolved from the fertile wisdom of Mr. Campbell's brain, or probably the sentiments may have been written by one of the boys just out of school, and Mr. C. may have offered it to the columns of THE LOCOMOTIVE ENGINEER, thinking his overpowering title might add *strength* to the production. Here it is, *verbatim*:

"A practical engineer ought to know that any M. M. who allows a traveling engineer, is not held in position on account of his good qualities as a mechanic or engineer. Did you ever know of a good practical engineer or M. M., who would employ a traveling engineer? Well, I guess not, unless a friend of his came along, and he has all the engineers that he can employ, then he picks up the idea he can employ him as traveling engineer; but as soon as he can give him a regular engine, good-by traveling engineer, until some other friend comes along. No master mechanic, who knows the duty of an engineer, will employ a traveling engineer. I am surprised that any superintendent would admit anything of the kind to be paid for on transportation rolls; but as long as companies will employ incompetent men for superintendents and master mechanics, such ignorance may be expected, as employing traveling engineers. I *do* think, in *my own opinion*, that money paid out to a traveling engineer is worse than that of paying out money for cylinder oil that makes 5,000 miles, and requires new valves and false valve seats for engines, also new packing for cylinders. A master mechanic should know the duties of an engineer before he accepts the position of M. M.; then a part of his duty is to know the condition of all his engines in his charge. His next duty is to keep those engines up in good repair, keep their valves square, and packing from blowing. The engineer's record, as to how he pulls a train, and handles his engine, will soon tell on him, then the M. M. can handle him without any go-between called a traveling engineer. When the M. M. does not know the duties of an engineer, I would advise him to employ a fireman that does.

Now, Mr. Editor, this will hit some M. M.'s pretty hard (especially the Supt. M. P. & M., of the H., E. & W. T., and S. & H. railway), but you just tell them to take my advice as to employing a fireman.

I have been a traveling engineer in pay of the company, and I have also been a traveling engineer without pay, and *I think*, in *my own* mind, that railroad companies were making more money when *I was* a traveling engineer *without any pay*, and common engineers were happy."

Your readers will not have to ponder very long, before accepting the striking candor and truthfulness of this last paragraph.

Now, when one takes into consideration the extent of the railway system over which Mr. Campbell throws the mantle of his divine title and sublime authority (190 miles, 16 locomotives and 570 cars), such sentiments do not seem out of order, and it would be strange if *one* man of ordinary intelligence could not be superintendent of motive power and machinery, master mechanic, general foreman of shops, and traveling engineer combined and then not overtax the physical energies or nervous system in the least.

When Mr. Campbell acted as traveling engineer *without* pay, he probably earned all he was worth, whether in service or *simply rustling for a job*.

"Eyes and see not, ears and hear not."

For the readers' information, we would offer, in explanation of our last article on the traveling engineer, that, at the present time in our section of the country, the master mechanics who keep the best class of machinery in suitable repair are those who highly value the services of competent traveling engineers. Such talent naturally works for *pay*, and *paying* results.

Your readers will readily understand that these views were mainly expressed with regard to railroad systems embracing several hundred or thousand miles, and having in service at least 50 locomotives to a division, or in the neighborhood of 500 locomotives to a system.

We owe the readers an apology for not having used a microscope in discovering such a vast title enshrouding the magnificent H., E. & W. T. and S. & H. railway system.

We recognize the fact that in all nature there exists a diversity of talent, and varying degrees of intuition and animal sense.

The finely strung nervous system of Bishop, the mind reader, has been experienced, and by the merely delicate intuition of his nerves, he could comprehend the feelings and transmute the thoughts of a fellow-being into vocal sound.

From this exalted type of the comprehensible being, we can look down the ladder, and note the fine gradations of animal power, until we find at the base the dense type of organism, void of perceptive power beyond the routine of selfish occupation, viz., 190 miles of narrow gauge road, with 16 locomotives and 570 cars—everything in shipshape, and resting on the shoulders of the magnificent and talented superintendent of motive power and machinery. J. E. PHELAN.

Dickinson, D. T.

[The editor took upon himself the responsibility of giving a title to Mr. Campbell's article, and to tying his title to his name.]

The True History of the "Neversink."

Editor The Locomotive Engineer:

In this month's number of THE LOCOMOTIVE ENGINEER there is an inquiry about the exploded engine "Neversink." About 1840, Baldwin built an engine by that name for the Philadelphia & Reading R. R. Co.; she was a single driver engine, and weighed about 13 tons gross; was made famous by hauling two car loads of passengers—about 60 people—up the old "Inclined Plane" on the "State road" at Philadelphia—was handled by Bill Petit, mechanical draftsman for Baldwin at the time. She was rebuilt by the P. & R. into a 6-wheel connection engine—weight about 18 tons—14½x20 inch cylinders, 46-inch wheel, after drawings by Predgold, of England, cylinders were on the smoke-box above the frame. Guides were set at an angle of about 25°. She blew up on a Saturday night in June, 1845 or 1846, on Mill Creek bridge, about 9 miles above Philadelphia, on the P. & R. R. R., killing the engineer, Bill Sullenberger, together with the fireman, conductor and front brakeman; being the fourth locomotive engine that had blown up in the railroad world up to that time.

This *may* be the engine to which you refer, as at that time the only sun pictures were the daguerreotypes

E. J. RAUCH.

A Spring Removing Kink.

Editor The Locomotive Engineer:

Herewith I send a sketch of an arrangement for removing driving springs on light engines, which we find very handy.

It is used by blocking up one end of equalizer in the usual way (we use a small screw-jack here) then put bar through loop and the end in hanger, pull down and remove key.

We use it on springs of 9, 10, 11, 12 plate, with from ¾" to 1¼" draw, and save a great deal of time over the old chains.

Boston, Mass. E. H. WALTEN.

"Looking Backward."

Editor The Locomotive Engineer

"He stole that," I suppose you will say, as you open this letter; but young fellow, I used it before the man who pinned it to his book was born, and besides that, if I want to say "looking backward," I am going to say it. I did commence this little piece "Glimmering Rearwards," but scratched it out, as being too giddy for a man of my years.

I laid off this trip, Mr. Editor, to be home on the occasion of the anniversary of the first half century of my life's run.

If I keep on thinking, and talking, and breathing till 8:41 and a half, I will be 50 years of age—mileposts seem to be getting closer together, somehow.

As I sat before the open fire just now, when it was getting dark around the edge of this great big world, my mind's eye was "looking backward," over those 50 momentous years, and I was thinking that, if the measure of a man's years can be figured by what is done in those years—the progress that is made—that old man Methuselah, was a very young pup, compared with a grizzly dog of my days, getting along in the sere and yellow leaf.

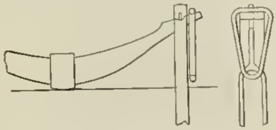
I haven't done a thing all day but talk over the old times with Mrs. A., and "look backwards," but she—Mrs. A.—has been busy. Women think at work, men make a business of it. Even now, with all the work done up, and her chair drawn up into the little family circle, she is quietly darning something. And as I "look backward" over the years that she and I have been together, I feel ashamed to think that she has done the most, said the most, been seen the least, and got the least credit. She has not been my partner, except in the sense of a silent partner. She lost her own name and identity the first move; she is Mrs John Alexander; the mail all comes addressed to me, the door plate has my name on it, and the children are all branded Alexander, as plain as the nose on your face

I was just trying to find a railroad comparison to a good wife, but I can't. The best I can think of, is a tug. A switch engine would not be fair, switch engines do lots of work, but, my, they make a fuss about it. I have known, afore now, a modest looking three legged switch engine to shackle onto a row of cars, and start out past the passenger depot, like a road engine bound for St Louis or Omaha, and shouting, "Watch me!" "watch me!" "watch me!" and then go to the far end of the yard, and throw the load into the back track, when you wasn't looking, and commence pottering around, pretending to be awful busy; but pshaw, that is not the good wife—it's the hired girl. Mr Editor, did you ever go down to the Battery, in that gigantic Sodom of yours, and notice a great ship come up to the wharf? Grand, ain't it? The great monster ship, with the scars of the storm battles upon it, laden with the freight of far-off climes, glides up the quiet waters of the bay—against the ebb tide. Flags flying, sails furled, not a sign of life or power; no smoke, no noise, but steadily coming up stream. The people look at the ship, and praise its lines and staunchness, and gigantic size and power to go on long trips, but mighty few inquire what is making it travel so steadily and so surely to its place at home. Go around to the other side, and there we see a little tug, lashed fast to the great monster's side, out of sight behind its greater bulk, and guiding and forcing it in the proper channel—the ship's wife.

I never knew a ship to take a tug, unless it expected the tug was going to do it some good, and I never knew a tug to tie up to a ship unless it was convinced and confident that it could handle and be of a good deal of use to that ship—that's marriage.

Of course when the tug is first lashed fast to the big monster, she commences to push or pull, trying to get the ship to go the way *she* wants it to, and then she kicks up some foam and makes a fuss, exhausting into the air, and blowing off—that's a honeymoon spat.

But just the minute the ship commences to come *her* way, down comes the pop, "biff," the exhaust is silent in its own condenser, but the little tug is digging her toe nails in, and doing more work than ever—just like a good wife.



SPRING REMOVER KINK

My advice to every old hulk of a railroader who is trying to make port with a load of sand ballast against a head wind, with the rudder tangled up among the boulders on the bottom, is to put up signals for a tug—only be sure you don't throw a line to a canal boat or a scow.

I look around on my little circle with satisfaction and pride, yet "looking backward" but a little into the years that are now but history, there was another little face in the circle—a baby's face. She came to us like a tender little offering upon the altar of our home love, out of the mysterious bounty of the Goddess Mother, Nature, she came; back into that mystery she has gone again, leaving in our hearts a tender sorrow, and a deeper love. Like the frost ferns upon the pane, like the little Alpine flower that blooms amid the eternal snows of the everlasting peaks, beautiful as a dream, and tender and delicate as a mother's love, there is no transplanting, no plucking without destruction. She came, and went away again. She was, and is not. Like the remembered vision of a beauteous scene; like the echoing cadence of a passionate song, she has become to our hearts a sacred, holy memory

And my friends, my comrades, those who started out with me to fight the battle of life—what of them? "Looking backward" through the vista of the years, I have counted them one by one. Ah, how they are scattered. Some are driving their iron steeds among the crags and snows of the Andes and the Rockys. Some swelter beside their giant hogs in the deserts and the plains. One is at the bottom of the deep blue sea. Two—and beardless boys they were—sleep beneath the withered flowers yearly strewn upon the soldiers' grave. Some are on the old road, some here, some there, but the great majority have come in—like the wrecks they made—dead.

Some, simply silent and beautiful, with the fires of life extinct, have been towed in; but most of them have come as dismantled and battered hulks of their former greatness and power, and all have gone over the silent river Styx, to that great shop, where all the victims of the lap orders and misplaced switches on the road of life go in—but from which none are returned to their old work, and their old runs

Now, I was going to get you to "looking backward" to the best railroad story you ever heard me tell, but you have said, "Bile 'em down to two columns or less," so I will just stop right here, and say "To be continued in our next."

JOHN ALEXANDER.

How to Run Very Soon After Firing.

The old-timer came in again Saturday, and sitting down in the holy of holies, he spit at the editor's feet in mistake for the spittoon, and opened out.

"That reminds me of old Davie Upton. Davie was master mechanic of the old Cheshire road, way back in the 40's, and afterward on the Central, out at Rochester

"Davie had a fatherly way of talking to his men, everybody was Sonny.

"One day, way back in early war times, a young feller came into Davie's office and struck him for a job.

"'What did you want to do, Sonny?' asked Davie.

"'Well,' said the boy, 'I'd like to get on firing for a while, then go running.'

"'Yes, yes,' said Davie, sorter to hisself; 'I'll tell ye what you'd better do, Sonny, you'd better enlist and go to war, then you could fire and run, too.'"

A great deal of complaint comes from men running the fast trains, with new 12-wheeled cars, about the poor holding power of the brakes You must remember that the brakes only apply to eight wheels, and the total braking force is thus cut down Take a drawing-room car weighing 81,000 pounds, with 8 wheels braked a total braking power of but 45,000 pounds can be used, while with a shoe on all the wheels under the car, a total braking force of 72,000 is available. A train of these cars, drawn by an engine without a driver brake, needs a great deal more room to stop in than one with modern equipment

Slowly but surely the federation of the engine and trainmen of the country is going on, the union is being effected without noise or smoke, and its thoroughness is little known or understood That Reason shall be elected permanent president, Common Sense, secretary, and the Golden Rule adopted as the constitution and by-laws, we sincerely hope That such an organization will be powerful there is not the least doubt, and, as long as that power is used to aid members of the organization because of the *right*, and not because of the *might*, no one can complain—and no just man will.

Miss Nell Nelson has had a ride on a locomotive from New York to Philadelphia, and if all she says in the N Y *World* is true, the boys were not very careful of her "Perched up between the *steam chest* and the cab" is rather an airy perch The *copper* boiler also disturbed her. We hardly expected a woman to see things right, but was not prepared to hear her misrepresent the kindly engineer, who is alleged to have referred to his pet engine as "he" and "him." A real, live engineer would as soon think of calling his wife "Mr." or his mother "it."

Something of the way the old "Monster," illustrated on the first pages of this paper, looks to a person not on the road, may be gathered from the remark made by the wife of a P R. R official, on seeing a picture of one in his office: "Why, John, this engine was in an awful wreck, wasn't she?"

The *Railroad Brakeman's Journal* has been changed to the *Railroad Trainmen's Journal*, the name of the order it is the official organ of having been also changed. When changes improve we believe in changing—this is an improvement

Traveling Engineers.

There seems to be a wholesome difference of opinion among prominent railroad men, as to the use of traveling engineers, or road foremen of engines.

On great systems, where the superintendent of machinery must have a number of master mechanics in charge of distant districts of the road, we cannot see why the road foreman of engines is not a great help—acting as an assistant to his superior officer, and representing him away from the home office. The traveling engineer should be above the division master mechanic in rank, or be a division officer under him—not two men of the same rank contending with each other.

The selection of traveling engineer is a point that is given too little attention on most roads, where men are often selected for this place because they are the oldest runners, and as long as they live hold the office, although there may be several changes of their superior officers—fancy a man taking the place of another who has died or retired, and commencing to wear the dead man's spectacles, regardless of the fit.

Traveling engineers are a fashion—they come and go—if a big road has one, the little road appoints a bigger one. That they are of use to the service on some roads, and under some conditions, and of no use under other and wholly different conditions, there is little doubt.

But the followers of the different disciples are well able to argue their case, and are invited to do so. But, try to avoid personalities.

Horatio Allen.

America's First Locomotive Engineer.

At the head of this article will be found a portrait of a man whose name should be familiar to every engineman in America, for it was he who first opened a throttle and moved a locomotive on the western hemisphere. Mr. Allen was born in Schenectady, N. Y., May 10, 1802, and died at his home at Orange, N. J., on the last day of 1889. Mr. Allen was educated for a civil engineer, and surveyed the first road built by the Delaware & Hudson Canal Co., at Honesdale, Pa.

Hearing of the success of George Stephenson's locomotives in England, he resigned to go there to investigate, and on the eve of his departure was commissioned to purchase the rails for the D. & H. C. Co.'s sixteen miles of road, and to buy three locomotives. He returned with three locomotives, two of Stephenson's and one of Foster, Rastrick & Co.'s. This locomotive, the "Stourbridge Lion," was destined to be the first to run in America.

There were no engineers then, everybody was afraid of the little seven-ton machine, everybody said it wouldn't go around the curve, and everything else.

Steam was first raised on August 9, 1829, and Mr. Allen himself took his stand on the footboard, and said:

"If there is any danger in this ride, it is not necessary that the life and limbs of more than one should be subjected to that danger."

He was going to see his machine through. Mr. Allen had never run a locomotive or other steam engine—and never did afterward—but the light engine was then and there run out, around the curve, and into the woods of Pennsylvania, three miles, and returned to the place of starting, without mishap.

That was all the running the "Stourbridge Lion" or her engineer ever done. She was decided to be too heavy for the track, was laid up for years under a shed, and finally sold for stationary purposes. Her boiler and one cylinder—as they now are—were illustrated and described in this paper for September, 1888. Mr. Allen was identified for some years with the engineering departments of several of the early roads, and was for many years at the head of the Novelty Works in this city. For some years he has lived in quiet retirement at his place near Orange. A few months more than sixty years passed before the first American locomotive engineer lost sight of the progress he inaugurated. In that time he saw the roads of his country grow from 16 miles to more than 160,000 miles, from one locomotive to more than 30,000. Saw the invested capital of the industry reach more than $9,000,000,000, and the army of employes reach over 1,000,000. The day he stepped off the footboard of the "Stourbridge Lion" he was the only man in America who could, by the wildest stretch of imagination, be called an engineman; he lived to see their number increase to 70,000. Horatio Allen ought to be remembered as the father of locomotive engineers in this country. We reproduce this portrait from *The American Railway*, a most excellent book, published by Chas. Scribner's Son's.

Following the Leader.

For some reason best known to themselves, a flock of sheep will follow anywhere a bellwether will lead—even into a lake—but that is no reason why sane human beings should do so—unless we confess that they have no more brains than the average head of mutton—which we do not.

Wherever we look back into the history of the human race we find little or no progress where the people simply followed leaders; progress has always been made where people ignored their leaders and did a little thinking and judging for themselves. The high priests of many a nation have kept its people in bondage simply because the people have blindly accepted what the priests have said, without bothering themselves whether their teachings were correct, and for their own good.

What was all right for the ancients will not do for us—if it would, we would be wearing breech-clouts instead of coats, pants and vests. Every thing has changed, even religion has been modified a great deal to adapt it to the wants of this age; but still we find plenty of laboring men who have set up in their hearts leader idols, and they blindly accept what they say as the law and gospel.

One man believes in a certain party, he is a politician of the regular ward school; whatever the party leader or the party organ does or says is *so* with him; it's simply so, no ifs nor ands about it—this is following the leader.

Here is another man that follows the same line of reasoning in regard to business transactions, in religion, in love and marriage, or—in worst of all—labor orders, here is where there is more blind leader worship than in any other place.

We do not object to men loving and honoring their brainy men or those who represent them before the public, nor to the maintenance of these men of brains in exalted positions; we object to such as worship their acts without knowing anything about the acts, and to the leaders who think that the way to lead is to force the rank and file to believe and do as they do.

The safety of the people, of labor organizations, of churches, of nations, lays in the masses thinking about the questions of the hour—especially true of labor organizations.

Then the man who pretends to lead his fellows by organizing a great body guard that come and go at his beck and call, who applaud his acts and shout down and denounce those who, by word, or deed, differ from him, is no leader at all. He is a curse, a false idol.

The true leader of laboring men will not try to have the members of his order do as he does, or think as he thinks; that is not his mission, and he knows it. His whole aim is to induce the individual members of his order to think for themselves, to debate each and every topic that comes up in the affairs of the order. His is an arduous task, and he spends no time in seeking a re-election. He knows full well that it is the average intelligence of the members that will keep him and his order off the rocks, so he simply does and says things to make his men think and study the problems for themselves, he is careful to express no decided opinion on a new and complex subject until he has put the case before his constituents and heard it discussed, then he gets a consensus of opinion that is far safer for him to follow than an idea of his own, perhaps biased in some way almost unknown to himself.

Always bear both sides of any case before deciding anything about it, then go quietly off by yourself and forget who or what you are. Put yourself in the place of the parties on both sides, look at the subject from every point of view, and try and decide the case as you would wish it decided if you were in either place; if they differ, split the difference, come to some decision in the case as near fair as you are capable of deciding, and then express your convictions, regardless of who frowns or who smiles. Be honest, be just.

Have ideas and opinions of your own, but do not confound opinions with crotchets and hobbies; think, reason; forget the results to yourself, and think of the results to the majority of your fellows—what is the best for the majority is usually a good thing to have—even though it hurts some one.

When you find a man who goes to the front, and is counted a leader, see if he seeks to enlighten, if he reasons with his fellows, if he seeks their aid and council, if he presents arguments instead of statements, if he denounces no one who differs with him. If he is this kind of a man he is safe enough to follow, for he simply calls your attention to an important subject, gives you his reasons, and leaves you thinking on the subject—he has done good, if it never again comes up.

If, on the other hand he simply announces so and so, if he pats all those who are with him, and slaps at those who differ, he is the leader, *not* to follow. He is sure to jump into oblivion some day—don't be too close behind.

Read books, hear lectures, sermons and speeches, not to adopt or renounce the arguments or theories advanced, but to aid you in your research in the matter, to help you form some opinion of your own—to help you think.

The best labor leader in the world—and he never pretends to lead at all—is the man who *thinks*. He promotes discussion and argument, he educates, he builds on sure foundations, for he puts into the individual members of his followers the reasoning power; each is an intelligent factor, reasoning for himself; in a combination of such men there is little danger of the majority making very bad decisions in cases of trouble—every man is a leader.

The worst labor leader in the world—and he is a self-acknowleged one—is the leader who does all the thinking for his crowd; they are the force in his hands—he rules by force, he crushes the individual thinker with his frown, he usually rides rough-shod over opposition, nurses favorites, and rings of heelers. He is the brains—his followers the hands and feet. The combination won't work, it don't balance. Nature furnished one set of brains for every pair of hands and feet, and never intended that men should form themselves into associations, where one pair of hands kept still, and one brain worked, and a thousand other brains kept still, while four thousand feet and hands pawed gravel.

Get away from this leader—be a leader yourself. Don't get into any man's harness and let him drive you—ride.

We Move.

From far and near come the signs that locomotive enginemen are waking up to a recognition of the fact that there is room for improvement in themselves as enginemen. Discussion is rife, the lodge rooms are full of "engine talk," books are being purchased, models set up, and a gradual increase of self improvement is evident all over the country. It is time this came, and can but benefit all who take part. The greatest benefit will be to the companies employing these men, and they are the first to recognize it. Early this month we received a letter from a well-known master mechanic, headed, "Why is it that engineers and firemen are so afraid they will learn something?" Ten days later we got another letter from the same man, reading. "Hush, don't say a word; the engineers and firemen have started a debating club. What is the price of that valve motion model? If they last a month, we will give them one." Good deal in this; think about it.

An Awful Example.

Usually the best way to illustrate a natural law is to carry the case to extremes—sometimes it is a good way to show up unnatural laws. It is a well-known law that there is a greater pressure at the bottom of a glass of water than at the top, although we cannot always notice it; if we imagine a glass a hundred feet high filled with water we see at once that a hundred feet of water is loaded upon the bottom of the glass.

The rule of making a smoke-stack one inch larger in diameter than the cylinder loses its attractiveness when we imagine a cylinder one inch in diameter and a stack twice as large.

It is a well-known law in railroading that to let everything run down for the sake of paying dividends leads to ultimate ruin, but this law is so well known and generally recognized that there are very few railroad managers foolish enough to carry it to extremes. The following, from the press dispatches of January 26, shows just what can be done in this line, and is interesting reading—except when we come to the lists of men who have been murdered in the experiments:

"Twenty-three wrecks in three weeks have caused a wholesale discontinuance of passenger trains on the various roads that make up the system of the Central Railroad of Georgia, which is a part of the Richmond & West Point Terminal Company's system. This has developed the fact that this once splendid railroad is now in a most deplorable condition as regards its facilities for handling both freight and passenger business. Twelve important passenger trains have been discontinued, ten to-day and two last Sunday. This will make an aggregate reduction in passenger-train mileage per day of 1,500 miles. Various reasons have been given, and the truth is that trains have been taken off simply because so many engines and cars have been broken up recently in wrecks due to the bad condition that these roads have been allowed to sink into that there are not enough left to make up the trains. Major Cecil Gabbett, General Manager of the Central of Georgia for about four months, admits that the system is in very bad condition.

A resident of this city who is very close to Mr. Gabbett, in discussing the situation last night, said: "There are not enough engines and coaches left to keep up the trains. Wreck follows wreck in quick succession, and the road is becoming more and more helpless every day. The newspapers contain accounts of frightful accidents somewhere on these roads nearly every day. Yesterday a collision between two freight trains occurred at Camp Hill, Ala., and five men were killed and two engines and many cars were demolished. This is the twenty-third wreck on this road in three weeks. I have before me newspaper accounts of nine wrecks of freight trains that have occurred in the last eight days on three of the Central's lines running into this city in which lives were lost, ten men were wounded, eight engines were torn up, forty to fifty cars were broken up, and many thousands of dollars' worth of freight destroyed. When Supt. Haylow was notified of the wreck at Camp Hill yesterday he did not have an engine to carry him to the scene of the disaster, although this is the center of his division and the terminus of five of his roads He had to wait some hours for an engine to come in before he could start. The company's shops are full of broken engines, and its yards abound in wrecked cars. It is stated that an expenditure of nearly $2,000,000 in repairing the roads, and the bridges and trestles, and in the purchase of engines, coaches and cars will be necessary to put the Central in position to handle its business satisfactorily. It has apparently been the policy to make the Central show large earnings and small operating expenses, without regard to the maintenance of the roads in proper condition. This is the result. So many men have been killed and wounded of late that it has become necessary to employ two traveling adjusters for the settlement of damages for personal injuries alone."

The Westinghouse Air brake Company report their total American equipment as follows; "The Westinghouse automatic brake is now in use on 20,000 engines and 200,000 cars This includes 100,000 freight cars, which is 10 per cent. of the entire freight car equipment of this country. Orders have been received for 50,000 of the improved quick-action freight brakes since December, 1887."

Books Received.

GIBBS' ROUTE AND REFERENCE BOOK OF THE U S AND CANADA FOR TRAVELERS Gibbs Bros & Moran publishers, 57 Rose street, New York.

This is one of the neatest, most complete and comprehensive books for reference of travelers we have ever seen.

The usual railroad guide is an enigma to all save a few of the initiated—specially true of ladies. There is too much of them.

This work has maps of each State and province The most direct routes of the railroads are shown by heavy lines, possible routes by dotted lines. Between all principal towns a light faced figure tells the distance, a heavy-faced figure the fare in dollars and cents. Thus, by simply looking at the maps, the distance and fare can be seen at a glance There are tables that show where connections can be made; and, for the use of commercial men, tables of different business houses, and how many of each in the towns shown on the maps A list of the hotels is also shown

ASKED & ANSWERED.

(5) J. B., Jr., Fireman, Brooklyn, asks:

Where is the *Locomotive Firemen's Magazine* published? *A*—Terre Haute, Ind.; and every fireman should read it.

(6) H. C., Buffalo, N Y, asks

Why are cylinders placed above the center line of the axles? *A*—On small-wheeled engines this is often done to get cylinders up out of snow and dirt; but most cylinders are raised so that, when engine rolls, the center line of axle will not come above center of cylinders.

(7) C. B., Baraboo, Wis., writes. I heard a dispute between two experienced engineers in regard to lead on valve motion, one claiming that lead increases the more the lever is hooked up, the other denying it, stating there is no more lead hooked in 6" than at full stroke. Which is right? If lead is increasing by shorter cut-off, how much will it be at 6" if there is 1/16" at full stroke? *A*—With the ordinary shifting link the lead increases as the engine is hooked up (see article on page 5, February, 1889). Radial gears, such as the Walschaert gear, have a fixed lead, the same at all points of cut-off An ordinary link motion, having one-tenth of an inch lead in the corner, the lead will increase to from a quarter to three eighths at a six-inch cut-off.

(8) Young Machinist, Oil City, Pa., writes:

Being a young machinist and subscriber to your worthy paper, I would like you to tell me through your paper why the right main pin, or main rod pin, when engine is going ahead, lead the opposite or left side To illustrate, suppose the right-hand main pin is on forward dead center, the left hand pin is on upper quarter. What difference would it make if all the crank-pins on left hand side were on the lower quarter—would it make any difference, or is it just a standard locomotive builders have adopted, irrespective of cause and effect? *A* It makes no difference in the working of the locomotive, whether the engines are right or left-hand leads, but the right is now universally used, because all quartering machines are right handed ones

(9) P. M New York, asks

1. Why does the eccentric, which controls the valve, always follow the crank in an indirect engine, and lead the crank in a direct engine? 2. Why will a pin run hot one way and cold in the opposite direction? 3. Why will a guide run O. K one way and black in the opposite direction? *A*—1 Because in the indirect engine it is necessary for the eccentric to *push* the lower arm of rocker *ahead* to draw the valve *back* and pull it *back* to push the valve *ahead*. The direct engine has no rocker, and the eccentric leads the pin, to be in position to move the valve direct 2 It has long been noted, that almost any machinery that has long run in one direction, will heat if run in the opposite, and the cause is thought to be because of the roughing up of the molecules of the journals and boxes. Probably local changes are the cause as a rule. 3. When a locomotive is running ahead, the tendency of the cross head is to push *up*, both in the forward and backward stroke, while in backing up the tendency is to force it *down*

(10) B. Liner, Indianapolis, writes.

We recently cut up some very old locomotives, with cylinders placed well up on the smoke arch, and inclined more than any I ever saw, these engines had 3/16ths of an inch clearance; the men working with me say it was on account of the poor workmanship of the times, and because mechanics then worked to 8th of an inch measurements, instead of 100ths and 1,000ths, as now I am inclined to think there was a reason. Can you help an apprentice boy, by stating what it was, if there was one? *A*—The clearance was given on account of the incline of the cylinders If the main driving box moves up or down, as it passes the center, of a locomotive having a cylinder on a level with the driver center, it can but increase the angularity of the rod, and bring the piston back in the cylinder, but, as the possible movement of the box is but 2½ to 3 inches, this can affect the piston but little. Suppose now we carry the matter to extremes: put the cylinder vertical, directly *over* the driver, the clearance would have to be increased to the full movement of the box, and this clearance can be decreased as the cylinders are placed nearer a horizontal line. The more incline, the more clearance is necessary.

Some Fire-Box Devices to Aid Combustion.

The illustrations on this and the next page show the plan used by Mr. Cushing on the U. P. to improve the combustion in locomotive fire boxes. Fig. 1 is a side view of the box, showing the manner of holding the brick arch, and the arrangement of the steam and air jet apparatus at the front and back.

There have been in use for many years, on different roads, devices for admitting air over the fire, the commonest kind being simply hollow stay-bolts. While these have had their friends and their enemies, there is little doubt that the circumstances under which they were used made all the difference in the world about their success or failure. Where deep fire-boxes and deep fires are in vogue, as well as coal that crumbles or clinkers, the hollow stay may have been a good thing; on another engine with a shallow fire box and a shallow fire of good lump coal, they may have done more harm than good; most of us that have fired and run engines, know from experience that admitting air over the fire by partially opening the door will generally prevent, or abate in a great measure the rolling of black smoke.

The next step after the hollow stay was the steam jet over the fire; this prevented smoke in a measure, and would sometimes do more in that direction than air. Then came the steam jet that was surrounded with an air inlet, something on the plan of the Bunsen burner, the central jet of steam drawing in a large volume of atmospheric air and mingling it with the gases in the furnace; this was a combination that sometimes worked where neither the steam nor the air would alone, but as often failed.

Mr. Cushing's device is a combination of all the schemes mentioned; his jets are made like Fig. 2; the steam from a half-inch pipe is led to the cock and is coupled to an elbow that terminates in a jet, as shown, the flow of steam being regulated by a globe valve in the cab. The frame or body of the device has openings around the outer end, and an internal plug with openings to correspond to those in the body of the device, the plug is turned by a handle, as shown, that is connected to a rod, so that all the cocks on the end of a fire-box can be controlled at once and always alike. Now with this arrangement steam alone can be used by closing the air cocks; air alone can be used by opening the air-cocks and shutting off the steam, or the air and steam can be mingled in any desired proportions to suit the coal, the design of the furnace, or the ideas of the men handling it.

Fig. 1 shows the arrangement of the operating handles, both being controlled from the left side of the cab. Of the device, Mr. Cushing says.

"I put on four gates, as per sample, on front end of fire-box, and four back. On our standard eight-wheel engines we are locating air-gates as shown on print, however, their location can be modified to suit depth of water leg, etc. I get the best results by having the front gates just high enough to be about two to six inches above top of fire when it is at its maximum thickness, and back gates do well set about four or five inches, or about one row of stay-bolts, higher. This, I find, helps the admixture of the gases better than when set on the same line. Opposite each air gate, tubes are inserted in water leg. I am putting those in here of 1½" lap-welded steam pipe. I find it answers very well. It is something we carry in stock for our Baker heaters. After 1½" tubes are put in and air gates fastened in position, we then connect steam pipe. This steam pipe as shown is ½ from boiler, but where it branches off to front and back gates, it is reduced to ⅜". Front cocks are operated by bell crank and handle *D*, back cocks by handle *E*. By the use of these handles, atmospheric air can be excluded or admitted, by the use of the globe valve, steam can be used through all gates, or shut off, as desired. When it is desired to entirely prevent throwing black smoke, the admission of both steam and air at same time gives best results. With the use of Iowa coal we scarcely ever find it necessary to close cocks from atmosphere, but leave them open, or partially so, as desired. When used in this manner they serve the same purpose as a hollow stay-bolt, with the advantage that supply of air can be regulated or entirely cut off if necessary. Steam can be used at depots, or in cities, or at any point to obviate black smoke, and, in conjunction with the atmospheric air, will be found to greatly aid combustion."

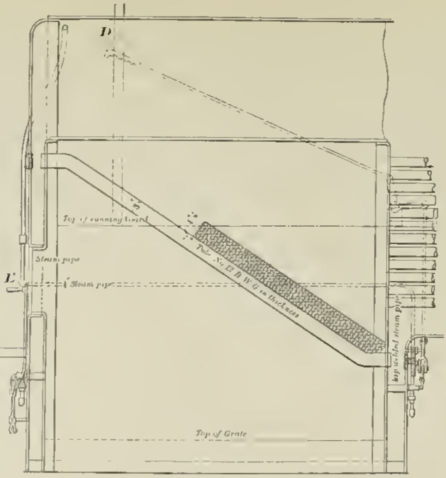

Fig. 1

Fig. 3 shows the arrangement of the jets on the front of the fire-box, looking back, showing the arrangement of the lever for the front; the back lever *E*, Fig. 1, simply coming up above the deck on the left side near the fire-door.

The large brick arch is supported on three 3" water tubes, that run from the lower part of tube sheet to the back of fire-box over the door; wash-out plugs are arranged at both ends of the tubes to keep them free of deposit. Four-inch brick are used, the lower one being made as shown in Fig. 4, an opening being provided at the bottom to prevent collection of coal or cinders on top of the arch.

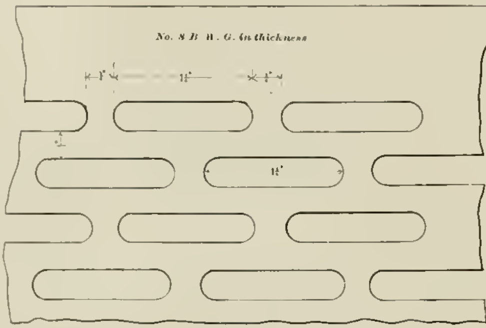

Fig. 3.

(*See page* 25).

The plan of placing brick arches on water tubes is far superior to the one of resting the edges on studs in the side sheets, and letting the weight of the brick keep them together in the center of the arch, as with the loose brick there is no danger of knocking the arch down with coal or fire tools, and it is easily removed to allow inspection and repair.

Large hand-hole plates are, as a usual thing, oval, and the plate on the inside of the boiler held in place by a central bolt and a bridge. On the U. P. they use a very strong device that requires no gasket, has a ground joint and is held to the seat by direct pressure over the joint, as shown in Fig. 5. Three studs serve to hold the outside plate against the plate proper, which has a ball joint; the central stem simply serves to hold the plate when it is being put up, the pressure being directly over the ball joint.

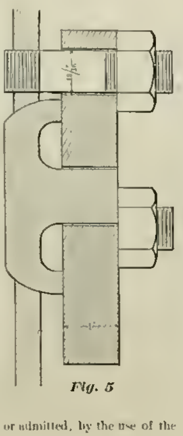

Fig. 5

Boston Shops of the Fitchburg Road.

On a recent tramp through New England the writer spent a couple of hours in the shops of the Fitchburg road at Boston, or rather Charlestown, but a stranger never knows when he is out of one and into the other, unless he asks a policeman. These shops are located close to the river, in fact, on the very bank; they are old, and were originally built when the road had but twenty-five locomotives, and are now used to keep up nearly 200.

The machine shop and erecting shop is a long building, the engines being rebuilt on long tracks, no separate pits being used, there were 12 or 14 undergoing repairs at the time of our visit. The machinery is mostly old, but has received fair care; but, where all kinds of work are done in one room, it is impossible to keep tools clean. The road owns many different classes of engines, from many makers. We noticed some consolidations having the links ahead of the rocker, with a connection back of it.

A number of Taunton engines in the shop were receiving new jackets; these engines were lagged with asbestos mortar, and the jackets had been put on before the mortar was dry, the Russian iron was eaten full of holes and was very rotten, but had been in service but a couple of years.

On some of the consolidation engines where the spring hangers had cut the frames, the trouble was cured by making the hangers stiffer, it was the springing of the hanger that allowed every little movement of the box to throw it against the frame.

Mr. Stewart is improving the convenience of many of his passenger engines by placing the air-pump below the running board, so as not to obstruct the view of the engineer, and in putting the engineer's brake valve on the side of cab, in front of him. Just why the brake valve should be on the boiler-head, no one knows, when on the side of the cab it is where a man can reach it when looking out of the cab window, it does not get hot, takes less pipe, and is easier cleaned. On engines where the boiler comes through the cab, this reform is especially necessary. On this road, cast-iron links are used with good success.

Double nozzles are used, but they are but half round, and the pair look like a single nozzle with a bridge in it. Mr. Stewart recently made some exhaustive tests with stacks, and believes he has improved the steaming of his engines by putting in an interior pipe, tapering from a point about a foot above the base, where it is the smallest, to the top. Freight engines have diamond stacks with cast top.

Some of the boilers in the shop are having the fire-door raised about ten inches; were too low to keep fire on the grates behind.

On this road, every engine is equipped with the Ashton blow-back, safety valve, the steam blowing off into the tank. Mr. Stewart uses them as a check on careless firing. It is a dischargeable offense to let the water get too hot to work through the injectors. The roundhouse is very old, entirely under cover, table and all, dark, and impossible to heat properly. A new blacksmith shop has recently been built, and the old shop room added to the main shop.

Many of the Manchester engines have lugs on the sides of the four-bar guides, in the center, and a post between them, held by a central bolt; this makes a stiff guide, and makes a brace of the lower guide for the top one.

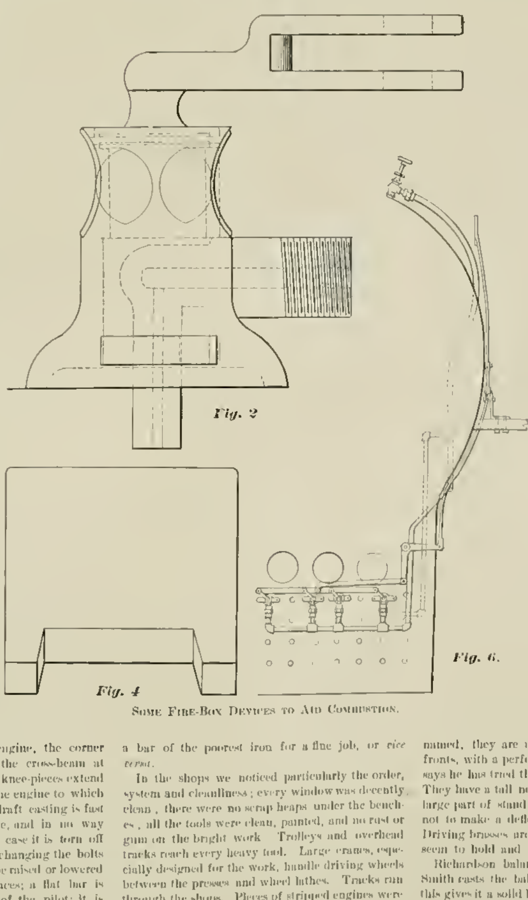
They have the best arranged wooden pilots we have ever seen, for convenience in taking off or putting on, and one that allows of the use of one sized pilot for all heights of engine, the corner posts of the pilot extend above the cross-beam at top, to which the slots are fixed, knee-pieces extend down from the buffer beam of the engine to which the corner posts are bolted; the draft casting is fast to the buffer beam of the engine, and in no way connected to the pilot, so that in case it is torn off it does not break the pilot. By changing the bolts in the corner posts the pilot can be raised or lowered without disturbing the heel braces; a flat bar is used here to support the nose of the pilot; it is bolted to the nose, but has a slot in the other end, that enters the cast draw head in front and is held there by the pin that holds the coupling bar. This brace is flat, lays under the draw bar, holds just as much as truss rods, and is easier to get off.

Our friend and correspondent, W. de Sanno, has removed from California to his old home at Corry, Penn. He will be heard from in a new field at an early day.

In the Boston and Maine Shops.

Last month the writer spent a very pleasant and instructive half hour in the Boston shops of the B. & M. road, which are under the charge of Wm. Smith, superintendent of motive power.

This is the best shop we have seen in the East; it is located on the river bank, in a crowded portion of Charleston, but the buildings are well kept, many of them new, painted and clean. On a rack in a little material yard, but under cover and beside the smith shop door, were piled the different sizes and shapes of iron and steel bars, used for all purposes. We observed that the ends of the bars were painted in several different colors. A board with all the colors on it, nailed to a post, tells what *quality* or kind of metal the colors represent. Different brands of steel, used for totally different purposes, are thus kept separate, no matter how long in stock, and there is no excuse for a man taking a bar of the poorest iron for a fine job, or *vice versa*.



SOME FIRE-BOX DEVICES TO AID COMBUSTION.

In the shops we noticed particularly the order, system and cleanliness; every window was decently clean, there were no scrap heaps under the benches, all the tools were clean, painted, and no rust or gum on the bright work. Trolleys and overhead tracks reach every heavy tool. Large cranes, especially designed for the work, handle driving wheels between the presses and wheel lathes. Tracks run through the shops. Pieces of stripped engines were piled orderly, by themselves, near the tools that must work on them.

While Mr. Smith was giving some man some instructions, we asked a latheman how it come that he had so many new tools. He answered:

"Well, we had a fire a few years ago that got rid of everything, but Bill (Mr Smith) won't have anything but the latest and best. If a man or a machine gets behind the times you can bet he sets them out quick."

That tells the whole story.

The erecting shop is an enclosed roundhouse, turntable in the center, and a high tower over it; the engines are backed off the table. This plan gives room enough to keep all the stripped parts, on which there will be no work, close to the engine, and prevents unnecessary handling, facilitates getting around, and prevents men from getting in each other's way.

Between many of the pits, machines are running, and the system of arranging shafting around a roundhouse is interesting. This is done by running a shaft from the main shop into the erecting house nearly to the table; from this a belt runs, at right angles, to a shaft more than half-way to the wall. This second shaft carries a pulley at its far end that belts back to another shaft, and so they zigzag around the house; yet the shafts are all paralleled to one another, as the belts are also paralleled to each other.

The lighter class of work is done up-stairs, and here is located one of the best equipped tool-rooms in the country. It is very large and well supplied with almost everything one could wish to see in such a place. In a room adjoining the tool-room there are any quantity of templets stored. We could not but help noticing the extra care taken with these templets. Every hole that must be used to lay off work is bushed with a hardened steel bush; and templets are used for every conceivable purpose. Any pilots on the road can be changed to other engines without boring new holes; they are all alike, even the headlights are bolted to the bracket board through holes bored to templets—any one will go where any other one will.

The tool-room keeper has every convenience, dumb waiters supply tools to the lower shop, men are not allowed to come up stairs to ask for them, nor go to the blacksmith to get tools dressed. The foremen all have desks and individual wash sinks, wear white shirts and—are foremen.

Sinks for washing, hot and cold water, clothing closets, and all the latest and best conveniences are provided for the men.

There is a separate room where the Westinghouse brake work is done, and we noticed throughout the shop a tendency to keep the same men on the same kind of work.

The engines are well kept—clean, nicely painted, and all manned, they are mostly eight-wheelers, extension fronts, with a perfectly straight stack. Mr. Smith says he has tried the taper stack to his satisfaction. They have a tall nozzle stand, single nozzle. The large part of stand is flattened in the center so as not to make a deflector of it in front of the flues. Driving brasses are in three pieces, driven in, and seem to hold and wear all right.

Richardson balanced valves are used, but Mr. Smith casts the balance plate solid with the cover, this gives it a solid bearing, when he wants to lower the plate he dresses off the joint on cover, which is left thick for this purpose.

It was here that the machine was invented for turning up pins cast solid in crossheads by a geared tool-holder passing around the pin. The original machine, made many years ago, was lost in the fire, but a copy of it is here and at work, it is not so handy a tool as the one built by Pedrick & Ayer now, but it does good work.

Mr. Smith has discarded solid rods, and takes extra pains with those in use, which are the strap and half-brass style. They use painted canvas on the roofs of cabs, and find it last longer than tin.

In the office the same order prevails, the clerks and time-keepers are separated from superintendent of motive power and his secretary, and all the little details do not annoy him. Mr Smith has a cordial way of steering newspaper fiends all through his place and showing up all that is of interest, taking them into his office, setting up the *Flor de Connecticut*, and saying:

"Now I have got just *one* favor to ask of you."

Of course, the newspaper man is anxious to do something in return, and promises—he came that on the writer, but we asked what it was.

"That you don't say one word in the paper about what you have seen here."

All we have to say on this subject is that any one who wants to carry out any joke like that on us has to spring it before we go through the shop. Like the man from Texas, we ask "What are we here for?"

The Staff System for Working Single Lines.

The *Railway Herald*, of London, has just paid one guinea as a prize for the following description of the "staff" system of running trains on single track lines in Great Britain. It was written by Mr. F G. Smith, Station Inspector, South Dock Station, Millwall Extension Line, Poplar, E

"If this article is not of interest to railway men, I hope it may be to the public who read the *Railway Herald*. That there are a great number who do not understand the working of the 'staff system,' I glean daily by the questions I am asked, especially by the seafaring portion of our passengers, as the following few examples will show. 'What's that thing for, governor, is that what they drive the engine with?' 'I say, old man, is that thing loaded? Mind it don't go off.' Or, 'I say, Mr. Inspector, what makes you change those "brass affairs," over for, they are both alike, aren't they?' Well, perhaps the train is approaching, so I have no time to explain the details of the working, so just say, 'It is for your safety, sir. It is a guarantee that two trains cannot approach one another on one section at one time, therefore making a collision impossible' 'Oh, yes,' he says, 'I see; thank you,' and away he goes. Yes, he may see, but in ninety nine cases out of a hundred he does not understand, nor can he be expected to, on such a brief explanation. I myself have never been sufficiently informed to speak with certainty as to the origin or invention of the 'staff system,' so will simply confine myself to a short description of the 'working,' believing at the time that it is no breach of confidence to my employers, as I have never been led to believe there is any secrecy in it, and I think it cannot be too generally known to the traveling public, the care a railway company takes for their safety. The branch line I assist in working consists of two sections, an 'up' and 'down' section, the trains passing one another on a loop line at an intermediate station, and from this loop line station I want you to understand I am working. There are two staffs—one staff for each section—and although perhaps alike to a casual observer, they are vastly different, one being round, and the other square. Each staff has engraved or marked on it the name of the staff station at each end of the section to which only it applies.

"Each staff is warded similar to an ordinary key, and keys they really are, as I will shortly explain. In connection with the staffs are iron boxes and paper tickets, printed and printed of a color corresponding to their own staff—not that this is necessary to prevent us making mistakes, it is merely a quick guide for us where there is more than one box, for understand, reader, the way in which the staffs are warded makes it impossible to unlock the wrong box. The tickets are called 'train staff tickets' Each ticket has the name of the journey for which only it is available printed plainly on it, and has to be filled in, that is 'timed, dated and signed,' by the person in charge of the station from whence it is issued. 'Each ticket is available for one journey only.' Now, in working with the staff alone, after delivering the staff of the section to be traveled on to the engine driver, he proceeds on his journey. You must naturally wait till he returns with the staff before you can send another train on that section, for the simple reason your boxes are locked, you cannot get a ticket, and there is but the one staff for the section. You say then, What are the tickets used for? They are used when two or more trains are wanted to follow on the same section. Thus, you wait till you get possession of the staff for the section to be traveled on, unlock the box, make out a ticket, and hand it to the engine driver, at the same time showing him the staff of section he is to travel on, and he proceeds on his journey. Immediately he gets to the station the ticket authorizes him to travel to, he hands the ticket to the person in charge of the station. His train is then shunted on to a siding to make room for the next incoming train. You will now see that, as a 'ticket train' cannot return, how impossible it is for two trains to approach one another on one section and cause a collision. I may add the used tickets are dealt with by the person to whom they have been handed, that is 'cancelled' and returned to the superintendent of the line. The person in charge of the station is held responsible for the proper working of the staff, the engine driver is responsible for getting the right staff for the section he is to travel on, the guard is also held responsible that he sees his driver has the right staff or ticket before starting his train. 'In all cases the ticket precedes the staff.'"

We know of no place in North America where the staff system is used, and the description of its working is therefore of interest.

"Put Yourself in His Place."

About the most fortunate people to be found are individuals who have enjoyed the felicity of getting shaken up or slightly hurt on railroads in or about New York, where courts and juries delight in giving damages. Cases which are really robberies are called justice in New York, because the parties stolen from are rich corporations. Three cases were decided in one day last month, giving heavy damages that never would have come into court had the defendants been private individuals. A jury before the Superior Court found a verdict for $1,500 in favor of Morris Quinlan, aged nine, against the Manhattan Elevated Railroad Company. A board fell from the track and struck him on the head, injuring his eyesight. David Mosseman recovered a verdict for $5,000 from a jury before Judge Allen in the Court of Common Pleas against the Metropolitan Elevated Railroad Company. A crowbar fell from the track and crushed his foot. Joshua F Page recovered a verdict for $15,000 from a jury before Judge Beach in the Supreme Court against the cities of New York and Brooklyn for injuries received from a collision of cars on the East River Bridge.—*National Car and Locomotive Builder*.

We fear our friend, in penning the above item, did so without hearing both sides, and "putting himself in the other fellow's place." The article seems, at least, to be the child of passion rather than of prudence.

It is far from our inclination to single out rich or poor to punish, by fines or otherwise, for misdemeanor or criminal carelessness, but the Elevated Company have a valuable franchise from the citizens of New York, affording them an elegant opportunity to make money—and drop boards and crowbars on people Heavy fines are, perhaps, the best preventative for carelessness, and they are therefore used.

The writer would not take the chances or sustain the injuries in any of these cases for the money paid, and we do not believe that the editor of the *Car Builder* would either, after calmly "putting himself in his place."

A Quick Steamer.

L. Holloman, of Tampa, Florida, seems to have his wits about him.

A valuable engine was in the roundhouse when it caught fire. When the engineer arrived the building was in flames, but he determined to save his engine He ran in the burning building, threw a pile of waste in the furnace of the engine, threw kerosene on it and lit it, and then was compelled to retreat to the water tank, as the heat was so intense that it was fairly scorching him. As soon as he thought the engine had steam enough to move it he threw the throttle wide open and ran ahead, and fairly came out through the flames with it In recognition of his service Mr Ybor presented Mr. Holloman with $50.—*Engineer*.

What a steamer she was! Even with the water in boiler at 212° all the waste and oil that could burn in those few minutes would not get up steam enough to move the engine. Guess she had some steam on hand, or got up her steam by the heat of the burning roundhouse—or the sun might have been shining on her through a window.

About Color-Blind Tests.

The color-blind tests now being made in England are going through the same forms tried here. It is the old story of an expert being placed in a position to force upon men a color test that is of no service to the railroad companies, or the employes, and only serves to show that the examining surgeon has studied up some optical delusion hokus-pokus.

Railroad men are required to distinguish between red, blue, green and white signals, and it is of no earthly use to oblige them to distinguish *shades* of wool, or anything else.

The only fair color-blind tests must be made with actual signals in the open air, and THE LOCOMOTIVE ENGINEER has always advocated this test, and condemned any "catch" tricks Our advice to all railroad men, where color tests are being made, is to invite practical tests, but to resist the removal of men who cannot tell the "shades" of different skeins of wool, or tell the names of letters shown in a room at some distance—they are a fraud.

We are pleased to note that the United Enginemen of England, with their consulting engineer, Clement E. Stretton, at their head, are demanding a practical examination in a practical way—without fringe.

Arrested the Wrong Man.

Near the gates of Rose Hill Cemetery at Chicago, where an average of thirty funerals a day pass, the Northwestern road crosses the street.

This crossing has no gates and no watchmen, and the trains come upon it from a short curve. On January 23 the Milwaukee express, engineer Mahoney, struck the mourners' carriage of a funeral here, and killed six people, and, of course, has been arrested.

Had engineer Mahoney failed to make his time because he was afraid of killing people at crossings, another engineer would have been put in his place.

There are several men who need arresting for this crime—for crime it is—before engineer Mahoney is placed under the ban of the law. The first should be the officers of a road that maintain unguarded crossings at such a busy street, then the city officials should be taken in hand who permit such a danger to exist; and after that arrest, all the male citizens of Chicago more than twenty-one years of age, who tolerate officials who wink at such man-traps. After these, it would be well to arrest engineer Mahoney—if the crime has not been proven on those tried before him.

The engineers of this country are getting tired of being arrested for manslaughter in which they but act the part of the knife in the hands of an assassin.

Coolbaugh, McMunn & Pomeroy, 45 Broadway, New York, is the name of a new firm that will work for a railroad trade. They will represent Carnegie, Phipps & Co. in all their railroad work, axles, couplers and boiler steel; the Boies steel wheel and the Frost dry carburetter system of train lighting. It is especially gratifying to see men from the ranks of the railroad army get up. Mr. Coolbaugh is an old-time train dispatcher, of the D., L. & W., but has been for some years on the road for the Boies wheel. Mr. McMunn was for years with the American Steam Brake Co., and lately with the Martin Steam Heater Co., and Mr. Pomeroy is a mechanical engineer who has been for some years, as he still is, secretary and treasurer of the Suburban Rapid Transit Railroad, of this city. If energy and "rustling" will establish a business, these three men ought to establish one.

The Locomotive Fireman's Magazine for 1890 is out with a new dress and a new cloak. The *Fireman's Magazine* never follows—it leads. It never does anything because some one else has, or because it has. When an improvement is suggested, and, on investigation, looks well, it is adopted. Every New Year's since we have known it, it has come out in a new cover, and we think the last the handsomest and best. It is plain and business-like. The *Magazine* has 100 pages—and there is something worth reading on them.

Mr. Lockwood, the owner of the Shaw locomotive, deserves to win in his arguments on the hammer blow. He has been hammering away on the subject for the past five years, and seems to just be warming up to the subject—hasn't got to thirsty yet.

Who has a good drawing or other picture of a Ross Winan camel-back locomotive?

A New Attraction.

One of our readers, Engineer J. H. McDonald, of Monett, Mo., writes us of an unsual sight he recently saw from his locomotive. He says:

To-day (January 22d) at 11.35 A. M., I was coming east on train 36, and was just pulling into Hallowell, Kan., seven miles east of Oswego, when my fireman halloed three times:

"Look there! look there! look there!"

I sprang to the gangway on his side of the engine, and saw a sight I shall never forget. One-quarter of a mile from the track was rolling a large two-flued boiler, and an immense cloud of steam was to the west of it, which, when cleared away, revealed a two-story mill with one side well shattered, and we knew the boiler had exploded. As we were on time, and nothing due soon, we all, except the fireman, jumped off and ran over to the mill, and saw the boiler and ruins as we approached.

The near neighbors carried away two men, whom we supposed to be dead, but learned since that they are alive and may get well. One of them had his leg broken, and both were considerably scalded. I examined the boiler, and found the end blown out and the two flues with it. Most of the end was, I think, less than one-eighth inch thick, and I took hold of one piece, which was four inches wide and about 18 inches long, and fast to the boiler at one end. I could bend it up and down like a bit of galvanized iron. There appeared a ridge around the boiler where it looked quite thin, which, I think, had been stove out by the boiler lighting on end. My fireman says it went about three hundred feet high, but most eye-witnesses think he is mistaken—that he saw pieces of the smoke-stack. At any rate, the boiler is one hundred yards from where it stood. One of the citizens of the place told me that one engineer had quit work there a few weeks ago because he thought the boiler dangerous, another said he had known that boiler over thirty years, and it was an old one when he first knew it, and they had been looking for it to blow up for a long time.

[We hope that the Western roads won't get to racing each other in showing up strange and startling scenery along the routes. Cyclones, water-spouts and earthquakes are hard to get, but boiler explosions are cheap, and therefore liable to be used more. We don't like the idea.]

More Like It.

An associated press dispatch from Chicago, says:

The jury in the United States Circuit Court yesterday awarded Henry Bush damages of $40,000 in his suit against the Northern Pacific Railroad Company. In October, 1888, Bush was fireman on a construction train in Idaho, which was run into and wrecked by a "wild" train.

Bush was so badly injured that he lost the use of his legs. He alleged negligence on the part of the division superintendent. The award is the second largest ever given in the United States.

When a young man, at the very threshold of his usefulness, goes out on a road, and is maimed for life by the carelessness of officials or other employes, it is no more than just that he be paid heavy damages—enough to enable him to live decently off the income from it.

This idea that from $100 to $1,000 is enough for killing and crippling men is wrong—put yourself in his place, and think what you would want.

The compound built by the Schenectady Locomotive Works is doing good work on express trains on the Michigan Central road. She has but two cylinders, and is arranged so that high-pressure steam is used in both cylinders until the first revolution is made, when the intercepting valve between the cylinders automatically changes her to a compound. She rides well, steams well, is economical on fuel, and, more surprising yet, is very good on a start. She is now undergoing her trial trips, is being indicated, etc., and we will know by next month what she is worth in train service. There has been some little annoyance from her low-pressure valve pounding the seat when shut off and in the corner, this has been helped by cutting out the inside lap.

Piston Rings.

By J. J. BINOLET.

Some time ago we got two steam hammers 8" and 10" cylinders, and in taking the pistons out to get the size of the rings to have duplicates made, in case of breakage, I was surprised to find the 10" rings were only ½" wide, and made of steel, which I conceived would make good scrapers, if the cylinder ever got dry. We replaced them with cast-iron ones of ½" wide by ¼" thick, and in looking over some steam pump pistons I find the rings very narrow. Now, after long experience with cylinder packing, I find this to be true, the smaller the surface the quicker the wear, and *vice versa*. When we first began to use the spring ring, or, as sometimes called, the steam ring, we thought ⅝" square the best size, thinking that the narrower the ring the less the friction, but we soon found it was necessary to have a good stock on hand to replace broken and worn-out ones, then we got to ⅞" square, and we soon noted the difference in the length of service, and as it has been said experience makes fools wise, we tried to profit by it, and finally got the rings to 1" wide by ¼" thick for 15" to 20" cylinders, leaving ½" on each end of piston head, and ¼" between the rings, making the heads as light as possible, and I found that having the rings the largest part of the wearing surface, the cylinders were kept nearer round. Some of these rings run over two years on passenger trains making 220 miles per day. About every four months we would take them out, and pene them on the inside until the ends would stand open about ⅛" with a cross pene hammer, slip them in again, and they were good for four months more. Some of these rings were ⅛" or less thick when thrown away. I see occasionally pistons advertised as self-balancing, or that distribute the weight of piston equally over all parts of the cylinder. I never found any of that kind except on some English engines that had the piston run through the front cylinder head, with a stuffing-box in each head. It is really amusing to hear men talk of extra springs, bolts, steam let into the piston head, etc., to keep the weight of piston from wearing on the bottom of cylinder. The next best thing to do is to make the rings the largest part of the wearing surface.

Watertown, N. Y.

A New Disease for Engineers.

Walking down Champa street, Denver, from the convention hall, one day last fall, the writer was overtaken by a party of delegates, and, after trading cards and grips, we all steered for Larimer street.

A little way ahead of us walked a tall man, wearing a broad-brimmed hat and a railroad swagger.

"That's an engineer from Texas, I'll bet four shillings," remarked one of our crowd.

"How do you figure that out?" asked another.

"See the way he carries his head, sort o' to one side, the right ear about an inch higher than the other?"

We all said "Yes."

"Well, that is what we used to call the 'crane neck'; some call it the 'water-crook.' That is caused by a man's having to look so long and anxious at the lower end of the gauge glass to see if there is any wet steam in the boiler after shutting off."

The speaker stopped to light his cigar, and then resumed.

"I used to run in Texas myself, and if I had stayed there six months longer, fooling with that bad water, I should have had a permanent set in my neck. I got away just in time."

Watson & Stillman, of this city, manufacturers of the Vreeland transfer jack, have recently improved that very useful shop tool by placing the pump at the end instead of the side of the carriage, and otherwise arranging smaller details so as to make them accessible and handy.

Our correspondent, De Sanno, has invented and is now perfecting a locomotive valve motion.

Been There Myself.

By W. D. HOLLAND.

In looking over Mr. D. W. Cowan's article, headed "A Licensed Engineer's Idea," in your January number, I was rather surprised to hear of the immense knowledge those gentlemen are under the impression they have in the South. D. W. Cowan says Mr. Cushing's questions are only for young engineers and firemen, but still he says he has been running an engine two years, and he knew better than that himself, in speaking of one of Mr. Cushing's questions, in which he gets things very badly tangled up in trying to solve. He also quotes, "We are all licensed engineers down here, and that is where we are ahead of the engineers in the Northern and Western States." (Wouldn't that kill you?) It is a well-known fact that any one can buy a license in Alabama at a trifling cost, in fact, a smart school girl can answer the questions by reading over a few mechanical books on "How to Obtain a License for Engineers." He concludes by saying: "A man has to be a first-class man to run an engine down here. We have a book to study on railroading, and have to run a train and protect it." That Book of Rules must have been revised lately, from the way they railroaded there a while back—that was when both trains started out of each end of a division of probably 100 miles, and would keep moving till they met each other, or where the darkness of night would overtake them, when they would silently repose till the following morn, when they would proceed on their long journey; but should they meet each other on the main line in daylight, then the one that was hauling logs, which would be the inferior article, would, of course, back to the next siding and let its superior pass. Can it be really possible that all this has come to pass in these last few years, and, as Mr. Cowen says, we all first-class men? Would it not surprise the snow-digger of the North, or the wild and woolly men of the West, to saunter back again and strike some freight man for a ride, and not to hear that old familiar phrase in return, "Stranger, I can't tote you, as I have been on this year line for 20 years and never toted a man yet"?

Oakland, Cal.

Work on This Line

In a distance of from 1,200 to 1,500 miles, the Central Pacific road does not touch a coal field, and the coal burned on the road comes from the far East, and from Australia and New Zealand. This coal costs the Central Pacific Company from $7 to $8 a ton, and the road annually consumes 900,000 tons of the fuel, or about $7,000,000 worth.

As fuel is now burned in the furnaces of locomotives there is a waste of from 50 to 75 per cent., that is, if the heat could all be utilized, a ton of coal would do almost twice as much for us as it now does. Figuring the waste in connection with the annual cost of coal for the Central Pacific Railroad at 50 per cent., it would be $3,500,000, and at 75 per cent., $5,250,000. The amount of coal used by the railroads of the United States is a stupendous aggregate, and the amount lost through the waste of the energy of the coal is an appalling sum.

Inventive genius can find no grander field than this search for a way to utilize every pound of energy that exists in a ton of coal.—*Ex.*

About the first thing the proprietors of a new invention do is to get out circulars and reports of tests, and claim from 20 to 80 per cent. saving over ordinary devices. If railroads would buy all the devices that are offered to them under these promises, they could put enough patents on their engines—if the promised saving could be done—to run 500 locomotives a year on one ton of coal. This percentage business has been overworked.

The machine snow-plows have had elegant opportunities to show off their merits in the great snow banks in the Rocky Mountains. There is lots of snow there yet, ready and waiting to be "lit."

The Strong locomotive A. G. Darwin was in a bad rear-end collision on the C. H. & D. early in January and was somewhat stove up.

The English compound on the P. R. R. has been repaired, and is at work again.

Heavy Mason-Farlie Locomotive for the Central Mexicano.

Our large illustration this month shows one of five heavy Mason-Farlie locomotives recently turned out by the Baldwin Locomotive Works for the Mexican Central road. These engines have the frame of the tender fastened solidly to the fire-box and boiler, the slab frame extending ahead just under the running board to the heavy center casting under the boiler, as shown. To those not familiar with the Farlie engine it may be necessary to state that the engine is separate from the boiler, and can move under it, just as a truck of a car can move under the car body. There is a heavy saddle casting bolted to the center of the barrel of boiler, that rests on an immense casting across the frame of the engine.

The steam pipe comes down through the bottom of the front end, and has a ball joint between it and a pipe that extends back almost to the center casting; here is another ball joint—held together with coil springs—that joins a return pipe to the cylinder saddle, where it joins by another ball joint.

The exhaust nozzle extends up into the arch through a slotted casting, the slot being covered by a slide that fits up against it, held by springs; this slide is tight around the nozzle, and will admit of considerable movement without opening the front end to the atmosphere.

In rounding a curve, the steam pipe opens out, like a pair of lazy tongs, and keeps up the supply of steam, and the engine is enabled to dodge around under the boiler as much as the truck does under the tank.

In these engines the regular shifting link motion is used, the tumbling shaft shown being fast to the boiler, and connected to the tumbling shaft proper by ball joints. These engines are equipped with the clumsiest and meanest reversing gear we have ever seen—the rack and pinion style. There is a quadrant, cut full of small teeth, the reversing lever comes up just *under* this quadrant, and forks around it; journaled in the forks, and meshing into the teeth in the quadrant, is a small pinion, and on an extension of its shaft a hand-wheel—like a brake wheel—about 12" across, is provided to turn the pinion. On a projection of the forked end of lever, and ahead of this hand-wheel, is a smaller spoked wheel, on a set-screw, which is used to hold the lever where wanted. The device is very unhandy, requiring both hands to set it, and is slow. The common reverse lever is at once the simplest, quickest, cheapest and safest device for reversing a locomotive engine, occupying less room, and requiring less care than other devices.

These engines are exceptionally neat, well designed, and well finished, they are very large, and set up high; the boiler head in the cab is lagged, and every improvement at hand. On top of the cab, and raised above the roof some six inches, there is a corrugated iron roof, or canopy; we suppose this is to make the cabs more endurable in the heat of a Mexican summer.

This class of engines are noted for their easy riding qualities, and the cabs are particularly comfortable in winter, there is no pounding between engine and tender, no draw gear to break, no water or air hose, and no gangway, but there are objections to them in their great length, the flexible steam pipe, etc. Like all other railroad devices, they have their advantages and disadvantages.

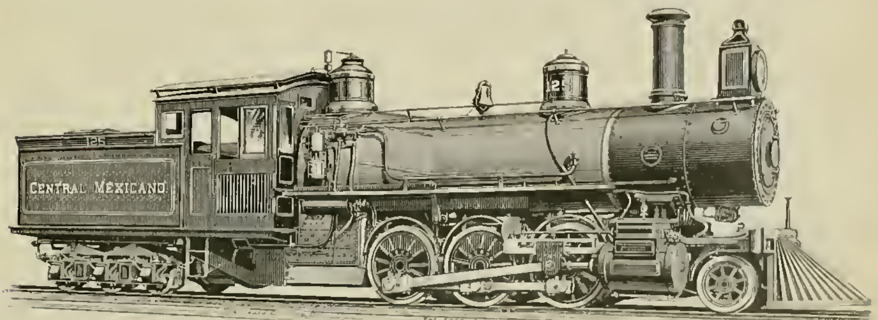
The principal dimensions and weights are as follows:

Total weight with tank ¾ full of water, no coal	173,900
Weight on driving wheels	93,200
" on front truck	17,700
" on front truck and driving wheels	110,900
Weight on rear truck	63,000

Cylinders 20" diameter by 24" stroke.
Boiler 56" diameter, wagon top.
Dome 28" diameter.
Fire-box 81" long, 53" wide and 77½" deep.
230 iron tubes 2" diameter, and 13' 8" long.
Heating surface:

Fire-box	151½ sq. ft.
Tubes	1,645¾ " "
Total	1,797 " "
Grate surface	29¾ " "

Wheel base, driving 9' 1", total 40' 11¼".
Driving-wheels, three pairs connected, 48" diameter, with 43" centers.
Driving-wheel journals 7½" x 10".
Truck wheels 30½" diameter, steel tired.
Truck wheel journals, front 5" x 10", back 4½" x 9".
Tank capacity 3,500 gallons.



Wm. Stroudley, Supt. of M. P. of the London, Brighton & South Coast Railroad, of England, recently died. Mr. Stroudley was the designer of many forms of locomotives and cars, and his fast passenger locomotive, the "Edward Blount," received the gold medal at Paris last year. This engine has a trailing wheel or truck back of the drivers, but none ahead. Mr. Stroudley had the reputation of having the neatest and cleanest locomotives in Europe; he came up from the ranks, was a practical man in every sense, and a remarkable organizer. When he took charge of the L., B. & S. C. shops and motive power in 1870, they were considered the most disorderly and badly managed ones in the country; he brought these from the bottom to the top.

The net earnings of the Pennsylvania lines, east and west, for 1889, were $21,510,457, an increase of almost $3,000,000 over 1888. This is the more remarkable because of the dull year in anthracite coal trade, and the cost of the great flood in June. This flood cut out a proportion equal to $1,149,882 from the earnings, beside the cost of repairs to permanent way, and the replacing of wrecked rolling stock, in itself something enormous.

Originality.

The following news item is floating around, and it is said that a number of railroad officials, fearing that the plan might become as contagious as the other Russian grip, have recommended vigorous quarantine measures, and the vaccination of American juries against it.

"An engine driver on the Central Asian Railway, who sustained concussion of the brain in a serious accident on General Annenkoff's line some time ago, has just sued the railway officials for damages in a court at Samarcand, and obtained very satisfactory and somewhat original compensation. The court decreed that he should be paid 7,000 rubles down at once, and in addition should receive 30 rubles, or $15 a month, with an extra 10 rubles for every child which might be born to him."

Justifiable Homicide

When the next issue of this paper comes out there may be a new steersman at the wheel—the present editor may be the occupant of a vermin-infested cell at the tombs. There is a demon in our heart, and he is quietly whetting his scythe with a leer of revenge upon his face.

After the last paper was out, and we had looked it over, we went from the hallowed presence of our blonde type-writer, held up our right hand, and swore by the whiskers of the Great Horn Spoons that the next time any printer made us call E. J. Rauch E. J. *Ranch*, or made us say that the Webb compound had only *one* exhaust to a revolution, or made us call a valve stem a valve *steam*, or a port a *part*, or lap *lop*, that we would murder him.

We swore that we would lay in wait for him among the murky passages of the back stairs, and stab him with a petrified editorial, haggle him with a meat saw, and tramp on his remains, and flay the air with him until the coroner could find nothing but dried blood, besprinkled with a few whiskers, and, perhaps, a few buttons, but nothing else

Steam Snow Plows

The great blockade of snow in the Rocky and Sierra Nevada mountains gave the different designs of rotary snow plows a chance to be tried. The Leslie, Jull and Cyclone all bored their way a considerable distance into popular favor.

These large wheels are comparatively light for the size of the cylinders that drive them, and the break-downs appear to be caused by the empty fan revolving at a high rate of speed striking a heavy drift, thus throwing a very heavy load upon the machine. So far, we believe, the speed of the plows has been governed entirely by hand. Why would not a good steam engine governor prevent racing of the engines, and supply steam in accordance with the work ?

Heavy Damages for Jumping.

A dispatch from Mansfield, O., says

"The jury in the case of Boyd W. Miller against the New York, Lake Erie & Western Railway Company, for $30,000 damages, brought in a verdict to-day. It gives Miller $21,850 damages for injuries he sustained at Akron about two years ago, when he was running a road engine, which collided with a switching engine in the Akron yards Miller was an engineer, and, to avoid injury, he jumped from his engine when he saw that a collision was inevitable. His injuries from jumping were such as to totally disable him for work. The case has been tried twice The first verdict was for $30,000 "

We have always advised men to jump when it was the only means that seemed at hand to save their lives. It seems that this court does not blame the man for jumping, and award him damages the same as if he had stayed on the engine and been injured there.

The engineer, fireman and conductor of the Rock Island freight train that ran into a passenger train in Chicago, killing seven persons, have been acquitted. Leaving the engineer and conductor to take care of themselves, we fail to see why any jury would not award fireman La Cloche damages for false imprisonment—he had no responsibility and no chance to prevent the accident.

A Handy Crane for Handling Steam Chests, Covers, Valve Seat Planers, etc.

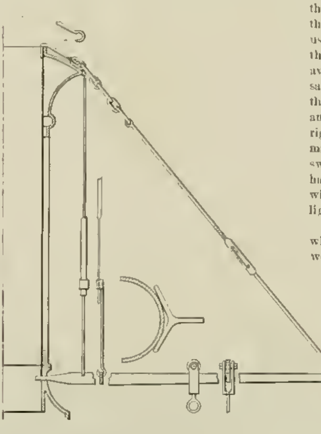
The device shown on this page was designed by Master Mechanic H. D. Gordon, now in charge of the new shops of the Pennsylvania road at Altoona, while he was at the head of the mechanical department of the Philadelphia, Wilmington & Baltimore road, at Wilmington, Del.

Cranes for handling air pumps, chests, lids, etc., that fastened to the hand rail, were found impractical on account of the light hand rail in use on the P. R R

This crane is strong, rigid, can be attached without screws or bolts, to stacks of any height, will swing considerably, and handle work six feet from the stack

The arm that carries the trolley has a fork at its inner end, that rests against the base of the stack, this arm is an inch thick, 2¼" deep at the large end, and 1½" at the outer end.

The support, or truss to top of stack, hooks onto outer end of arm, and carries on its upper end a few links, terminating in a hook ; when the hook is dropped into the stack, the links admit of the truss conforming to the different forms of stack tops, in the center of this truss there is a turnbuckle, to admit of lengthening or shortening the truss to keep the arm level.



From the stack hook, a lighter chain and rod reach to the trolley arm at base of stack, to hold it up, this is adjusted as to length by a pin and socket, as shown.

This device is very light and portable ; one man can put it up and lift any chest, chest cover, or valve-seat planer alone.

It is of no use to give dimensions, as the size of engines in service would have to govern that It is a very handy roundhouse tool.

Some Kinks in a P., W & B Shop.

The P., W & B. road is under the control of the Pennsylvania, but its shops and engines have an individuality of their own.

The main shops of the company are at Wilmington, Del , are under the management of Master Mechanic Turner.

These shops are quite extensive, but cramped for room, and awfully crowded, machines elbow each other good-naturedly, especially in the tool-room, where each machine knows all about the family secrets of his neighbor.

Most of the tools are new and of approved design, and the work turned out is first-class All the tools for the shop are ground in the tool-room by a Sellers universal tool grinder In the tool-room are a large stock of counterboring tools, every bolt-hole in their work being counterbored at each end, so that the head and the nut come down fair

The usual design of a counterboring tool has a center plug turned up true, that fits the hole to be counterbored. This is expensive to make and temper, and this guide is constantly being distorted by grinding the cutters Here the guide is separate from the cutter, and has a shank with the Morse taper that centers it in the tool. It is easy to see that different sized guides can be used for one size of tool; that, as it is removed in tempering and re-grinding, it is not changed, and fewer tools will do the work

Rod brasses are here made entirely on milling machines, and at very little expense.

The method of holding cellar in driving and truck boxes is subject for illustration in another column.

In the shop there is a novel crane over each engine pit. A separate frame is built inside the shop, of timbers about eight inches square, posts stand at the back end of and between the pits to support the frame, the front end posts being against the front of building and between the doors. At the back end two timbers lying side by side form a track between the posts, and on them run two wide-faced wheels of small diameter, say eight inches, these wheels carry the back end of a wooden track that is pivoted in the center of the cross timber at the front—only moving behind On this swinging timber runs a trolley that carries beneath it a chain hoist operated by hand. The back end of this track can be swung from one side of the pit to the other by ropes coming down at the posts. By using this simple rig in stripping and assembling the parts of a locomotive, much hard lifting is avoided It will pick up a cab, dome cover, bell, sand-box, air pump, chest cover, etc., and put them on the floor or a truck beside the engine, and, of course, can be used to replace them. The rig is cheap, and can be used to good advantage in many ways. Take, for instance, a saddle tank on switchers, they are a clumsy and unwieldy thing to handle where no crane can be brought to bear, but with so simple a rig as this, a couple of men make light work of it.

In the shop yard they load and unload car wheels, as well as place them on the scales for weighing, by a simple air cylinder, such as shown in our March, 1888, number. This works very quickly and safely.

The boiler shop is supplied with good tools and modern appliances for power riveting, etc., and the blacksmith shop has a good many dies for standard work. They run a number of power hammers of the belve pattern, and a number of steam hammers They have a special rig of their own for holding long truss rods while the end is being upset for the thread.

The crowded condition of the shops has called for several innovations to save room. Locomotive boilers are set up over heating furnaces, and the fire-box and flues made to do duty as part of the chimney These boilers were popping off at 60 or 70 pounds of steam.

There are several engines about the shops, and one very large upright boiler is used at the boiler shop, to save room. The boiler-room is also made to do duty as a tool-room for the erecting shop.

They use a large tumbling barrel to clean flues It has wooden staves put on spirally; a two-inch stream of water is kept running into the barrel, and the whole thing is boxed up in a heavy plank shed that very effectively drowns the noise. We were told that a surprising difference was noted in amount of work the barrel would do using water, over the old dry plan.

A 85-foot drop table is used, this table is raised and lowered on eight screw-jacks, operated by worms on two shafts driven by power.

One of their kinks, in the shape of a crane for chest covers and seat planers, is illustrated elsewhere in this issue.

Wm. Wright is general foreman here, and the drafting-room is in charge of F S Evans. This room is badly located, being used as a sort of hall to the pattern store-room, and is in the second story, right beside the main track, where all the passenger trains stop—the pops and bells keep the ears busy, while the smoke interests the eyes and the drawing paper. Yet, with all these disadvantages good work is turned out, and a systematic scheme followed in filing away drawings and blue prints.

Perine's Rod Cup.

The accompanying engraving shows the arrangement of a new rod and eccentric cup, recently patented by D. M. Perine, an engineer, of Baltimore.

As will be seen, the feed is of the plunger type, but has a shoulder that fits upon a seat, thus preventing the oil from running out when the engine is at rest, the feed only occurring when the cup is in motion. Feed is regulated by a screw, as shown.

A conical spring is used to keep the cover tight, the under side of the top of the cup is concave, and the pressure of the spring keeps the disk with the leather top in the center and tight.

With these cups, simplicity and quickness in filling is a great feature; with the old style it is necessary for the engineer to unscrew the tops with a wrench in order to fill them; with this he has only to press the end of his oil can against the closed hole in the top, withdrawing it when the cup is full, the opening closing automatically, oil and dust tight, doing away with all danger of cups being loosened or broken off by constant screwing on or off of tops or loss of tops from failure to screw them up tight.

In this way a great amount of time is saved, and a great quantity of oil, as engineers will often pour the oil direct upon the bearings and journals, on account of not having time to unscrew the tops, three-fourths running upon the ground, and is a total waste.

About Brakes Leaking Off.

If the piston in the cylinder of the air-brake does not travel more than three inches to apply brakes, the brake will leak off through the leakage groove in the bottom of the cylinder. This often happens in freight service, where the brake beams are hung from the body of the car; when the dead levers are taken up, when the car is heavily loaded, the shoes are brought nearer the center of the wheel when the car is light, and the piston travel is short.

When this trouble strikes you, don't lay it to the new engineer's brake, and equalizing discharge valve, there is a cause for all these things—find that cause.

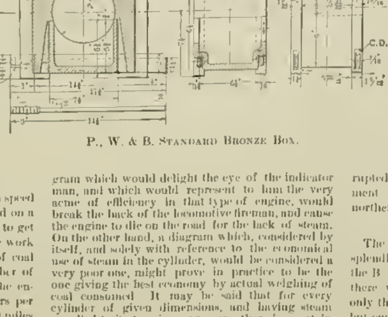
Standard Bronze Driving-Box, P., W. & B Railroad.

On this page will be found drawings of the standard driving-box for 17x24-inch cylindered locomotives of the P., W. & B. road. These boxes are made of solid Crown bronze, and are provided with the cellar-holding device., recently patented by J. M. Wallis, Supt. of M. P.

As will be seen, the cellar is held up by two wedges located in slots cored in the sides of box; the wedges do not pass through holes in the ears of the cellar, but under shoulders at the bottom; the cellar makes a fit against the box each side of the axle, and the cellar being held rigid, cannot wear loose, and is always ready to come out when the wedges are loosened.

These wedges are held in by half nuts on the smaller end. On engine trucks, where there is not room, or where these nuts would be hard to reach, the wedges are held in by a set-screw through the box.

On a recent visit to the Wilmington shops we saw solid bronze boxes weighing 850 pounds, being finished for some heavy engines in process of construction.



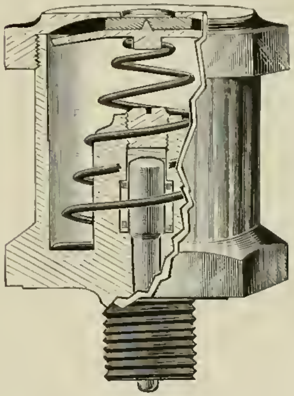
P., W. & B. STANDARD BRONZE BOX.

The Railroad Gazette says: The maximum speed on the elevated roads is 25 miles per hour, and on a level line it requires from 1,000 to 1,200 feet to get up speed. The average horse power to do the work required is 145. The average consumption of coal per mile is 45 7 pounds. The average number of miles run per ton of coal is 49 4 pounds. The engines work on an average of about 20 hours per day with two crews, each crew averaging 70 miles and making 208 stops during that time.

The Indicator on Locomotives.

A writer in the *American Machinist*, who evidently knows what he is writing about, has the following to say on the above subject

There is one point in connection with the use of the indicator on locomotives, which we are persuaded is quite too frequently overlooked. It is too often forgotten that the boiler and the furnace are inseparable parts of a locomotive engine, and that, owing to this fact, it frequently happens, and indeed is usually the case, that what would be nearly the ideal indicator diagram for a stationary engine would indicate poor results for a locomotive having the same size cylinders and doing the same amount



PERINE'S ROD CUP.

of work at the same initial pressure and speed.

The performance of a stationary engine in no way affects the economical performance of the boiler which supplies it with steam, and an indicator diagram from such an engine merely shows the performance of the engine only, indicating among other things the pressure at which steam is admitted to the cylinder, regardless of whether that pressure is economically or wastefully maintained in the boiler, the manner of using the steam in the cylinder having no effect whatever upon the economical combustion of fuel in the furnace

With the locomotive the conditions are essentially different, because the exhaust is depended upon for the blast by which the fuel is burned and the steam kept up. It thus frequently happens that a diagram which would delight the eye of the indicator man, and which would represent to him the very acme of efficiency in that type of engine, would break the back of the locomotive fireman, and cause the engine to die on the road for the lack of steam. On the other hand, a diagram which, considered by itself, and solely with reference to the economical use of steam in the cylinder, would be considered a very poor one, might prove in practice to be the one giving the best economy by actual weighing of coal consumed It may be said that for every cylinder of given dimensions, and having steam supplied to it at a given pressure, there is a certain distribution of steam which is the best one for that cylinder when doing the given amount of work. This distribution will be shown by an indicator diagram, which will represent the ideal conditions for that engine and for that work But if the engine is a locomotive engine, the effect of the exhaust upon the fire must be taken into account, and there are many things about the boiler and fire box, and in the front end, which may have an effect on the character of the exhaust required to give the best results. The kind of coal used, the form of the grate-bars, the size and number of flues, the diameter of exhaust nozzles, or the variation of an inch in the height of the petticoat pipe, may materially alter the character of the blast needed to produce the most efficient combustion of fuel, and, as this blast is furnished by the exhaust steam, the steam distribution and the indicator diagram representing the best possible performance will be correspondingly modified. This, of course, is no argument against the use of the indicator on locomotives, but should serve as a reminder that the indicator, like everything else, should be used only for the purpose for which it is adapted, and it certainly was never intended for the indication of boilers or fire-boxes. The use of the indicator has in the past been confined mainly to engines in which the exhaust has no direct effect on fuel consumption, and the theory of the indicator has been developed by such use of it Those who propose to use it in locomotive practice must make the proper allowances for the different conditions, and failing to do so they should not blame the indicator, and declare it to be a humbug because they fail to get satisfactory results from it

This is a matter too frequently ignored, it should always be remembered that the best indicator diagram from a locomotive is in the nature of a compromise between the cylinders and the boiler.

Murder, Just the Same.

The press dispatches of February 24th contained the following from Erie, Pa.,

"This afternoon as the west bound Nickel Plate passenger train reached the 150-foot high bridge over Walnut Creek, near Swantown, the engineer saw a man in the middle of the bridge The train was running at the rate of forty miles an hour, and to reverse it on the bridge would have imperiled the train and its 100 passengers Although the poor fellow stood wringing his hands in agony, and looked pleadingly at the engineer, the brave man at the lever kept on and sent one man down 150 feet into eternity rather than imperil the lives in his keeping. The man was unknown and was penniless."

We can hardly believe this, but it may be true. If this engineer could have stopped by any means, and did not, murder, pure and simple, was committed It is a poor bridge that won't stand the strain of stopping upon it; and if this was such an one the officials of the road should be prosecuted. If there was no danger of the bridge, and the engineer could have stopped, it is his hand that is red with his brother's blood. We are inclined to believe that he saw the man when it was impossible to stop, and that the theory here given was agreed upon by the witnesses, and used by the reporter. Such items are mischievous and tend to educate the masses into the belief that train and enginemen are careless of human life, and the railroads running on weak and rotten bridges, then, when the public, who have got these ideas, get on a jury, they proceed to do injustice to get even. When a man is "unknown and penniless" here seems to be an excuse for experimenting on him.

The railway from Lulea, in the Gulf of Bothnia, to Elyegaard, in the fjord of Ufoten, Norway, which is now in course of construction, is the most northerly in the world It traverses the mountains between Sweden and Norway, and the work is sometimes interrupted by the severity of the weather. The government railroads of New Foundland are the most northerly in the Western hemisphere.

The Hall automatic block signals have made a splendid record on the N Y , N. H. & H., and on the B & A For one year on the first-named road there were 365,005 operations of the signal, and only thirty-seven unnecessary stops made—this is but one in 9,865, on the B & A there were 20,761 operations, and not a single unnecessary stop

Some Boiler Shop Kinks.

John Mitchell, foreman of the D. & R. G. boiler shop at Denver, has in use a great many tools and appliances of his own invention, not the least useful of which is the device shown in the accompanying sketches.

The frames of these boiler blocks are made of plate, strongly stiffened with angle irons all around them. Fig. 1 shows the forward one, and the manner of securing a boiler to it. Fig. 2 is the back or center support, and has no holding-down tackle.

By mounting a boiler on the rollers as shown, and holding the front end down by the top rollers, the boiler can be turned in any desired shape and secured there, the entire fire-box end being free.

This shop has to deal with a great many heavy boilers with shallow fire-boxes, and this rig is found particularly efficient in this work.

When riveting crown stays, the boiler is turned bottom up, as shown, and the men get on top of the crown sheet, where they can work down; when it comes to side sheets the boiler can be laid on its side if desirable.

Fig. 3 shows another horse or block, somewhat lower in the center than the other—the radius of the circle being greater than that of any boiler in use. Around this circle are heavy angle irons, with holes in them to receive loose pins, as shown at *a*. This block can be placed under the boilers at any point, when they are on the blocking, and its use is to hold, or help hold, the sledge while the boiler makers are heading down a rivet or stay.

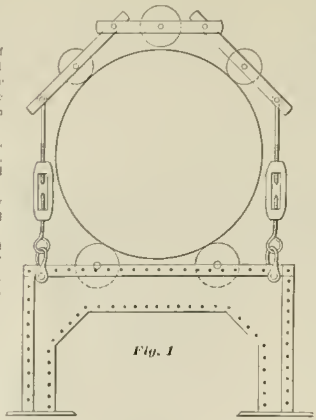


Fig. 1

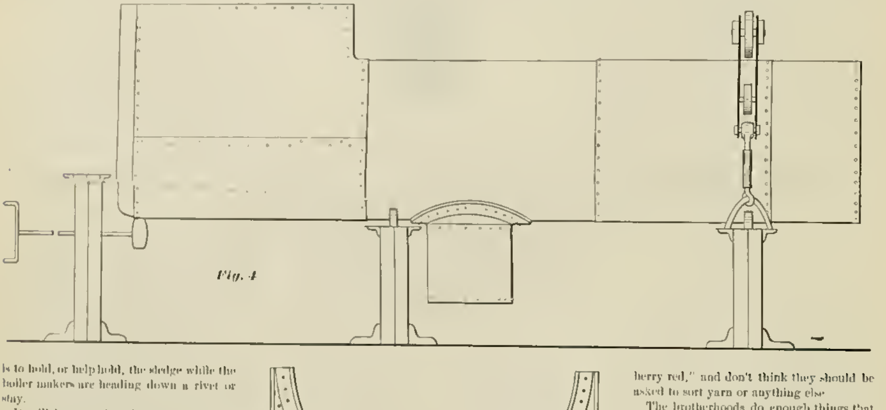

Fig. 4

It will be seen that, by using the sledge as shown, it is very easy to follow seams, either longitudinal or circumferential, the long iron handle gives a great leverage, the sledge holder is away from the noise, and it has been found that the sledge boy will hold up harder, if he can do it, by laying down on the double handle, than if he has to hold a 25 pound sledge up over his collar bone.

By this system of blocking, any tools, such as drills, can be got to any part of the fire-box, outside or inside. There are no castings used, and the rig can be made of boiler shop scrap—and it is a good one.

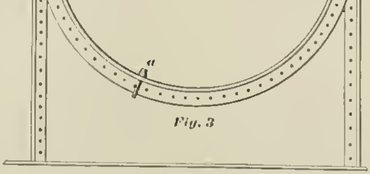

Fig. 3

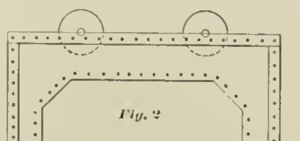

Fig. 2

The Baldwin Works are turning out a number of locomotives for the Argentine Republic; they are 8 wheelers, very much like American engines, but have some of the ideas imported into that country from England. Copper fire-boxes, stays and flues; pumps on a cross-piece between the frames, driven by an eccentric; iron cabs, and wrought-iron wheel centers. Baldwins now make their own wrought iron wheels by a process recently patented by Supt. Vauclain; the wheels are built up of properly shaped pieces, and the whole mass welded in dies under a powerful hammer. There is liable to be considerable use for small wheels of this kind, but wrought-iron driving wheel centers are not so good as cast-iron ones, and cost much more; wrought-iron is more of a yielding substance than cast, and tires on such wheels soon become loose. These South American locomotives are painted a light color, yellowish gray or bronze.

A Color-blinded Item.

A number of locomotive engineers of the Central of New Jersey, who were removed and given positions as firemen and yardmen, several months ago, on account of color blindness, have recently asked, through their Grievance Committee, to be restored. We are glad to observe that Superintendent Olhausen refused their demand, and that the men were sensible enough to acquiesce. Requests for such unreasonable and even dangerous action as this are among the most foolish acts of the engineers' brotherhood, and go far to injure their cause when they present reasonable demands.—*Railroad Gazette.*

The above item seems to have been penned with the idea of putting the brotherhood in a false light; a number of the engineers on this road have assured us that there has nothing of the kind occurred. Color-blind tests have been made, and one or two men on the western division were temporarily taken off, and at their own request were given shifting engines, the brotherhood has not demanded the reinstatement of any men taken off for this cause. The men are most of all interested in having to run on a road where there are men who are color blind, and would be foolish to fight to keep a dangerous man in the service.

These engineers, like those on every other road we know of, are anxious that every man should go before a committee and be able to tell the color of a distant signal, through the open air—both by day and night. They don't know "crushed strawberry red" from "mashed raspberry red," and don't think they should be asked to sort yarn or anything else.

The brotherhoods do enough things that can and ought to be criticised, without such papers as the *Gazette* accusing them of something, just to be able to condemn it.

The Pennsylvania Railroad are going to build a unique monument at Bordentown, N. J. It will be erected on the spot where the first rails were laid in the State, and where the "John Bull" started out for the first time. Isaac Dripps handled her throttle on that occasion, and he recently visited Bordentown, to point out the exact spot of the birth of the Camden & Amboy Railroad. Part of the monument will be made of the original rails, and spikes used at that time. The "John Bull" is preserved in the National Museum at Washington.

In the shops of the Consolidated Safety Valve Co., at Bridgeport, Conn., there is a system of copper wires arranged overhead, so as to touch all belts. These wires are all grounded to a water pipe. Supt. Richardson made some experiments some years ago to determine what deposited large quantities of dust on ceilings, hangers, and around belts, and came to the conclusion that it was caused by electricity generated by the friction of the belt. Whatever the cause, the grounding of the wires in contact with the belts seems to have cured the disease.

An Improved Rubbing Iron Between Engine and Tank

On this page will be found a cut of a chafing iron, designed by Wm. Wright, general foreman of the P., W. & B. shops at Wilmington, Del. Most chafing irons that are set up by a wedge have the wearing surface directly on the wedge, and, after the engine has run some time, a hollow is worn in the wedge, and it is impossible to get it past this place until there is a great deal of slack between the engine and tank, and even then the tendency is to force the wedge back to the old place, often shearing or bending the pins, and making it hard to remove them. With this device there is no wear on the wedge, as it carries the chafing iron with it toward the tank, but not across it. The wedge has projecting ribs, as shown at *f f*, in Fig. 1, that hold it firmly against the buffer irons fast to the tail piece of the engine frame. The wedge enters the chafing iron proper, and is held to it by the flanges shown, *d d*. The chafing iron is held from moving in the direction of its length by the pin *G*, that is shown in both cuts; this pin is held in a slot in the buffer iron that admits of an outward movement only. The wedge is held in the buffer iron by a pin entering it through any of a number of holes, as shown at *H*, Fig. 2, or any other device now in use.

The face of the chafing iron is chilled, and is curved to admit of the engine and tender rounding any curve in the road, without cramping. This device is in use on switch engines on this road, doing the work in the Philadelphia yard, where curves of 75 feet radius are common.

Improved Variable Exhaust.

Master Mechanic John Campbell, of the Lehigh Valley road, at Delano, Pa., has recently put into use a variable nozzle with some novel features.

In the center of the stand, and on top of the partition, a chamber is cast, that is bored out to fit the plug, which is raised and lowered by the lever, as shown; this lever is inserted in a slot cored in the partition, and in no way comes in contact with the exhaust steam. By this arrangement there is no pressure on the plug that tends to lift it, and the actuating levers do not become fouled and unable to work.

Mr. Campbell uses a 5⅝-inch nozzle in his 8-wheeled passenger engines, with cylinders 20x24, and on consolidation engines with large fire-box, a 6-inch nozzle is used.

An Acrobatic Locomotive

Under the head of "A New Model Locomotive," the *Evening Telegram*, of this city, describes the Swinerton locomotive, with a single pair of driving-wheels, and a traction increaser, as follows:

"Residents along the line of the Central New Jersey Railroad have been greatly interested of late in the trial trips of a new model locomotive. The engine has a self-balancing apparatus which throws the entire weight on the single driving wheel at starting, and on the pony trucks, when under headway. It has also a compressed air device which rings the bell and ejects sand on the track at the proper time."

H. Tandy has resigned the office of Supt. of M. P. of the N. Y., Ontario & W., to take charge of the Brooks Locomotive Works as Supt. Mr. Tandy was at one time connected with the works as draftsman, and has received training that has fitted him for the place. As a rule, a railroad M. M. does not get the proper training for a manufacturer, although quite a number have succeeded at it. There is a great deal of difference between building different designs of locomotives for other people, bidding for the work in the open market, and making a profit out of it, than in building engines of your own design in a shop where lots of time can be charged to repairs. There are very few railroad shops building new locomotives, in connection with repair work, where it can be told, even approximately, just what the new ones cost.

Horatio Allen was the first man to run a locomotive in America. Who was the first to fire one?

On a large bridge at Belwa, India, bees have built no less than sixty-five hives or "combs," averaging nearly two feet long, upon the girders. The engineering department has been ordered to remove the unwholesome pests at all costs. The bees are said to make it lively for trainmen in daylight, but excuse the night men.

IMPROVED RUBBING IRON.

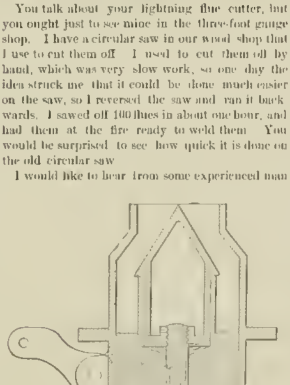
Correspondence

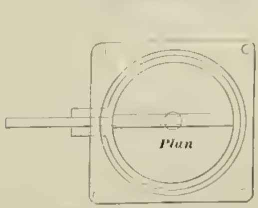
Some Kinks on Exchange.

Editor The Locomotive Engineer:

You talk about your lightning flue cutter, but you ought just to see mine in the three-foot gauge shop. I have a circular saw in our wood shop that I use to cut them off. I used to cut them off by hand, which was very slow work, so one day the idea struck me that it could be done much easier on the saw, so I reversed the saw and ran it backwards. I sawed off 100 flues in about one hour, and had them at the fire ready to weld them. You would be surprised to see how quick it is done on the old circular saw.

I would like to hear from some experienced man





NEW VARIABLE EXHAUST.

the quickest and best plan of cleaning old flues. I do not approve of the old way of rolling them, as you waste too much of the iron, or whatever material they are made of, also scraping them between two files wastes them away, and using a pick puts them too much, and putting in a strong pickle will injure the flue, so let us hear a good plan that is not injurious to the flue.

Now, Mr. Editor, this is my plan of swapping ideas; this idea of cutting flues is, so far as I know, original with me.

Do you know of any good boiler compound for taking scale from a locomotive boiler while in service, that will not injure the boiler, so that we could use that a month or so before bringing engine in shop, and the flues would be clean.

E. A. CAMPBELL, Supt. M. P. & Mach'y.
Houston, Tex.

A Texas Love-Letter.

Editor The Locomotive Engineer:

Please act as post-office department for forwarding the following note to my own true love,

MY DEAR MR. PHELAN:

Since your love letter has appeared in THE LOCOMOTIVE ENGINEER I feel that I owe you an apology for disturbing your intelligent brain, but you forgot to include in the numbers of the cars that this road has, one coach, one baggage car and one pay car; and whenever we appoint a foreman we get one who is a first-class runner and machinist.

Suppose we had 30,000 miles of road, and should keep up this plan with 100 engines on each division, where would your traveling engineer come in? Two men on one engine are company, and three are a crowd—especially on a narrow gauge engine, when you have to take a magnifying glass to find it, as you did. It looks strange that an article penned by a brainless man, or a school-boy, should upset as intelligent a man as yourself.

To your vast storehouse of assumed knowledge please add the following: "That abuse is not argument", "that argument is indeed weak which is mainly sustained by a tone and language common to the fish women of Billingsgate."

Come again and give us another letter. I feel satisfied that two as intelligent writers as you and I can swell up the subscription of THE LOCOMOTIVE ENGINEER to what it should be.

Let us hear from you soon. Good-by, darling.
E. A. CAMPBELL, Supt. M. P. & M.
Houston, Tex.

P. S. Mr. Editor, do you not feel proud to have such intelligent writers as us two for your paper?

[Yes, we are proud of you. People who know so little about railroads and railroad men that you can't notice it on them, said there would be a row when Campbell saw Phelan's letter. The editor had no fear of that; we have lived among railroad men too long, know them too well, and have listened to just such talk around roundhouse stoves too often. We let in these little sassy letters occasionally to make the men feel at home. Now, boys, you have had your say, take your seats and be ready to recite your lesson next month. No more bent pins go!]

Reverse Gear on English Engines.

Editor The Locomotive Engineer:

I desire to set you and the numerous readers of your valuable paper right, in regard to what you claim to be the difference between English and American engines, especially as to reverse gear. You say English practice is to have reverse lever on left-hand side. With few exceptions this is not true, as you would find if you went there. During several years' experience in running and considerable traveling in England, I found the general practice to be, to have the reverse lever on the right hand. The only exceptions that I remember seeing, were a few old-time engines on the L. & N. W. R., and a few others, most of which are, ere this, broken up. They also had a coal bunker on the right-hand side, where the engineer should stand, which blocked up the gangway, and the only possible way to get down off the footboard, was on the left hand side. These seemed to have been built more as an experiment than for general practice. We see by the sketch of the North Star, in this year's January number, that the reverse lever is on the right-hand side, as well as by sketch of Webb Compound in April, 1889, number.

While reading of Sir Daniel Gooch, in the December, 1889, number, my mind wandered back to the latter part of the fifty's, and in fancy I saw the engines (loco.)—probably designed by Sir Daniel Gooch—at the Tredegar Iron Works, South Wales, where he served his time, and I wish it were possible to get a sketch of them as they looked then. The boilers were of an enormous size, being singleflued, with the fire at one end. The machinery was all on top of the boiler, close to engineer, as he stood on the footboard. It was quite a feat to reverse one of these engines. The cylinders were placed "slantindickler," and were coupled to the front drivers, four wheels coupled, the wheels being bald, and running on a flanged rail or tram road. These engines were whitewashed periodically, about once a month or so from the top of stack to the rail.

Perhaps some of the numerous readers of your paper can give you a little more information respecting these engines, their valve gear, etc., for they should certainly be classed as historical locomotives. I would like to write you more respecting the difference in the English practice of locomotive building, but know that there are many of your readers who would be able to do the subject justice, which I am afraid I could not do. Wishing you every possible success in your much needed venture. DAVID REES.

Macon, Ga.

[Our remarks about English locomotives with reverse gear on the left side were made upon the assurance of many English engineers, who say it is done because the engines run on the left-hand track on double-tracked roads. We have drawings and photos of modern engines on the North British road, showing reverse lever on the left side, also a photo of two classes of locomotives on the Great Southern & Western Railway, of Ireland, with left-hand reverse gear. Also engravings of a tank locomotive for suburban work on the London, Brighton & South Coast, that is a left-hander. We also have a picture of a 6-wheeled "goods" engine built in '82, on the London & Northwestern, with screw reverse on left side. There are, no doubt, many locomotives in England with reverse gears on the right side—they don't seem to have any standard rule, as we do here, each road meeting its own conditions.]

About Screw Cutting.

Editor The Locomotive Engineer:

I have been reading your paper, and I thought I would try my hand explaining screw cutting.

I have worked in several shops, and I found that most of the workmen, and even some of the foremen, did not know how to figure out a set of change wheels.

The easiest method I ever saw is to multiply the pitch of the thread to be cut by the number of threads to the inch on the lead screw, and then multiply the product by any number to bring it to the required answer, according to the change wheels.

To find the pitch of any complete screw, take the number of threads to the inch, and place one above it. For example; the screw is six threads to the inch, place one above the six equals one sixth the pitch; one thread is one-sixth of an inch.

Where the screw has a fraction, as 2½ threads per inch, reduce to an improper fraction and invert it. Example: 2½ reduced $\frac{5}{2}$ inverted, $\frac{2}{5}$, the pitch.

When the thread is one to every one, two, three or four inches, the exact pitch is given. Then the foregoing rule is just the reverse, thus, $\frac{1}{1}$, $\frac{2}{1}$, $\frac{3}{1}$ or $\frac{4}{1}$.

And if there is a fraction annexed, reduce to an improper fraction, thus, 3½ pitch = $\frac{7}{2}$, 8¼ = $\frac{33}{4}$, 2¾ pitch = $\frac{11}{4}$, etc.

Find the number of threads per inch to be cut, and then find the number of threads on the lead screw per inch, and multiply the pitch of the screw to be cut by the number of threads per inch on the lead screw.

Example 1.—Find the change wheels to cut five threads to inch with a lead screw four to the inch. The pitch is $\frac{1 \times 4}{5} = \frac{4}{5} \times 6 = \frac{24}{30}$, 24 on spindle, and 30 on lead screw.

Example 2.—Required the change wheels to cut six threads to inch, with lead screw two to inch. The pitch is $\frac{1 \times 2}{6} = \frac{2}{6} \times 10 = \frac{20}{60}$, 20 on spindle, and 60 on lead screw.

Example 3.—Find the change wheels to cut 2½ threads to the inch, with lead screw six to inch. The pitch is $\frac{2 \times 6}{5} = \frac{12}{5} \times 5 = \frac{60}{25}$, 60 on spindle, and 25 on lead screw.

Example 4.—Required to cut a thread to every one inch, with lead screw two threads to the inch. The pitch is $\frac{1 \times 2}{1} = \frac{2}{1} \times 20 = \frac{40}{20}$, 40 on spindle, and 20 on lead screw.

Example 5.—Required to cut a thread to every 2½ inches, with a lead screw two to the inch. The pitch here is $\frac{5 \times 2}{2} = \frac{10}{2} \times 10 = \frac{100}{20}$, 100 on spindle, and 20 on lead screw.

LEWIS CORYELL.

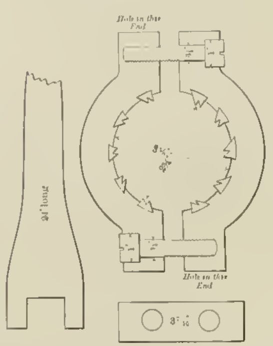
Marshalltown, Iowa.

Details of Hand-Turner for Crosshead Pins.

Editor The Locomotive Engineer:

I have received letters from the West asking for more details of our tools for truing off wrist pins than what you gave in your general description, and if you think it worth while you can publish enclosed sketch.

We have two sizes; this is from the largest one. I had the body pieces forged from soft steel. After planing them up, drilled and tapped for the screws; the heads of the screws are let in to the pieces to get them out of the way, and slotted to use a screw driver. Before boring them out we put two blocks about ½" thick between them, true them out and square them up $\frac{1}{32}$" narrower than the width of the wrist pin space; this allows the cutters, when finished, to project $\frac{1}{64}$" on each end, and this allows for truing out the corners.



I plane the places for the cutters dovetailing, and turn them out the right size—which, on this tool, is 2⅝" diameter—then mark them for the cutting teeth, drive them out and plane out the teeth. I make two teeth on each cutter, as I have found they work steadier than with one tooth.

To turn this tool we use a wrench made like sketch, drilling two holes in one end of each piece, to receive the prongs of the wrench. One of our men trued off two wrists a few days ago, without taking them out of the guides, in about five hours; they could have been done quicker if they had been taken out, but that would make it necessary to set the guides again. WILLIAM FOSTER.

Providence, R. I.

A Good Suggestion from a Blacksmith.

Editor The Locomotive Engineer:

I have read your paper since the first number was published. I like it—it is fair. In it I occasionally meet or hear of some old friend. This is always a pleasure, and would be increasing three-fold did your paper come weekly instead of monthly. I am not an engineer nor a fireman—only a blacksmith—maybe it is outside my business to write you, but you write of the blacksmith shops you visit, and I have caught on to ever so many *kinks* that you tell about; they have been worth the cost of the paper several times over.

I am chock full of respect for "trusts." Seems to me a man don't amount to much if he ain't in one. Last fall I went (by invitation) to the opening exercises of the Brotherhood of Locomotive Engineers Convention. Big trust, that. They didn't have to toot their own horn, either. One gentleman got up to speak, and somebody who sat next to me said he was *Meek*, but he didn't talk that way—told the men what their trust had done for them, and said that there was lots of room for further improvements.

Everybody listened, and, if any one felt *Meek*, you can bet it was not the speaker.

No sooner had this gentleman sat down than up *Chotes* a gentleman tall enough, if he were filled out, to weigh a ton. He kept pretty well on his own road—*broad gauge*. He was a regular pointer, you had no trouble to see a point when he made it.

Seems to me that nothing great is attained in this world that has not personal selfishness and improvement for a foundation.

We see master mechanics' associations, master car builders' associations, societies of mechanical engineers, etc. They are all working for the best interests of the roads they represent, by advocating a *uniform* standard of work.

They are encouraged by railroad managers, and yet who stops to think that, if most of these gentlemen were to prepare plans for a simple tool or complicated machine, about the first thing they would do would be to prepare drawings for the necessary forgings? Much of the future value of the tool, or success of the machine, would depend on the proper forgings of the parts. There are few, if any places in the mechanical department of a railroad where money is spent faster than in the blacksmith shop. How can a part be saved? The days are past when, in order to be a good smith, you must weigh 200 pounds—*kinks* have taken the place of surplus flesh.

So, if we are to save, we must adopt and use the best *kinks*. How are we to get them? Simply by going where they are, look them all over, and start back with a determination to improve them if possible, but to use them anyway.

I think I hear some one say, "Where would you go to see the best?" I do not hesitate to say the shops of the Pennsylvania Railroad are where most can be learned—they have a thorough system. Five years hence, if Mr. Cushing remains in control, I should expect to say the Union Pacific's new shops at Denver or Cheyenne. Perhaps in the future railroad managers may deem it economy to advocate a society of foremen blacksmiths.

Should they have doubts as to their ability to talk intelligently on matters pertaining to their business, they would be quickly removed by an hour spent with Mr. Cook, of the Altoona shop; Mr. Green, of Renovo; Mr. Stewart, of the Illinois Central, Mr. McPherson, of the Northern Pacific, Mr. Judy, of the Fort Wayne shops; and, with all respect to the other foremen along the Pennsylvania road, I think Mr. Judy's shop just a little ahead of any for practical kinks.

All this would take time, and, until something of the kind materializes, will not some of our superintendents of machinery and master mechanics—the progressive ones, I mean—occasionally send their foremen away to *look* for *kinks?* If, in the year following, the extra amount of work turned out does not doubly pay expenses of trip—well, if it don't, they need another foreman, that is all.

Like my friend John Alexander, I am growing old, would not expect to derive much benefit from such a society—then why advocate its formation? Simply this: I should like to see the services of a class of men with whom I have labored many years more fully understood and appreciated, and, as a consequence, better paid. It will not be necessary, I hope, to use a magnifying glass to see where the selfishness comes in here.

A RAMBLER AFTER KINKS.

Denver, Col.

[That a society of foremen blacksmiths would be a grand good thing both for the men and the roads, there can be no doubt; that trips about the country, visiting shops, would pay for all foremen—blacksmiths and every other kind—there is also no doubt. But it will take time to bring about these reforms, and, in the meantime, all are invited to use the columns of THE LOCOMOTIVE ENGINEER to trade kinks. The writer of the above communication is not behind the procession in the use of kinks. Sketches and descriptions are in order.]

Device for Turning Crosshead Pins, and Other Work that Cannot be Turned in a Lathe.

Editor The Locomotive Engineer:

I send you herewith blue prints of a lathe attachment for turning up solid pins in crossheads, boring out driving-boxes, and such other work that cannot be revolved in a lathe.

It consists of a loose pinion shown in detail at *a*, Fig 6, attached to the live center of the lathe by a bushing *b* screwed over the center so as to be used as an arbor for the pinion. A gear wheel or segment *d*, as shown in Fig. 1, meshing into the pinion fastened to the lathe face plate by stud *e*, Fig. 1. The face plate is secured to shear of the lathe by a plate *e*, with one or two bolts, so as to make it firm.

The pinion of the back gear is to be taken out or shifted so as to enable the back gear to be the driver

Extending the shaft of said gear to the inside of face plate by a socket, *f*, Fig. 4, with a crank attached to the same, it would leave nothing more than the well-known Pitman *h*, Figs. 2 and 5, to make the motion complete. To adjust the stroke, have crank *g* slotted, and for adjusting the motion use the cone pulley on the lathe.

The crosshead is held between two clamps, Fig. 3, adjusted by set-screws. Slot *m*, Fig. 3, in each of the clamps, is to fit pin *a*, Fig. 6, which is firm on pinion, and by which the crosshead receives its motion, making as near a complete revolution as possible

In shops where there is no slotter, this device can be used to bore out driving box brasses, by using a boring bar, as shown in Figs. 7 and 8, using the device the same as for crosshead work. It is necessary, however, to make a short clearance space at *x*, Fig. 7, to allow the tool to feed and start.

We have used this device in the Fargo shops for the past six years with very satisfactory results.

DEVICE FOR TURNING CROSSHEAD PINS.

Wanted—Information About Traveling Engineers.

Editor The Locomotive Engineer:

In the last few issues of your paper there has been quite a heated discussion on the compensative ability of the present traveling engineer to a railroad company, between Mr. Phelan, of the Northern Pacific, and Mr. Campbell, of the H., E. & W T R R. Both gentlemen seem to have such extreme radical ideas, that, should they keep up the debate, there is no doubt the settlement of it would be by the havoc of war.

It seems as though Mr. Campbell wishes to exterminate the traveling engineer off the face of the earth, while Mr. Phelan's idea is that they are the only jewel in the railroad's diadem, and that every road should have one. In the last issue he sends a stinging rebuke to his majesty in the South, and accuses him of throwing the blanket over a title which would make the Pooh Bah of Japan cry with envy. The discussions are rather amusing, but how are we to find out which is right or which is wrong, when they are drifting from the green fields of discussion to the brickyard, "and throwing bricks at each other? There is no reason why the narrow gauge road does not give the gentleman of the South as much experience as the Missouri Division of the Northern Pacific does to Mr Phelan; either gentleman can easily get over their respective dominions in the short space of half a day, at the regular rate of speed. It is my opinion that the traveling engineers are nice fellows, they work both ways —good and bad, good when they never show up, and bad when they emerge from a neighboring cornfield to catch you serenely screwing down the "pop" to keep from doubling the hill, or, still worse, when you are back talking to some nice young lady friend in the Pullman, and the Con. ahead pulling the plug.

Still, it is a fact that, if the division M. M., general foreman and roundhouse foreman do not know the exact condition of the engines, and the ability of the engineers, there is no one on the face of the earth that does; that is why the traveling engineer is ornamental, but not useful.

When an engineer is hired he is examined on machinery by the M. M., on the time card by the superintendent or train dispatcher. He is then sent out, and it takes but a short time to find out whether he is incompetent or otherwise, without the assistance of a traveling engineer.

When the authority of the traveling engineer exceeds that of the division M. M. it is bad, when he is no mechanic it is worse.

I was on a certain road where the traveling engineer wore the crown jewel. One day I received a message from him telling me he had found an engine with the cylinder working 1½ inches, and wanted to know what to do. Well, who ever heard the like? I had a notion to wire him to put her in a box car and send her in. On going to the dispatcher's office I found she had been doing O. K. up to the discovery, when he side-tracked her; I ordered her in with her train. On examination I found the keys had worked out between the frames and cylinder, and caused her to work a little. I found out it was discovered by the eagle eye of the fireman, who reported it to the traveling engineer, hence the dispatch. As far as fuel and oil are concerned, we can easily determine economical or extravagant uses by engineers and firemen, by the monthly performance sheets. I shall conclude by saying I would like to see the principals debate this question from a mechanical point of view. I would like to have Mr. Phelan tell why the traveling engineer is a blessing to a railroad company—as some day I might have to hire one.

Oakland, Cal. W. D. HOLLAND.

Who is the Youngest Subscriber?

Editor The Locomotive Engineer:

I saw in the February issue of your paper an article headed "The Michigan Central Compound," in which the writer (G. L. Fleitz, of Detroit,) says that he is probably the youngest subscriber of THE LOCOMOTIVE ENGINEER. If he is, he is under sixteen, for that is my age, and I have been taking your valuable paper for six months.

San Francisco, Cal. WM. W. DAVIS.

Another Window Cleaner—Side Rods.

Editor The Locomotive Engineer:

We have an engineer on this road (N. Y. C.) who says, "There is no strain on side rods when engine is drawing train, provided she don't slip." This engineer has been running on this road about twenty years, and thinks he ought to know what he is talking about, and so do I. Can you enlighten him on the subject?

I send you drawing of window sweep used on our engines. Make bolt or thimble of six square brass, about ⅝ diameter, to go through sash; put nut on inside. Take 5/16" round steel and bend it like drawing, put a piece of rubber hose on end that sweeps the window, let rod extend through thimble far enough to take spring and handle; spring will draw the sweeper against the window.

We are using the new Westinghouse engineer's brake and equalizing discharge valve, and engineers say they are no good. I wonder if engineers on other roads have as much trouble with them as our engineers do. I would like to hear from some of them. W. F. REDVEA.

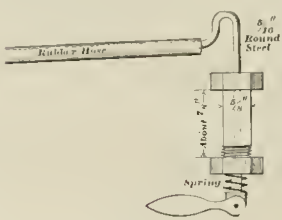
Syracuse, N. Y.

[If an engineer of twenty years' experience thinks the side rods do nothing except when the engine slips, it would probably take as long to prove to him that they do—life is too short to try. Engineers have had trouble everywhere because they did not understand the action of the new engineer's brake and equalizing discharge valve, and expected it to operate just as the old valve did. Where it has been explained to them, and they understand it, there is no complaint.]

Some More Kinks.

Editor The Locomotive Engineer:

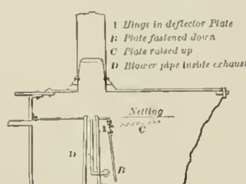
In the upper peninsula of Michigan, there are over 1,100 miles of track on which passenger trains are run, besides some double track, and all the sidings, ore tracks, branches to mines and logging roads, 300 miles more. Some who have never been in that country imagine it to be a wilderness, but it is a great and growing country, and some of



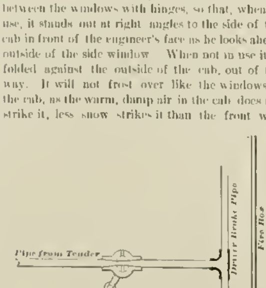
WINDOW CLEANER.

the finest mining machinery in the United States is hard at work there. The railroads are away up to the front in their locomotive equipment, there are a number of kinks in use there which may be new to some of the readers of THE LOCOMOTIVE ENGINEER.

A very comfortable thing used on the Soo Line



is a storm window for the engineer. It is a narrow sash, 6' wide over all, as long as the side window is high, with a pane of glass as large as the sash will take in and have strength to hold it. This sash is fastened to the strip in the side of the cab between the windows with hinges, so that, when in use, it stands out at right angles to the side of the cab in front of the engineer's face as he looks ahead outside of the side window. When not in use it is folded against the outside of the cab, out of the way. It will not frost over like the windows of the cab, as the warm, damp air in the cab does not strike it, less snow strikes it than the front win-



dows. You can get at it to clean the snow off without opening the front window, and it protects your eyes from rain and snow when you are looking out.

Some of the boys have a piece of looking glass in the top part of this storm sash, so they can see the tail end without looking around. That is handy too.

On some of the driver brake engines where the driver brake cylinders take air from the tender triple valve and reservoir, there is a plug cock under the deck in the air pipe, before it branches off to each side. This plug cock is connected in the same manner as a lazy cock in the feed pipe, so that it can be worked from the cab, where the handle is placed so as to be reached, without the engineer taking his eye off the track.

There is a ¼" hole drilled through the side of the shell and plug, like the "waste" the plumbers put in the side of a "shut off." The plug, after drilling, should be turned half round so the ¼" holes will not come together when the cock is open to allow the air to pass through to the driver brake. If the brake skids the wheels on slippery track, this cock can be shut with the ¼" hole toward the brake cylinder pipe, and the brake will release. The driver brake can be set after the tender brake sets, and released before the train brakes do, if so desired.

I do not believe in cutting out the driver brake—when it is in good order—under any circumstances, but some have to do it *they think*, and it is a wise plan to have a good arrangement for doing this.

On the lower peninsula they have a kink or two worth trying also.

It is quite a job to take down the deflector plate in the extended smoke arch when you want to wash out, bore out the flues, or, in fact, do any work back of this plate. If it is located in front of the exhaust pipe it can be hinged at the top and lifted up against the netting when necessary, and fastened there while work is being done. There is a strip of angle iron riveted to the side of the smoke arch which the deflector plate is fastened to, when down in its place, by bolts with split keys. With this arrangement, after the lower edge of the apron is fixed at the proper height, where the engine will steam well, it will not be altered every time it is taken down and put up again after the old style. The D., G. H. & M. Ry. use this and like it.

Most of the blower pipes come up at one side of the exhaust nozzle so that the jet of steam does not go up the center of the stack; consequently it does not produce the effect it should. It is in the road of all the pipes and bolts, and about half of the time is not put up as it should be. This pipe can be in the center of the exhaust pipe casting either as part of the casting or a hole drilled through the partition between the two steam passages, and a ⅜" pipe screwed in from the top. If the exhaust pipe pattern is got up with a view to putting the blower pipe in the middle of it, it will not add much to the cost. The steam pipe can be screwed directly into an elbow in front of exhaust pipe, where it will make a tight joint, and can be taken out from the outside. A brass bushing will be needed where the wrought-iron pipe is connected to casting, or the threads will not come apart easily. CLINTON B. CONGER.

Lansing, Mich.

A New Valve Gear.

Editor The Locomotive Engineer:

Having bought your paper regularly from a newsdealer ever since its start, and considering the valuable information one gets from it, and feeling that perhaps anything new in the line of valve gear would be interesting to your readers, I send you blue prints of a valve gear invented by one of the engineers on our road—the Boston & Albany—H. R. Fay. It has not as yet been applied, but I believe, however, that arrangements have been made and contracts signed for an engine to be built within ninety days by the Portland Locomotive Works for the Complete Combustion Company of this city, and this valve-gear is to be put on; the engine will weigh about forty five tons; the boiler is to be a wagon-top, with this company's form of fire box, which has water grates high up, the front ends entering a water space bridge wall that drops from the crown sheet, the draught going in on *top* of the fire, and forcing the flame down through the grates and to the flues.

This motion accomplishes quicker port openings, with shorter travel of valve, does away with increase of lead on hooking engine up, or has a stationary lead, which is adjustable, it has but two more pins than ordinary link motion, but whose movement is shorter, consequently less wear; in case of breaking either hook, eccentric or strap, or even the link, by taking off broken parts engine can be run to destination.

It has two eccentrics; the main one, which moves fixed link under frame, connection being made from block in link with bell crank at top outside pin of rocker arm; the eccentric which moves this fixed link is always set blind. The reversing is accomplished by moving block in this link from one end to the other, as shown in cut. The fixed link is an advantage, for the reason that finer points of cut-off can be had than with the movable link, the lower arm of rocker is slotted; the movable block in this slot—connected with eccentric, which is set on pin quarter—can be adjusted by "gibs," or with a lever from cab if desired, this eccentric has a throw equal to lap of valve, and fully controls lead. It can be applied to any engine with ease, and the only objection which has yet been thrown at it is that it is not desirable that the lead may be in hands of the "runner," that is, if lever from cab is used. Some of our oldest engineers say that the same objection was made to link motions. The remedy is simple. A "gib" fastening the movable block in lower arm of rocker will overcome this, and, besides, can be moved up so as to take up for lost motion, and always keep engine square, even after long and hard wear.

This valve gear is composed of two separate motions, which can be operated independently or together. Fig. 1 shows valve gear in side elevation, in full gear ahead; Fig. 2 shows front view of cut-off shaft, 59, and arms 61 and 62; Fig. 3 shows side view of Fig. 2, making more plain slot 63 and block 64 in arm 62, eccentrics are set as follows: Cut-off eccentric 56 is set with main pin 76, and

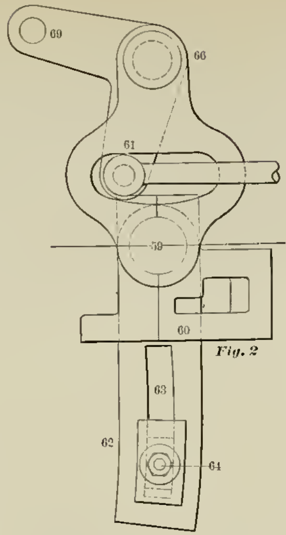


Fig. 2

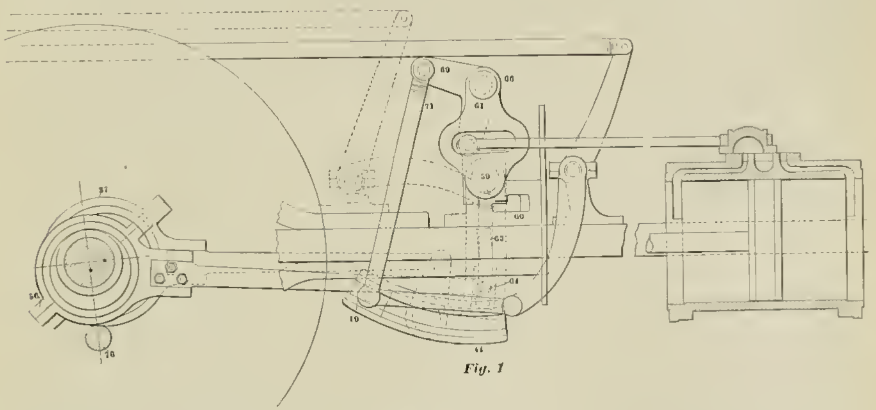

Fig. 1

has a throw sufficient to oscillate pin 66 to throw lap of valve over; the slot 63 is about five inches in length—as designed in this particular case—but could be varied according to dimensions of engine to be constructed. These dimensions were from working model designed on or from B. & A. R. R. standard passenger engine, 18 x 22" cylinder, 4½" travel of valve, 1" ports and 2½" exhaust port, ⅞ outside lap. Main eccentric 37 has throw to give desired travel to valve, giving rocking motion to link, whose movement is kept central by shaft and rocker arm 42, Fig. 2, this motion is communicated to bell crank 69 and 61 by means of rod 71 from link block 46, this eccentric 37 is set a little back of quarter, behind main pin 76, say at angle of 92 or 93 degrees, practically on that quarter.

By a lever in cab, block 64 can be moved in slot 63, or by doing away with such lever, and its rods and arms, making block 64 adjustable, it gives a constant lead, by raising 64, lead can be increased, when 64 is at bottom of slot 63 the lead is taken away, and the raising or lowering of this, either with lever from cab, or through its being made adjustable, fully controls the lead; also, if block 64 is raised and lead increased the lost motion of valve gear can be kept up with, and valves kept adjusted at opening points against general wear of gear.

It will be seen that this point of adjusting lead

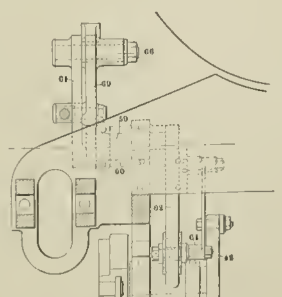

Fig. 3.

gives the engineer the advantage of adjusting his engine to all conditions of train grade or speed; he has full control of lead and cut-off, and width of port openings, giving a variation of 20 per cent. increase in expansion, and like reduction in compression over common link motion at short points of cut off.

Now with the two motions working together it will be seen that the radial center line of link is at right angles, or nearly so, with the center line of adjustable lead or cut-off eccentric motion, and it will operate engines with single valve, forward or back, in a more efficient manner than link motion as ordinarily used, with the advantages heretofore named; also a point in its favor, should eccentric, hook, or link, or any part of either motion be broken on road, take off broken part or parts, and the other motion will help the engine along, avoid long delays, and not making it necessary to block up or disconnect on broken side.

This valve gear gives quicker opening and closing of ports, and a point of rest when open, and is square at all points of cut-off, forward or back. This gear can be applied to any locomotive without any change, except the motion itself.

H. L. HOLMES,
Locomotive Engineer B. & A. R. R.
Boston, Mass.

[It is not our custom to show up untried devices, but as this one is ingenious, and shows thought, and is about to be tried we break the rule. A model of this motion shows nearly theoretically perfect valve handling. Now what it will do under steam is another thing.]

A Pennsylvania Railroad man says young men are selected as drivers of the locomotive on fast trains, because old men do not have the nerve to stand the strain of the terrible speed of these trains, and even the nerviest young man gets afraid of them after a while. Then they get to letting up a little in speed, the trains run behind time, the engineers are given other runs, and new men are put on in their places.—*Ry. Age.*

Speed affects some men after a while—they can't stand the strain; but fast running is natural for other men, and they get fat and old without getting enough of it.

It is a pleasure to be able to record a case where two labor organizations combine to make a social and financial success of their annual ball and banquet, instead of each having a small blow-out, and striving to see who can eclipse the other. We have before us an invitation to a ball, given on the evening of Feb. 14th, by Saratoga Lodge, No. 209, B. of L. F. and Champlain Div. No. 217, B. of L. E. Of course such an affair will be a success every time—how could it help it?

The foundations for the new elevated railroad in Chicago are going in, and the Keystone Bridge Co's. rolling mills are at work on the iron for the structure, with a contract to have one mile complete in March.

T. B. Twombly, after a service of more than twenty years, has retired from the position of Supt. of M. P. of the C., R. I. & P. Geo. F. Wilson has been appointed to fill his place.

The Difference Between Compression and Back Pressure.

It is perfectly plain from the arguments of a good many mechanical writers that compression and back pressure are too often confounded, and that compression is too often called back pressure.

Back pressure may be stated as pressure which opposes the movement of the piston by the live steam, therefore resulting in a loss of power that could, without this back pressure, be used in doing effective work.

Compression gives back to the piston as much power, on the return stroke, as was used in producing it. So long as the exhaust port is in communication with the cylinder in a working engine, there is back pressure on that side of the piston.

As soon as the port is closed, back pressure ceases and compression begins. Compression is simply the confinement of steam in the cylinder, and that steam compressed by the piston, driven by a greater steam pressure, on the other side, and by the momentum of the moving parts.

As all pressure on crank pins, while piston is within about two inches of the end of the cylinder, only produces excessive friction and does no work, compression is used to help equalize this pressure in arresting the moving parts; it supplements the lead by filling the clearance with a pressure nearly as high as the steam chest pressure, and saves loss in cylinder condensation by keeping the walls of the cylinder heated.

As action and re-action are equal, the compressed steam will give out, in effective work, as much power as it took to produce it, less the friction, which is probably more than paid for by the saving in heat before mentioned.

Unless the compression causes a greater pressure than that in the chest, it is advantageous, and necessary, especially at high speeds. The great trouble with those who have tried to improve the link motion for locomotive use, has been that they have confounded back pressure and compression, and have tried to produce a gear that would do away with both. The more back pressure is reduced, the better.

When compression is taken away (and you can get a card with a square heel on it) something must be introduced to do its work—in reducing the shock and friction at each end of the stroke—live steam will have to be used to re-heat the walls of the cylinder, initial pressure will be reduced, larger water tanks be needed, and steam shovels on the tenders to do the firing.

Union Meetings—A Suggestion.

In a recent conversation with a locomotive engineer, of more than average intelligence, the subject of union meetings was brought up.

"We want to have one here this spring," said he, "but I would like to see it turn out something beside a picnic and a love feast, but I don't see just how we can bring about a change, or what change is desirable." There is food for considerable discussion and thought in those few words. The writer is strongly in favor of the union meetings, even as they are, it is a rest for the men who can attend, gets them out of the rut, and gives a new lease of life, but, like most of those who have taken an interest in these meetings, do not see so very much good that can come from them as now conducted, other than that of a social nature.

Why would it not be a good idea for the engineers and firemen to combine their forces and make a new departure in the union meeting business? Or, if this is impractical, let each order hold meetings of their own.

We hope we do not go beyond our limits in offering a suggestion or two.

Why not district the United States, say the New England States, into one or two districts, New York, Pennsylvania and New Jersey into another, and so on, making districts any convenient size. Then hold regular union meetings, say twice a year in each district.

Hold two-day meetings, and a morning and evening session each day.

There is bound to be some question that is more or less local and of concern to the order—let these be discussed and disposed of at the first setting, all speeches glorifying the men or the order left out.

At the first evening session admit members with their ladies, have a neat ten-minute speech or two, a poem by Shandy McGuire, or some other poet from the ranks, and a general social, good time.

For the second morning have a discussion; subject chosen at one meeting for the next. Let the subject be one that concerns the relations of the engineman with the companies, and have men appointed to investigate the official side of the argument, and present the case from that side. Three speakers on a side, limited to twenty minutes or half an hour each, would make the matter interesting. After the discussion or reading of the papers let the audience ask questions or make remarks.

In this discussion men would only be talking to the members of the order, and men in their own walk of life, and no embarrassment would be felt. Bulletin orders, new rules and time card changes could be well ventilated this way.

On the second evening again admit ladies, and have a short lecture on some subject tending to make us more familiar with the mechanics of our trade. One time a talk on combustion and the laws of heat, the next on valve motion, using a model and explaining how to set valves, etc. Again, something about friction, the indicator, air-brakes, injectors or any other subject.

Plenty of men will be glad to volunteer to give these lectures, the makers of many of the devices will be only too glad to send men with proper models to make speeches. Such meetings would be of interest, they would rest, amuse, and at the same time tend to make better engineers and firemen of us.

Railroad officials would be only too glad to help in these meetings in the way of transportation; there need be no expense, except, perhaps, individual hotel expenses; any lodge room will do for the meetings; there need be no fund, no officers, and we have not the least doubt but that all would thoroughly enjoy and profit by them.

With something like this in successful operation, our orders would have something to show that would go to prove that brotherhood men enjoyed educational advantages that others could not enjoy, and therefore were better engineers and firemen than others.

The plan here outlined is crude, but it is well worth thinking about.

Watch Inspection—A Fair Plan.

As the complaint comes up regular from one place or another that officers of the companies are obliging the engineers and conductors to have their watches inspected by some certain watchmaker—or rather watchseller—appointed by the aforesaid official, it is suggested that the time has arrived for a general understanding of the rights of all in this case.

There are many of these plans that, on their face, are plainly money-making schemes that ought to be killed at once. On the other hand, many of the plans proposed for watch inspection have been with the good of the service in view, and these should not be killed in order to get rid of the first species. The general plan is to oblige the men to have their watches inspected by some certain person, and their good running condition certified to once in six months, for which the men have to pay from 50 cents to $1 fees. On all roads the men own their own watches, and use them in the service of the company, and these watches ought to be of a high grade, and in good condition, but just what that grade or that condition ought to be, varies with the men, and is liable to be very wide in its range.

Absolute safety, uniformity and accuracy will only be accomplished when the companies own the watches, and issue them the same as running orders, and wound and set.

This change would cost the companies considerable money, and is therefore not liable to be adopted.

Taking the next best plan, why would not the following rule be fair? Where inspection is ordered by the companies, and no work done to the watches, the companies to pay for the inspection. Where the inspection is ordered, and the inspector agrees to clean and keep the watches in running order—except breakages—the men to pay for the inspection. In one case they would be receiving something in return for their money, in the other, nothing.

The property of the corporations, and the lives of the public and the employes depend on the quality and condition of the timepieces used, and they should be the best. But when it comes right down to the right and wrong of it, there would be just as much reason in the railroad companies demanding that the engineers should furnish their own engines and keep them in repair. The watch is on a smaller scale, and we are used to it—that's all.

Prejudice.

The poet who wrote:

> "A sea horse is a sea horse
> When you see him in the sea,
> But when you see him on the land,
> A land horse then is he,"

very fully defined the prejudice with which we look favorably or unfavorably upon the very same things under different names or under different conditions.

The entire American people are terribly prejudiced against street locomotives, or dummies.

Street locomotives are now built that are almost noiseless, entirely smokeless, and are handled with greater ease, can be stopped with as much promptness and started with less shock than can horse cars, electric cars or cable cars. They are able to run on ordinary track, and can be operated cheaper than other power systems of surface travel in cities.

The old bugaboo that they scared horses has long been obsolete; there is no noise, escaping steam or smoke.

They look much as any other car does, and have not quite so good a chance to run over and kill people; but you suggest dummy locomotives, and the entire population protests. Why?

They will permit the stringing of high tension wires for the electric railway, whose cars are just as dangerous about running over people, are just as liable to scare horses, and expose from one end of the line to the other a live wire that it is death to touch, and one that is liable to be crossed by innocent telegraph and telephone wires, and cause fires or deaths.

These same people will let their children play in the streets along which all kinds of heavy trucks are rumbling with horses at a trot. They look without fear at great catamarans, under whose gigantic frames are swung iron or granite columns tons and tons in weight, they are drawn up hill and down with no sign of a brake—the people are used to them.

Cable cars gather in their regular quota of dead and maimed, the slot catches the calks on horses' shoes and breaks their legs—but it's all right, the people do have steam engines in the streets, and are happy.

If dummies were used, men trained to handle them intelligently would have to be employed, and care thus increased. Electric and cable cars are to all intents and purposes locomotives.

There is not one single valid argument against modern steam motors in our streets—prejudice alone keeps them off.

English, German or French prejudice is funny or ridiculous, but American prejudice—well, that's different.

Air-Brake Practice.

Some time during this month there will issue from this office J. E. Phelan's book on "Air-Brake Practice." The articles that originally appeared in this paper have been rewritten and revised, and several new chapters added. There are rules for figuring the power and leverages of driver brakes, as well as for all kinds of brake rigging.

All the rules and formulæ have been verified by the Westinghouse Co. as correct and up to date. The work will be neatly bound in cloth, with a flap, so that the book can be carried in the pocket. There is a pocket in the cover where plates of all the brake appliances are illustrated. The plates can be taken out, laid on the table or hung upon the wall for better examination. The engravings are very large and clear, being new ones for this work, and every part of the air-brake system is illustrated both in perspective and detail.

As the work is written by an engineman, for enginemen, it stands to reason that it should be clear, to the point, and couched in such language as they can comprehend. It will, no doubt, be the leading work on this subject, and destined to clear up many a mistery now tangled up in the brains of the men and the air-brake appliances in use.

New Clothes.

The editorial department of this paper has a new suit of rooms—one suit. Haven't moved out of the building, or anything like that, but made a new place out of the old—like a boy's new pants made from the cast-off pair of his father's. Since getting into the new den the walls have been adorned by the arrival of a handsome framed photograph of a locomotive from the Baldwin, Dickson, Rhode Island, New York and Richmond Locomotive Works, while the Brooks donated three, which, with the Pittsburgh that we had, makes quite a roundhouse of the place. All we need now is a switch engine to have a full band. When we get that, and the windows cleaned, the editor is going to wash his neck, put on a clean collar, and have his hair cut. Then the whole concern will look like the general superintendent's special engine on dress parade.

ASKED & ANSWERED.

(11) C. S. C., Madison, Wis., asks.

Suppose the Southern Pacific road could utilize the hot springs on its line for feed water for their locomotives, what would they gain, using 150 pounds pressure, provided the water was 180°, where it is now 60°? *A.*—They would gain the amount of heat required to raise the feed water 120°. The total heat units in one pound of water, at 150 pounds pressure is 1223.5; the water now contains 60 units, leaving 1163.5 to be imparted. By using the feed at 180° we will gain 120 units, which is just about 10 per cent. of the whole; this is providing no heat is lost in handling—which, of course, there would be.

(12) Stoker, N. Y., writes.

Please answer this question, and assist a stoker. I am firing for a man that wants the blower put on when he shuts off; he claims, if the blower is not put on, that the black smoke goes to the cylinders. Now, what I want to know, does it, or, if it does go to cylinders, does it do any harm? *A.*—When the engine is drifting, the tendency of the pistons is to pump the air out of the chest, and discharge it through the nozzles, but this is comparatively slight. When an engine is reversed while running, the tendency is to pump air through the nozzles and store it up in the chests and steam pipe. Smoke would help gum up the oil, and cinders would cut.

(13) A. E. A., Albany, N. Y., asks.

What is the Sweeney air compressor for air brakes, and where is it used? *A.* The Sweeney compressor is a pipe connection, with suitable valves, from the steam chests of a locomotive to the reservoir of the air brakes. It use is to supply a large volume of air quickly on mountain grades, and to handle the brake in case the air pump gives out, or cannot be made to supply enough air. It is operated by opening the valves and reversing the engine, allowing the pistons to pump air back into the brake system. It is a very cheap device, and an additional safeguard on mountain roads. It is in use on the Central and Southern Pacific systems.

(14) C. C. W., Ottawa, Ill., says.

I haven't been able to find out the function of the little reservoir under the engineer's seat, and connecting with engineer's brake valve. *A.*—The small drum under running board is to increase the area of space over piston in the engineer's brake valve. With the new valve, this little drum is a sort of sample case; the engineer knows just how big it is, and what pressure and volume of air it contains; when he wants to set the brakes, he lets out a given amount of air, that he can see and feel, and virtually says to the new equalizing valve, "about that much," and the valve lets out from each car just that much *pressure*, regardless of how many cars there are in the train.

(15) "On Time," Los Angeles, Cal., asks.

I want to secure a license as locomotive engineer. Can I do so by correspondence? If so, to whom will I make application? I have read and heard a considerable on this subject. I also think it is one that should interest every steam user, for it is a noted fact that our country is getting overrun by "stoppers and starters," that call themselves engineers, and will work for half pay, to the detriment of true and honest men. *A.*—"On Time" says he has not been on a locomotive for some time, and we have no doubt of it. We know of but one State where locomotive engineers have to have government licenses, and that is Alabama; and, so far as heard from, they do not send them out by mail. The best license that can be had is a promotion on merit by the officer in charge of the motive power of a railroad, and that promotion endorsed by most of the men on the road, who are not afraid to risk their lives on the ability of the holder of the license.

(16) Young Inventor, Cincinnati, O., asks:

1. How many locomotives, or about, are there in daily use in the U. S. A? 2. How much does the fuel cost the railroads to run a locomotive on an average per 100 miles? 3. What does a locomotive cost the railroads when they are bought new, both passenger and freight? 4. About how long does a locomotive last—that is the life of one? 5. About how many miles is a locomotive required to run a day? *A.*—There is no accurate data on any of these subjects. 1. There are about 32,000 locomotives of all classes in service in the U. S. 2. Fuel is as cheap as $2 per ton in some localities, and as high as $14 in others. 3. The average cost of locomotives, averaging all classes, for the past year has been about $8,700. 4. Some parts last 20 to 30 years, depending on the service; boilers go from 15 to 20, with renewal of fire-box every 5 to 8 years; frames generally last the longest. 5. The widest possible difference, but the average of a very large per cent. will be about 100 miles.

(17) E. H. P., E. St Louis, asks:

Please tell me why the engine I am running will pull 13 loads up Ozark hill in the fourth notch on the quadrant, and a full throttle, and will only pull 13 loads when she is in the corner. The engine is a common 10-wheeler 19 × 24, 4½ foot wheel, pressure 150 pounds to square inch, built by the Rome Loco Works. There is nothing in the world wrong with the engine; she is in first class fix. What I want to know is, why will this engine pull as much hooked back to the fourth notch as she will in the corner, full throttle. *A.*—You do not state the speed, but we assume that it is moderate; when the engine is working in the 4th notch she admits steam earlier, gets all she can use and have time to get rid of it. You must remember that the steam has to get *out* as well as to get *into* the cylinder. In full stroke steam follows almost to the end of stroke before exhaust takes place, then the steam admitted to the other end of the cylinder has to work against the back pressure in forcing the steam *out* on the other side of the piston. In moving very slowly, like a start, the steam has *time* to escape, but at any speed at all, is has to be forced out. This shows the efficiency of the link motion; the steam you use at the earlier cut-off is almost entirely used in pulling the load, while a large per cent of that used at full stroke is lost in getting rid of the excess steam used on the other side of the piston.

(18) E. O., Wilmington, Del., asks:

Please give a simple rule for getting the horse-power of a locomotive, and also of giving the size ports to any size cylinder. *A.*—It is customary to allow half the boiler pressure for the mean effective pressure, which is the average pressure from the beginning to end of stroke. The following rule is used for any engine, and where used for a locomotive the result should be doubled, because a locomotive has two cylinders. *Rule.* Multiply the mean effective pressure in pounds on a square inch of piston by the length of stroke of piston in feet, multiply this product by the area in square inches of the piston, and again multiply this last product by the number of strokes made by the piston in one minute, and lastly, divide this total product by the 33,000, the quotient will be the indicated horse power. Probably the following formula will help to impress this rule on the memory: Let $I\,H\,P$ stand for indicated horse-power; P for the mean effective pressure in pounds on a square inch of piston; L the length of stroke in feet; A the area of the piston in square inches; N the number of strokes made by the piston in one minute. We then have

$$I\,H\,P = \frac{P\,L\,A\,N}{33{,}000}.$$

Here it must not be understood that the word *PLAN* has any particular relation to the horse-power of an engine, but the letters forming this word should simply be understood to be symbols of the factors which enter into the calculation; neither does it make any difference in which order we take the factors, but, placing them in the order here given, they form the word *PLAN*, which may help to impress the rule upon the memory. The divisor 33,000 stands for that many foot-pounds. An engine which raises 33,000 pounds through one foot in one minute is said to exert one horse-power. This unit of horse-power was established by Watt, and has been in use ever since. There is no set rule about size of ports.

(19) 59er, Minneapolis, Minn., writes:

A four wheeled coupled shifting engine, main rod connection on back drivers, breaks the left hand side rod, and forward strap on right-hand side rod. Engineer finds back end right hand side rod bolts badly sheared (and they finally have to be drilled out), so that it is impossible to take said rod down. How would you proceed to shop, three miles distant? 2. Can you furnish me a list of standard screw threads, or let me know where I can find them? *A.*—1. There can be no rule given for a case of this kind. Of course, if the side rods were down, the engine would be all right to run, and, as the right one can't be got loose from the pin, the only way would seem to be to get the loose end to swing by a rope, or over some guide, either that it finds itself or is found for it. We remember a case of broken side rod on an eight-wheeler, where about five feet of the rod on the back pin found its way through the planking of the running board ahead of the engineer's seat. Just how it got there could not be seen; for, in moving the engine a complete turn, it would not come out by eight or ten inches, and the engine was finally run to the shop with it dancing up and down in the cab. Of course in cases of this kind, the engine must be run very slowly. 2. The standard screw thread most used in America—known as the Sellers standard—was recommended by the Franklin Institute, December 15, 1864, and has been adopted by the United States Navy, the Master Mechanics' and the Master Car Builders' Associations, as well as most of the makers of screw-cutting devices, locomotive works, etc. In this screw the angle of the thread is 60°, and the thread is flat on top, and at bottom 1/8 of the pitch. The standard sizes are as follows:

Diam of Screw	Threads per Inch	Diam at Root of Thread	Diam. of Screw	Threads per Inch	Diam. at Root of Thread
1/4	20	.185	2	4 1/2	1.712
5/16	18	.240	2 1/4	4 1/2	1.962
3/8	16	.294	2 1/2	4	2.175
7/16	14	.344	2 3/4	4	2.425
1/2	13	.400	3	3 1/2	2.628
9/16	12	.454	3 1/4	3 1/2	2.878
5/8	11	.507	3 1/2	3 1/4	3.100
3/4	10	.620	3 3/4	3	3.317
7/8	9	.731	4	3	3.566
1	8	.837	4 1/4	2 7/8	3.825
1 1/8	7	.940	4 1/2	2 3/4	4.027
1 1/4	7	1.065	4 3/4	2 5/8	4.225
1 3/8	6	1.160	5	2 1/2	4.480
1 1/2	6	1.284	5 1/4	2 1/2	4.730
1 5/8	5 1/2	1.389	5 1/2	2 3/8	5.038
1 3/4	5	1.490	5 3/4	2 3/8	5.203
1 7/8	5	1.615	6	2 1/4	5.423

The Whitworth standard, used mostly in England, has top and bottom of threads rounded. Angle of Thread, 55°, depth of thread equal to the pitch of the screw.

On the Lehigh Valley.

(Editorial Correspondence.)

Last month I took a hurried look around some of the division shops of the Lehigh Valley Railroad.

The Lehigh Valley road, with leased lines, and those controlled by it, comprises 804 miles of road. But the trains of this company run over the tracks of other roads as follows: 50 miles of the Pennsylvania, 15 of the N. Y. C. & H. R., 188 of the N. Y., L. E. & W., and 21 of the Central of N. J., making in all 1,078 miles of track covered by their trains. The road proper was first chartered as the Delaware, Lehigh, Schuylkill & Susquehanna R. R. Co., in 1847, and under its present name in 1853. It is comprised of no less than thirteen different lines and branches, the longest 65, and the shortest less than two miles long.

It was the consolidation of this road with the Lehigh & Mahanoy road, in June, 1866, that gave the name to the Consolidation locomotive, the first of that popular class of freight haulers having just been completed by Alexander Mitchell, at Delano, Pa., and named "Consolidation" in honor of the event.

The L. V. road itself owns 160 locomotives, and over 42,000 cars, 27,000 of which are coal cars. The principal business of the road is anthracite coal, and in 1888 the road moved 7,050,147 tons, or 579,534,915 tons moved one mile, and at an average rate of one and a quarter cents per mile. The passenger receipts for that year were over $1,100,000, freight, nearly $2,200,000, mail and express, over $82,000, and coal, over $7,200,000—a total earning of almost $11,000,000, on an operating expense of but little over $7,000,000. So that you see the road does a big business.

I have explained before that there is no superintendent of motive power upon the road, each division master mechanic is independent, builds or buys his locomotives, as he sees fit, tries any experiment he thinks advisable, and tries to have his engines do better work and more work than the other fellow's.

There are all kinds of locomotives there, but there are very few poor ones. Most of the master mechanics were in charge of the motive power and machinery of the different roads before they were consolidated, and have under their care an endless variety of mining, pumping and coal-breaker machinery not heard of on most roads.

DELANO SHOPS.

The shops in the little town of Delano, Pa., were the original shops of the old Lehigh & Mahanoy road, and were built some 30 years ago; they are of stone, and pretty well preserved. The engines are housed in two square houses, facing each other, but some distance apart; there is no turntable; the yard in front of the houses lets engines upon a **Y** on which they are turned; the road branches several ways from the town, and engines can be headed in any direction with little trouble. This arrangement is handy enough for the location, as room is cheap, and, in case of fire, all engines can be got out of the house and away; in these houses they put a sheet-metal cover or muffler on top of the stacks to prevent the fire from burning too fast; the fires are not banked nor holes made in them. Just enough opening is left at top of stack to carry off the gas.

In the machine shop there is a good assortment of tools, many of them new, and all at work.

In the erecting shop were several engines undergoing repairs, and one new passenger locomotive, a mate to the 443, illustrated in our November issue, just ready to come out. This engine has one of the variable nozzles shown on another page, the clear opening being 5 3/8 inches, single.

Solid bronze crossheads are used, and bronze liners on the inside of guide, the crossheads having babbited strips in them.

Solid bronze is used also for eccentric straps.

Cylinder castings have a valve seat about an inch and a half high, and wear out the cylinders without the use of false seats.

Most of the engines have one safety valve, with a releasing lever back of the gauge in the cab, then a Lynde encased pop is used for regular work; the pipe from this valve case extends back to the top of the cab, and has a **T** piece on it, with ends about a foot long; these ends are drilled full of small holes, making a very good and efficient muffler, and a very cheap one.

Some of the engines have one pump, and Little Giant and Sellers injectors are used, a lever reaching from lever of the left hand one across the boiler, so that both can be used by the engineer from his position.

At this shop no screw-globe valves are put on engines—all work with a lever.

There is a large drop-pit in use, that has been in service almost since the shops were built, and seems as good as ever.

A few engines have an extension about a foot long, but most of them are provided with cinder-boxes, set outside of the front end and between the frame, all using a straight, open stack.

Hard coal engines require a large fire-box, and all the boilers extend through the cab. A hinged seat then becomes necessary, and instead of boring the cab full of holes to fasten up hinges, a light, triangular casting is bolted to side of cab; in the two top corners are slots, larger at top than at the bottom, into which the iron ears on the seat drop; at the lower corner of the triangle there is a pocket or step for the iron brace that holds the seat up—on some of these a coil spring is used to lessen the wear on the rider's spinal column. These seats can be lifted off, repaired or replaced, without unscrewing anything.

Passenger engines have a front-end buffer that folds back on the draught iron when not in use. They take off the long air hose on front of engines, and put it away, as it is used only in emergencies.

Many of the side rods have a short key entirely within the strap, the full width of the brass, that is held against the tapered end of the rod by a set-screw in the strap.

All passenger locomotives are named.

This shop, like most of the others on the road, have recently built some freight engines with wide fire-box, for burning pea coal. These are Consolidation engines, with a fire-box extending over the wheels, like the Wooten; they have a grate area of 69 square feet, and run with a six-inch nozzle. The 100, just finished here, is as neat and comfortable a freight engine as the writer ever saw. On these engines all four pairs of wheels are flanged, and, although the road is a crooked one, they cut the flanges nowhere; the D., L. & W. have always run their Consolidation engines with all flanged drivers, without trouble, giving plenty of lateral motion to the forward and back pair of drivers, and shortening the radius bar to the pony truck, so as to let the forward pair of flanges get to the outside rail. These engines have a rigid wheel base of 15 feet. The back heads of these fire-boxes are flanged *out*, so as to be easier to take out fire box; they are fitted with the Weaver grate.

A separate shop is fitted up to do frog, switch and crossing work, a great deal of this class of work being necessary around the mines. They use a circular cold sawing machine here to cut off rails. Crossing work has to be very well done, is heavy work, and is a good deal of trouble to a shop. I have never been able to see just why such a shop is not turned over to the road master's department—it would save lots of kicking.

In the blacksmith shop, a very neat little spring trip-hammer, of home make, is used to weld flues, and it does very nice work, at the rate of 200 per day.

The car shop is small, and used chiefly for rebuilding. They have in use here a very efficient end stop, for car and tender journals; it is a round bronze plate, about 1" thick, the size of the journal; on its back are two lugs for a 5/8 bolt, which goes through the box sideways, holding the stop in place at the end of the journal. It is used on journals with a collar, and is well liked, saving end wear of brasses and heating of journal; the stop is easily taken out, can be put into an old box, and is not patented.

The division officers are housed in a handsome building near the depot, and a person sitting in the handsome rooms of Master Mechanic John Campbell, finished in quartered oak, and furnished to match, steam heated and Brussels carpeted, would not imagine that he was in one of the interior villages of Pennsylvania.

HAZLETON SHOPS.

No two shops on the L. V., are alike, or anywhere near alike; the shops at Hazleton were built long years ago, principally to repair mining machinery. Most of them are very old, dilapidated and unhandy, no two shops having floors at the same level, or roofs at the same angle; there are machine tools in the boiler shop, and boiler shop tools out doors, where there is room is the place that tools have been set up. They have, however, a very nice stone engine house, but the constant settling of the ground—the town is built over coal mines—has badly cracked its walls.

Within these old shops a great deal of machinery is housed, and a vast variety of work is done. No less than twenty distinct classes of machinery are built. Some very fine looking locomotives are turned out here, and several of them have Master Mechanic Clark's cut-off gear, where a separate eccentric works a cut-off valve on top of the main valve; these locomotives make as pretty an indicator card as a Corliss engine, but the road has no place to test such a gear.

In the shop there were a couple of new Standard engines, one little mining engine nearly completed—the 61st of their build—these little fellows have been all sizes from 7x16 to 11x16 inch cylinders, and for gauges, all the way from 36 to 52 inch.

A little further away, a very large double hoister, with cylinders 17x24, and proportionately heavy machinery, is in process of erection.

At another point, a large, plain, slide-valve stationary engine is being rebuilt to an automatic cut-off.

Here are mining pumps, many having parts made of brass where the iron rusts or is eaten out too fast.

At another point, crusher rolls for coal breakers.

A large foundry is operated, and all the chilled car wheels used are made on the ground. There is a separate room for setting diamonds in drill heads, for taking out a sample of rock or mineral far under the surface.

This work has grown little by little; it is not like the work on any other road, or any other part of this road, and practical experience in the place is necessary to successfully carry it on.

Master Mechanic Clark, who, like Mr. Campbell, came up from the footboard, has had charge here a long time, knows what is needed, what can and cannot be done. He has invented a great many appliances in all departments of the work; among others, a steam driver and tender brake; this brake is handled by a foot lever on the deck.

We noticed in the machine shop a 12" circular saw, running on an arbor between the centers of a lathe, and used for cutting off flues. The flues are clamped between two plates on the carriage, in the place of the tool post, and are fed up to the saw by hand. The lower edge of the saw runs in a tin dish of oil. Flues are cut off about as fast as a boy can hand them to the man on the machine. In the erecting shop they chip out the ribs in cylinder saddles, and make a joint by pouring in zinc.

SOUTH EASTON SHOPS.

The Easton shops are the largest on the road; the original shops were small, but the present plant consists of a dozen or more of substantial buildings of brick, built within the past ten years; they are large, but pretty closely crowded together. The grounds are enclosed by a neat iron fence, a separate building housing Master Mechanic J. I. Kinsey and his assistants. Grass-plots are kept up in odd places, and there are no piles of scraps or dirt about the yard or in the shops.

All the cars used by the company are built here, and the car shops constitute a large part of the plant.

If Wm. Mason could come back to us, and would visit South Easton, he would find there a Mason Locomotive Works, very little has been changed from his Standard 8-wheeler.

I believe Wm. Mason's locomotive of 20 and 25 years ago was nearer our best practice of to-day than that of any other builder.

Wm. Mason did not claim to be the originator of his locomotive; he was a mechanic of excellent judgment, and, before he built a single locomotive, thoroughly investigated the subject, and combined the best points of all the builders. He was one of the earliest advocates of "standard" parts. He made all his eccentrics, links, rockers, etc., one size; they were strong enough for all sizes of cylinders that he built, all main rods were of one length. In after years, when he was forced to build 10-wheelers, he just added to his 8-wheeler—put on a little more length of boiler, and another pair of wheels—ahead of that they were just like his 8-wheelers. John I. Kinsey does the same.

The engines built here are therefore alike; there are less patterns and castings required for repairs, and more uniformity of work.

Steam pipes are fitted to the side of chest; cylinders, many of them inclined, are bolted to a center casting; valve yoke is the Mason fork, the main stem going through a notch in back of valve, with cross-pieces both sides, links are suspended from above the center; Mason's fancy bell stand, headlight brackets, etc. Don't imagine these engines are behind the times; they do as good work, cost as little to build or repair, and look as well as any engines running into this city.

Seven or eight engines were in for repairs, and a new one was about ready to come out—they build one about every six weeks.

In the shops the tools and the floor are kept clean; the tools are conveniently grouped, and well served with cranes.

In making crossheads, they take the rough casting, and bore the taper hole for the rod; into this bore they force a mandrel, with a taper end, and lay this mandrel across a pair of V blocks on the bed of a small planer; a collar on the mandrel, just back of the taper fit, is just the width of the body of crosshead, the part that goes between the guides; if the planer tool is set to this no other measurements are necessary for that, then there is a little post behind the crosshead, and held in a slot of the planer bed, that is just the height the tool wants to stand to finish the wings of the crosshead; by loosening the bolts that clamp the arbor to the V pieces, the rig can be turned over, another little block sets it level and the piece is finished without a measurement being taken, or a caliper used.

Piston rods are put into the piston on a taper, but against a collar, keyed, and then are riveted down.

They have in use here a very handy device for handling valve-seat planer and chest lids. Since locomotives have got so big, and the covers so heavy, it is the work of two or three men to handle them, and when it comes to putting a seat planer on, there is hardly room for enough men to get around one to handle it. General Foreman A. Turner designed and built the handiest crane I have ever seen for this work. He took a 4-wheeled platform truck, with about 12-inch wheels, and platform perhaps 3x5 feet, and built a heavy plank box, about 2 feet high, on it; on the back end of this box he built a small iron crane—gas pipe standard—and an arm that would reach perhaps 4 feet; this crane is operated by a crank, located at base of crane, through gearing, and will lift 400 or 500 pounds easily; in the forward end of this box, which has a cover, he made a place to keep the valve seat planer when not in use.

Now, when they want to take up a chest and face a seat, one man can go and get the crane, planer and all, and take it to the roundhouse or back shop. All the tools he needs to take up the chest are in the box. He can lift the cover and the chest alone, take up his planer and set it, face off the seat, replace everything, and put the rig in its place without bothering anything or anybody else. If I had a shop big enough to have a valve seat planer, I should make one of those cranes. There is a splendid, large roundhouse here, but I was told the engineers have to take out and put in their own engines. Getting out is all right, but putting engines in house, where a large number are in service, causes men to lose a great many hours time, which ought to be paid for.

On the side of one of the shops, in plain sight, and perhaps 300 feet from the office building, is a station signal box, such as used on the road; this is used in testing men for color blindness, and is a correct and just test—in the open air and using the regular road signal—but I am told that they also rawhide men a little with the yarn test.

J. A. H.

The cost of removing weeds from the South Australian Government railroads is nearly £16,000 per annum. For over three years past the engineer-in-chief has been experimenting, and he has now had constructed a machine which will weed the broad-gauge lines effectively at the rate of four miles per hour. It is believed that £1,000 per annum will be saved to the South Australian Railways Departments by using the apparatus.—*Indian Engineer.*

All the different colonies of Australia, Victoria, New South Wales, and Queensland have different gauges of railroads, ranging from 3 feet 6 inches to 5 feet 2 inches. Efforts are now being made to adopt a standard gauge.

Simple Lessons in Drawing for the Shop.

BY ORVILLE H. REYNOLDS

FIFTH PAPER.

This paper will be devoted to the construction of simple figures, affording interesting practice and familiarizing the student with a few exercises which will be useful in the shop.

Fig. 16 is a mass of diagonal squares, to construct which lay off a rectangle any size; with the T-square draw horizontal lines and with the triangle erect perpendiculars to these lines, completing the outline of figure; lay off on left side, and base, any number of equal parts, say four, and with the 45° triangle draw diagonal lines, beginning at corner, and intersect points made on side and base. Reverse triangle, and draw to meet lines already made through points on side and base.

Construct the same figure as above, and at each point found on side and base, draw a horizontal and perpendicular line respectively, producing Fig. 17; this rectangle contains a series of 45° triangles. If, now, this were a piece of metal, and grooved with a V-shaped tool at each horizontal and perpendicular line, it would have a number of pyramids whose points would be at *E*, *E*, etc.

Types of this exercise in locomotive practice are found on the tops of steam chest casings, and also on running boards, when latter are made of cast-iron, the pyramid-shaped points insuring a high co-efficient of friction on the fireman's boots.

Draw an angle of 60°, and divide it on side and base as before, using the 60 triangle for the diagonals. Many designs, as equilateral triangles, hexagons, etc., may be formed, giving good practice in handling of triangles, as well as producing some pleasing combinations of geometrical shapes.

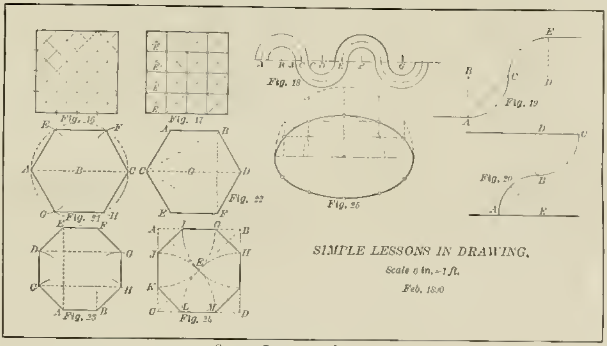
Fig. 18 is given for an example in joining of arcs; draw base line *A*, *G*, and describe a semi-circle *A*, *C*, with radius *A*, *B*. On the base line lay off radius *C*, *D*, equal to *B*, *C*, and with *D* as center, describe semi-circle on under side of the base line, perform same operation at *E*, *F*, from *F* as a center with same radius as before, but above the line, and the center line of the figure will be complete. Now lay off on each side of *C* half the width of figure as *A*, *C'*, and with radius from *D* to *A* and *C'* respectively, describe the semi-circles as shown. The successful production of this figure, simple as it looks, depends wholly on the care taken in joining the curves. Radii must be absolutely correct or the curves will not join smoothly.

Fig. 19 shows two parallel lines connected by a reversed curve made by two arcs of equal radius. Join points *A* and *E*, and bisect line *A*, *E*, at *C*; divide *A*, *C*, and *C*, *E*, equally by perpendicular lines, at *A* and *E* also erect perpendiculars to the parallel lines, then intersections *B* and *D* will be the centers from which to describe the arcs.

Fig. 20 is an example of a reversed curve of two equal arcs joining two parallel lines, when centers of the arcs lie on the parallel lines. Join the points *A* and *C*, and bisect line *A*, *C*, at *B*; then divide *A*, *B*, and *B*, *C*, into equal parts, and erect perpendiculars; the centers of the arcs will be at intersections *D* and *E*, with the parallels.

The same care in dividing the lines and locating the centers must be taken in the two last examples as in Fig. 18, if good results are expected. Figs. 19 and 20 are often met with in shop practice.

Fig. 21 shows the construction of a hexagon with the compasses. Draw the circle *A*, *C*; take radius *A*, *B*, and from *A* and *C* as centers cut the circumference at *E*, *F*, and *G*, *H*. Straight lines



SIMPLE LESSONS IN DRAWING

drawn from A to E, E to F, etc., make an inscribed hexagon.

Fig. 22 is a hexagon constructed without the compasses. Let A, B, be a given side, now the interior angles of a hexagon are equal to 120°, and the exterior ones are equal to 60°, therefore we may draw A, C, and B, D, with the 60° triangle. To find the length of the sides, locate the center between the lines A, B, and E, F, and through it draw C, G, D, with the T-square, this determines points C and D. Draw C, E, and F, D, with the 60° triangle, and the figure is complete.

An equilateral triangle may be formed by joining the alternate points on the hexagon, as shown by dotted lines, C, B, F, in Fig. 22.

To prove the construction of the hexagon, take for a radius the distance from the center to the points found, and set it off around the hexagon; if construction is correct the dividers will fall into each point.

In Fig. 23 we have an octagon, to construct this figure draw A, B; make A, C with the 45° triangle equal to A, B. At C, draw the vertical line C, D, and set off on C, D, the distance A, C, then draw D, E, with the 45° triangle to its intersection with the perpendicular line A, E. Determine H by a line through C, and intersect it by a line drawn with the 45° triangle from B; draw H, G, to the intersection of line drawn through D, and with the 45° triangle draw to F, when a horizontal line from E to F completes the octagon. This construction, it will be noticed, is entirely with the T-square and triangle; another method is to describe a circle, and step off eight points equally.

Still another and easier method of construction for an octagon is shown in Fig. 24. With the T-square and triangle produce the square A, B, C, D; draw the diagonals intersecting the center at E; from the corners A, B, C, D, with a radius A, E, describe arcs passing through the sides at G, H, I, J, etc.; draw with the 45° triangle through these intersections with the square, and the octagon is produced.

The next exercise is an ellipse (Fig. 25), and is constructed by describing two circles—one representing the major axis or long diameter, the other the minor axis or short diameter. Draw radial lines intersecting both circles, and from intersection of radii with circle representing the minor axis, draw horizontal lines. From intersection of radii with circle representing major axis, draw vertical lines, the crossing of horizontal and vertical lines gives points in the ellipse, which can be joined either by the compasses or a template of thin wood or cardboard, taking in as many of the points as possible.

The radial lines should be numerous, as the greater the number of points the easier will it be to join them smoothly, and make presentable figure.

It is not absolutely necessary that the exercises be finished in ink, they can be left in pencil if neatly done, but, as they will be milestones on the road of progress it would be well to ink them in, that they may be better preserved.

At Dickson's

At the Dickson Locomotive Works at Scranton they have a number of heavy passenger locomotives in process of manufacture for the D. & H. C. Co., and have just closed a contract for twenty-five with a new road now being built out of Scranton.

Some new wide fire-box stationary boilers have just been put up in these works. They are fired with pea coal, and the draught, aided by a blower, is regulated from the fire-room. These boilers are very large, and there is a stone pit, some eight feet wide and two deep, under the round part of boiler, then there are doors in the *front* of fire-box, from which to clean the fire. Thus there are no pokers, slice bars, clinkers or smoke in the fire room. All ashes are taken away from the pit without making any dirt, as there is room to store them and wet them down in the pit.

Locomotive boilers are here lagged with asbestos mortar, but band iron strips with projecting rivets are fastened to the boiler, and from these rivets wire is used to secure the mortar and bind it together.

These works are now making straight steam pipes in front ends, and saddles cast with steam and exhaust passages separated, like the D., L. & W. engines, described elsewhere.

Attention is here paid to getting the engineer's brake valve where he can reach it, something not generally done.

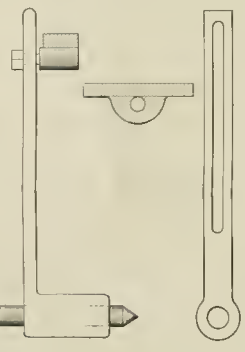
A big improvement in the quantity of scrap bar has been made here by putting all wrought scrap in a tumbling barrel, and taking off all rust and scale. Superintendent Devine says that, since this practice has been commenced, they scarcely ever lose a weld.

Valve-setting Kink.

At the shops of the Providence & Worcester road at Valley Falls, R. I., they use a very neat little kink in valve setting.

Instead of tramming from the wheel cover, guide yoke or frame to the wheel, they have a bracket that bolts on the underside of the running board, to which a tap bolt holds a slotted bar, as shown in cut; this bar carries at its lower end a nicely fitted prick punch. When this is placed over a wheel, and the point of punch brought down to the line drawn on the tire, it constitutes a tram, stays in place, and will show if the frame moves up or down on the box, though this is of little consequence.

When the point is just where you want it, a slight tap with a hammer makes a decent mark, where you want it. To insure against the device being



accidentally moved, a measurement is taken from a point on the arm below the running board to the board itself, and simply trying with a pair of dividers insures accuracy.

In a D., L. & W. Shop.

We have before mentioned some of the practices in the Scranton shops of the D., L. & W. road, but at every visit something new or different from average practice is found.

The D., L. & W. was one of the pioneer lines of Pennsylvania. Its motive power was early placed in the hands of a man of ability, and with ideas of his own, and the locomotives yet bear the ear-marks of that individuality.

The engines are all hard coal burners, have short fronts, and, most of them, diamond stacks.

The back end of boilers—with fire-box on top of frame—are inclined so as to make the tubes through the back head that hold up the grate bars, between the water grates, straight. Water grates must be inclined to secure a circulation, and many years of experience here have shown that an inclination of one and a quarter inches to the foot gives the best results.

A great many wide fire boxes are in use, with box over the wheels, and on engines of this type they are placing a heavy cross-bar on top of frame, and supporting the fire-box in the center at each side, where the expansion hangers at the back and front are alone used it was found that the frames sprung up under the box.

These big fire-boxes have crown bars over the center, and crow-feet and straight stays on the sides, many of the old boilers being changed by cutting off water leg at side seam, and putting the "Mother Hubbard" on there.

There are a great many engines with long fire-box on top of frame, but between the wheels, and many deep fire-boxes have been changed to this form. Mr. Graham, superintendent of M. P., finds in this change 18 per cent. increase of grate area.

In all new engines they are using straight steam pipes in the front end, and the walls of the live steam passages in the saddle are separated from the walls of the exhaust passage by an air space. This change cannot help but save some heat now wasted. Most of the big fire-box engines have the dome in the center of cab, and all the gauges, etc., are faced toward the engineer. Consolidation side rods have but one knuckle joint, the front one, the back section of rod is independent; this requires longer pins on two back pair of drivers, but the rods are found to wear longer, and give less trouble.

Consolidations have all drivers flanged, and they do not cut flanges as bad as some engines we have seen where half the tires were bald; the secret of this success is no doubt found in the fact that plenty of lateral play is allowed in the forward and back pair, and a very short radius bar for pony truck is used.

One neat little kink on road engines is their iron pilot plows, these plows are nearly as high as the pilot, but are made in two pieces each side, the lower piece hinged strongly to the top and folded up against it when road is clear of snow; this prevents, in a great measure, the raising of dust and dirt that is thrown upon the working parts by the movement of the air-tight plow through the air.

In the shop there is a very good cylinder boring-bar of their own make that is run by power—it is very much like the bar made by Pedrick & Ayer.

False seats have lugs on the lower side, that fit into the ports and prevent displacement of the false seat.

Snap rings are used on pistons, and, in some cases, are given a new lease of life by springing into them a ring of spring steel wire.

For lining up guides, etc., by the cylinder, the old split-hair line is discarded. They use a long bar of about 2½ inches diameter, and as long as any cylinder and guide combined, this bar fits a gland with a taper outside plug, this gland, when forced into the stuffing-box, centers the back end of the bar, and on the front end a spider is used with a taper fit for the counterbore of the cylinder. The same bar will answer for all sizes of cylinder by providing different sized heads and glands for it. This rig is strong, not liable to be sprung out of true or to derangement when once placed in a cylinder—a great fault with the line—a helper can adjust it. The fit for the bar, both in the head and gland, are long, so as to insure the taper of both pieces entering their seats fair.

This shop does all the work for the steamers, ferries, docks and coal mines of the company, and the shops are full of more or less of this work all the time.

There are two large roundhouses here, and on the occasion of our visit they were full of engines, and there were as many more in the yard. The open winter has been a dull one for coal-handling roads, and, while it has saved thousands of dollars, and much suffering to the poor, has put many of the boys on half time.

H. J. Small, Superintendent of M. P. of the Southern Pacific, says of the crews on the snow-plow trains: "The pusher engine crews remaining with their engines during the entire siege, getting what sleep they could on their engines during delays, many of their meals being prepared by themselves, using the fire-box as a range and the coal scoop for a frying pan. They thus kept themselves in readiness to obey signals at any time, day or night. It was an exhibition of endurance and fidelity to duty that is seldom witnessed." Let the S. P. officials make a note of this, and remember it when the men send to headquarters and ask some slight favor, or that a wrong be made right.

The Chesapeake & Ohio road proposes to establish a line of ocean steamers from Newport News, Va., to Liverpool, *via* New York.

The Beginning of the End.

The *N. Y. World* of February 25th has the following information:

"The telegraph operators on the Long Island Railroad have been informed that they must leave the Order of Railway Telegraphers or lose their places. This is the decree of Czar Corbin."

This order is the youngest and weakest of all the railroad organizations, and is, therefore, the one to be attacked. Such action by Corbin and other men like him are doing a great deal for organized labor, although they do not know it; there is but one defense for a weak order like this, and that is federation with all other orders, and Mr. Corbin is doing more than any labor leader to accomplish the complete amalgamation of all. We were not for federation at first, but can see only good in it now, and are therefore for it. It is all that is left except abject submission.

The Pennsylvania Railroad Company is erecting on the site of the old Mount Pleasant Park, in Jersey City, one of the largest roundhouses in the world. It will be 323 feet in diameter, and will accommodate forty-five engines. The roundhouse is to be in the centre of the new railroad yards, in which there are to be five miles of tracks.—*Ex.*

The Swinerton locomotive "Onward" is running on the C. Ry. of N. J. The elevated locomotive that is being equipped with pologonal tires has not yet been tested, but probably will some time during the month.

A great railroad man once said that if he could save what coal he could hold in his hand for each mile made, he would pay all the dividend the stockholders could wish.

The *R. R. Trainmen's Journal* has greatly improved of late, although it has long been the leading journal in its particular field. It is alive.

Illinois leads all her sister States in railroad mileage, having 10,079 miles, Rhode Island has the least—214

President Blackstone, of the Chicago & Alton, in his annual report of the road's business, under the head of "Remarks," gives it as his candid opinion that the only correct and proper solution of the railroad business of this country is for the government to assume control of and operate the railroads, just as it does the postal business. Mr. Blackstone gives at length his ideas of how this can be done, how the employes in all departments can be well selected, and politics kept out of the service just as it is kept out of the army. His idea is that when the government takes a road all employes should be considered as on probation for the first year, if they give good service for that time their jobs be then secured, and removal possible only for cause after trial, "during good behavior" being their time of service. It is remarkable to hear such a proposition from a successful railroad president, and still more remarkable to know that the sentiment is backed by the board of directors. Mr Blackstone thinks that adverse legislation and the legislative fixing of rates will eventually force something of this kind upon the country.

We have received from the inventor, H. C. Cunningham, Topeka, Kan., one of the train order files, illustrated in our issue of January. It is one of those simple little things that save time, worry and mistakes, and is well worth having

---

L. B. Eaton, one of the best known supply men in the country, who for a long time handled the Gardner governor, has taken a position with the Martin Anti-Fire Car Heater Co., of Dunkirk, N. Y.

The great Forth bridge in Scotland will be formally opened March 4th. It is the largest bridge in the world—is 8,929 feet long; there are two spans of 1,700 feet each. The span of the Brooklyn bridge is 1,595 feet.

It is estimated that there are 12,100,000 horse power in steam engines in the United States—this includes locomotives and steamers

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III. NO. 4. NEW YORK, APRIL, 1890. $1.00 per Year or 10c. a copy.

Assorted Stock.

"Now don't go and print this," said the old-timer, familiarly throwing his leg over the corner of our desk, "and I'll tell you a good little story. 'Twas a right smart while ago that I was firin' for old Hank Betters, when one night, jest as we was ready to pull out, a saw-mill-looking chap came up and struck Hank fur a ride."

"Ever carry ingineers?" said he.

"Well, yes," said Hank, "when we can get the real article put up in their own juice."

"I'm a ingineer, and I wan'ter get over the road."

"What road ye offon?" said Hank, wipin' his hands on a bunch of waste.

"Empire Line," said he, namin' a fast freight line, that don't own a single ingine.

Hank knowed in a minit that that feller was no railroader, and like as not would take to the brush if the pop went off; but he reached right out for the feller's hand, give it a hearty shake and says:

"Why, yes, I remember you now, uster run over there myself; couldn't place you for a minit; yes, yes, you uster run one of them ingins with *one* driver and *two* startin' bars, had ter key 'em up with a shovel—Barrow ingins—I remember 'em. You was a good runner on a grade, but they are awful particular here and we can't carry ye; good-night."

Parliamentary investigation into the running of trains on railroads entering London from the south, shows that, upon an average, only about 60 per cent. of passenger trains enter the city on time.

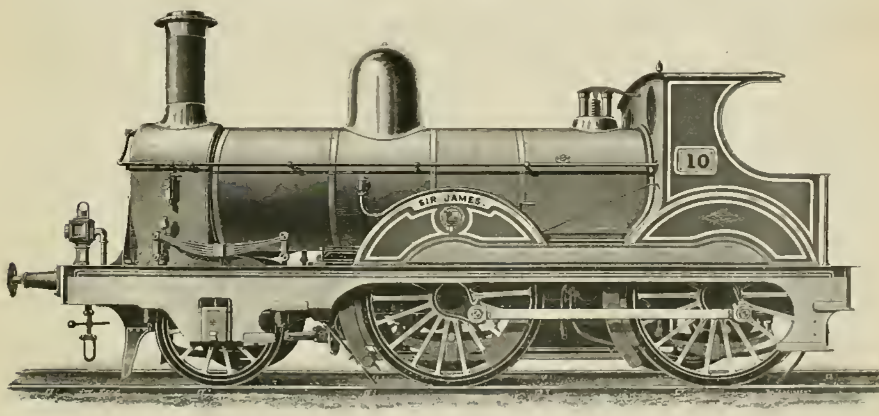
An Irish Locomotive.

The accompanying picture, for which we are indebted to *The Engineer*, London, Eng., represents the very latest design of engine used on the Irish express trains.

The engine was built by Dubs & Co., Glasgow, from the designs of Mr. John G. Robinson, Locomotive Superintendent of the Waterford & Limerick Railway. The engine is of the Irish gauge, 5 feet 3 inches.

The leading springs are of a pattern not used in this country, and were, we believe, designed by Mr. Gooch, of the Great Western road.

The engine we illustrate is named after the present chairman of the line, Sir James Spaight, J. P. The following are the principal dimensions:



An Irish Locomotive.

Diameter of cylinder	17 in.
Stroke of piston	24 in.
Diameter of wheels, coupled	6 ft.
Diameter of leading wheels	4 ft.
Working pressure	150 lb. per sq. in
Heating surface in tubes, brass	1,000 square feet.
" " fire-box	110 " "
Total heating surface	1,110 " "
Area of grate	18 " "

The total weight of the engine, in working order, is 81,676 pounds, of which 55,328 pounds are on the drivers.

The automatic vacuum brake is fitted to the coupled wheels and tender wheels. The leading axle is fitted with traversing axle-boxes, with inside and outside bearings.

The tender holds 2,000 gallons of water, and 3½ tons of coal. It is carried on six wheels, and weighs fully 50,300 pounds. The total wheel base of engine and tender is 35 ft. 2 in. The engine has given entire satisfaction, and reflects great credit on the builders for workmanship and finish.

Comparing this locomotive with American 8-wheelers, with which our readers are all familiar, will show them the essential difference in practice between the two countries.

The cab is the most noticeable difference, except that this engine is inside connected. The total absence of equalizers would make this a very hard engine to ride on our uneven roads, and the coupling arrangements, with provisions for taking up the slack, seem light, trappy and slow.

The Ramsbottom safety valve, so common in Europe, is never seen here; in this arrangement two valves are held to their seats by one spring.

In one of the little strips of green park in the streets of Macon, Ga., there is a monument to the memory of Wm. M. Wadley, who died in '85, president of the Central Railroad of Georgia. This monument was raised by the employes of the road of which he was the head, "To the memory of a good man, who came up from the ranks."

On March 10th, a special train on the Pennsylvania made the trip between Washington and New York in 4 hours and 17 minutes, beating the record 55 minutes.

The Master Car Builders will meet at Old Point Comfort, Va., in June.

Out of Town.

John Rice, of Freeport, Ill., sends us this clipping from *Owen's Work*, and asks us what we think of it:

"Bagging or bulging of boiler-plates over the fire is in nearly every case traced to the use of oil in the boiler. Oil is inadvertently fed to the boilers by the false economy of turning the exhaust steam into the water tank, where the oil is caught and pumped into the boiler. Oil gathers the scum and dirt into a cake, which settles in a crust on the crown sheet, keeping the water away from the iron, which becomes heated, and the pressure causes it to bulge down."

We think the mechanical editor of the above paper is away at present. One door does not make a building.

Manly Action.

Under the new schedule of wages that is to go into effect March 1 on the Rock Island, freight engineers, who have been receiving \$4.15 per 100 miles, will hereafter receive \$4. On the Chicago, Kansas & Nebraska branch of the road, the engineers who have been receiving \$3.85 will hereafter receive \$4. The heretofore existing four grades of engineers will be reduced to three. Passenger engineers on all trains will receive 3½ cents per mile, and switching engineers \$2.70 a day.

It is easy enough to say, "The men on the other end of the road are not getting standard pay, and must have it"; but when a body of men say, "The boys across the river are getting less than full pay, we are getting a little more, cut us down to standard, and raise theirs up to it," it shows more of a brotherly spirit than usually exists.

We should have been glad to see all the men on the road get \$4.15, but there was no hope of that, and the way things were evened up speaks volumes for the spirit of fairness in the rank and file. Besides that, they got rid of one grade of pay. This road had four grades—one is enough.

Relief Cock for Air-Brake Reservoir.

Harvey S. Park, of Chicago, has just sold to the Westinghouse Co. a neat little invention of his, in the shape of a relief cock for auxiliary drums on automatic brake cars.

All railroad men know the result when the pressure in the train pipe and engine drum is not sufficient to release the brakes and re-charge the drums—either the air in the drum must be reduced, "bled," or that in the train pipe increased above the pressure at which the refractory brakes are set. With a long train this is a slow process, and the usual plan is to open small cocks on the drums provided for that purpose; this is wasteful of air, takes time, and there is always danger of the cocks not being closed properly.

With Mr. Park's invention, all that is necessary is for the trainman to pull the valve open—it closes itself automatically.

The valve is screwed into the reservoir, and a wire or cord attached to the levers, as shown, is run to each side of the car, to facilitate handling.

In the body of the plug there is a stem E with a piston B; on the lower end of this stem there is a valve F, on a seat a, and held there by the pressure, and also by a spring l. When it is found necessary to "bleed" a car, the cord or wire is pulled and the end of one of the levers h pushes the stem down and opens the valve F, the air follows the passage b and enters the chamber P above the piston, forcing and holding it down, and escapes through the port d and the passage c.

As soon as the pressure is reduced below the pressure required to compress the spring, the latter will force up the stem and close the valve.

Thus it will be seen that a relief valve is obtained, the normal condition of which is closed, but which can be opened instantly, and will of itself close, requiring no attention other than opening it.

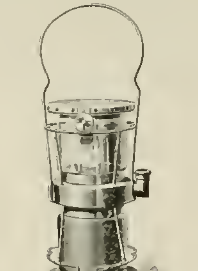
There is no doubt that this little device will save time and worry, and be another safeguard in the automatic brake equipment.

A Double Lantern for Railroads.

On this page will be found an engraving of the Metzler reversible lantern, made by the Metzler Lantern Company, of Philadelphia, Pa.

This lantern has been on the market for two or three years, and has been improved and developed up to its present standard. It is about the height of an ordinary lantern, but the globes are slightly shorter, and the cap and base, which are alike, are broad and flat. The oil tank is in the center of the lamp, with the filling cap outside, as shown on the right of the cut; this admits of filling without opening the lamp in any way.

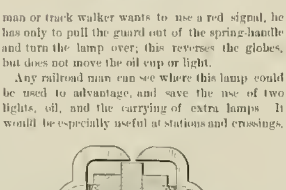
Two globes are fitted as shown, and, of course, can be of any colors, preferably white and red, the upper globe surrounds the light, the lower one is darkened by the oil cup. If a trainman, station



RAILROAD SIGNAL LANTERN.

man or track walker wants to use a red signal, he has only to pull the guard out of the spring-handle and turn the lamp over; this reverses the globes, but does not move the oil cup or light.

Any railroad man can see where this lamp could be used to advantage, and save the use of two lights, oil, and the carrying of extra lamps. It would be especially useful at stations and crossings.



RELIEF VALVE FOR AIR-BRAKES.

The Best Agreement in America Between a Railroad and Its Engineers.

The following agreement between the management of the Central Railroad & Banking Co., of Georgia, and the engineers of the line, is the best one for the men we have ever seen, granting at once more privileges, more rest, and greater pay for the work done. Further reference to this case will be found in our editorial columns.

1st. The pay of enginemen on all divisions except the South Carolina shall be as follows: Enginemen, \$4 per day for every day they are on duty, Sundays included. Enginemen on work trains, \$3.25 per day for every day they are on duty, Sundays included. Enginemen on switch engines shall receive \$3 per day for every day they are on duty, Sundays included. Twelve hours to constitute a day's work, one hour for meals. Enginemen on branch roads, where their run is 60 miles or less, shall receive \$3 for every day they are on duty, Sundays included. When their run is over 60 to 100 miles, \$3.75 per day for every day they are on duty, Sundays included. Where their run is over 100 miles, they shall receive \$4 per day for every day they are on duty, Sundays included.

For the South Carolina Division the pay of enginemen shall be as follows: Road service, \$3.75 per day for every day they are on duty, Sundays included. Work trains, \$3 per day for every day they are on duty, Sundays included. Switch engines, \$2.50 per day for every day they are on duty, Sundays included. Branch roads, \$3.75 per day for every day they are on duty, Sundays included. The three enginemen now receiving \$4 per day shall remain so, for every day they are on duty, Sundays included. Enginemen shall be construed to be on duty so long as they are subject to be called on, and respond to service, that is, until they are suspended, discharged, or leave of their own accord, on leave of absence, or do not respond.

Where men are not now receiving the rates of pay herein mentioned, it is agreed that they will be advanced thereto from date of this agreement.

2d. When, in the judgment of the company, a diminution of force is necessary, the men promoted within the last twelve months from date of this agreement shall be reduced in order of seniority, to trains and engines of lower grade, and to firing. If further diminution is necessary, the engineers promoted prior to the time herein mentioned will then be suspended in order of seniority, and for pro rata time.

3d. Enginemen of freight and passenger trains shall not be required to run more than one consecutive round trip at night (embracing two nights), nor two consecutive nights on first division of main stem, and Macon to Montgomery, and Columbus to Birmingham, except in cases of emergency. Should this emergency arise, he shall be paid an extra day. All runs shall be so arranged as to afford a proper amount of rest to each man. All delays of more than two hours over schedule time shall be paid twenty-five cents per hour, first hour included.

4th. Enginemen on all freight trains shall run, first in, first out, from all terminal or relay points.

5th. Hostlers shall be provided at Savannah, Macon, Atlanta, Columbus, Birmingham, Montgomery, Albany, Augusta and Port Royal; but nothing in this article shall be construed to prevent the master mechanic from requiring the men to report at the roundhouse for the purpose of giving their engines proper attention, and after they give their engines proper inspection and attention they shall not be required to stay at the shops any longer.

6th. Enginemen of trains leaving Savannah, Macon, Atlanta, Columbus, Augusta, Montgomery, Birmingham, Albany, and all other terminal and relay points, shall be called between the hours of 9 o'clock P. M. and 6 A. M., one hour before leaving time. The caller shall have a book, which the party shall sign at the time he is called, for a radius of one mile, as long as one can perform the service at each place.

7th. An engineman who may be suspended will be given a hearing within five days from the time his report is rendered, with the understanding that the company shall take as much more time for the investigation as they may deem necessary, at their own expense. In the event the decision of the division officers be deemed, by the party on trial, not to be in accordance with the evidence developed, or to be unduly harsh or severe, he shall have the right to appeal to the general manager, in the event he is not found at fault, he will be paid for lost time. The investigating committee shall consist of division superintendent, division master mechanic and a general grievance committee man.

8th. At all points where there are roundhouses and foremen, enginemen will not be required to clean out boilers, or pack engine or tender trucks; but this article shall not be construed to relieve them from taking reasonable care of their engines, and doing the usual work thereon.

9th. There will be a place provided in southwestern yard at Macon, where enginemen will put the engines of all freight trains when hostlers are not on hand to relieve them. Hostlers will be furnished with books in which engineers will be required to report work to be done on engines. Hostlers will register for engineer whom he relieves.

10th. When engineman is off sick, his time will begin from the time he reports for duty.

11th. Enginemen attending court or other business for the company, which takes them from their engines, will be paid full time and necessary expense.

12th. All matters not covered by this agreement shall be determined by the present practice of the company.

13th. There shall be an examining board, consisting of three engineers for each division, selected by division master mechanic, to examine all applicants for position or promotions.

14th. This agreement shall be and remain in force for the period of one year from date thereof, and shall not thereafter be changed by either party, except after ninety days' notice in writing to the other. Either party violating this agreement intentionally shall be dismissed from the service of the company.

Improved Form of Steam Pipes and Passages.

The accompanying illustrations show the modifications in steam pipes and saddle passages designed by Supt. of M. P., Chas. Graham, of the D., L. & W., and used on that road. This form of pipe and passage has also been adopted by the Dickson Locomotive Works.

Instead of the old-style of steam pipe, with a short **T** pipe, or "nigger-head," with the faces of ball joints on each end of pipe at right angles to each other, this pipe is perfectly straight. The **T** pipe extends out on the sides, to make the joints come directly over the passage in the cylinder, a double ball joint is used at the junction of the **T** and steam pipe proper, and the joint is held by a single large bolt going through the pipe and **T** with a ball joint under the head; no shearing or twisting strain can be brought on any of the bolts.

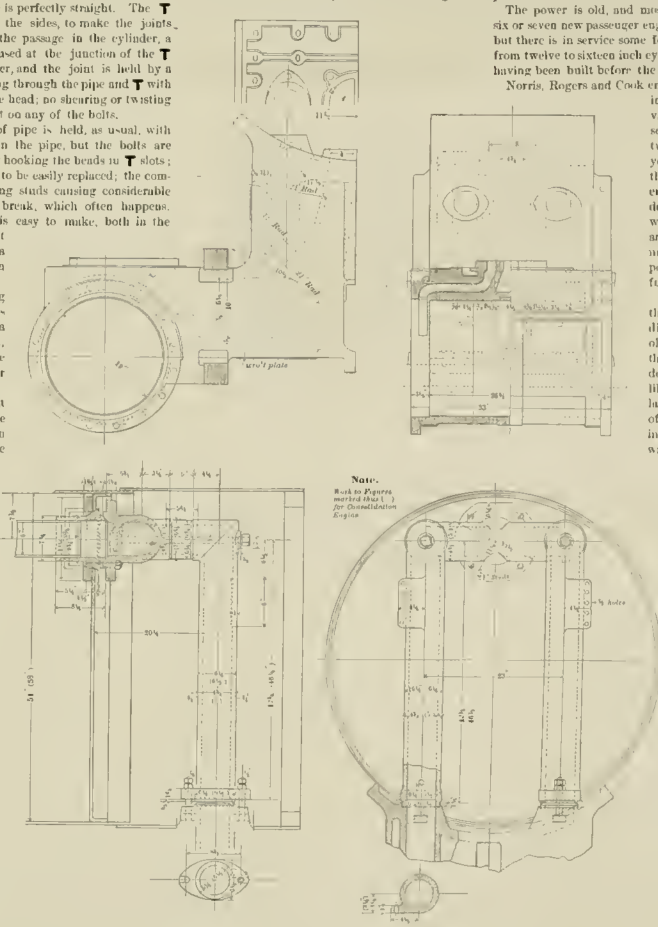
The bottom joint of pipe is held, as usual, with bolts through lugs in the pipe, but the bolts are held to the saddle by hooking the heads in **T** slots; this allows the bolts to be easily replaced; the common practice of using studs causing considerable trouble when they break, which often happens. This straight pipe is easy to make, both in the foundry and shop; it can be swung in a lathe or easily set on a drill press or mill.

By casting a long lug on each pipe, as shown, and drilling a number of holes in it, a substantial and true support is made for draught pipe.

The improvement in cylinder saddle passages consists in separating the live steam passages from the exhaust passage and the outside of the saddle casting by an air space; in no place does one wall of metal separate these two passages; on the side of the saddle there are two openings covered by circular wrought-iron plates, and another and larger one at the bottom of the saddle; these allow inspection, and are convenient in making the castings.

Where live steam, at least 100° hotter than the exhaust, is carried for a long distance only separated from it by a half-inch wall of cast-iron, a splendid conductor, a great deal of heat must be abstracted by the cooler body and lost. This form of saddle costs very little more than the old style, and must result in a saving of heat—just the same as covering a steam pipe does.

To save making separate drawings for different classes of engines on this road, two sets of figures are used, those enclosed in brackets ( ) being used only for consolidations.



Improved Steam Pipes and Passages.

S. A. Alexander, of York, Pa., has a new edition of his well-known Ready Reference for Enginemen, out for 1890. It goes without saying that it is better than those that have preceded it—and there were no winged insects on them.

A Railroad With a History.

During a recent visit to the South the writer had the pleasure of riding over the line and visiting the shops of the Western & Atlantic Railroad.

This little road runs from Chattanooga, Tenn., to Atlanta, Ga., a distance of 138 miles; it has 44 miles of sidings and branches, making in all 182 miles, it is standard gauge, laid with 56 pounds steel rails.

This road was built by the State of Georgia in 1850, it was valued at $8,000,000 in 1870, when it was leased for twenty years to the present company, who give bonds for the full value and pay $25,000 a month into the State treasury as rent.

There are some sixty locomotives in use and about 1,200 cars.

During the war this road was one of the principal arteries of supplies to the Confederacy, and many of its stations are historic, as the stage on which many a hard fought battle was won and lost.

With its northern terminus at the foot of Lookout Mountain it follows the winding Chickamauga, whose waters have been red with human blood, and runs almost directly south to Atlanta, Ga., passing through, on the way, Big Shanty, Kenesaw Mountain, Marietta, Smyrna and other battlefields.

The road is pretty well built, and a good deal of it stone ballasted, but the heavy rains at the time of our visit had softened up the bed so much as to show many low joints. It is easy to see that the road is no old one; large trees are growing in the pits dug to make the embankments.

The shops are at Atlanta, and are under the charge of Master Mechanic M. L. Collier, the shops are old and small, being little buildings built against the outside of a roundhouse that is a complete circle.

The power is old, and mostly small, they have six or seven new passenger engines that are modern, but there is in service some forty locomotives with from twelve to sixteen inch cylinders, many of them having been built before the war.

Norris, Rogers and Cook engines, that have been in battle, are here. A visit to the roundhouse seems like going back twenty-five or thirty years for a like visit, there are the little old engines with a preponderance of brass, many with the steam chest and cylinder heads left uncovered, and the iron polished, and all gracefully showing their age.

In the roundhouse there are a half dozen dismantled and rusted old hulks of this sort that have been long dead, and now seem like honored remains laying in state. In one of the stalls, undergoing extensive repairs, was the "General," the engine stolen from the Confederate camp at Big Shanty, in 1862, by a number of daring Federal scouts, and run north in an attempt to destroy the bridges on the line, and cut off the supplies of the Confederate army at Chattanooga.

One cannot look at this old engine and not feel a thrill for the brave men who fought and died over her in the great national struggle. The reason that these old engines are still in service is undoubtedly caused by the fact that the lease is about to expire, and the officials of the State are unwilling to allow the lessees anything for betterment of the equipment.

They have one kink here that looks worth copying; they use but one cylinder cock to a side, and that is located in the center of a pipe from each end of the cylinder; this cock can be made of good size, reduces the number of valves to keep ground in, and does away with considerable light rigging.

The turntable here was too short for the new engines, and Mr. Collier lengthened it in a novel way. Close to the outside of the rails, about six feet from one end, he pivoted heavy iron bars, perhaps three or three and a half inches square, at the point near the rails these bars were drawn to a thin wedge, and the other end was left full size and slightly bent up; there was heavy support put under them at the end of the table, but they were left free to be moved sideways, and on the pivot at the small end; when an engine is to be turned, whose wheel base is longer than the table, the outer ends of these heavy hooks are placed on the rail, and a pin holds them there, then the tender truck is backed upon the inclined extension, and the engine is turned with one pair of wheels elevated above the tracks converging at the turntable.

All the engines are named; most of them are equipped with steam driving brakes, diamond stacks and short fronts are the rule, but the new engines have the extension and the open stack.

The road is a connecting link for several lines, and has a very heavy local trade, the earnings of the road amounting to about a million and a half of dollars annually.

It looked rather strange to see several sections of every freight train with one of those little engines ahead of each section, they are rated all the way from five to twelve cars. A consolidation of modern size could pull forty cars there easy; but in order to use such heavy power the bridges on the line will have to be renewed, and that will take some time.

It is a good road for engineers, as they get $4 per day whether they work or not, with a good rest at each end of the line.

A Peculiar Journal Brass

The journal bearing shown on this page has been patented by F. W. Johnstone, Supt. of M of the Mexican Central Ry.

Attempts to increase the bearing surface of journal bearings by extending the brass downward and enveloping more of the journal result unfavorably on account of the brass hugging the journal as the crown wears down, thus increasing the amount of pressure brought upon it without adding to the support of the load carried, and the result is a more rapid wearing away of journal and brass, and a tendency to heat. Mr. Johnstone overcomes this difficulty by making the brass in three parts, the center portion forming a crown bearing, and the two wings pivoting upon it in such a manner that the load which rests upon them is thrown upon the journal at right angles to its periphery, thus avoiding any tendency to wedging and hugging the journal, as each square inch of bearing surface supports an equal proportion of the load, and at the same time brings it to bear upon the journal in as favorable a position as that supported by the crown bearing or center piece.

It will be seen that all the load carried rests upon the two wings. If, then, we have 8,000 lbs. on a journal, the load is so distributed that 4,000 lbs. is carried by the crown or center piece, and 2,000 by each wing, which is in proportion to their areas of effective bearing surface.

In the ordinary M C. B. brass bearing 3¾x6¾, there are 22.78 square inches of effective bearing, while with this divided brass the bearing is 4½x6¾, equal to 30.87 square inches, or 33 per cent. more than the M. C. B.

This large increase of bearing decreases the pressure per square inch, and allows of more efficient lubrication. These brasses have been giving good results on the truck and tender journals of the Central Mexicano engines for the past four years, and the wear of the brasses has been found to average but one ounce loss in 1 976 miles.

Coroner Lindsay, of Brooklyn, held an inquest, last month, over the body of Daniel Ostrander, one of the employes of the Kings County Elevated Railroad. The deceased was cleaning the engine at the Eastern Parkway and Pennsylvania avenue, when he was struck by some projection, and had his skull fractured. A verdict in accordance with the facts was rendered. Cleaning outside while a locomotive is in motion is at once dangerous and careless. If firemen are required to keep their engines clean, they should be given an opportunity to clean while engines are standing still.

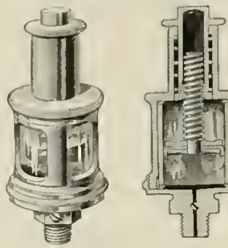
The C., B. & Q. have just ordered 6,750 sets of air-brake for freight service. The road will be entirely equipped at once.

An Improved Grease Cup.

For many purposes heavy grease is taking the place of thin oil, and its use has been a success on locomotive pins, guides and trucks on a number of roads.

The cup here shown has some conveniences not found in other cups of its kind, and is, withal, a very neat and attractive cup. It is filled by taking the cup off the base, and screwing the piston up, when the cup is filled the screw is relieved and the large spring shown around the top sleeve compresses the grease, forcing it out of the feed hole at the base.

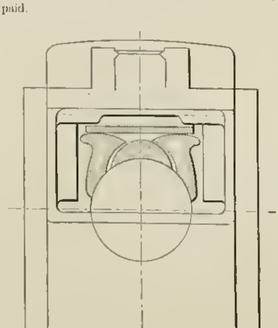
This feed is an important feature of the cup; it can be adjusted, opened or closed by simply turning the screw head shown in the shank of the cup, the body of the screw being a small plug valve as shown in the detail. Most grease cups require the relief of the pressure by screwing up the piston; this leaves the feed open.



Benners Grease Cup.

The cup is heavy, has no sharp projections, and the glass enables the engineer to see and regulate the feed It is being placed on the market by The Benners Lubricating Company, of Elizabeth, N. J.

Air-Brake Practice, by J. E. Phelan, is now ready for delivery. The book is gotten up in first-class shape, and will be sold at $1 25, postage paid.



Peculiar Journal Brass

M Nicolai, the engineer at the head of the commission that has been investigating the question of a Siberian railway for the Russian Government, has reported that the whole line can be completed by 1900, at an expense of about $130,000,000.

Don't always wait for a precedent—do things because you think them right, not because some one else has done them.

Send for club rates for Phelan's book on Air-Brake Practice.

The Lake Shore Accident.

On the evening of March 6th, a passenger train on the Lake Shore road broke in two, at a little place called Hamburg, near Buffalo, and the rear part crashed into the forward section, killing six people, and injuring seventeen.

The train consisted of ten cars, four baggage and express, two day coaches, four Wagner sleeping cars, and one dining car.

At Dunkirk the train parted in starting, the five Wagner cars breaking off, this was caused by a Cowell and Miller coupler coming together; in breaking apart, an air-hose was pulled off, and the brakes on both sections of the train were set.

The cars were coupled with link and pin, and a car repairer got a hose to put on in the place of the ruptured one; but the conductor—as he testified himself, before the coroner—told the repairer to let it go, as they had brakes enough to hold them, and went ahead after bleeding off the brakes in the rear cars, and closing the cock in rear end of pipe on the last day coach.

The train ran some 30 miles in this condition, and again parted. The train passed one station, where the people on the platform noticed that the] cars were some three feet apart, and it is thought that it ran some two and a half miles in this condition. One of the passengers testified that the bell rope was not stretched hard enough to break it, until a few minutes before the crash.

The conductor was on the forward section of the train, and when he found that it had parted, signaled the engineer to stop.

The engineer testified that the brakes were applied from the train, and the stop made without his help.

Be that as it may, the rear cars crashed into the forward part of the train, telescoping the day coach, with the fatalities recorded above.

The conductor was a man of 30 years' experience, and he testified against himself in a manly way, taking upon his own shoulders the whole weight of blame. He swore that he prevented the replacing of the hose, to save time, that, had it been replaced the accident could not have happened, that he could have prevented the accident by switching the car with defective coupler behind, or by setting it out, that the accident could have been prevented had he manned the hand-brakes of the rear part of train, and notified the men to look out for a breakaway. None of these things were done, and the conductor honorably takes to himself the blame, and says his anxiety to make time caused the death of the people in the coach.

As soon as the conductor stopped the forward part of the train he jumped to the ground, saw the rear end coming at high speed, and, realizing what he had done, wildly signaled with his lantern to the engineer to go ahead. This the engineer tried to do, but could not, because he could not release the brake.

The conductor says he does not remember of having opened the conductor's valve in the cars, and does not think he did.

It is plainly evident that the conductor, suddenly realizing the blunder he had made, lost his head; he was a man of too much experience to have stopped the forward end of the train with his wits about him.

Most of the papers in the country blame him, and justly, for gross carelessness, one or two blame the management, averring that they insist on fast time, and will brook no delay—there may be something in this—but it remains for the *Engineering News*, of this city, to blame the engineer equally with the conductor.

We quote from its columns:

"If a train in this condition was to be run at all, one would have thought that all the train crew would at least have been on the alert, since they must all have known of its condition, in a general way at least, and a second breakaway was the most natural thing in the world to expect. Had they been so alert, it should have been easy to stop the rear part before collision, or at least greatly diminish its force, by hand-brakes, for too much has been made of the down grade on which the breakaway occurred It is only 16 ft. per mile, and 3¼ miles long, falling 52 ft. in all. Not a single man of the crew was, in fact, on the alert. The breakaway was not discovered for some time after it occurred, and when it was discovered, the conductor did at once what it is drilled into every railroad man from his youth up must not be done under any circumstances in such a case. He gave the signal to stop, two taps of the bell, thus showing that he had been giving no serious thought to the condition of his train, for it is inconceivable that he was not aware of the danger of such a stop, before it was certain that the rear part was stopped. Much has been made of this incident, as if he were alone to blame; and his conduct was certainly the extreme of negligence. But this alone would not have caused the accident. The engineman was almost equally to blame He admits having previously received from the bell cord, when it parted, the significant *one tap* signal, which is recorded in all train rules as meaning, 'train parted,' and then the Lake Shore rules, as well as common sense and general practice, require that 'the forward part must not stop until *the engineer* is sure that the rear part of the train has stopped.' To this signal however, as also to a succeeding one, he says he 'paid no attention.' He claims that he had nothing to do with stopping the train, but that brakes were applied from the train, and he 'could not release them,' but his testimony on this point seems most doubtful, and he *could have released them, even if so applied, had he been on the alert and made the effort in time.*"

The last sentence simply shows that the writer knows little of the principles of the automatic air-brake. The engineer could not release the brake in *any* length of time unless the conductor's valve in the cars was closed—if the brake was applied from there. The only way to release the brake, is to establish a pressure in the train pipe *greater* than that in the brake cylinders; and it is plain that this cannot be done when a valve is open, or there is any other opening from the train pipe to the atmosphere.

It is far from our purpose or our spirit to hold an engineer blameless, simply because he is an engineer; but it seems that this man was helpless, and the brakes—for the time being—beyond his control.

That our esteemed contemporary does not know what it is talking about, when it gets on the subject of air-brakes it is only necessary to quote it again. Speaking of the bad condition of the couplers on the rear part of the train, it says

"And with the air-brakes on them absolutely useless and dead. *For, although there was doubtless much air pressure still remaining in the auxiliary reservoirs under each car, the train pipe being entirely open to the atmosphere through the unrepaired brake, made it impossible to utilize this air for braking.* The brakes were only released after the first break, by bleeding each car separately."

The italics are ours.

All men who know enough about the air-brakes to publicly accuse other men of manslaughter for not handling it properly, ought to know that it was impossible to release those brakes, when set at Dunkirk by the first break, without restoring the pressure in the train pipe, or bleeding out *all* the air in the brake cylinders and auxiliary drums. So long as there was a pound of air in the auxiliary drums and the train pipe was open, the brakes would set. So there could have been no air there to "utilize for braking."

One thing is certain—had the automatic brake been kept intact and given a chance, no accident would have happened, as it was the brake on the forward part of the train helped make the accident more severe.

When the automatic brake was first put into use it was thought that the conductor's valve in each car was an additional safeguard, and a cord was run from it the entire length of the car, but it was soon found that passengers meddled with it, and accidents were caused, and after the Spuyten Duyval disaster, a few years ago, the cord was taken out of pretty much all the cars in the country, leaving only a connection outside the closet. The old conductors' valve closed against a rubber seat with a spring, and when the handle was released they would close themselves, but they leaked and required attention, and it was thought best to replace them with a common plug cock, that had to be opened and closed by hand; with this arrangement it is possible to set the brakes and prevent their release, by opening this cock, just as the engineer claims was done in this case.

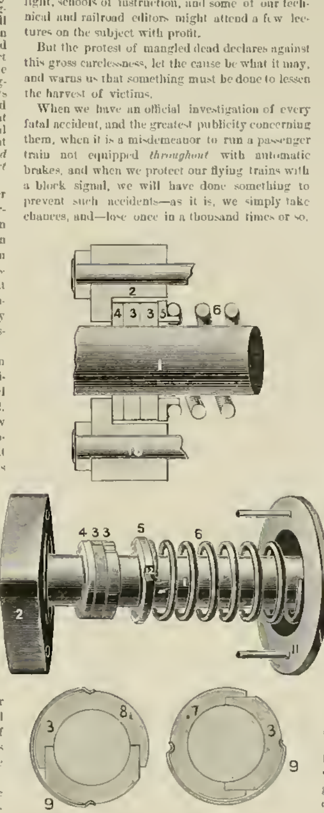
The writer has had some practical experience in the matter, and has long contended that these valves were a positive source of danger instead of safety, and we think their removal would be a good thing. It should be against the rules of any road, for trainmen to stop a train except in an emergency, and then a wire from each hose-head coupling to the end sill of the cars would make it an easy matter to disconnect the hose.

The engineers, as a rule, know more about the brake than other trainmen, and are therefore better able to handle it—there is many a trainman to-day that believes that air pressure holds the brake *off*, and that its reduction allows springs to set it.

What is wanted in this air-brake business, is more light, schools of instruction, and some of our technical and railroad editors might attend a few lectures on the subject with profit.

But the protest of mangled dead declares against this gross carelessness, let the cause be what it may, and warns us that something must be done to lessen the harvest of victims.

When we have an official investigation of every fatal accident, and the greatest publicity concerning them, when it is a misdemeanor to run a passenger train not equipped *throughout* with automatic brakes, and when we protect our flying trains with a block signal, we will have done something to prevent such accidents—as it is, we simply take chances, and—lose once in a thousand times or so.



The Partington Metallic Packing.

The accompanying illustrations show a metallic packing constructed on an entirely new principle, and of a different material from any other packing—the invention of a practical engineer of more than forty years' experience.

All other metallic packings have a common plan—the spring and steam forcing soft metal rings into a cone, thus closing them upon the rod.

All of these packings have one fault—they pinch the rod when steam is shut off and the engine is drifting, and in long runs down hill it often happens that the rings are hammered through the collar and come out as thin as tin.

In this packing no cone or small rings are used, and when steam is shut off there is no pressure on the rod, the rings are heavy, about three fourths of an inch square, and they are made of soft cast-iron.

The packing can be applied to any locomotive without altering in any way the stuffing-boxes.

The gland has a square recess in it, somewhat larger than the packing, and it fits steam-tight on the cylinder head Fitting the rod loosely is a heavy babbitt ring 4, that forms the joint between the gland and the first packing ring 3. There are two of these rings, made of charcoal iron, with a joint as shown in the detail drawing; the joints of the two rings do not coincide, and are kept from getting together by a pin in one ring loosely fitting a hole in the other, as shown. Behind these rings a brass ring fits flatly against the packing without touching the rod and supports the spring; this ring has openings on its outer surface that admit steam to the outside of the packing rings proper; the mission of the flat spring being merely to keep the pieces of ring in place.

The steam pressure closes the rings on the rod, and in drifting down hill this pressure is relieved and there is no tendency to crowd the rings into a cone.

We have been shown a set of these rings taken from a wrecked locomotive on the Canadian Pacific road, that have made over 50,000 miles, and the inside surface looks like a mirror.

This packing has been in use for some four years on the steamboats and on some of the locomotives of the C. P., and none of it has been worn out.

T. A. Summerskill, M M of the C. P at Portage La Prairie, Man., says he has it on a passenger locomotive that has made 80,000 miles without a leak or perceptible wear either of the rod or rings, and he estimates its life at 300,000 miles.

All the parts being larger and of stronger metal than other packing, there seems to be little reason to doubt its long life.

It is being introduced by Thomas Wallace, of 39 Nassau street, this city.

Byram Lodge, No. 271, Brotherhood of Locomotive Firemen, at Port Morris, N J, are building a hall and storehouse on the share plan—the lodge itself putting the surplus money in its treasury into shares, and individual members taking the remainder. The rents on storeroom, it is believed, will more than pay all interest, taxes, etc., and the lodge becomes a landlord, not only for its own hall, but for others beside. The plan appears to have been carefully worked up, and there seems little or no chance of failure. There may be the germ in this of a safe and profitable investment for lodge money, and the savings of individual members. If a little lodge like this, with less than 40 members, can see their way clear for a brick block, what could some of the city lodges of 200 or more men do in the matter, if they but put their minds to it?

Jenkins Bros., of this city, make more steam valves than any other concern in the country. The peculiar qualities of the metal they use for seats, which is not affected by heat or cut by wear, has given them an advantage over other makers. Why valves with Jenkins disks are insisted upon for steam heater work, and forgotten in locomotive work, we can't find out. The disk saves lots of grinding in. These valves have recently been reduced in price to a level with the common brass valve.

On the E. T., V & G. road, we saw in use seamless felt wicks for headlights These are so much better than Canton flannel wicks, are so much easier to put in and keep in shape, that engineers themselves would be glad to buy them if they but knew where to get them. They cost 25 cents a dozen, but we could not find out who made them.

The Savannah, Florida & Western burn more wood than coal, fat pine being very cheap along the line, less than two dollars per cord, while coal is dear. They have modern engines, but use the big balloon stack. It is one of the very few southern roads still employing colored firemen

---

A number of letters have been received asking us to republish the whole or part of the Examination Questions by Mr Cushing. This we cannot do so soon, but back numbers containing the questions can be had either at this office or through any newsdealer.

We have a picture of an engine known as the "Mud Digger," on the B. & O., years ago. Who knows anything about her?

Relief Valve for Wheel Presses

In the wheel room of the Philadelphia, Wilmington & Baltimore Shops, at Wilmington, Del., they have in use a very efficient relief valve for hydraulic wheel presses, the invention of the foreman of this department, Jos. M. Meloney, who has recently secured a patent on the same.

Fig. 1 shows the device as applied to the press, within easy reach of the operator. Fig. 2 shows the valve in detail. It will be seen that the valve 1 is held against its seat by the spring and the pressure, and that its upper end, at 3, is packed with rings to prevent annoyance from water; there are three openings from the valve chamber to the pump's body, as shown. The cam lever comes against a stop at 4, and its movement is from the operator, and only a short movement is necessary; when this lever is at right angles to its present position, the valve is wide open, and the lever will stay in that position until moved by hand. The inventor describes the trouble with the old style of relief valves as follows:

"In mounting car-wheels upon their axles by means of a hydraulic press it is necessary that the movement of the ram be arrested at the moment when the wheel is forced to the proper point on its axle, since the action of the press, if continued an instant too long, will cause a displacement of the parts, which can only be remedied at the cost of much time and trouble. In this class of mechanism the pressure employed is so great, varying from one to five tons to the square inch, that much difficulty has been experienced in devising a relief valve capable of being unseated and opened instantaneously and at any required point in the progress of the work. Heretofore it has been customary to use a valve having a threaded stem operated by a heavy hand-wheel at the end of the press. As this valve is seated against the pressure, a considerable effort is required to unseat it when it is once fairly closed, and the size of the hand wheel, together with the low pitch of the screw, renders it almost impossible to open the valve and relieve the pressure at the exact instant necessary. The result is that the operator finds it necessary to unseat the valve before the completion of the work and then await the moment for opening it and arresting the movement of the ram. This not only delays the work of the press, but causes a rapid deterioration of the valve seat, which is soon practically destroyed. Other devices have also been employed to effect the same result; but, owing to the peculiar construction adopted, the valve can only be unseated by the stroke of the pump, and the accuracy of the work is thereby liable to be seriously impaired.

"It is the purpose of my invention to provide a simple and easily operated relief valve for presses of this class, which shall be capable of unseating and opening instantaneously by a single movement of the hand of the operator, and whereby the operation of the press may be instantly arrested at any moment, the construction of the parts being such as to permit their arrangement upon the pumping mechanism within easy reach of the operator as he stands where he can see his work."

We understand that several wheel press makers are about to apply this invention to their machines.

Men running wheel presses will appreciate the convenience of this device.

In the repair yards of the Central Railway of Georgia, at Macon, we noticed some iron cars with the tubular frame, built by the Iron Car Co. of Harrisburg, Pa., that had been in a wreck, the ends of the box part were entirely knocked off, the drawheads broken, but the frame and end sill of the car were intact, proving that they are far above the average car in strength. These cars were equipped with the Thermond M. C. B. drawhead (Janney type), and the absence of slack no doubt contributed largely to the safety of the stock in a shock like a collision.

The *Frog*, of Denver, having spun a cocoon of wit and wisdom about itself, has just broke out into an illustrated railroad paper known as the *Western Railway*. It is just as much nicer than the *Frog* as a butterfly is nicer than a caterpillar—and there were few 'skeeters on the *Frog*. The new sheet is "incorporated," like the Western towns, and Cy Warman is Mayor, Police Justice and Town Pump, with Dicer Swift as poet "Lariat."

Egbert P. Watson, Jr., junior partner in the firm of E. P. Watson & Son, publishers of the *Engineer*, died of Bright's disease on Feb. 24th. Mr Watson was but 27 years of age, and just entering upon a useful career.

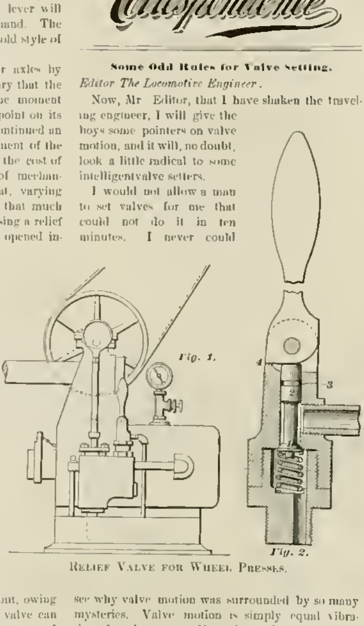
Correspondence

Some Odd Rules for Valve Setting.

Editor The Locomotive Engineer:

Now, Mr. Editor, that I have shaken the traveling engineer, I will give the boys some pointers on valve motion, and it will, no doubt, look a little radical to some intelligent valve setters.

I would not allow a man to set valves for me that could not do it in ten minutes. I never could see why valve motion was surrounded by so many mysteries. Valve motion is simply equal vibration of rocker arm. Now, boys, I will tell you how to catch on.



RELIEF VALVE FOR WHEEL PRESSES.

Take the center on one side and use that. Leave the other side on quarter, you need not use any tram, only the one you use to catch on center; by this means you use centers on one side and travel on the other. If you have uneven track, take centers from your main rod as it travels up and down.

Always gauge your valves with thickness of iron or tin that you want for lead.

Now for another pointer on it; if you are running a new engine, and her valves are square, you can keep her square as long as she stays out, by simply pulling down her shoes, and putting in a liner, which may amount to a piece of thin Russia or No. 8 iron. Setting up wedges causes your axle to be pushed ahead, which adds lead to the forward end of valve, and adds lap to the back end. In this way it is under control of engineer; your eccentrics and blades need never be touched, as your eccentrics generally come from the building shop keyed on. Blades generally come with two holes reamed out and fitted with bolts and with one oblong hole, so rods are set just right.

Now, boys, can any of you tell me how to gauge a valve without taking off steam chest cover, providing you know what outside lap she has? It can be done; and if you give it up, I will tell you in the next issue of THE LOCOMOTIVE ENGINEER.

Any locomotive, no matter how old she is, or how much lost motion she has, her valves can be set square, and she can do the same work she did in her first days, pull just as many cars, and run as fast, and when you take her in you will surprise the engineer and superintendent, unless her tires are worn bad, or boiler and flues are in bad shape. She will need little work. When valves are properly set, lost motion has nothing to do with engine working well. Of course your packing and cylinders must be good, and valves and valve seats good, so that there will be no blow in valves and cylinders, a tram should be called a valve gauge.

E. A. CAMPBELL,
Houston, Tex. Supt. M. P. & Mach'y

[Valve motion men will be after Mr. Campbell now—look out for them.]

Hopeful of the Future.

Editor The Locomotive Engineer:

Lately we read a good deal in the daily papers of the abuses to which enlisted men in the army are subject to from their officers, and the rank injustice with which the ordinary private is treated by court-martial. The court composed of the very men who heap indignities upon the private is not a tribunal to which he can look for either justice or mercy. There are other officials besides those connected with the army. Let us consider our railway officials, more particularly division superintendents, and superintendents of motive power. That they are not all angels nobody will dispute. As a general thing, in their intercourse with the ordinary private, or employe, they imagine themselves more of an autocrat than the Czar of all the Russias; to this rule, of course, there are many honorable exceptions.

The great army of railway employes (we refer to train and enginemen in particular) is composed of a finer body of men, physically, than the army of any of the monarchs of the old world, and mentally are equal, if not superior, to any other body of wage earners in this or any other country. Over this great army the superintendent holds full sway. He issues his orders and expects them to be obeyed to the letter. All very good, as long as the order has common sense for a foundation—something I am afraid many of them are lacking in. It is very necessary to have good discipline, but sometimes discipline is made a scapegoat of, to cover up great wrongs. The job of the average train hand or engineman is like "the sword of Damocles," suspended by a hair, and the hair is liable to be severed at any moment. That there are tyrannical, overbearing and autocratic officials in the railway service of the country is only too true. Many a happy little home has been broken up, many a man sent out a wanderer on the world's highway, simply because from some little infraction of duty he is cast adrift as a warning to others. I do not uphold anybody in shirking their duty; if there are any such, they should suffer the consequences; but I have seen many a man discharged for trying to do what he thought was right, but unfortunately for him his superintendent did not agree with him. When any mishap occurs, how very soon we are censured, but for duty well and faithfully performed we are never commended. Yet a kind word will do more good than a blow any time. Were the officials of many of our "great systems" a little more lenient, a little more in sympathy with those who are under them, it would be much better for those who are financially interested. Give a man to understand you are his enemy, he is not going to put himself out much to do you a favor; and it looks as if many railway officials consider every workingman his enemy, and treat them accordingly. Were he to act on the principle of friendship, and make them believe he was their friend, how much pleasanter, how much better it would be for all concerned. If some great corporations we know of were to adopt a friendly policy toward their employes, probably they would not have so much need of reorganizing their finances as they have at present. "Mighty oaks from little acorns grow," and "A small leak oftentimes sinks a big ship," are true maxims.

However, there is a lining of silver to the dark cloud that hangs over the position of the railway employe. The schoolmaster has been abroad in the land, and the good effects of his labor are becoming more apparent. Men are beginning to realize what has always been accepted as a fact, viz.: in union is strength. A confederation of the different classes of railway employes is coming. Just as sure as day follows night, united they will be invincible. Then the days of the tyrants shall pass away, no one-man power will go when the good time comes; then everybody shall have his just deserts, and no more than he is entitled to. In the coming of that good time, homes now desolate will be made bright, the face from which a smile has long since departed will light up anew, those whose hopes were crushed by tyrannical rules will take courage afresh, and have cause to bless the day when petty animosities and jealousies were forgotten, and the immortal words of Robert Burns will be exemplified:

> "When man to man the world o'er
> Shall brothers be, and a' that."

G. LEWIS.
Ft. Madison, Ia.

The "Neversink."

Editor The Locomotive Engineer:

Mr. Rauch probably remembers that the "Neversink" exploded its boiler during a heavy thunderstorm, and it was supposed that the engine was struck by lightning, as a flash and the explosion were simultaneous. One man's head was found across the Schuylkill river, and human limbs and entrails were seen hanging in the neighboring trees, and the almost perfect image of a man was imbedded in the smoke-stack.

The Shape of Signal Flags.

Editor The Locomotive Engineer:

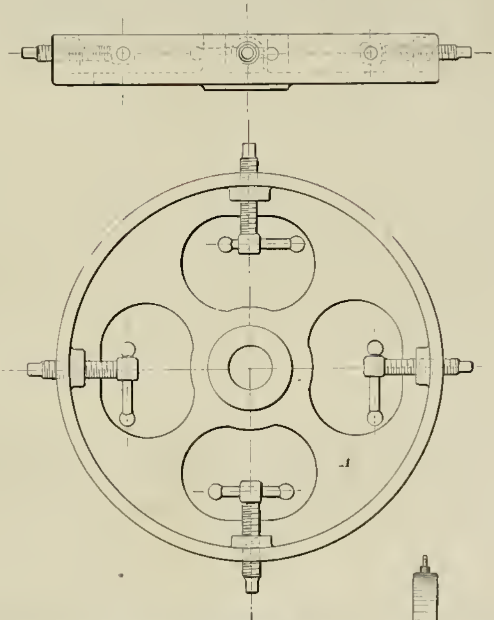
I am sorry to see you misunderstood what I said in regard to shape of signal board. The idea I meant to convey was that the *shape* of a signal is utterly out of the mind of a person that is looking for *color*. I insist that it does not make a particle of difference what shape a red flag is, if it is seen by the party that it is meant for; that is all that is necessary; that party will stop. A three-cornered flag will stop a train just as certain as a square one. As long as there is no rule calling a man's attention to the shape of a stop board, and where a red board stops him, I contend it's not at all necessary to observe the shape. I think if you care to inquire you will be surprised to find out that many times trains are stopped by being flagged, and not one engineer in five will recognize the man that flagged him, if he should make his appearance without the flag—all he noticed was a stop flag.

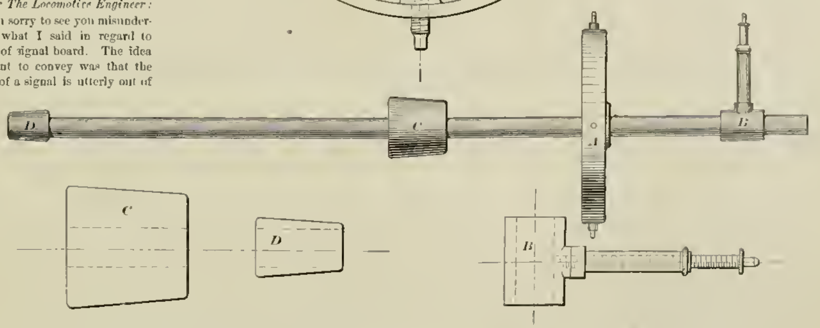
Clinton, Iowa.   WM. LANSING.

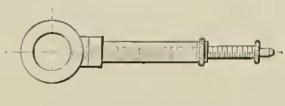
Cylinder Centering and Guide Lining—a Kink.

Editor The Locomotive Engineer:

The enclosed print represents our device for centering cylinders and lining up guides on Providence & Worcester road. *A* represents the spider or disk, which is 14" diam., with four screws long enough to fit an 18" cylinder. *B* is an adjustable pointer, which swings loose, still is a good fit on shaft. *C* is a tapering bushing which goes into the cylinder stuffing-box. *D* is a tapering bushing which fits into the crosshead. The holes through all these are the same size, $1\frac{3}{16}$ diam. to fit the steel shaft, about 5 feet long, turned as near true as possible, and a good easy fit for these holes, great care being taken to keep the shaft straight and true. Our manner of using it is to







CYLINDER CENTERING AND GUIDE LINING KINK

put the tapering bushing *C* into the stuffing-box, holding it in place by means of a strap or plate, which slips over the stuffing-box studs, put the bushing *D* into the crosshead, fasten up the bottom guides, lay the crosshead on, put the spider *A* into the cylinder with shaft resting in bushing *C*. Center the spider by means of the adjustable pointer *B*, then by sliding the shaft up to the crosshead it will easily be seen how much shimming is needed.

And when the shaft slides easily through the crosshead anywhere on the guides the crosshead guides are in line with the cylinder, and the piston can be put in and be all right.

In making this device we have tried, as far as possible, to get along without using wrenches. As you will notice on the spider, the screws are made with short, adjustable handles, that are loose, like the handle of a vise. The adjustable pointer has a knurled collar on the screw and a knurled check nut; these are easily adjusted when in the cylinder, where a wrench would be unhandy.

Providence, R. I.   WILLIAM FOSTER.

An Old Fireman of the "North Star"—Some Boiler Trouble in India.

Editor The Locomotive Engineer:

Please hold my papers till you hear from me; I am going home to England on a furlough, and will then send you my address. I was much interested in your January description of the "North Star." I want to say that the picture shows her as she now is, no doubt, but is not at all like she was when I was firing on her in 1858–9. If I remember right she and all the other "Stars" had one or two tall steam funnels on the boiler, these were for poppet valves. At that time she also had V links, or gab-motion, on eccentric rods, right and left valve gear, and in the reversing lever quadrant only forward and back nicks, or notches. The slide valves were on top of cylinders. The "North Star" at that time was a back tank engine.

I have had no end of trouble here this cold season from leaky tubes, and some of our fire-box roofs have cracked near the top tube plate angle, some of them as much as 18 inches; this class of engines have direct stays from roof to outer shell of boiler, and the weakest part has to give way. We are using very indifferent coal, which makes matters worse.

I have twenty-five goods engines on the road, and nine in the shop, so you see we are busy.

In another month, or by March, the hot season will commence, and most of our trouble from leaky boilers will cease.   LOCO-INDIA.

Nagpur, C. P.

Vertical Plane Couplings.

Editor The Locomotive Engineer:

In the *Railroad Gazette* of January 17th there is an article showing the cost of keeping up nineteen vertical plane couplers, and I wondered how much it cost to repair the damage to the draught gear of the cars with which those nineteen came in contact. I will venture to assert—for I am in a position to know—that vertical plane couplings do more damage to their own type, as well as to other cars that are not supplied with them, than any other kind of draught gear in use; and, in proportion to the number in use, they break and damage more links and pins. The so-called defunct links and pins would yield better results than any known vertical plane coupler in every respect (except, perhaps, a very small amount of closer coupling), if the drawheads were turned so that the link would be vertical; this would compensate for the varying heights of cars, both pins and links can be made secure from damage or from loosening, and the whole affair can be made as automatic as any vertical plane, and at less than half the cost. S. A. ALEXANDER.

York, Pa.

An Old-Timer.

Editor The Locomotive Engineer:

Engineer John Hawksworth, at present employed on the Chicago Division of the Atchison, Topeka & Santa Fe Railway, may justly claim to be one of the oldest locomotive engineers in active service. Mr Hawksworth commenced his railroad career in Old England in 1845, on a Yorkshire road. He came to this country in 1848 and was employed as engineer on what was then known as the "Erie & Kalamazoo," now a part of the Michigan Southern system. He was sent with an engine from that road to work on the construction of the Rock Island road out of Chicago. He soon afterwards entered the service of the Chicago & Alton, and remained with that company seven months, when he resigned, to accept a position with the C., B. & Q., and ran for that company from 1855 to 1863, when he returned to his first love, the Michigan Southern, and ran between Chicago and White Pigeon until 1866 at which time he returned to the C., B. & Q., and remained in the service of that company until 1888.

Although many years in railroad service, Mr Hawksworth is not a very old man—he is 60 years of age, and bids fair to enjoy many years of usefulness—that he can stand the "grief" of running a "Santa Fe hog" is sufficient evidence that he is still in his prime, and may he long continue so is the wish of the many friends of "Uncle Jack." L. H. G.

Chicago, Ill.

About Water Grates.

Editor The Locomotive Engineer:

I would like to hear something of the opinions of experienced men about water grates. All of our engines have them, and I think an article about the *disadvantages* of them might interest some of your readers, as we find it is about all disadvantage to firemen. Before starting, it is a job to get into the pit and hook out your grates, and with our poor coal, "Phila. mud," they need hooking out about as often as they can be got at, especially on long runs—136 miles—and it certainly is not any advantage in the amount of fuel used, as continual hooking and barring a dirty fire to get enough air through it to make steam does not lessen the quantity used, as most all enginemen will testify. We had a man come here with some new engines once, that made the remark he would not have them in a hoisting engine, let alone a locomotive. Now for the advantage. I suppose our officials will say it is a great deal less expensive to keep them in repair, as they never burn out. I know of no advantage to the men who run and fire engines with them in; some might say you never have to clean out your ash-pan, true enough. We can never get enough into it, unless it is with a new fire, when, if you are not very careful, you will get it full, and you are worse off than ever. I am not very well posted on shaker and dump grates, but I have fired them, and know that, with very dirty coal, they are an advantage to all parties, and if they are no advantage with dirty coal, they are certainly no detriment with good. A NEW HAVEN FIREMAN.

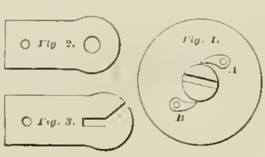
New Haven, Conn.

A Headlight Kink.

Editor The Locomotive Engineer:

Ever since I saw the description of headlight cover, that was given in THE LOCOMOTIVE ENGINEER some time ago, I have been thinking of telling you of an arrangement that some of the engineers on the Santa Fe use, that works admirably, and will be appreciated on any road that uses headlight curtains. Take a spring roller that is commonly used on window shades. Take the cap off the end that has no spring, measure the inside of case for length of roller, cut roller so that, when cap is replaced, roller will just clear nicely in case.

There are two kinds of brackets used with these rollers, one kind to go outside of window frame and one inside; get the latter; they will be something like Figs. 2 and 3. If headlight has a curtain, it will not be necessary to take it out or disturb it; put the spring roller in behind it. Fasten brackets with rivets through case. Put curtain on roller, being careful to get it on so it will roll up straight; this can be easily done by drawing a line the length of roller, and fasten edge of curtain to line with tacks or clamps. Take out "pawls" *A B* Fig. 1, so as to allow roller to revolve freely around spring. Put a light steel wire in bottom of curtain, bore ⅛ inch hole in bottom of headlight case in a perpendicular line with roller; you will need a wire to work this curtain. Take a light wire that will reach from cab to headlight—copper is the best, but common will do. Put the wire down through hole in bottom of case, out through space that is left in back of case for draught, thence back to cab, where a small hole can be made through cab sheet or cab, and wire put where it will be handy. A ring should be on this end of the wire. The wire should be of a length that when curtain is rolled up, the ring will be against the cab. Put the roller in place when you have made all the necessary arrangements, turn the roller until the spring has sufficient tension to raise the curtain quickly, then fasten wire in center of lower edge of curtain. Now it is ready for operation; if you want to darken headlight, pull down the curtain, hook the ring over any



A HEADLIGHT KINK.

thing handy in cab; when headlight is to be uncovered, unhook the wire, and curtain will go up like a flash. In stormy weather this is a comfort, is handy all the time, and don't cost much. Try it.

Newton, Kan. SANTA FE.

A Locomotive with a Peculiar Habit.

Editor The Locomotive Engineer:

There has been of late quite an amount of discussion and comment in our roundhouse and shops, caused by the unprecedented actions of one of our eight-wheel passenger engines; it is claimed by the regular runner of this engine, and has also been substantiated by other runners, who were at first incredulous, that this locomotive when traveling at the rate of fifty and sixty miles per hour down hill with throttle closed, reverse lever either hooked up or down in forward corner, would invariably slip (when rail is bad and dewy), and not catch herself until sand is given her, when she will settle down and continue the trip in good shape until the next down grade is encountered, when the action is repeated. (Frequently she does not slip but once on a trip, depending upon condition of the rail.) The engine is one of the company's make (known as the Wells engine). Wheels 60' diameter, 18x24' cylinder, weight on drivers 60,000 pounds, on trucks 33,000, tires good. Has been in service about five years, but has never until recently been guilty of such tricks. Can you, through the columns of your paper, give any reasonable solution of this, which is to us a mystery?

R. W. SIZER,
Mobile, Ala. Eng'r L. & N. R. R.

[It disproves nothing for us to say we can't believe that the engine slips under the conditions stated, simply because we can conceive of no reason for it. If it were possible, under the conditions stated, to suddenly lift the locomotive up to clear the rail, the wheels would undoubtedly keep on revolving until the stored up energy in them was exhausted. The steeper the grade the less the weight of the engine at the rail, and there is a possibility that on a steep grade and very slippery track, that if the high rate of speed of the train were suddenly checked, the water in the boiler lurched ahead, and the weight on drivers suddenly decreased, that the stored energy in the wheels might slip them for a turn or so, but we cannot imagine a case where this could happen until the slipping had to be checked with sand. There is a cause for this slip, if it really does occur, and we believe the men will find it. If Mr. Wells put this trick into the engine when he designed her, perhaps he knows something about it. If he would only design one that would slip her wheels, going *up* hill, with the throttle closed, what a revolution it would make.]

"A Cranky Injector."

Editor The Locomotive Engineer:

We have a No. 8 Monitor injector on the engine I am firing, which breaks very frequently while running, and especially when stopping (R. H. side), and no one seems able to determine its ailment. The injector mechanics all pronounce it in first-class order. The joints are all tight; strainer is kept clean, hose is tight, and tank valve has plenty of lift. It will break immediately if ram is opened over three-quarters of a turn, with feed full on, and cannot be worked with either in any other position. I see "Primer," in July, 1888, states, in describing similar symptoms, to "look to the dry pipe, which may be disconnected."

There is no other evidence to indicate such being the case on this engine, as the L. H. injector, which is also a No. 8 Monitor, will work splendidly at all times, both taking steam from same "duck's nest," as he says. It is not convenient for me to work it, however, as the boiler head comes clear back to the tank, while the injector is up ahead—hence the difficulty. Can any one suggest the probable cause of the trouble?

Oakland, Cal. WEST OAKLAND.

[It would appear, from the fact that you cannot open the steam valve full, that the instrument cannot get water enough, or is prevented from delivering what it does get. Put your left-hand injector in place of the right one; if it works, the trouble is in the instrument itself, if it acts as the right one does see that there is no obstruction in the water delivery and branch pipe; something may be the matter with the lazy cock, or feed valve; the older style plug valves were poor arrangements. Sometimes local repairers, in putting in new tubes get the steam nozzle too long, and carry it too far into the intermediate, or combining tube; this does not give the water room enough or time enough to condense the steam, and the instrument will not work; this trouble is also suggested by the fact that you cannot use a full head of steam. The fact that the injector breaks easiest when the engine is making a stop would suggest the splashing of water into the dry pipe, which will break any injector. Broken line checks often partially obstruct the pipe or boiler check and prevent a full delivery. When you find the trouble let the readers know what it was.]

To Empty Main Reservoir with New Engineer's Brake Valve.

Editor The Locomotive Engineer:

It is sometimes necessary to let all the pressure out of the main air reservoir, in order to clean, inspect or repair parts of the brake rig. With the new brake and equalizing discharge valve this is not so easily done, and the only way that presents itself at first sight, is the comparatively slow and tedious one of letting it out of the small pet-cock on the drum.

By taking off the nuts on handle stem, and turning the handle over, the valve can be turned clear around, one-third of a turn past the emergency stop will open full and direct communication from the drum to the atmosphere, and bleed the main reservoir as quickly as can be done by the old 3-way cock. BEN DIGGORY.

Pueblo, Col.

Cleaning Dope for Brass.

Editor The Locomotive Engineer:

Thinking some of the boys would like to know how to make some good polishing dope, which can be got up cheap, I will send a receipt which I have used with success:

6 sperm candles,
1 pint signal oil,
1 oz. gum camphor (pulverized),
½ oz. arsenic,
¼ bath brick (powdered),
½ pint ammonia.

Melt the candles in the can you intend to keep the dope in, then stir in the other ingredients, the bath brick last. This makes a good polish for brass, especially if warm.

A. W. MASON.

Tulare, Cal.

[This is just the kind of "kinks" the firemen are after, let's have more of them.]

That Scotch Locomotive Test.

Editor Locomotive Engineer:

I have to thank you for the copy of THE LOCOMOTIVE ENGINEER for February, which contains reference to the proposed sending of a representative American express engine to the Edinburgh International Exhibition of this year. In next week's issue of the London *Engineering* and *The Engineer* you will find further correspondence on the subject.

It is greatly to be hoped that you will immediately take steps to obtain subscriptions on your side toward the guarantee fund which is proposed to form for the purpose of reimbursing the Baldwin Company, the expenses incurred in sending one of their engines.

The exhibition will comprise five of the best English express locomotives, including two compounds on different systems. If Americans are sincere in their estimate of their engines, this is an opportunity of showing what they can do, which should not be allowed to pass. On the opening day of the exhibition a train is to be run from London to the exhibition (400½ miles) without stopping.

GEO. E. WATSON, Sec'y.

Edinburgh, Scotland.

[Not only the Baldwin, but most of the other locomotive works in this country are abundantly able to send a locomotive to Great Britain for trial, if they considered it would pay to do so, and would no doubt decline any charity in the shape of subscriptions in the matter.

All the principal locomotive works in this country are at present very busy on orders, and perhaps prefer to build for money instead of glory. As we said in a former article, the winning of this test would only amount to an advertisement for our work in some of the South American countries.

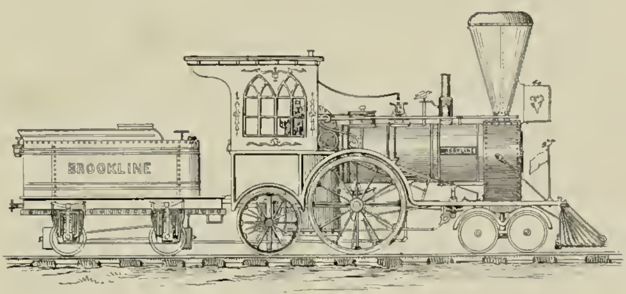
It is not necessary to build a special locomotive for this trial; what is the matter with sending one of the "class K" of the Pennsylvania—say the "long-legged ten"—over there? We should like to see a representative American locomotive in this test, and believe that one would not come out at the tail-end of the string. In this country our fast trains are heavy, but do not make the time the English expresses do, though they pull much lighter trains. American locomotives have never been beaten in trials with other builds in North or South America, or any other country, and we see no reason to fear that they would lose the belt the coming bout.]

One of the Old Stock.

Editor The Locomotive Engineer:

The enclosed photograph of the "Brookline" may be interesting to your readers, so I send it, with an outline of her history.

This engine, originally named the "Lion," was built at the "Bury Works," Liverpool, Eng., in the year 1835, for the Boston & Worcester R. R., now Division No. 1 of the Boston & Albany R. R. When first put in service she was without cab or truck wheels, and on the occasion of having the first cab, the directors found considerable fault, as it was thought the engineer could not see as well as before; her cylinders were 10"x18", the drop hook valve motion being used; her weight was about twelve tons; in the year 1846 she was taken from regular service, and only ran occasionally till the year 1852, when she was used in building the Charles River Branch, which is now part of the Woonsocket Division of the N. Y. & N. E. R. R.; work being commenced at a point where there was no rail connection, she was drawn across the country from Newton to Newton Highlands, some two or three miles, by eighteen horses, as well as the tender and construction cars; after completing this work of construction she was taken into shop of the Boston & Worcester R. R. at Boston and overhauled, and truck wheels put in place of small wheels, which were put in rear of driving wheels (as seen in picture); she was then named Brookline; in 1853 she was put on the Brookline trips, in which place she continued to run for twelve years, being run by Mr. J. M. Alger, who is still running on the B. & W. Division of the Boston & Albany R. R. About the year 1866 she was laid by, and, after passing through various hands, was named "Farmingdale," and sold to some eastern road; during the thirty or more years she was in use by the Boston & Worcester R. R. she ran over 700,000 miles, or more than any other locomotive up to that time in the United States.



ONE OF THE OLD STOCK.

The Boston & Providence R. R. had an engine like her, built by same firm, and about the same time, named the "Roxbury." Neither of these engines when built had steam gauges, their pressures being told by the old fashioned spring balance; the first one, the "Lion," had a mercury gauge, put on by the engineer. the fire-box was quite small, a large armful of wood almost filling it—that being the fuel used; the fire-box was circular, as was the shell which enclosed it.

Boston, Mass. H. L. HOLMES.

A Fireman's First Trip.

Editor The Locomotive Engineer:

I enclose an account of my first trip over the Missouri Division of the N. P. R. R. We are using Red Lodge coal here now, and firemen have an easy time compared with what they have had.

Like many others, my first firing was done on a switch engine, and after I had fired her three or four days I made up my mind that *I* could keep most any kind of an engine hot. And right here I would like to ask why master mechanics and others seem to have that same idea that I had, and think any man ought to be able to keep an engine hot after three or four days on a switch engine, when really the man has not had a chance to learn the first principles of firing.

I would like to see a change made, and see men sent out on the road with an experienced fireman, and given a decent start at their trade. It will be money in the pocket of some railroad company that will try it.

Well, as I said before, I thought that *I* could fire most anything, so I felt pretty good when I was marked up to go out on the 318. We had a tank of Pittsburgh coal out of Dickinson, and the way that engine stayed hot would have tickled the firemen of the hot place to death.

When we got into Glendive, some one asked my engineer how I got along, and received the reply, "Good"; "will make a first-class man," which did not injure my self-respect at all.

Coming back we had a tank of what the boys called "Bull Mountain," a *kind of coal* that comes from the top of the eastern range of the Rockies It is fine coal, so fine; in fact, that when the wind blows it is a question whether it reaches the fire-box or blows out of the gangway.

We had a full train as usual, and I did first-rate for seven or eight miles, and then the pointer began to drop back. My engineer shut off the injector, and she picked up slowly to 140, when the injector was put on again, and there began a struggle to see whether that pointer should stay where it belonged or not.

I kept her at 140 for fifteen or twenty minutes, and then she started back again.

Up to this time I had been firing very carefully—only one or two scoopfuls at a time—but now I began to get desperate, and put in three or four at a time; and the more desperate I got, and the faster I put it in, the faster that pointer went back, until it had settled to the neighborhood of ninety pounds. About this time I went to put in a scoopful of coal, meaning to drop it just under the door; imagine my feelings when I found that it would not drop, but that *that* fire-box was full right up level with the door! I turned my scoop over to look at my fire and found as neat an imitation of the Dakota Bad Lands as could be made without practice.

I went out on the back end of the tank and got the ash-hoe and leveled down some of the Buttes, then let them burn awhile, then stirred them up again, and kept this up three or four miles with once in a while a scoopful of fresh coal until we stopped for water; there we cleaned our fire, and then we repeated the performance, and we repeated it four times during that trip

After I had fired a trip or two I noticed that if a scoopful of that coal was thrown in one place without scattering, it would make a clinker, and I found that when the fire-box filled up, all but six or eight inches of its contents would be dead ashes; so I figured If I scatter my coal so that those clinkers will not form, and keep those dead ashes shaken out of the fire-box into the ash-pan, where they belong, I will have the best fire I can get from "Bull Mountain." I tried it, and I have not had to clean any more "Bull Mountain" fires

Since I made that trip I have learned some other things about firing, which I should be glad to tell for the benefit of young firemen, as I presume that any old fireman knows as much or more than I do.

About Keeping Up Pay.

On a recent visit to the South the writer stepped into the Savannah roundhouse of the Central Railroad of Georgia, and found a little knot of men gathered at the train board, and a discussion going on—animated discussion is always of interest.

One man had a dinner pail, and he was rather sassy and independent to the other who had none—men *with* are often patronizing or sarcastic to those *without*.

The man with the pail was an engineer, the man without, the master mechanic, and the talk was caused by the fact that the engineer had just come down to go out on a train due to leave two hours or so before; the transportation department were kicking to the M. M., and he to the engineer.

Shortly after our arrival on the scene the discussion ended up something like this:

M. M.—You know that it has been the custom here for years for the engineers to come and examine the board every afternoon; no calling is done in daytime; as per your agreement. You had more than twenty-four hours' rest, and should have come—why do you make all this delay and kicking from the superintendent's office?

Engineer. I didn't feel like coming down last night, didn't have any one to send but my children, and thought I wouldn't get out till now, and I don't care much; what's the hurry about this train, anyway?

Another engineer stepped up when this one went his way, and reported himself over the grip and ready for duty.

All right, said the M. M., want you to-night on train so-and-so—designated by number.

The engineer kicked, said he didn't suppose he would have to go out before the next night—still he had reported for duty.

This was an interesting state of affairs, and we proceeded to "get acquainted" and find out the cause—wanted to know why a man did not want to go to work when he had just reported for it.

We found that the engineers on this road have the best agreement—for them—with the company, of any engineers in the country, the full text of which is published in another column, under the head of "The Best Agreement in America between a Railroad and its Engineers." It is interesting reading.

"These men receive $4 per day, Sundays included, whether they work or not; they get twenty-four hours' rest after each trip, and if called to go out before the twenty-four hours are up get an extra day for going.

They receive twenty-five cents an hour for all delays over schedule time, or twelve hours when running extras.

Hostlers are provided at all terminals.

They receive pay from the time they *report* for work after laying off—instead of from the time they go out, as on other roads.

With all this advantage over their brother engineers in the same section of country, we never listened to better kickers in our life—perhaps we got into the wrong crowd—we hope we did.

No one can accuse us of ever trying to reduce pay or remonstrating against the size of any engineer's check, and we are only too glad to record a case where a large road is so willing to pay their enginemen well and give them long hours of rest. If this contract is broken it will be because of the dissatisfaction of the engineers, and the annoyance they are giving the officers of the company.

Four dollars a day is the standard pay of locomotive engineers, it is fair and reasonable, but we heartily wish it was six instead of four. One hundred miles is considered a day's work in all parts of the country.

Other roads in the South are paying $4 for 100 miles, and the men consider that they are receiving standard pay. The engineers of the Rock Island just suffered a cut of fifteen cents per day to bring the pay of the whole line up to $4, or standard.

Wishing to impress upon the Georgia Central men the desirability of nursing what they have got, deserving it, doing such good work, and in so cheerful a manner that their pay and their close relations to the management of the company will stand as a pattern to the rest of America—we draw some comparisons.

From Savannah to Macon it is 190 miles; in the month of January there was made on this division 78,452 miles by freight engines, there being in service forty engineers. These men drew $124 pay, and $3.30 each extra pay. This is only 1,961 miles each for a month's work. Had they been running on a mileage basis for standard pay, they would have received but $78.45 each.

In February only 68,118 miles were made, and there were forty-two men; this month their pay was $112, but their extra pay was $14.67 per man. Had they been running on a mileage basis with full pay their checks would have been less than $65 each.

Suppose the Central road should offer to pay half a cent a mile *more* than standard pay, could the engineers of the country sustain the men in a resistance against the cut?—for it would be a cut on present pay.

If a mileage basis were adopted just about half the engineers on this road would be out of jobs—for the older men would want about $120 worth anyway.

The management of the road are satisfied to pay the present rate, and do not want to see a change in the agreement—don't force them to make one. It will be mileage, sure.

The grievance committee is too easy to get out—let it rest. An engineer on this road recently ran a locomotive with a hot eccentric till the strap broke, ran with the main pin so hot that the brass stuck to the pin—abused the engine. Instead of discharge or 60 days, he was put back on freight; he ought to have considered himself lucky; but the grievance committee went to the general manager and asked his reinstatement—and did not get it; some discipline is necessary.

Engineers of the Georgia Central, you are better paid for the work you do than most engineers; be an example to them—deserve that pay. Don't let it be written in the history of the order that you kicked your own wages down. Don't give the officers of the road a chance to regret the agreement or desire a change. Don't forget that, as you receive the highest pay, so had you ought to be the best engineers in America. Don't get it into your heads that other men cannot run there; there are few who can't. Don't kill the goose that lays the golden egg. Don't be unreasonable or unjust—you cannot afford it.

All this is said in the kindliest spirit, and to help, not to hurt you—advice from one engineer to other engineers.

In traveling about the country we note with care the condition of enginemen, what advantages they enjoy, what burdens they bear. You have jobs to be proud of—be proud of them.

A Comparison.

A locomotive engineer might well be likened to an artillery marksman. He knows very little about building his gun, but he can repair slight breaks, or use it partly crippled. He cannot figure out the velocity of the projectile, but he can hit the mark with it. Both the marksman and the engineer use the machines in their hands as a means to an end. The execution done depends upon their skill, and the quality and condition of the device in hand.

Locomotives earn money for their owners only when they are in motion—moving cars—then the man who can move the most cars for the greatest distance, with the most safety and least expenditure of money, is the best marksman—he hits the bull's eye.

The scientist and the savant, who can figure the projectile's velocity, the recoil, the gas pressure in the gun and the spiral of the rifling, is not the man sent to battle to do execution with the engine of war—the marksman goes.

The scientific man was useful in building the gun, not in thumbing the vent or swabbing the piece.

Men who can figure out all the theories, and who know all the rules about steam engines, who can tell the strength of all the materials, the names of all the gases, and prove that the cylinder stack and nozzle want to be all one size, are not the boys who make a success when they try to run a locomotive that is subject to chills over a hilly road with a heavy train, and be on time at every fish-plate—the engineer does that

Successful locomotive running is marksmanship, of the Creedmore order. Be a marksman.

A Valuable Book.

The *Engineering News*, of this city, one of the best high-class journals on the continent, recently issued in supplement form, a large map of the U. S., showing by colored lines, the roads using automatic air-brakes, and by another color those using automatic couplers of the M. C. B. type.

This plate was accompanied by a table, showing the number of roads using the devices named, the miles operated with and without the brake, and the total number of cars equipped.

The condition of the equipment is fully discussed, results of tests shown, etc.

The Westinghouse Air Brake Co. have complimented our contemporary by issuing this piece of work in pamphlet form, which they are sending free to those interested in the subject. Send for it.

ASKED & ANSWERED.

(20) Brakesman, Leavenworth, Kan.

You can find the full name of any railroad in the United States, in Poor's Manual of Railroads, published by H. V & H. W. Poor, New York. S. of M. or S. M. means superintendent of machinery; S. of M. P., superintendent of motive power; when & R. S. is added to the latter, it means, "and rolling stock."

(21) Fireman, Argentine, Kan., asks:

1. How is the proper location for a rocker-box determined? 2. Why does reverse lever tend to pull in direction engine is running when working steam? Please answer through columns and oblige. *A.*—There is no particular place to put the rocker box; the build of the engine often determining its location. 2. The friction between the eccentrics and the straps causes the lever to pull in the direction the engine is running; the slip of the link on the block causes the jerk.

(22) W. A. J., Baltimore, asks:

1. Will you please tell me in your paper how driving wheel tires are made; and, 2, what you think of this. A machinist told me that he always keys the side rods on back center and finds them loose on front center, and if keyed on front center will find them tight on back center. *A.*—1. Driving wheel tires are rolled. 2. There may be a slight difference in some cases as stated, but it is not the rule; it is caused by slight difference in pins or driving-boxes, and side rods should never be keyed close enough to show a bind. Nine out of ten are keyed too tight—they fit too well.

(23) B. G. D., Charleston, S. C., writes:

We have a great deal of trouble in our boiler department in flanging steel boiler heads, more especially the round head on front end. In flanging they bulge or raise up in center of head. The boiler makers straighten them by pening or with a tool they call a fuller. I think this injures the material, and I am satisfied that the pening crystallizes the steel and makes it brittle; but the boiler makers say not. Can the bulge be prevented or removed by other means, and what causes it? What book treats on this subject? *A.*—In flanging by hand a round head there is always a tendency to slightly bulge the head, and it is usually straightened in the way mentioned. If the sheet is hot there is no danger of injury to the steel. In machine flanging no trouble is found, as the die or ram of the machine holds the center of the plate down solidly while the flange is formed. "A Manual of Steam Boilers," by Thurston, or "A Treatise on Steam Boilers," by Wilson & Flather, are considered the best and most recent works, both published by Wiley & Sons, this city.

(24) P. M., New York, writes:

1. In page 200 of Forney's Catechism of the Locomotive, in answer to Question 290, Mr. Forney says the driving boxes "are arranged so as to slide up and down in the jaws." I am informed by an A 1 machinist that the driving boxes are stationary, and frame and wedges work up and down instead, please decide? 2. In page 13 of January number of your paper, under heading of "Elementary Lessons in First Principles," your correspondent says that hooking up link motion is equivalent to moving eccentric on the shaft, will you please explain how this applies to back motion? *A.*—1. When a locomotive rolls, the jaws, together with the frame, move up and down on the box, but when a wheel runs over an obstruction or into a depression, the box moves in the jaw. 2. To increase the lead, it is necessary to advance the eccentric on the shaft, *in the direction it is to run;* when you hook up, going ahead, you do not advance the eccentric, but you move the line of motion back on it, which amounts to the same thing. In backing up you do the same thing—move the motion back—practically advance the eccentric on the shaft in *the direction the engine is running.* See illustrated article on subject, on page 5, February, 1889.

(25) J. W. Peterson, Boone, Iowa, writes:

We have been working on two air brake questions for some time, and to find out whether or no our conclusions are correct they are referred to you or the readers of your paper. Both questions have come with the advent of the brake valve of '88 with equalizing discharge. What we want to know is: 1. "Why, when the handle of brake valve is thrown to release position after an application, there is often a blow from service stop exhaust port for a longer or shorter time, depending on the amount of reduction. 2. Why, when making emergency application, both pointers on the double gauge assume the same position? Westinghouse experts have answered the last question by saying that the rush of air from rear of train is so rapid in an emergency application that it forces the hands up to same position. Hope some one will be able to explain satisfactorily. *A.*—1. When the valve handle is thrown from service to full release the air from the drum rushes through the large open ports and commences to fill the train pipe, and also passes through the very small ports to the top of the piston of the service stop valve; the air, having been reduced in the service stop drum, does not instantly regain its pressure, and the rush of air into the train pipe and under the piston of the service stop valve holds it up until the pressure equalizes; this, of course, allows air to escape at the service stop port for a period, more or less, according to reduction made; often this is augmented by the piston of service stop becoming gummed and slow to act. 2. When the emergency is used the gauge is entirely cut off from both the engine drum, the train pipe and the service stop drum. If the valve handle has been standing at full release, both pointers will be together, and an emergency application simply cuts off the pressure to them and leaves them there; if the handle has been at running position, the pointer showing the pressure in the engine drum, and the service stop drum will show most pressure; and when an emergency stop is made the only way we can see to account for bringing the pointers to the same mark would be that the movement of the handle past the service stop had reduced the pressure enough to account for the movement of the pointer. If everything is tight this had not ought to occur. The fact that, with the new engineers' brake and equalizing discharge valve, the gauge is shut off from all working pressure in an emergency stop, has scared a good many men, who thought that the brakes were not applying because the pointer did not indicate a reduction of pressure. This fact is not well enough understood.

IN THE ROUNDHOUSE AND REPAIR SHOP.

On the East Tennessee, Virginia and Georgia.

The East Tennessee, Virginia & Georgia Railway owns 1,006 miles of road, and controls in all 1,624 miles, operates over 200 locomotives, over 6,000 cars, and earns between five and six million dollars yearly, being considered one of the best roads in the South, and as there are some 300 subscribers of THE LOCOMOTIVE ENGINEER on the line, I thought it worth a visit. On the last day of February, I packed my grip, and took a corner in a Pullman, with a ticket in my pocket for Knoxville, Tenn.

AN INCIDENT.

When I go off on one of these little trips I make it a point to notice everything that has a railroad point in it, and in this case I only had to wait four minutes for a subject. A lady entered the car, and seated herself near me, just as the train started, she had come out of the coach, and had passed the conductor who was on the station platform. The Pullman conductor approached her, and asked for her ticket, she handed him her coupon ticket; he wanted the Pullman ticket, but she had none. She defined what a first-class ticket called for, and said the ticket agent in Boston had told her that her ticket called for "everything," "all modern conveniences," etc., and no one could tell her that modern conveniences did not include sleeping car. She asked if the conductor called that passenger car first-class; was there a place to wash? A ladies' dressing room? Did they even have a towel in them? couldn't any one come in and demand half the seat? etc., etc. Both the lady and the conductor were cool, polite and respectful, but firm and determined, in vain did the conductor tell her that she must always buy a separate ticket for a sleeper, that Pullman had nothing to do with the road, and that railroad tickets were simply for the ride, and Pullman's for the trimming; and it was an hour before she finally put up $2 extra for a berth, and then only after taking a receipt for it, and declaring that she should demand it back of the agent who had deceived her.

All day on the first of March we rode through the historical Shenandoah Valley, skirting the southern slope of the Alleghanies. All through Virginia the valley is wide, with well-cultivated farms on every hand. From Hagerstown, Md., to Bristol, Tenn., I went over the Shenandoah Valley road and the Norfolk & Western, striking the eastern terminus of the E. T., V. & G. at the latter point.

KNOXVILLE, TENN.,

is the headquarters of the road, and is a rather lively little city, situated on very hilly ground, in the center of the great marble-producing district of this State.

The motive power of the East Tennessee road would attract the attention of a railroad man anywhere, not because it is odd, or antiquated, but because it is modern, up to date, and shows care and attention in its maintenance, that speaks well for the shops; a degree of cleanliness and order that notifies you in advance just about the kind of enginemen you will find, and a uniform appearance and sameness of outline that says, before you think of it, "This must all be under one head that is striving to maintain a standard—there must be a superintendent of motive power here."

IMPROVED CONDITIONS.

The railroads of the South were for a long term of years the worst on the continent, dilapidated, run down, with all kinds of second-hand motive power and rolling stock, and only two streaks of rust and a right of way for a track. This has changed now, and some of the best modern locomotives and cars in the country are running over rock-ballasted track in the South. The East Tennessee road is one of the roads that has fixed up everything, but

THE SHOPS.

Any mechanic or railroad man familiar with running repairs would be surprised to go through the shops of this road after noting the general good condition of the power; and there is but one explanation, and that is the use of ability and brains in getting much out of little, and making order out of chaos.

The Knoxville shops are simply a row of old sheds in no way adapted to the work, and the roundhouse is worse, built before the war, for little engines, it is still used, and the modern 18 x 24 locomotives reach clear through it and stick out at each side; it has no drainage, and water from the pits runs into the turntable pit, where the sediment and mud is removed on push-cars. The shops are separated from the roundhouse by the passenger depot and yard, and the shops themselves have been built piece-meal, without any apparent plan. What Mr. Thomas and his assistants have done with this plant is a surprise to outsiders, and ought to be a source of much satisfaction and pride to the officials of the company.

NEW SHOPS.

The foundations are in for new shops outside the city, and I was told that these were going to be modern and first-class in every particular, but it is an odd thing that the management of roads will only put up decent shops, after every other known improvement has been made in the shape of buildings.

THE POWER.

There are yet in service but a few old engines on some light work, most of the power is new, of Baldwin or Schenectady build, with standard parts of Mr. Thomas' design—were it not for the name plates on the smoke arch, it would be very hard to tell one make from the other.

All of them have extension smoke arches, and short, straight stacks; they are painted black, lettered in yellow, and the strips are left off.

TENDERS.

As fast as they go into the shop, the flange on the back of tank is cut off for about one-third of its length, and run across the back on top of the water space and ahead of the manhole, then a neat hand-rail is run around the back and sides, giving the "hurricane deck" a finished appearance. This allows the water spilled in filling the tank to escape to the ground, prevents the lodging of cinders and the rusting out of the top sheets of the tank.

The tenders have heavy iron frames, and, in some recent collisions, some of these frames were driven full length into heavy cars without breaking them up to amount to anything

Heavy, triple arch, diamond trucks are used under all tenders; these have short arches, getting the wheels close together, they use the standard M. C. B. box of the Pullman type, and are using a solid-end stop. On some of the new ones the Westinghouse hollow steel brake beam are used.

A GOOD CHECK

A large cast-iron check case, that reminds you of the old pump check, is used, and known here as the Thomas check, all the men speak well of this check, and say that since its introduction on the road their leaky and stuck checks have disappeared

BALANCED VALVES.

Balanced valves are used, and we noticed some with the entire back of the valve cut out, but this did not work well, and valves with a back on them are being substituted, as the engines having them in come to the shop.

A ROAD KINK.

Iron signal flags are used; these are small, perhaps 10x14, and painted the proper color; on the back edge of flag there are riveted two loops that drop over iron flag-staffs fixed permanently on the pilot of every engine When the flags are not in use they are placed in a tin pocket, of the proper size, that is fastened to the outside of the back of the headlight

INJECTORS OUTSIDE.

Injector steam pipes are tapped into the dome, and there is nothing of the injector or piping inside the cab, except the operating handles.

A STEAM BOX

is used in the cab, this is a plain box, set up well off the boiler head, and having all the steam cocks in it except the gauge cocks and water glass This box is plain, and carries everything on it, and is so arranged as to be easily cleaned. By closing one large valve to its dry pipe any cock can be taken out and ground while steam is on

NOZZLES.

They have excellent coal here, and extra large nozzles are the rule, consolidation locomotives using 5¾ and 6 inch right along, and 8 wheelers using 4½ to 5. I had a great deal of conversation all along the line of the road with engineers and firemen on this subject. In every instance they told the same story: "They steam all right with the best coal, but if it is poor they are hard steamers."

This road, like many others, keeps a coal reserve, and engines are required to burn coal, about half the time, that has slaked for six months or a year on some chute or the ground.

I am a big nozzle man myself believe in running just as big a nozzle as an engine will make steam with, using *average* coal. My experience as an engineer and a fireman have proven, to my own satisfaction at least, that where a nozzle is so large that steam cannot be easily maintained with a medium quality of coal, that the fireman will use more coal in shaking and poking at his fire to get the best results out of it than is saved by the extra opening of the nozzle "Fighting the fire" wastes coal, keeps the crew in bad temper, causes runners to take unnecessary chances in "petting" their engines for water, and distracts the attention of the engineer from his more important duties with the throttle and the rules of the road

Just as quick as one of these engines starts off you notice the sound of the exhaust and know there is a great, big, generous nozzle in there I like to hear it—it sounds economical—but I have heard it when there was only a little wet steam in the lower gauge, and twenty cars and ninety pounds of wind were making me wonder how I was going to make a siding for the express. I did not like the hollow mockery of its laugh then, and would have given something to have choked it down to half—then and there.

WEDGE AND CELLAR BOLTS.

In going through the repair shop I noticed that they use but one of the two small wedge bolts, used where there are cast-iron thimbles between the lower end of pedestal jaws, have no trouble with their staying in place. For cellar bolts on driving boxes a very large split key or cotter is used.

CHAFING IRONS.

There are no makers of locomotives in the country that put heavy and large enough chafing irons between the engine and tender, the wedge is usually three or four inches wide when it ought to be six or eight and proportionately strong, with a chilled face. This part of a locomotive is usually changed to suit different ideas, and meet the requirements of the work; on this road they are putting on extra large wedges and chucks of their own design.

A SAFETY STIRRUP.

On pony trucks they put a heavy loop of inch-square iron from the cradle of the truck around the long equalizer. If the center pin bolt in front breaks, the long equalizer simply drops an inch or two into the loop and is safe, and does not rest on the axle, this accident happens very often on consolidation engines, and is dangerous and annoying. With this arrangement there is no necessity to stop when the pin breaks, much less to jack up and block up. They have had trouble here with the hole in back end of radius bar wearing large, and are improving them by doubling the thickness there and enlarging size of pin

SOLID ROD EXPERIMENTS.

Solid-ended rods are in use to a great extent, and good results have been had by boring out the brass from an eighth to a quarter of an inch larger than the pin, except a ring at each edge of a quarter of an inch, and filling the whole face of the brass with Magnolia or American metal. This has worked very well, but I should be afraid of it in case the soft metal should melt out—which it is prone to do—in that case it would mean a job of disconnecting, if the trouble was with the main rod.

It has been found here that the main bushing for side rods on consolidation engines wore out the fastest by half, and on some new engines of this class there will be solid-ended rods, except the main connection, which will have a strap and half brass box and double keys, to facilitate keeping the connection of the proper length.

SOFT METAL BEARINGS

Crossheads are lined solid with block tin; I see this used for crossheads in many places, and always with good results.

Car brasses are made in the shops, are cleaned out with an emery wheel and lead-lined.

Half shell driving brasses are used, but nowhere on the road do they use any soft metal in them. In this shop the top of brass has three recesses about half an inch deep and wide nearly across the brass —one at the crown and one at each side—these recesses communicate with the oil holes in the casting of the box, and from these are drilled six holes through to the face of the brass It is claimed that there has never been a case reported where all these holes were found stopped up at the same time.

EXPOSED STAY BOLTS.

Periodical examination of all stay bolts is made, and in order to do this the lagging and jacket ends on the side of wagon top on a line with the top row of stays to the side sheet, this leaves a bare spot in front of the cab that looks odd, but when kept nicely blacked does not look at all badly. On consolidation engines and others where boiler comes through the cab, there is a section of lagging and jacket, bound by light angle irons, that can be lifted out of the way by loosening a few bolts; this provides for the examination, and does not roast the occupants of the cab.

NO MONKEYING IN THE FRONT.

It is an offense punished by fifteen days' suspension for an engineer or fireman to open a front end, except in case of accident on the road; this rule had to be adopted to stop the changing of nozzles, cutting of draught pipes and distortion of deflectors and nettings.

Some of the engines have U S. metallic packing, but most of the freight engines have the old stuffing-box. Several engineers asked me why the U. S. packing was not made any more, they seemed to have an impression that it was out of the market A new form of metallic packing, designed by one of the L. & N. men, is being tried, and the chances of success look favorable.

DRIVER BRAKES

Eight-wheelers have the "push-down," spread, driving brake, and the freight engines either the vacuum or the American, with the equalizing pressure rig for six and eight-coupled engines. They have the same trouble here I hear of every where—all brake hanger rig for freight service too light, hangers and pins constantly breaking, and the shaking of the rig when brakes are off wears the hangers, and makes the whole rig trappy and weak.

Freight mills have a large ventilator in the roof of cab. All steam gauges are tested monthly.

MACHINE TOOLS.

In the shop there are a good many good tools, and some that it will hardly pay to move to the new shop; still it is a dearth of tools instead of a stock of bad ones from which they suffer. The machine shop has a fair equipment, the blacksmith shop is not well equipped, having only one steam hammer, and that not the best or latest design. The wood shop has some good tools, but the big planer is about all the old, plain stationary engine ought to turn; but she has that to do and all the rest of the plant beside; the erecting shop is an old roundhouse, and does very well for that purpose temporarily. The greatest objections that I have ever seen to

TEMPORARY SHOP

arrangements are that they last too long. The average railroad management build shops "that will do" when the road gets about twenty-five locomotives, and want it to "do" till they have 200. To the average "manager" who is trained in the transportation department, or the school of barter, all locomotives are made of iron, and all ought to do the same work, regardless of circumstances.

SMALL TOOLS

In the tool-room there are a few machine tools, but not the best for the purpose, and a good many hand-tools developed there for their work that are invaluable. They make their own flue expanders on a pattern designed by the tool maker, and there are many small tools about with his ear-marks—one is a tap to thread holes for the bent tubes that support brick arches in fire-boxes, in which the thread on the pipe itself is made to guide the tap.

ROLLING STOCK.

The passenger cars of the system have the Janney coupler, automatic brakes, whistle signals, and are fairly up to the standard; they use a pop valve, set and sealed at fifty pounds, on the pipe between the auxiliary drum and the brake cylinder, to prevent the sliding of wheels; freight cars are heavy, but with plain draw gear and brake shoes on but one truck; their 4-wheeled cabooses are the heaviest and best I ever saw; they have a solid frame and rigid drawheads, like a tender, and can stand all the pushing a consolidation can give.

The number of broken cars on the repair tracks is a fair indication of the volume of business, and these are full; heavy trains pulled over a hilly country on a crowded, single track calls for lots of break-in-twos, and rear end "circumstances," and more and more shows up what automatic brakes would do to preserve things in their proper shape.

HOW MANNED.

Mr. Thomas and most of his master mechanics and foremen are graduates of the P. R R., Mr. Thomas having learned his trade at Renovo. The Knoxville shops are under the care of the following staff: J. B. Michaels, division M M , with the following foremen: J. P. Clare, machine shops; R. J. Farrel, erecting shop, R. D Simpson, tin shop; J. A Jamison, boiler shop; F. A. Cummings, blacksmith shop; A C. Rourke in the roundhouse, days, and A. J. Dunn at night; T. P. Roberts is the tool maker, J J. Bossinger M. C. B., Frank Smith foreman car painter, Wm. Ham foreman carpenter, and John Householder has charge of woodwork on locomotives.

The engineers and firemen run 100 miles for a day, and there is no graded pay—the first day a man goes over the road with a train he is paid full pay. Thirty-five cents per hour is paid for delayed time. Hostlers are provided to receive engines as they come into the yard, and put the train away and take engines to the house.

IMPROVED WORK BOOK.

Blank forms are provided to report repairs on, and a place is left for the man making repairs to report work done, and charge his time; thus a record is made of work reported, that done, and that left undone, and the whole thing is copied and sent to the Supt. of M. P. This plan has many advantages over the old work book, where all work reported is crossed off, whether done or not, and many a man has unjustly lost his job over the work book. There can be no dispute with this plan—it is a good one.

DEPUTY ENGINEERS.

At the roundhouses men are provided to pack, clean signal and headlights, and do other work usually done by the engineers, as the freight engines are "chain-ganged," no crew having a regular engine.

ON THE ROAD.

Through the courtesy of Supt. Huger, I was treated to a ride on the 217, one of their best passenger engines. We left Knoxville in the evening but an hour or two before dark, and I had a chance to see the condition of the road. The line is built over uneven ground and is pretty crooked for a standard gauge; the line is laid with fifty-six-pound steel, and rock-ballasted, with modern bridges in most places and good station buildings.

A FAST RUN.

Engineer McNab, of the 217, is a cool, jolly runner, with a pride in his engine and his work. It was he who, a few months ago, took Jay Gould's special cars over this crooked division in such a hurry—making 112 miles in 107 minutes.

AT CHATTANOOGA

the East Tennessee road have only a yard and turntable, and it is not a very good yard either, but it does very well. Our correspondent, H. T. Hooker, is in charge here as general foreman; has a car fitted up for an office, a car for a storehouse, and a car for a shop. It is under such conditions that kinks and short cuts are devised for work, and the best there is in a man brought out.

SAVING OIL.

A great deal of the work here is the oiling, cleaning and caring for the passenger cars; and one fact is worthy of note—they use more oil for illumination than for lubrication, ten barrels of burning oil being used to seven of lubricating. Nowhere on the road is oil furnished to car repairers or train crews to pour into hot boxes and run off, packing waste, thoroughly saturated with oil, is furnished; this cannot be put into a box on top of what is there already; the old packing has to be removed and fresh substituted, and better results with less oil are accomplished.

SAND

of a good quality seems hard to get—it is too fine. At Chattanooga they use two Big Sandy driers, and they dry more sand than any device I ever saw for the amount of fuel consumed and surface exposed, the secret of their efficiency being in the fact that the moisture evaporated can escape at once to the air instead of having to be forced through eight to twelve inches of wet sand. A car a day is no big job for these driers.

ATLANTA SHOPS.

The Atlanta shops are the best ones that I saw on the line of the road, they are located some two miles from the center of the city, on high ground; the main shop is a long square building of one story, the offices and store-room occupy a separate building, and a new roundhouse is located conveniently near, the car shop burned about a year ago, and the blacksmith shop suffered the same fate about three months since; a temporary blacksmith shop has been built, but the car-work is all done in the main shop. The yards about these shops are clean, and are kept in order; there is room and no crowding, but, aside from the roundhouse, which is a first-class one, the shop is not well designed for a railroad repair shop. A railroad shop, in which it is necessary to keep in repair the motive power and rolling stock of several divisions of a big road, should have separate stalls, so that engines can be taken in and out without disturbing other work; this shop has four tracks entering the end of the building, and locomotives are put in one behind the other, and it is easy to see how this can inconvenience their handling, let alone the absence of that get-at-ability that is had with the separate stall plan; there was plenty of room in this case to get the work in and out without the use of a transfer table, which would have made it cheap.

The shop is only moderately well supplied with tools—some old, some new. There are several rigs of their own make, one especially for turning eccentrics, another for finishing and grinding rods, that are interesting and efficient.

A coach was being rebuilt on one track, and engines on another; as it is necessary to paint the cars in the shop it is disagreeable, as the shop must be closed to keep out dust. I believe there is a plan to put up a new car shop here this summer.

I noticed that on some of the freight engines a heavy weight is attached to the long arm of the vacuum driver brake, to hold the rig still when off, and prevent its shaking.

Driving brasses are put up without babbitt, but only two oil holes are drilled in the brass here.

THE PILOTS.

The pilots are like those described on the Fitchburg, where the draught casting is not attached in any way to the pilot, but in freight service they use a wrought draw head that will couple to a freight car without the use of a long bar.

Colored men are employed for laborers.

Mr. C. F. Thomas, who has been in charge here for some time, has, since my visit, taken charge of the Macon shops of the Central of Georgia. The engineers seem well contented here, have no classifications, get paid for delays, have good engines to run, and one and all spoke regretfully of Mr. Thomas' leaving, and expressed the hope that the next man would be as good.

AT MACON

Here is a little roundhouse and shop under the immediate charge of General Foreman Tracy, but the principal repairs are done at Atlanta.

SOME TIME-CARD COMPLICATIONS

On some of the divisions of this road, where branch trains run for some distance over the main line, the time-card is very confusing to a stranger, as there are odd and even numbered trains running in the same direction, being distinguished by the numbers alone, but the boys are used to it, and steer right along in safety.

J. A. H.

The Armagh disaster on the Irish Great Northern Railway, last year, has already cost that corporation £65,688 for damages alone, and they are not done settling yet by a good way. The wreck will cost close to half a million dollars.

Simple Lessons in Drawing for the Shop.

By Orville H. Reynolds.

SIXTH PAPER.

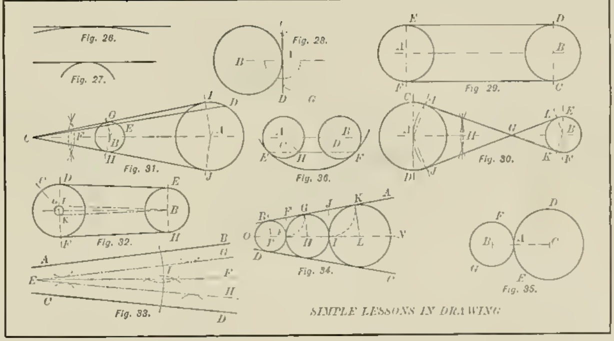
In pursuit of the light which is revealed to the earnest seeker, we are brought to a realization of the importance of geometry, for the exercises in previous paper were geometrical problems, although called by another name.

Let the interest once become awakened to the great truths laid before us by the geometrician, and it will be unflagging to the end.

The application of this science to the drawing board is absolutely necessary to success, for the reason that the whole fabric of mechanical drawing rests on the principles of geometry.

To continue: Figs. 26 and 27 are intended to show how difficult it is to draw a straight line to a circle, and touch the same in the right place, or what is known as making a true tangent. One of the arcs is of great radius, the other of lesser, and, without a definite point to draw to, the tangent is frequently drawn either within or without the circle, now, when it is remembered that a true tangent is perpendicular to the radius drawn from the point of tangency, and that point is on the circumference, the force of the foregoing is appreciated.

Fig. 28 shows how to draw a tangent to a circle from a given point in the circumference. Through the given point *A*, draw radial line *A B*, then the perpendicular *C D* to that line will be the required tangent. To find the perpendicular line, describe a semi-circle on line *A B*, and from its intersection with *A B*, describe four arcs as *C D*, then the line drawn through intersection of arcs at *C D* will touch circumference at *A*, giving true tangent.



SIMPLE LESSONS IN DRAWING

Fig. 29 represents two pulleys connected by an open belt, *i. e.*, one not crossed, if, now, there was no slack whatever in the belt, the pulleys would be connected by straight lines, and it is plain that the belt would furnish a good example of tangents. To construct Fig. 29, draw center line *A B*, and describe two circles of same size any distance apart, draw diameters *C D* and *E F* perpendicular to the center line, and the points where these diameters cut the circles are the points of tangency of the belt, joining the points by straight lines, we have true tangents.

Fig. 30 is an example of tangents drawn to two circles of unequal diameters, and is clearly represented by two pulleys which are driven by a crossed belt. To produce this figure, draw center line *A B* and describe given circles, perpendicular to the center line draw diameters cutting the circles at *C D* and *E F*. Draw *C F*, which will cross the center line at *G*; with the dividers bisect *A G* at *H*, now with radius *H A* and from *H* as a center, describe an arc on large circle at *I* and *J*, draw *A I* and *A J* from the center through arcs. In the small circle draw *B K* parallel to *A I*, and *B L* parallel to *A J*; draw straight lines from *I* to *K*, and from *J* to *L*; both lines will pass through *G*, and will be the required tangents.

Fig. 31 shows tangents drawn to two circles of unequal diameters; this construction can also be exemplified by two pulleys, and the tangents be supposed to represent an open belt.

Draw the center line *A B C*, on which describe given circles *A* and *B*. From centers *A* and *B* draw parallel radii *A D* and *B E*, from *D* to *E* draw a line, and produce it to meet the center line at *C*. Bisect line *C B* at *F*, and from *F*, with radius *F B*, describe an arc cutting small circle *G B H*. Draw the radii *B G* and *B H*, and from *A* draw *A I* and *A J*, parallel to *B G* and *B H*;

lines then drawn from C, through G and H, will meet the large circle at I and J, and tangents will touch both circles as required.

The above is also a method of drawing tangents to a circle from a point without it. The point C being the point without the circle; $C\ G$ and $C\ H$ being the tangents for circle B.

Another method of drawing tangents to circles of unequal diameters is shown in Fig. 32.

Draw the center line $A\ B$, describe the given circles, and draw in the larger circle A, radius $A\ C$, on which lay off $C\ G$, equal to radius of small circle B; from center of circle A describe a circle with the radius $A\ G$. Draw tangents $B\ I$, and $B\ K$ from center B. From A and B draw perpendiculars to these tangents, cutting circles at $D\ F$ and $E\ H$, draw straight lines from D to E, and from F to H, the lines will be the tangents sought.

How to bisect an angle when the vertex is inaccessible, is shown in Fig. 33. Draw the inclined lines $A\ B$ and $C\ D$; draw arcs near each end and between both lines; draw from E to G, and from E to H, lines tangent to the arcs; from E as a center, and with any radius, describe an arc as at I. Bisect this arc, and draw through it from E, producing the line to F when line so found will be center line of angle whose vertex is not shown.

Fig. 34 represents a number of circles between two inclined lines, circles at once touching the lines and each other. Find the center between the two inclined lines $A\ B$ and $C\ D$, by the method shown in Fig. 33, producing center line $N\ O$; from the point P, on this line, draw $P\ B$ perpendicular to the line $A\ B$; and from P describe the circle $B\ D$, touching the given lines, and cutting the center line at $O\ E$. From E draw $E\ F$, perpendicular to the center line $N\ O$, cutting line $A\ B$ at F; from F describe an arc, with a radius $F\ E$, cutting $A\ B$ at G, draw $G\ H$ parallel to $B\ P$, which is also perpendicular to $A\ B$. Take the center of the second circle at H, and describe it with the radius $H\ E$ or $H\ G$, touching circle $B\ D$ at E. From $I\ J$ draw perpendicular to center line $N\ O$, cutting $A\ B$ at J; from J describe an arc, with a radius $J\ I$, cutting $A\ B$ at K; draw $K\ L$ parallel to $G\ H$, or perpendicular to $A\ B$, and at intersection of $K\ L$, with center line $N\ O$, will be the center of the third circle, which, being described with the radius $L\ I$ or $L\ K$, will touch both inclined lines, also the second circle. This construction can be reversed, the larger circles described first and smaller ones after, making interesting practice.

In Fig. 35 we have the problem of describing a circle from a given point, so that it shall touch another given circle. If now $D\ E$ is the given circle, and B the given point, draw a line from B to the center C, and produce it to cut the circle at A. From B as a center, with a radius $B\ A$, describe the circle $F\ G$, which will touch the circle $D\ E$, as required. It is plain that it makes no difference whether the point B is within or without the given circle.

Fig. 36 is an arc touching two given circles. This construction is as follows: Connect the centers of the circles $A\ B$ by a straight line from C to D; draw a line from F, passing through D, indefinitely; at C draw $C\ H$, parallel to $D\ F$; draw $F\ H$ parallel to $C\ D$, and produce it to E; draw $E\ C$ and produce it to its intersection with line drawn from F to G; then from G, with a radius $G\ F$ or $G\ H$, describe an arc, touching both circles.

In these studies of straight lines tangent to circles and circular arcs, and of circles tangent to each other, no proof has been attempted, neither has the principle involved been explained; it being deemed unnecessary in these papers, for the reason that they are likely to cover more ground than was originally intended.

The acceptance of these and other problems as correct will save both time and space.

Railroad men have been noted for the fancy names given to their fast trains, hence we have "The Cannon Ball," "The Gee Whiz," "The Thunderbolt," "The Eli," and many others, but it remained for the trainmen of the Chicago Division of the "Santa Fe Route" to give a name to the new fast freight run that is both complimentary and expressive. They have dubbed it "The Nellie Bly."

The Fastest Time between Philadelphia and New York.

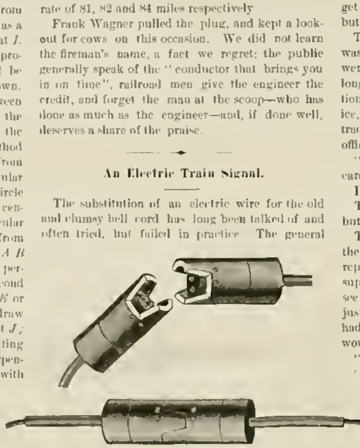
Early this month the Philadelphia & Reading ran a special from Philadelphia to New York, a distance of 89.4 miles, in the remarkable time of 85 minutes. The engine, the 366, a Wootten boiler, 18x24, 8 wheeler, was not prepared for the run, but taken out of the house hurriedly for the emergency.

The first revolution of the drivers was made at 11.38 A. M., and the real running began at Wayne Junction, on the outskirts of Philadelphia, which station was passed at 11.44½. From this point the road is peculiarly adapted to the attainment of high speed, being straight, free from heavy grades, and in excellent condition of maintenance. The fifty-four and nine-tenths miles between Wayne Junction and Bound Brook was covered in 49¼ minutes, an average speed of 66¾ miles per hour. The highest rate of speed reached was 87 miles per hour, and stretches several miles long were run at the rate of 81, 82 and 84 miles respectively.

Frank Wagner pulled the plug, and kept a lookout for cows on this occasion. We did not learn the fireman's name, a fact we regret; the public generally speak of the "conductor that brings you in on time", railroad men give the engineer the credit, and forget the man at the scoop—who has done as much as the engineer—and, if done well, deserves a share of the praise.

An Electric Train Signal.

The substitution of an electric wire for the old and clumsy bell cord has long been talked of and often tried, but failed in practice. The general



ELECTRIC TRAIN SIGNAL.

cause was that the connections between cars and in the buttons were too open, and gathered moisture that completed the circuit, and operated the signal when it was not intended to operate, thereby becoming a danger instead of a safeguard.

The Johnston signal has now been in successful operation for a couple of years and has proven a success.

The batteries are carried on the engine or a car, and on passenger cars the cable takes the place of the bell rope, having buttons every few feet in its length, as well as on the platforms; pushing a button rings the bell in the engine.

On freight cars the wire can be fastened anywhere, on top, under the eaves or under the car.

The connections between cars are covered with a strong hose and the heads are water-tight. Should the train part, this signal not only rings the signal bell in the cab, but one in the caboose or other cars as well, so that all the trainmen are notified of a break-in-two, an advantage over the rope and the air signal that any railroad man will recognize.

The cheapness of equipping trains with this signal ought to place it on freight trains forthwith, as there is now no reliable way for the conductor and engineer to communicate quickly.

A man named Archer has recently patented a snow-plow that just melts the snow by a gas flame in front, and thinks it will solve the snow blockade problem. There is no use in half doing a thing. Mr. Archer ought to put on an attachment that would run the melted snow into moulds, and let it freeze in the right shape for market.

A large union meeting of locomotive enginemen will be held at Elmira, N. Y., on the 6th.

"The Prince and the Pauper."

One of the supply men in the oil line tells a pretty good story on the purchasing agent of one of our trunk lines. This purchasing agent is one of the autocratic kind that sit behind three rows of sentinels, the first of whom demands to know what you want to see "Him" about, and the next asks for your card; you then wait twenty-four minutes, when the third emissary appears and informs you that "He" is too busy to see any one, but will be glad to see you at 11:15 day after to-morrow.

Well, our oily friend had received a bluff or two of that kind from the Prince, and had given up trying to see him on business, although the main office of the oil company was located in the same city as the headquarters of the road, whose supplies were bought by the Prince.

This road used tallow for cylinder oil, and through some miscalculation of the Prince, the supply ran short—then out, they tried all about to get tallow to piece out till an order could be filled, but it was no go—there was not a barrel in sight.

This news came to the ears of the oil man, who was then in charge of the main office. There were 10 or 15 barrels of tallow in an odd corner, long reserved for an emergency in their "combination" business; here was a chance to break the ice, do the Prince a favor, and enter the wedge of trade; he put on his coat and went to the railroad offices.

"Could he see Prince So-and-So?" If he had a card the slave would see.

He had a card.

The Prince could not possibly see anybody then, but would probably be at leisure next week.

The Pauper started home; in the yard he met the M. M., and mentioned the fact that he had been repelled by the halo of the Prince — said he supposed that a purchasing agent's place was to see everybody—but still, it was nothing to him, he just heard they were short of tallow, and, as they had a few barrels they could spare, thought they would offer it in a neighborly way, to help out.

"Have you got any tallow?" exclaimed the M. M.

"Ten or fifteen barrels for our own use, that's all."

The M. M. made a bee-line for the general office.

The supply Pauper went home, locked the door, and posted his office boy.

In ten minutes the telephone bell rang.

"Hello!"

"Hello, yourself!" said the boy.

"This is the Purchasing Prince of the Thus & Such Ry. Is Mr. Supply Pauper there?"

"Yep."

"Tell him to step to the 'phone, please."

"Can't, he's too busy."

"But it's important business."

"Everything is important with *us*."

"Tell him it is Mr. Prince."

"Dassent disturb him, you can't get him by telephone."

Thirty minutes later the Prince bounced into the outer office of the Pauper.

"Mr. Pauper in?"

"Yes, sir."

"I wan'ter see him."

"Card, please; take a seat."

After ten minutes the boy returned. "Mr. Pauper is too busy to see any one this week, but says if you'll come in next Thursday at 3 P. M. he can see you."

"But this is a matter of importance."

"Can't help it; I must not disturb him again to-day."

The Prince bolted out, and as he passed along the hall it was noticed that the halo was dim.

He got that tallow by sending a letter by special delivery, in which the role of Prince and Pauper were reversed.

The Prince still rattles around in a cavern of exclusiveness several sizes too big for him, but men on the road say that when that particular oil man throws in his card the Prince thaws out at once, and will always see him on days when his own wife has no show at all.

The Master Mechanics' Association will not meet in Chattanooga this year, on account of lack of hotel accommodations. New place not yet decided upon.

Bert Hilliard, of Ottowa, Ill., Persey Warner, of Salisbury, Conn., and Jere N. Hall, of Raleigh, N. C., write to say that they are younger than Mr. Wm. Davis, and thus entitled to the youngest subscriber prize.

On the East Tennessee road they bush cylinders that are worn too large; slightly broken cylinders are easiest repaired by boring them out, and putting in heavy bushes

The last sentence in the Georgia Central agreement, on page 62, sounds rather odd—the company agreeing to discharge itself if it violates the agreement.

In making out accident reports, tell the whole truth—let the officers draw the inferences and supply the falsehoods.

If you have sent us questions do not be surprised to find them missing in the next issue—they have to take their turn.

The New England Railroad Club recently discussed the M. C. B. vertical plane coupler—and condemned it.

Whatever your position, try to be the best man on the road in that position.

Is there a library on your road? If there is, do you patronize it?

PATENT OIL CUPS.

These Oil Cups do not require a handful of tools to regulate. The cuts give a good idea of their appearance and construction. The spindle is easily manipulated and remains in any desired position, no extra tools are needed for adjustment, and there is plenty of room to easily clean them out. They are in extensive use by the Northern Pacific, Southern Pacific and Phila. & Reading R. R. Cos., and are pronounced superior to any other Cups ever used.

Sample Cups sent out for inspection and trial. Circulars on application.

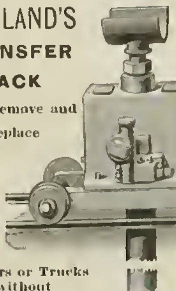
VREELAND'S

TRANSFER JACK

Will Remove and Replace



Drivers or Trucks without Jacking Up.

HYDRAULIC TOOLS FOR RAILROAD WORK

No Floor Space required for the Vreeland Transfer Jack. No Overhead Tackle No Blocking No Danger Drivers and Trucks taken out in less time than it takes to jack Engine up.

IN USE ON 10 RAILROADS.

Hydraulic Press for forcing pins into Locomotive Drivers, either under the engine or out. Also useful about Railroad Shops, for forcing on and off Balance Wheels, Cranks, Gears, Pulleys, etc Inclosed Piston. Cannot Clog. Valves are large and fall to their seats, no rush of water being required to seat them Parts easily examined or repaired. Pump is independent of cylinder casting Movement of ram, 12 inches. 60 to 150 tons pressure.

THE LOCOMOTIVE ENGINEER.

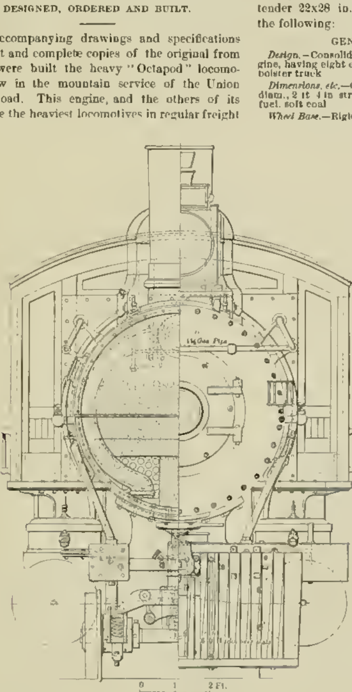
DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III, NO. 5. NEW YORK, MAY, 1890. $1.00 per Year or 10c. a copy.

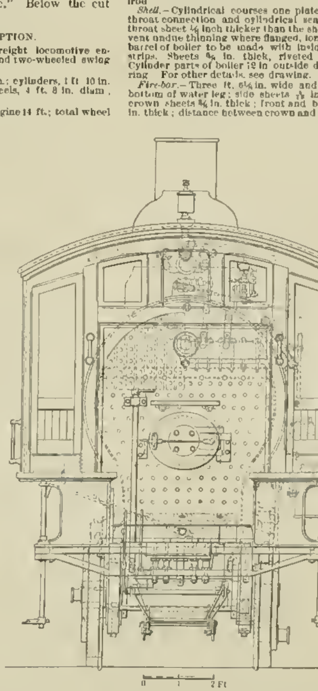
A Modern Freight Locomotive.

COMPLETE DRAWINGS AND SPECIFICATIONS, IN DETAIL, SHOWING HOW A LOCOMOTIVE IS DESIGNED, ORDERED AND BUILT.

The accompanying drawings and specifications are exact and complete copies of the original from which were built the heavy "Octapod" locomotives now in the mountain service of the Union Pacific road. This engine, and the others of its class, are the heaviest locomotives in regular freight service. The monster 12-wheeled locomotives of the Central Pacific weigh but 123,000 pounds, the big "Octapods" on the Northern Pacific 150,000, and this 153,000 pounds. The "Decapods" are 12-wheeled and weigh 150,000, but there are but a few of them in the world, and are used as pushers. The original drawings of this locomotive were some five feet in length, and had all the sizes and distances apart of all centers marked on; in reducing them to the requirements of the paper, these sizes had to be left off in order to show the design clearly, but a scale has been substituted so that any piece can be measured



HALF FRONT, SECTION. HALF FRONT VIEW



REAR VIEW

The first page of the specifications had an outline sketch with principal sizes given, as shown on page 83, above which was printed .

"Specification 114 for a broad gauge engine and tender 22x28 in. Union Pacific." Below the cut the following:

GENERAL DESCRIPTION.

Design.—Consolidation pattern freight locomotive engine, having eight coupled wheels and two-wheeled swing bolster truck

Dimensions, etc.—Gauge, 4 ft. 8½ in.; cylinders, 1 ft 10 in. diam., 2 ft 4 in stroke; driving wheels, 4 ft. 8 in. diam , fuel, soft coal

Wheel Base.—Rigid wheel base, engine 14 ft.; total wheel base, engine 22 ft. 8 in.; total wheel base engine and tender 49 ft ¼ in ; length of engine and tender over all, 62 ft. 7¾ in.

Weight – Weight on drivers, two gauges water, about 138,000 pounds ; weight of engine, two gauges water, about 153,000 pounds.

Heating Surface —Heating surface of fire-box, 178.00 sq. ft.

Surface —Heating surface of tubes, 2,114.00 sq. ft.: total heating surface, 2,292.00 sq. ft ; area of tube openings 831 sq. in.: heating surface per square inch of cylinder area, 3.05 sq. ft ; square inch cylinder area to square inch tube opening, .912 sq. in.; steam pressure, 160 pounds".

DRAWINGS.

For list of drawings referred to in these specifications, see pages 13 and 14 of specifications Drawings and such interlineations, notes figures and details as may be upon them are to be considered as a part of and illustrating these specifications

BOILER.

Kind.—Boiler to be made of form known as Wagon Top, with dome 1 ft. 10 in high, and 2 ft. 8½ in. diameter placed on same

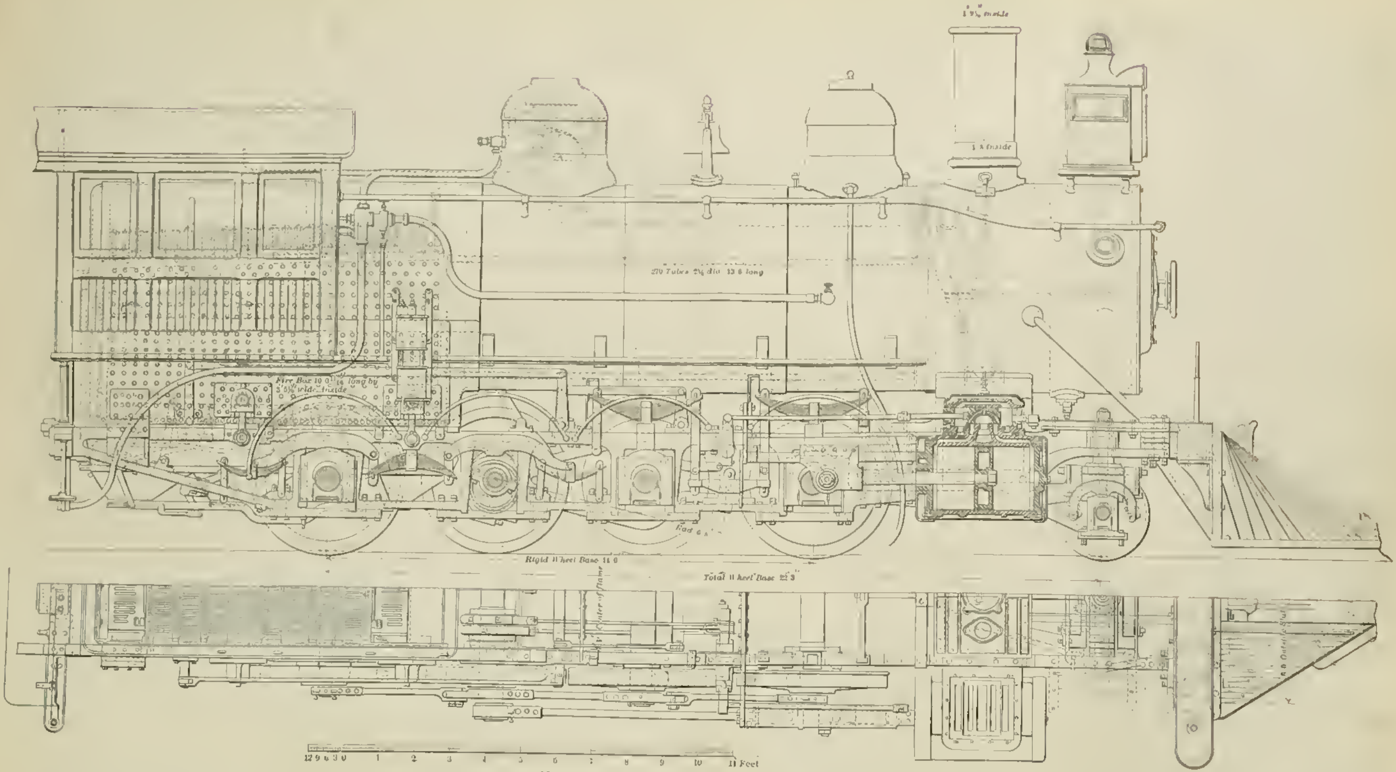
Material.—Shell, fire-box and flue sheets of steel ; brand of steel as shall be elected. Stay bolts and braces, Sligo iron

Shell.—Cylindrical courses one plate each ; horizontal, throat connection and cylindrical seams double-riveted, throat sheet ⅛ inch thicker than the shell of boiler, to prevent undue thinning where flanged, longitudinal seams on barrel of boiler to be made with inside and outside welt strips. Sheets ⅝ in. thick, riveted with 1 in. rivets. Cylinder parts of boiler 62 in outside diameter at smallest ring For other details, see drawing.

Fire-box.—Three ft. 6¼ in. wide and 10 ft. 11/16 in long at bottom of water leg ; side sheets 5/16 in. thick ; back and crown sheets ⅜ in. thick ; front and back tube sheets, ½ in. thick ; distance between crown and top sheets 1 ft. 11⅝ in. front, 2 ft. 2⅝ in. back ; water space, back and sides, 3½ in., front, 4 in. Stay bolts of Sligo stay bolt iron 1 in. diameter, placed not over 4¼ in center to center, screwed and riveted over sheets at both ends ; after being riveted over, each stay bolt to have hole drilled in outer end 3/16 in diameter by 1 in. deep

Crown Bars —Crown sheet supported by 27 crown bars, each made of two bars of iron ¾ by 7 in., welded at both ends ; ends to have a firm bearing on side sheets ; distance, center to center, about 4⅛ in.; crown bar bolts to be screwed in from inside of fire-box ; cap, washer and nut on top of crown bar The ¾ by ¾ in square part " C. C." only to screw crown bar bolts in by. Put three thimbles only as B. B B., between each crown bar and crown sheet thimbles 2 in long, located as shown

Tubes —National Tube Works " Franklinite Tubes" with copper ferrules on both ends, rolled at front end and swedged, rolled and beaded at fire-box end, 270 in number, 2¼ in. outside diameter, No. 11 B W. G. in thickness and 13 ft. 6 in. in length. Material for tubes to be iron, tough and of even grain, and as specified below



MODERN FREIGHT LOCOMOTIVE. PLAN AND SECTION.

PHYSICAL TESTS, MATERIAL, &c

Stay Bolts.—Stay bolts and braces to be Sligo iron, and to have a tensile strength of 50,000 pounds, and an elongation of not less than 28 per cent in a test section originally 4in long, the diameter of specimen in no case to be more than ¼ the original length

Boiler Steel.—All steel used in construction of fire-box and shell must conform to the following requirements A test strip 24 in. long by 1½ in wide, taken from any sheet, must have, without annealing, a tensile strength of not less than 50,000 pounds per square inch, nor more than 65 000 pounds per square inch, with an elongation of not less than 28 per cent on a length of 4 inches. Reduction of area at point of fracture to be not less than 50 per cent. of original area. Boiler to be strongly made, and braced at all parts All plates to be planed at edges and calked with round-pointed tool. Boiler to be of best workmanship and best material of its kind throughout

Tubes.—Tubes to be lap welded and of uniform thickness and quality. Each tube must flange when hot without crack or sign of distress; must expand and bend over when cold without sign of cracking or fatigue, and by immersion in diluted acid show a perfect weld Under these tests the iron must show a clear grain, free from sand and cinder. A specimen 1½ in. long, cut from tube taken at random, must stand hammering vertically, and show but slight splitting when crushed down solid. They must also when tested show a tensile strength of not less than 55,000 pounds per square inch, and a ductility of 15 per cent To be subjected to an internal hydraulic pressure of not less than 300 pounds before insertion

Test.—Boiler to be fired up before lagging is put on and tested as perfectly tight under a hot water pressure of 200 pounds per square inch, and to be capable of carrying with safety a working pressure of 160 pounds per square inch

Cleaning.—Cleaning holes and blow-off cocks located as per drawings

Throttle and Steam Pipes.—To have balance valve placed in dome, wrought-iron dry pipe, etc

Grates.—Union Pacific Shaking Grate "7—D" of finger pattern as shown, of cast-iron, with one drop grate in front and one at rear end of box

Ash pan.—Hopper pattern, body of pan of $\frac{3}{16}$ in. sheet-iron, hopper frames and doors of cast iron.

Smoke Box and Stack.—Extension front end and straight stack. Smoke-box proper of $\frac{1}{2}$-inch steel, 6 ft. 1 in outside diameter Extension of $\frac{5}{8}$-inch steel, 6 ft 1 in. outside diameter by 2 ft. 9 in long, to be furnished with hand hole, cinder hopper, etc Stack of iron or Bessemer steel $\frac{3}{16}$ in thick

FRAMES

Of best charcoal hammered iron, with pedestals welded on Top bar 4 in wide and $5\frac{1}{2}$ in deep Front rails 4 in wide, bolted and keyed to main frames, and with front and back lugs forged on for cylinder connections Distance over frames, 4 ft 2 in All holes to be marked from one template, and drilled and reamed out to exact sizes given.

Pedestals.—Pedestals protected from wear of boxes by cast iron gibs and wedges Pedestal tie bars securely lugged and bolted to bottom of pedestals.

MACHINERY.

Cylinders.—To be made of the best close grained hard and strong cold blast cast-iron, free from honeycomb or other defects; cylinders to be set horizontally as shown on drawings, each cylinder cast in one piece with half saddle right and left, cylinders reversible and interchangeable, accurately planed, fitted and bolted together in the most approved manner All bolt holes to be reamed and turned bolts a driving fit, valve seat and steam chest seat raised above face of cylinder to allow for wear

Diameter, 1 ft 10 in; stroke, 2 ft. 4 in, distance, center to center, 7 ft $1\frac{1}{8}$ in; length of ports, 1 ft 4 in., width of steam ports, $1\frac{3}{4}$ in; width of exhaust port, $3\frac{1}{4}$ in

Pistons and Rods.—Solid heads of cast-iron with cast-iron snap rings 1 in wide by $\frac{5}{8}$ in. thick Piston rods of best hammered charcoal iron, 4 in diameter by 4 ft $4\frac{11}{16}$ in. long out to out, to be ground and keyed to crossheads, and ground, riveted and nutted to pistons.

Rod Packing.—Piston rods and valve stems fitted with the "Jerome patent metallic packing."

Guide Yoke.—Extending across frames, made of best quality of hammered iron.

Guides.—Two guide bars for each cross-head, made of steel Top guide $2\frac{3}{4}$ in. by 7 in., bottom guide $3\frac{1}{2}$ in. by $4\frac{3}{4}$ in., fastened as shown

Crossheads.—Made of best cast-steel, "Lairds" pattern, with babbitted bearings

Valve Motion.—Most approved shifting link motion, graduated to cut off at all points of stroke; links of Lowmoor iron, case-hardened; sliding blocks, pins, bushings, lifting links and eccentric rod jaws, of best refined hammered iron, well case hardened; sliding blocks with long flanges to give increased wearing surface, rocker shaft of refined iron, and made without weld; journal, 4 in diameter by 1 ft. $2\frac{1}{8}$ in. long, with arms $1\frac{5}{8}$ in thick Reverse shaft of refined iron

Main Valves.—Engine to be equipped with Richardson-Allen balance valves

Eccentric and Straps.—Eccentric must be made to fit true on driving axle, and to be fastened on same as shown; outer rim of same to take strap must be turned off smooth and true, and eccentric straps must be fitted up to go on same a fine, true working fit Eccentric straps and blades must be fitted up so blades will be true to same, and be so set.

Blades.—In forging blades they must not be butted to stub end or foot by which they are bolted to strap, but stub end, and not less than 8 to 12 inches of blade must be forged solid. After work is put on same the blades will then be welded up with most approved form of lap weld.

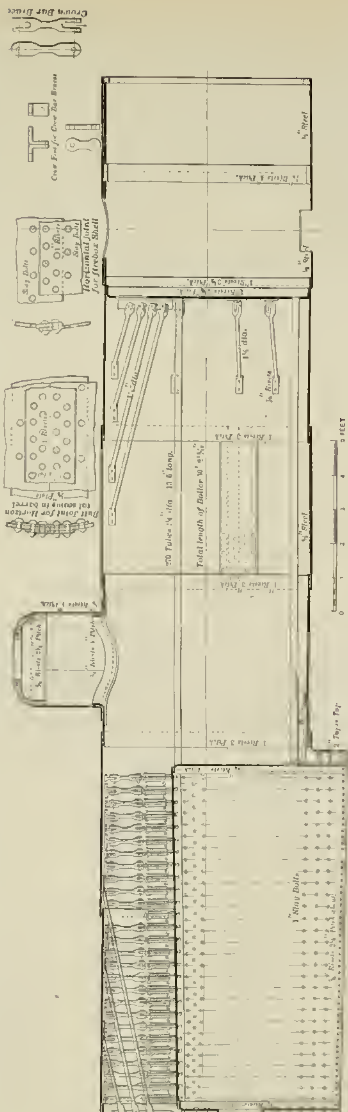
Driving Wheels.—Number of pairs of driving wheels, 4; diameter of driving wheels 4 ft. 3 in.; diameter of driving wheel centers, 3 ft 8 in; thickness of tires, finished, $3\frac{1}{2}$ in; width of first and fourth pair of tires, $5\frac{1}{2}$ in. flanged; width of second and third pair of tires, 6 in. plain Tires of Krupp crucible steel; centers of cast-iron, with solid hubs and spokes, and hollow rims. Driving wheels must be forced on axles a smooth parallel fit, with a pressure of not less than 70 tons nor more than 80

Driving Axles.—Made of best hammered iron Journals $8\frac{1}{2}$ in diameter and 9 in. long, wheel fit, $8\frac{3}{4}$ in diameter.

Driving Boxes.—Of cast-iron, with round solid brasses, babbitted; cast-iron cellars, shoes and wedges; style and size as shown

Driving Springs.—Union Pacific No 67, 16 leaves, $\frac{3}{8}$ by $3\frac{1}{2}$ in. by 3 ft, 3 in. over all, U P. No 68, 15 leaves, $\frac{3}{8}$ by 4 in by 2 ft 7 in. over all; U. P No 69, six leaves $\frac{5}{8}$ by $3\frac{1}{4}$ by 2 ft $\frac{1}{4}$ in. Springs to be of approved manufacture.

Rods.—Main and parallel rod of best quality of charcoal hammered iron, forged solid; main rod fitted with necessary straps, keys, bolts and brasses, side rods fitted with necessary keys, bolts, brasses and bushings, etc., all as per drawings Brasses of best ingot copper and tin alloyed in proportion of 7 parts copper and one tin.



LONGITUDINAL SECTION.

Crank-pins.—Of best quality charcoal hammered iron. Wheel fit, main pins, $6\frac{1}{2}$ in diameter, first, second and fourth, 5 in diameter For other details see drawing Pins must be turned a smooth parallel fit, and be forced to place with a pressure of not less than 30 nor more than 40 tons

Equalizing Beams.—Of best charcoal hammered iron.

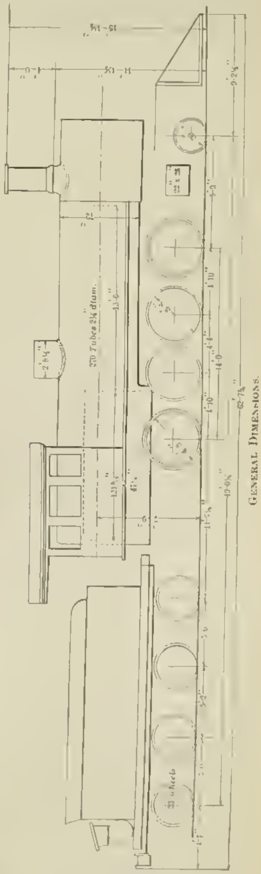
Feed Water.—Supplied by two No 10 Monitor lifting injectors arranged with cocks and valves for convenience in working

ENGINE TRUCK

Plan.—Center bearing swiveling, two wheel truck with swinging bolster and radius bar, wrought-iron frame and pedestals.

Wheels.—Cast-iron, 30 in diameter, to be pressed on axle a smooth parallel fit, with a pressure of not less than 35 tons nor more than 45 tons Wheels must be located on axles so as to give a total lateral motion of $\frac{3}{4}$ in. between wheel flanges and rail; see gauge Wheels must conform to U. P. Wheel Specification No 765

Axles.—Union Pacific No 24 of best hammered iron 5 ft $7\frac{1}{2}$ in long, with inside journals 5 in diameter by $10\frac{1}{4}$ in long



GENERAL DIMENSIONS.

Springs.—Union Pacific No 121, double coil, spring to be of approved manufacture.

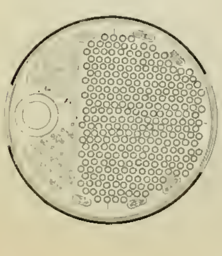
ACCESSORIES

Cab.—To be substantially built of ash, and fastened together by joint bolts and corner plates, and securely braced to boiler and running board. Width of cab, 9 ft 8 in. For other details see drawing

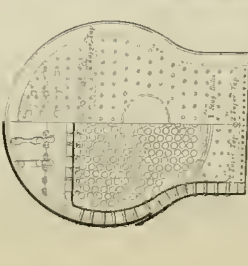
Pilot.—Union Pacific pilot "D," to be built of oak and iron, provided with cast-iron push bar casting and wrought iron push bar

Finish.—Cylinders lagged with wood and neatly cased with sheet-iron, painted, cylinder head covers of cast iron, turned and painted Steam chests with cast iron tops, bodies cased with sheet-iron, painted Dome to be lagged, sheet iron casing, top and bottom rings of cast-iron, to be painted; hand rails of iron, running-board nosing of 2 by 2-inch angle iron. Boiler lagged with wood, neatly jacketed with American planished iron, secured by iron bands of same material

Furniture.—Engine to be provided with sand-box, support for headlight, headlight, bell, $5\frac{7}{8}$ inch steam whistle, U. P. pattern; steam gauge, gauge cocks, cab lamp, blower, engineer's and fireman's seat boxes and cushions, gong in cab, wheel covers, etc.; and it must be clearly understood engine is to be furnished with all modern improvements and appliances necessary to the com-



FRONT TUBE SHEET.



FIRE BOX. BACK END.

pletion and equipment of a first-class locomotive engine and tender, though mention thereof may have been omitted in specifications and drawings

Headlight.—Union Pacific standard headlight "B," with Williams' patent safety headlight burner, No 1 pattern To be furnished with illuminated numbers, frames for same, etc, all as per specification and drawings to be furnished.

Flags and Flag staff—Engine to be furnished with metal flags and flag staffs, two green flags, two white flags, made of 18 B. W. G sheet-iron or steel. Staff of cast-iron and 1/2 inch gas pipe.

Steam Gauge—Two Crosby steam gauges, one placed in convenient position for engineer in cab, and one at back of fire-box for fireman. Dial, 6 3/4 in. diameter, with brass or other equally good case. graduated not over five-pound marks up to 200 pounds per square inch.

Safety Valves.—Three 2 1/2-inch Ashton locomotive pop safety valves, one of same to be fitted with lifting lever attachment, to be arranged in dome cover as shown.

Cylinder Lubricators, etc—Main valves and cylinders to be oiled from the cab by Nathan Mfg Co.'s No 9 locomotive sight-feed lubricators, placed in cab and connected to steam chest by copper pipes running under jacket, pipes proved to 300 pounds pressure. Vacuum valves in cylinder. Connecting rods and guides fitted with the Pedrick & Ayer oil-cups, size, etc, as per drawing. Lubrication of all bearings to be carefully provided for, and oil-cups attached where required. Also to be furnished with U P. hand cylinder oil cups arranged in conjunction with the automatic cup

Brakes—To be equipped with 8-inch air pump as per plate B 7 Westinghouse catalogue 1886 Automatic brake applied to tender Air pump to be oiled from the cab by Nathan Manufacturing Co's locomotive sight-feed lubricators Driver brakes as shall be elected To be fitted with the Ross Meehan shoes, also LeChatelier back-pressure brake appliance. Main reservoir located at rear of tank, and to be 2 ft diameter by 6 ft 4 1/2 in long inside

List of Tools—Two heavy jack screws and levers, one pony jack two frogs, one tie line, one switch chain, one heavy pinch bar with steel point and heel, one plugging bar, one grate shaking lever one poker, one slash bar, two coal picks, one ash hoe, two scoop shovels one steel buggy bar, one axe, one saw, three cold chisels, two flat and one cape, one hard hammer, one copper hammer, two monkey wrenches, one each 12 and 15 inches, a complete set of wrenches for all nuts and bolts on engine, one set of driving-box packing tools, one packing iron, one packing hook, one broom, one tin box for torpedoes, two flagstaffs U P standard, one water bucket, one tallow bucket, one gallon oil can, two half gallon oil cans, two engine oilers, one cylinder oil-can

Extra Supplies and Material—Two short draw bars, one long round coupling pin, one long flat coupling pin, two tender brasses, six flue plugs one hose feed pipe, one pair of air-brake hose and couplings two headlight chimneys

PAINTING.

Location of lettering, numbers etc, to be as shown by drawing For color, manner of mixing paints, etc see special specification attached

TENDER.

Tank Tank to be strongly put together with angle iron corners, and well braced, top and bottom sheets of No 6 iron, inside and outside sheets of No 8 iron Capacity, 2,900 gallons

Frame To be substantially built of first quality oak, well seasoned and free from all defects, to conform to drawing.

Truck—Union Pacific standard tender truck "O," rigid center bearing truck with wrought-iron, square corner frame and equalizers Pedestals cast-iron, rear truck only to have side bearings.

Safety Chains Each truck to be furnished with four 3/4 in safety chains, attached by clevis and pin to truck frame and to hook on tender frame For location of hooks on tender frame, see drawing

Springs. Union Pacific No. 54 thirteen leaves, 3/8 by 3 1/2 in. by 3 ft 3/4 in. long over all, to be of approved manufacture.

Journal Boxes—Of cast iron, to be cast square and smooth inside and outside, and to be free from lumps or other imperfections, seat for lid to be planed and lug drilled, and tapped 3/4 inch, nine threads

Journal Box Lids—To be the Fletcher swing lid of pressed steel, as made by the Morris Box Lid Company, to conform in size to drawing to be held in place by a 3/4 inch bolt screwed through lug on box and by nut and cotter

Dust Guards—Of white wood, 11/16 inch thick

Journal Bearings—Union Pacific No. 40, to be made of new metal composed of one part tin and eight parts of ingot copper, covered on bearing side about 3/16 inch thick with fine babbitt, made as follows

87.4 parts tin.
4.2 " copper
8.4 " antimony.

100

Bearing face of brass to be formed to radius of 2 3/4 in bearing face of babbitt to radius of 2 1/2 in A sample bearing to be furnished contractor by the railway company, and in no case will they be accepted unless up to standard in every respect as specified

Journal Bearing Keys—Of the Bissell pattern, to be made of wrought-iron, with stop plate of brass to be securely riveted to same Stop plate to be of same composition as journal bearings.

Packing.—Journal boxes must be packed with woolen waste only, one and one quarter pounds to each box and well oiled, safe to run without re-packing

Wheels—Cast-iron wheels, 34 in diameter, to be pressed on axles a smooth parallel fit with a pressure of not less than 35 nor more than 45 tons Wheels must be located on axles so as to give a total lateral motion of 3/8 inch between wheel flange and rails; see gauge. Wheels must conform to U. P. Wheel Specification 755.

Axles—Union Pacific axle No. 40, 7 ft 1/8 in. long, 4 1/2 in. diameter at center; journals, 4 1/4 by 8 1/2 in.; wheel fit, 5 in diameter. Axle to be stamped on each end "40," with about 1/2-inch figures; after stamping smooth off ends to remove all burr. Axles must be furnished subject to all conditions called for by specification A, No. 756, attached. The date when axles are put under tender must be stenciled on with black on a white ground.

Tool-Boxes—Three tool-boxes of hard wood, bound with iron and furnished with locks and keys, and to be placed on tender Tender to be provided with coal gate and shovel plate. See detail.

GENERAL FEATURES OF CONSTRUCTION

Gauges—All parts of engine and tender accurately fitted to gauges and templates, and to be thoroughly interchangeable

Case hardening.—All finished movable nuts to be made of iron, case-hardened

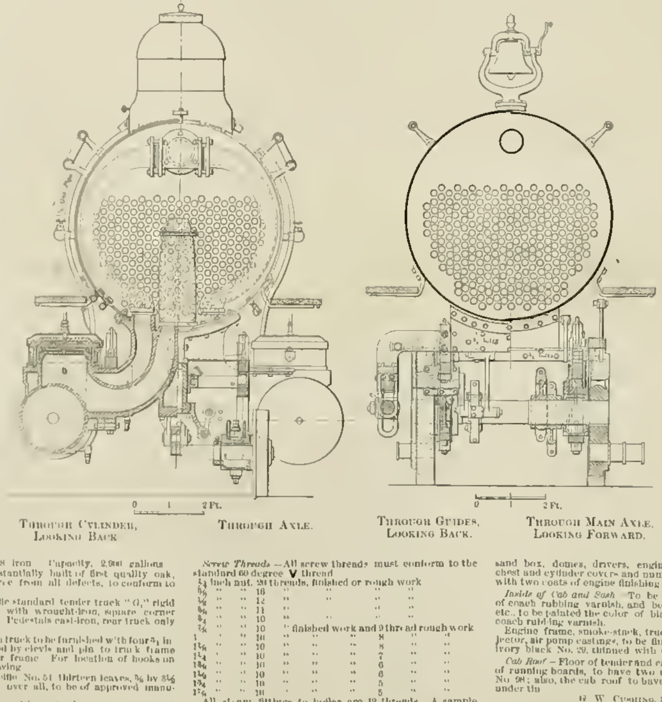
Brasses—All wearing brasses made of the best ingot copper and tin alloyed in proportion of seven parts copper to one of tin, unless otherwise specified.

Babbitt.—All babbitt used in construction of engine and tender must be of the following compositions:

87 4 parts tin.
4 2 " copper
8 4 " antimony

100

Forgings and Castings.—All forgings and castings must be first-class in every respect



THROUGH CYLINDER, LOOKING BACK

THROUGH AXLE.

THROUGH GUIDES, LOOKING BACK.

THROUGH MAIN AXLE, LOOKING FORWARD.

Screw Threads—All screw threads must conform to the standard 60 degree V thread

1/4 inch nut.	20 threads, finished or rough work		
5/16 " "	18 " " " "		
3/8 " "	12 " " " "		
5/8 " "	11 " " " "		
3/4 " "	10 " " " "		
7/8 " "	10 " finished work and	9 thread rough work	
1 " "	10 " " "	8 " "	
1 1/8 " "	10 " " "	8 " "	
1 1/4 " "	10 " " "	7 " "	
1 3/8 " "	10 " " "	6 " "	
1 1/2 " "	10 " " "	6 " "	
1 3/4 " "	10 " " "	5 " "	
1 7/8 " "	10 " " "	5 " "	

All steam fittings to boiler are 12 threads A sample nut and blank for each of the above, fitting Union Pacific standard taps and dies, will be furnished contractor All nuts used in the construction of engine and tender must conform to samples in outside dimensions as well as in diameter and form of thread

Pattern Numbers—Pattern numbers are given on drawings to be cast on all castings

CONDITIONS OF CONTRACT

All forgings, casting, boiler sheets, or other material used, must be first class in all respects. All wood and iron work, painting, etc, must be done in a first-class manner in all respects, and engine and tender must be fitted up in the most substantial and workmanlike manner, and be furnished with all the tools, trimmings and fixtures necessary to equip a first-class passenger locomotive engine and tender, though mention thereof may have been omitted in the specifications and drawings. Contractor must understand that by this is included all convenient trimmings and fixtures common to locomotive equipment, as well as the indispensable ones. Engine and tender must be turned over to this company all complete and ready for service. The whole to be subject to such tests and inspection as the superintendent of motive power and machinery, or his authorized agent, may require Any inferior material or any unfaithful or imperfect work discovered will be rejected The inspection of this work, however, will not relieve the contractor of any of his obligations to furnish material and workmanship as herein specified. Contractor to protect this company against all patent rights and claims.

G. W. CUSHING,
Sup't M P. and Machinery

Omaha, Neb., March, 1890.

PAINTING LOCOMOTIVE ENGINES AND TENDERS
SPECIFICATIONS NO. 768.
UNION PACIFIC RAILWAY COMPANY
OFFICE SUP'T MOTIVE POWER AND MACHINERY.
January, 1890

Priming.—Tank, sand box, steam domes, drivers, truck wheels, cylinder and steam chest covers, engine frame, smoke stack and all wrought-irons to be primed with a paint composed of 10 pounds English red lead standard color No. 77; 8 pounds Johnson's magnetic paint, standard color No 95; 1/4 pound Eddie's lamp-black, standard color No. 65; thinned with priming oil, composed of one gallon, best boiled linseed oil; one qt. turpentine; 1/2 pt. best Japan, and well rubbed out under the brush.

All wood-work, except inside of sash, to be primed with a paint composed of 4 pounds white lead, standard color No. 30; 2 pounds Prince's metallic, standard color No. 97; made quite thin with priming oil composed of 2 gals. raw linseed oil, 1 pt coach Japan, 1 qt turpentine, mixed.

Surfacing.—All nail holes, etc, to be filled with hard drying lead putty, and tank, drivers, all rough irons, and all wood except inside of cab, to be brought to a level surface with a paste filler composed of 5 pounds white lead, standard color No 30; 1 pound Prince's metallic, standard color No. 97; 4 pounds whiting, ground thick in coach Japan, and applied with a broad stiff knife, leaving none on the surface.

Second Coat—Tank, outside of cab, sand box, domes, drivers, engine truck wheels, cylinder and steam chest covers and pilot, to be second coated with a mixture of 5 pounds white lead, standard color No. 30; 5 pounds ivory black, standard color No 29; thinned with turpentine.

LETTERING.

Letters and Numbers for Freight Engines.—To have two coats of standard color No 8, as per pounce patterns furnished.

Letters and Numbers for Passenger Engines—All letters and numbers on cab, sand box, and front end to be in gold, standard colors No 30 and 32. Numbers on tank to be two coats of standard color No. 6.

Rods—To be finished the same as the drivers.

Sash.—To have double thick glass, outside of sash to have two coats of ground color, and grained light mahogany or bey wood Inside to be filled and finished on the natural wood.

Inside of Cab—To have two coats of green, standard color No 34, thinned with turpentine

Tender Frame.—To be coated inside before floor is laid, and all joints put together with mineral paint, standard color No 98

Inside of Tank, etc—Water space and coal space, top and bottom of tank, outside of boiler under the lagging, and inside of wrought-iron plates on tender frame, to have a good coat of color, composed of 10 pounds red lead, standard color No. 77; 10 pounds Johnson's magnetic paint, standard color No 95; thinned with boiled linseed oil, and thoroughly coated, especially the water space

Finishing—Tank, outside of cab, sash, sand box, domes, drivers, engine truck wheels, steam chest and cylinder covers and number plate, to be finished with two coats of engine finishing varnish.

Inside of Cab and Sash To be finished with two coats of coach rubbing varnish, and boiler plates, seat boxes, etc., to be painted the color of black walnut, mixed with coach rubbing varnish.

Engine frame, smoke-stack, trucks, all irons, chains, injector, air pump castings, to be finished with two coats of ivory black No. 29, thinned with engine finishing varnish.

Cab Roof—Floor of tender and cab, and top and bottom of running boards, to have two coats of standard color No 98; also, the cab roof to have one coat of the same under tin

UNION PACIFIC RAILWAY COMPANY,
OFFICE SUP'T MOTIVE POWER AND MACHINERY,
SPECIFICATION A—NO 756

FOR IRON AXLES

Iron axles must be forged under hammer to schedule sizes given in requisition, from iron double rolled from muck bar not more than 3/4 in. thick; the iron must be tough and fibrous, homogeneous and free from scrap

They will be ordered subject to the following conditions For every 100 axles or fraction thereof ordered, one additional to be furnished, from which one will be taken at random and subjected to the tests prescribed below:

To withstand without fracture three blows at 10 feet and two blows at 15 feet of a 1,640 pound hammer, striking axle midway between supports three feet apart; axle to be turned over after each blow. Tensile strength to be not less than 48,000 pounds per square inch, with an elastic limit of 26,000 pounds, and an elongation of not less than 18 per cent. on test pieces four diameters in length.

If the axle stands the prescribed test all the axles which it represents will be carefully inspected, and those only will be accepted which conform to size called for, and which are made and finished in a workmanlike manner.

If the axle does not stand the test, all the axles which it represents will be rejected.

All axles must also turn smooth and true, and be perfectly free from journal cracks, seams or other imperfections, otherwise they will not be accepted.

All axles must be cut square on ends, and to the exact length called for; to be accurately centered and drilled to conform to Union Pacific Center Gauge No 1 Gauge to be furnished axle maker from the office of Sup't Motive Power and Machinery.

Great care must be exercised to see that axles are cut off to exact length and centered to gauge

All axles must be stamped midway between ends with maker's name and place of manufacture, also metal of which they are made, which in this case would be "muck bar iron". the word "iron" alone is not considered sufficient. Letters which compose stamps to be not less than ½ in. long.

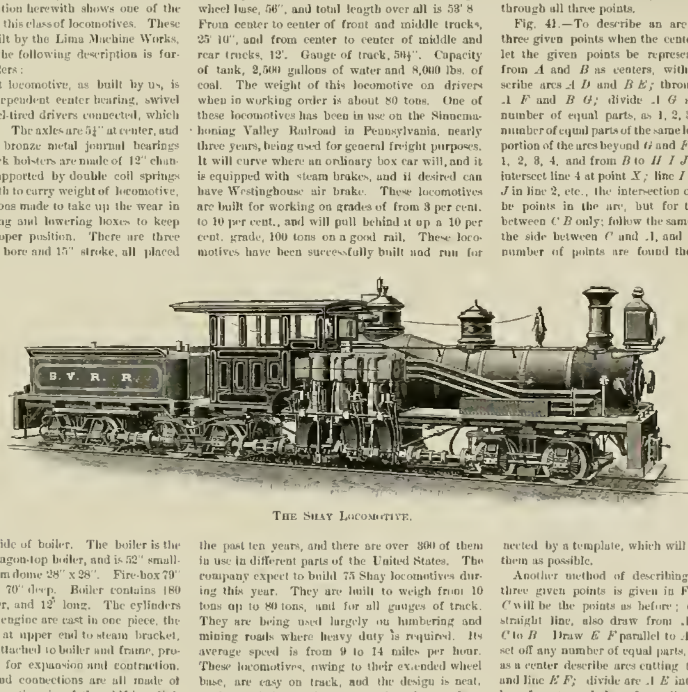
Omaha, Nebraska, December 24th, 1889.

The Shay Locomotive.

We have several times been asked to illustrate and describe the Shay locomotive, especially built to climb heavy grades, such as found in logging camps, some of which are upward of 500 feet per mile. The illustration herewith shows one of the latest and largest of this class of locomotives. These locomotives are built by the Lima Machine Works, of Lima, O., and the following description is furnished by the builders:

The Shay patent locomotive, as built by us, is mounted on 3 independent center bearing, swivel trucks, with 12 steel-tired drivers connected, which are 36" in diameter. The axles are 5½" at center, and wheel fits 6½" with bronze metal journal bearings 6½" x 7". The truck bolsters are made of 12" channel beams, each supported by double coil springs of sufficient strength to carry weight of locomotive, there being provisions made to take up the wear in axles, and for raising and lowering boxes to keep pinion shafts in proper position. There are three cylinders, each 16" bore and 15" stroke, all placed engage the gear rims on the center drivers of the locomotive proper. The fourth or rear section of horizontal shaft has two steel pinions with 18 teeth, pressed and keyed on, which engage the gear rims of the rear drivers, which support the tank; by this means the drivers are all connected. The cylinders all being on one side, the boiler is set to the left of the center, in order to equalize the weight on the track, and make the locomotive in perfect balance. The boiler being set to the left of the center, with the cylinders and all of the engaging machinery on the right side of the locomotive, gives the engineer a full view of the track and of the machinery, which is at all times under his eye. The whole weight of locomotive and tender is on the drivers, and the fuel and water is useful for adhesive power. The frame of locomotive and tender is made of I beams 12" deep. The total wheel base is 42' 6". Rigid wheel base, 56", and total length over all is 53' 8 From center to center of front and middle trucks, 25' 10", and from center to center of middle and rear trucks, 12'. Gauge of track, 56½". Capacity of tank, 2,500 gallons of water and 8,000 lbs. of coal. The weight of this locomotive on drivers when in working order is about 80 tons. One of these locomotives has been in use on the Sinnemahoning Valley Railroad in Pennsylvania, nearly three years, being used for general freight purposes. It will curve where an ordinary box car will, and it is equipped with steam brakes, and if desired can have Westinghouse air brake. These locomotives are built for working on grades of from 3 per cent. to 10 per cent., and will pull behind it up a 10 per cent. grade, 100 tons on a good rail. These locomotives have been successfully built and run for



THE SHAY LOCOMOTIVE.

on the right-hand side of boiler. The boiler is the style known as a wagon-top boiler, and is 52" smallest diameter. Steam dome 28" x 28". Fire-box 79" long, 48" wide and 70" deep. Boiler contains 180 tubes 2" in diameter, and 12' long. The cylinders and frame of each engine are cast in one piece, the cylinders attached at upper end to steam bracket, which is securely attached to boiler and frame, provisions being made for expansion and contraction. The piston rods and connections are all made of steel The valve motion is of the shifting link style, graduated to cut off equally at all points of stroke, links, blocks, lifting links, eccentric rod jaws, rocker and reversing shaft are made of steel forgings. The crank-shaft is three throw, made of solid iron forging with cranks set at 120°, journals 5" diameter. There is a heavy steel gear rim containing 37 teeth, 2¼" pitch, and 7" face attached to the outside face of each right-hand driver. The cylinders, being set vertical on the right-hand side of boiler, are connected to the crank shaft, which is at right angles (or horizontal), and coupled to the crank-shaft are horizontal steel pinion shafts coupled between each set of drivers, and on each side of engine with a flexible universal coupling, and between each pair of these universal couplings is placed a male and female coupling used for the purpose of extending and taking up the horizontal shafts, so as to allow free action of the drivers to accommodate themselves to the curves and irregularities of the track. On the first forward section of the horizontal shaft are two steel pinions, with 18 teeth, pressed and keyed on, which engage the gear rims of the forward drivers; the second section being the three-throw crank, which is connected to the engines, and forms the propelling power The third section of horizontal shaft has two steel pinions, with 18 teeth, pressed and keyed on, which the past ten years, and there are over 300 of them in use in different parts of the United States. The company expect to build 75 Shay locomotives during this year. They are built to weigh from 10 tons up to 80 tons, and for all gauges of track. They are being used largely on lumbering and mining roads where heavy duty is required. Its average speed is from 9 to 14 miles per hour. These locomotives, owing to their extended wheel base, are easy on track, and the design is neat. Owing to their peculiar construction, they set low, and have a neat and roomy cab.

Simple Lessons in Drawing for the Shop.

BY ORVILLE H. REYNOLDS

SEVENTH PAPER

To construct a straight line, which shall be perpendicular to a given line, and equi-distant from two given points, as in Fig. 37, let ends of line A B be the given points, from these points as centers describe intersecting arcs above and below the line; through intersections draw line C D, which will be the required line perpendicular to A B, and dividing it into two equal parts.

A perpendicular can be drawn to any other point on the line A B, by bisecting the distance between given points, as A E or B E, and using same construction as before.

Fig. 38 shows a perpendicular drawn to a line from a point not on the line. Draw line A B, and locate the given point as at C; from C as a center describe an arc cutting the line A B at E F; from E and F as centers, describe arcs cutting each other at D, then a line drawn from C to intersection of arcs at D will be perpendicular to A B, and pass through point C.

To draw an arc of given radius through two given points (Fig. 39), let A B represent the given points; take any suitable radius, as A E, and with A and B as centers, describe arcs intersecting at E; from E as a center, describe arc which will pass through given points as required.

Fig. 40.—To draw an arc which shall pass through three given points, as A B C, take on the compasses any distance slightly greater than half of A B or B C, and with B as a center describe an arc; without altering the radius of compasses, describe from A and C as centers smaller arcs cutting the first at G H and E F; lines drawn through intersection of these arcs will cross each other at D, then A D, B D or C D, taken for a radius, will produce an arc passing through all three points.

Fig. 41.—To describe an arc passing through three given points when the center is inaccessible, let the given points be represented by A B C; from A and B as centers, with radius A B, describe arcs A D and B E; through point C draw A F and B G; divide A G and B E into any number of equal parts, as 1, 2, 3, 4, and set off a number of equal parts of the same length on the upper portion of the arcs beyond G and F. Draw from A to 1, 2, 3, 4, and from B to H I J K; line H will intersect line 4 at point X; line I in line 3, and line J in line 2, etc., the intersection of these lines will be points in the arc, but for that portion of it between C B only; follow the same construction for the side between C and A, and when a sufficient number of points are found they are to be connected by a template, which will take as many of them as possible.

Another method of describing an arc through three given points is given in Fig. 42. A B and C will be the points as before; connect A B by a straight line, also draw from A to C, and from C to B Draw E F parallel to A B; on line A C set off any number of equal parts, as eight; from C as a center describe arcs cutting these equal parts and line E F; divide arc A E into a similar number of parts, and draw from C to the equal parts on arc A E; the intersection of these lines with the arcs drawn from A C to E F will be points in the curve, which must be connected as before

Fig. 43 shows how to construct a circle by points. Lay off A B the given radius; draw A C and B D perpendicular to A B, and equal to it; next divide the line A B into any number of equal parts, and line B D into a similar number of equal parts, continue line C A to E, and make A E equal to A C.

Draw from D, through points on A B, indefinitely; from C draw to points on B D; these two series of lines will intersect at 1, 2, 3, 4, etc., and will be in the circumference of circle of which A B is radius.

The points are to be joined by a template, as in the case of Figs. 41 and 42. A quadrant or fourth part only of the circle is shown laid off; the three other quarters can be done in same manner, producing a complete circle. A template for any particular curve can be easily and quickly made, as recommended for Fig. 25 (fifth paper). A reference to this figure will show an ellipse, in which the intersection of horizontal, vertical and radial lines form points in the curve.

Another construction is shown in Fig. 44, in which the curve is formed with the compasses, being made up of four circular arcs. This method, it must be remembered, is only an approximation to a true ellipse, which the compasses cannot make mathematically accurate. The reason for this is that an arc of a circle is not any part of an ellipse, but the simplicity of Fig. 44 makes it convenient for the draftsman to use when absolute truth is not required.

To describe this ellipse, make the minor axis *C D* perpendicular to the major axis *A B*; from *B* on line *A B*, lay off *B F* equal to *E C* or *E D*; from *E* on line *E C*, lay off *E G* equal to *E F*, produce *G F* and bisect it at *I*; from *F* lay off *F J* equal to *F I*; draw *J K* parallel to *G F*, and from *E* lay off *E L* and *E M* equal to *E J*; draw through *K L M L* and *J E J M*, and produce indefinitely; the angles of the square formed by *J K L M* are the centers from which the figure is to be drawn. From *J* and *L*, with *A L* or *J B* for radius, describe arcs cutting *N P* and *O Q*; from *K* and *M*, with radius *M C* or *K D*, describe arcs joining *N P* and *O Q*, completing the ellipse. It will be observed in this figure, that when two circular arcs are tangent to each other, that their centers are in a straight line passing through the point of tangency.

In Fig. 45 we have the construction of a spiral, as follows: On any line, as *A B*, lay off the two points *B* and *C*; with point *B* as a center describe semi-circles *D E F G*, with radii equal to *B C*, *B D*, *B E* and *B F*; with *C* as a center describe arcs *C G*, *C H*, *C I*, etc., joining *B C*, *B D*, etc., completing the figure. This method is not strictly correct, because true spirals are not made up of tangent arcs, it is, however, accurate enough for ordinary practical work.

How to divide the circumference of a circle into any number of equal parts is shown in Fig. 46. Describe the circle, and taking the radius on the divider points, set off six equal divisions, as *B, C, D, E, F, G*. From *B* to *E* is the diameter, and divides the circle into equal parts, *B D* is the chord of one-third of the whole circle, therefore *B D*, *D F* and *F B* divides the circle into three equal parts. Taking for a radius the chord *B D*, and with centers at *B* and *E*, describe arcs cutting each other at *X* above the diameter, and *X* below it. If distance *A X* be now set off from *B* and *E*, the circumference will be divided into four equal parts, as *H, B, I* and *E*.

With radius *A B*, describe arcs from *X* and *X* as centers, cutting circumference at *K L M* and *N*, this will bisect quadrants *B H*, *H E*, *E I*, and *I B*, and divides the circumference into eight equal parts.

With radius *A B* lay off from *H* and *I* the distances *O P Q R*, which bisects the arcs *B C*, *D E*, *E F*, and *G B*, completing the tri-section of each quadrant, and dividing the circumference into twelve equal parts.

The radius *A B* laid off both ways from *K L*, *M* and *N* as centers, will bisect the two arcs on each side of the ends of the diameters *B E* and *I H*, in *S, Y, U, T, W, Z*, etc., and divide the circumference into 24 equal parts.

Other subdivisions may be made indefinitely by bisecting the arcs already divided, as a bisection of the 24 parts just found will divide the circle into 48 equal parts.

This construction, it will be observed, is done with three distances—the radius *A B*, the chord *B D* and distance *A X*. To insure accuracy in laying off of the subdivisions, the points named must be kept true and free from mutilation by the divider points, which can only be accomplished by careful handling.

Fig. 47 is a further demonstration of equal divisions, to show how a circumference may be divided decimally, same letters of reference will be used for convenience With distance *A X*, and *O, P, Q, R*, as centers (assuming these points to have been found as before) describe arcs cutting each other at *Y* and *Y* on line *A X*; take the distance *B Y*, on the dividers, and set off *B, C, D, F* and *G*, dividing the circumference into five equal parts.

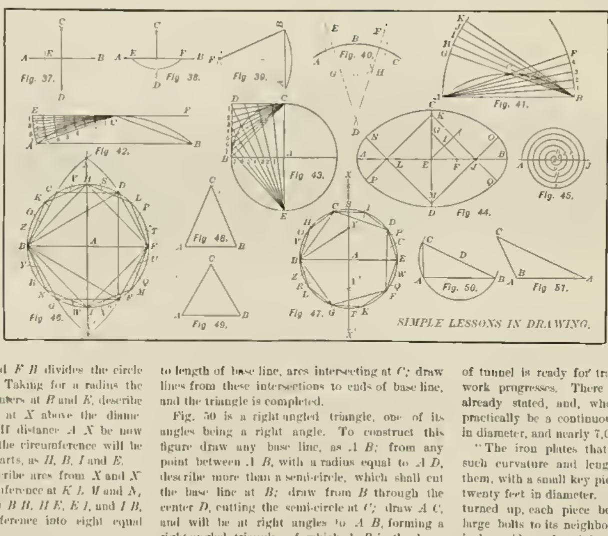
Bisecting the arcs *B C*, *C D*, *D F*, *F G* and *G H*, with distance *A Y*, the circumference is cut at *H, I, E, K, L*, and divided into ten equal parts.

Laying off the distance *B Y* from *S T*, perpendicular to diameter *B E*, will bisect arcs *D E*, *B H*, *E F*, and *B L*, in the points *U, V, W, Z*, and we have the circumference divided into twenty equal parts.

Bisecting arcs just found, we get forty equal parts, etc These constructions are time savers as compared to the cut-and-try process. Their value is apparent when drawing polygons, or dividing the pitch circles of toothed gearing.

Fig 48 is an isosceles triangle, so called because two only of its sides are of equal length; to construct this triangle, draw base line *A B*, and from each end of base line as a center describe arcs of any equal radius intersecting at *C*; draw from *C* to extremities of base, and figure is complete.

An equilateral triangle is one having all its sides of equal length, as in Fig. 49. To construct this triangle, draw any base line *A B*, and from each end of same as a center describe, with a radius equal to length of base line, arcs intersecting at *C*; draw lines from these intersections to ends of base line, and the triangle is completed.



SIMPLE LESSONS IN DRAWING.

Fig. 50 is a right angled triangle, one of its angles being a right angle. To construct this figure draw any base line, as *A B*; from any point between *A B*, with a radius equal to *A D*, describe more than a semi-circle, which shall cut the base line at *B*; draw from *B* through the center *D*, cutting the semi-circle at *C*; draw *A C*, and will be at right angles to *A B*, forming a right-angled triangle, of which *A B* is the base, *A C* the perpendicular, and *C B* the hypothenuse.

Fig. 51 represents a scaline triangle, *i. e.*, one in which no two of the sides are of equal length, and not one of the angles a right angle; to construct such a triangle, draw base line as before, take *A* and *B* as centers, and with any radius, as *B C* and *A C*, describe arcs intersecting at *C*, from which draw *C B* and *C A*

Believing that these and the foregoing problems cover sufficient ground for an elementary work, and it not being our purpose to treat the subject exhaustively, we will take leave of them for the present.

The St. Clair Tunnel.

A correspondent of the Boston *Transcript* gives the following interesting description of one of the greatest engineering projects of the day.

"Six hundred men are now digging the railroad tunnel under the St. Clair river, at Port Huron, at the rate of fifteen feet each day. More than 1,200 feet of the tunnel proper is now ready for trains on the Michigan side, and 900 on the Canadian. The remaining 4,000 feet will be finished at a wonderfully rapid rate, considering the nature of the work.

"The tunnel is over 6,000 feet long. The approaches are equally long, so that the entire length will be more than two miles. Of this distance 2,310 feet are under the river, 2,390 feet on the Michigan land side, and 2,100 on the Canadian. The grade is one foot to every fifty, except under the river bottom, where it is substantially level. It is an iron cylinder tunnel—the only one of the kind in the country. There is neither brick nor stone used in its construction. Neither are there any stays or supports—simply a mammoth iron tube built in sections underground. It is designed for a single track.

"Electric lights make it as light as day, air engines keep the atmosphere as healthy inside as above, and steam pipes hold the temperature at the proper point. It is as dry as a street in summer, and the disagreeable features common to subaqueous work are entirely absent. Work is pushed from both ends.

"The method of construction is simple. A great cylinder, weighing more than sixty tons, twenty feet in diameter and sixteen feet long, is driven into the blue clay, which constitutes the entire bottom of the river, by the use of hydraulic power, with as much ease as cakes of soap can be carved out of a general mass. Inside this cylinder, which is called a shield, twenty-two men are at work, removing the dirt. As fast as the shield is pushed forward, which is about two feet at a time, the clay thus brought inside the shield is dug out to the edge of the great cylinder. Then the hydraulic jacks are again started, and slowly, but irresistibly, the immense iron tube moves another two feet into the solid earth ahead of it. Each jack has a power of 3,000 tons, and the combined power behind the shield is more than 400,000 tons.

"Another ring of iron lining is put into place, and each foot of tunnel is ready for track laying as fast as the work progresses. There is no mason work, as already stated, and, when done, the tunnel will practically be a continuous iron tube twenty feet in diameter, and nearly 7,000 feet long.

"The iron plates that form the lining are of such curvature and length that any thirteen of them, with a small key piece, will make a circle of twenty feet in diameter. The edges and ends are turned up, each piece being bolted by a dozen large bolts to its neighbor Each one is eighteen inches wide, and weighs as near 1,000 pounds as the foundries can make them."

M. M. Mehan, traveling engineer of the Duluth, South Shore & Atlantic road, has placed us under obligations to him for eight views of their rotary snow-plow at work. These instantaneous views show just what can be accomplished by this powerful machine. Some of the views show the plow piling up the snow 75 feet from the track, cutting hard snow four feet deep. One view shows a solid trench, nine feet deep, where a side track was unearthed. A north Michigan winter is made on purpose—even the pictures look cold

F. C. Robinson, master mechanic of the Atlantic & Danville, at Portsmouth, Va., one of The Locomotive Engineer's earliest and best friends, has just been made General M. M. of the Chicago & West Michigan road. Mr. Robinson has come up from the throttle since this paper was established; he is only one of many who are going up and have only just started.

The Master Mechanics' Association will meet at Old Point Comfort, Va., on June 17th.

Management.

By J. E. Phelan.

How easy it is for a person to get set ideas and know it all, can be best understood by viewing now and then living examples of self-asserted wisdom.

When we fully consider how very little is really known by the wisest of men, it teaches us to believe that knowledge can be shared by rank and file without any chance for monopoly to any individual or company of men.

If we stop to consider the fact that in the aggregate the management of a railroad system of the present day exceeds in magnitude and diversity of talent employed, the ancient political systems set up for the government of serfs or people, we may begin to think that there exists room for diversified talent and industry in various degrees.

If we are to set our minds on the degrees of expansion encompassed in the creation of the world in six days, and when completed have the whole machinery of creation encompassed within the garden of Eden, with Adam as general manager or superintendent of motive power, we can very easily come in line to consider that there is not much to it any way, and that Adam may be fully competent to be general manager or superintendent of motive power and special head of all the other departments, or portions of the menagerie, without any especial need for assistance in any direction.

We often meet men who believe in letting matters run themselves. We have known men to occupy official positions who considered it a point of wisdom, thinking the most successful way to handle a department was simply to let matters run themselves—and the main duty of the officer so thinking, seemed to consist in showing up regularly and drawing a salary.

Such a management is all right under certain conditions.

But in successful railroad management the easiest way is not always the best way. Just as surely as the human body depends for health on good food and the observance of stated laws, just so surely does the successful management of a railroad depend on the observation of stated rules, pure principles of action, and vigilant performance of duty, on part of all employes—officials and others.

The weakness of human nature and the tendency to err is ever recognized. The old way in subjecting a serf, seemed to be in lashing into subjection, and bulldozing into line of duty.

But it is surely now time to have an age of reason, where intelligence may guide.

The correct principle of management in railroading is to govern by law, and have matters run in an orderly fashion.

Where this principle can be inculcated, from the general manager down to the humblest employe, we find matters running smoothly and according to rules—or law and order.

Railroads are conducted for purposes of revenue, and revenue is derived from traffic.

In looking after the various departments in the management of railroads, diversified talent is necessary.

In the complicated and intricate workings of railway management of the present day, for one man to say he knows it all is the height of folly.

The operating department of a railroad is a most essential part, and unless properly conducted gets away with more than a proper percentage of the revenue.

As a part of the operating department, the machinery department is especially a gormandizer of earnings, unless properly and economically conducted, and watched with untiring vigilance.

Here is a field for industry, patient research, and persevering diligence, not comprehended excepting by those who have burned the midnight oil in attaining profitable results.

In a well-conducted machinery department there is plenty of room for the superintendent of motive power, the master mechanics, the master car builder, the mechanical engineer or the engineer of tests, the general foreman, *the road foreman of engines*, and all the other employes of various grades of employment, even to the clinker pit man, who stands on the bottom round, but at the same time available for promotion.

This machinery department is an interesting industrial world in itself, to all excepting those who fail to comprehend its principles, and believe that such a combination can run itself, without effective guidance from an intelligent head.

To say that the mechanical engineer has a soft snap, simply because his duties are not fully comprehended, would be the evidence of vain imagination.

Go through the official list, and not any one has more intricate and interesting duties than the road foreman of engines, or traveling engineer.

But the traveling engineer identified with a successful management must be thoroughly competent and intelligent, and must do business in a manly way.

His duties must be in line of attaining successful results; in line of economy in caring for machinery, and properly conducting traffic.

With a system having several hundred locomotives, all equipped with modern improvements; with every engine and train, freight or passenger, equipped with automatic brakes; with an army of enginemen anxious and willing to do duty, and ever ready to follow intelligent advice, in line of good service, the traveling engineer enters a fascinating field, and can show abundant results from labor performed.

An incompetent traveling engineer should not be kept in service any longer than an incompetent wiper.

A competent traveling engineer having opportunity for consulting with the superintendent of motive power, the master mechanics, the mechanical engineers, draftsmen, and various foremen, mechanics and engineers, has a splendid opportunity for gaining diversified knowledge, and should be able to convey a profitable percentage of it to his associates on the road, where all the force can unite in a harmonious effort in doing right and performing duty.

When this subject can dwindle to the mere impression, not attaining force enough to create an idea, of a being occupying excessive space in a locomotive cab, to the discomfort of an engineer or fireman, it certainly seems like parties going rabbit hunting, who, while attempting to grab the head, simply catch at the nether extremity.

However, we will say the traveling engineer who does not know enough to properly locate himself in an engine cab, and get out of the way of engineer and fireman, has yet something to learn.

Talk is cheap; while the muffins made up from leaky vaporings around a roundhouse, while interesting to the taste yet lack body and nourishment, desired by the average individual.

Results are valuable. The many can read back numbers of The Locomotive Engineer with profit in valuable results.

From our observation in the past, where railway management is conducted economically and with profitable and intelligent results, all men retained in position have found opportunity to earn their salaries, we have not noticed many enjoying sinecures in our part of the country. The value of any employe, official or others, can be solely determined by results. To attain such results, intelligent efforts are at all times necessary.

Among the various employes, we know of none who can show better results than those accomplished by the industrious efforts of the intelligent traveling engineers.

The Schenectady Works are building a 10-wheeler and a consolidation compound for the E. T. V. & G. They are also building another 10-wheeler for the Michigan Central, but will reduce the size of each cylinder one inch, making them 19 and 28 x 24. The compound in service is on freight and doing well, but would not make up time on passenger. It has been found that all the compounds do extra well on trains of a certain weight, and drawn at a certain speed, and not so well on light and heavy trains—they are not so good all round engines as the simple ones, but are coal savers on work proportioned to their design.

Headlights have come down in price wonderfully of late, ten or fifteen years ago they were worth about $100, five years ago $60 to $70; now you can get a pretty good one for $25.

Pedrick & Ayer, of Philadelphia, have undertaken the manufacture of the Richards open side planer, which adds greatly to their work, and has caused them to commence the erection of two more stories to their present shop; when complete, this will be one of the neatest and most complete manufacturing plants in the business.

J. H. Vreeland was M. M. of the Jersey City shops of the Erie from 1876 to '89. About a year ago Mr. Vreeland resigned, but the boys thought enough of him to go down to his house one evening last month and present him with their respects and a gold watch and chain.

Correspondence

Lighting a Headlight.

Editor The Locomotive Engineer:

I know a little kink about lighting a headlight on stormy and windy nights. Take an old train order and curl it around on top of the lamp wick so as to leave a portion of it sticking up, and, by dropping a lighted match down the chimney it will ignite, and the headlight is lit. You will find this way much easier and quicker than the old way of putting a coat over your head. A Fireman.

Jackson, Mich.

He Was There.

Editor The Locomotive Engineer.

My Friend Davis, engineer of Newton City Water Works, loaned me a February number of The Locomotive Engineer. In it I find two accounts of the blowing up of engine "Neversink," P. & R.R. By referring to my time book I find the following:

"Thursday, January 14, 1847, engine "Neversink" blew up. Eight men killed." I was told it happened at or near Mill Creek Bridge.

I was working in the Reading shop at the time, as a machinist in John Dodsworth's gang. Lewis Kirk, Master Mechanic. John Bourne.

Newton, Kansas.

Before the "Neversink."

Editor The Locomotive Engineer:

At the risk of being thought "obstinate" by my old boss, S. A. Alexander, I submit the following: The case to which he evidently refers was before the "Neversink" explosion. It was a Norris engine, name forgotten, and happened near Reading during a violent thunder-storm. My informant said he was a witness to the transaction. Railroad men who examined the engine said it was caused by using cast-iron stay bars across the top of the crown sheet of the fire-box. The "struck by lightning" theory was advanced, I think, by a Dr. Lardner, an English scientist, without seeing the boiler, and was laughed at by those who examined the boiler after the explosion.

Newton, Kan. John Bourne.

Setting Valves.

Editor The Locomotive Engineer:

I once saw in a scientific paper, instructions about setting a slipped eccentric, to wit: take out pin (supposed to mean pin in end of blade), turn eccentric until pin will go in hole, fasten eccentric, and go. The above is about as vague as Mr. Campbell's pointers, so far as I can see them. Yes, valve motion is equal vibration of rocker arm, but suppose it don't vibrate at the right time, or suppose, for argument sake, it is a direct-acting motion. Don't know that I ever saw reamed holes in back end of blade; if so, what is the oblong hole for? The man who can set valves in ten minutes is a dandy. Would gauge a valve by putting it back until steam just showed at front cylinder cock, mark stem, and push ahead what you know lap to be, and mark; get back end same way—would set eccentric same way, allowing engine to be on center. Yes, lost motion does have something to do with an engine working well; they are slow about taking steam, and when they get it they slip badly.

Corry, Pa. W. de Sanno,
Engineer and Machinist.

More About that Cranky Injector.

Editor The Locomotive Engineer:

We have noticed the complaint made by "West Oakland," about the "cranky" behavior of a No. 8 "Monitor" injector on the right-hand side of his locomotive. Your editorial comment very fully answers the correspondent's complaint. We do not think that the party made a new steam nozzle, or made it too long, but it is more likely that, after removing the injector nozzles, he did not screw the steam nozzle down to its shoulder, which would have just the effect described by him. We would suggest to him to look for leaks in the packing of the water valve, to see whether the overflow check valve is tight, or admits too much air, and whether his main boiler check has a sufficient lift. All other probabilities are mentioned by you. The fact that the left-hand injector works perfectly satisfactory seems to establish almost beyond a doubt, that the trouble complained of is *outside* the right hand instrument.

Slipping Drivers in Going Down Hill.

Editor The Locomotive Engineer:

In your issue of April 1 notice a letter signed R W. Sizer, describing the slipping of his engine on going down hill, and also your editorial comment.

I believe Mr. Sizer may be quite right, as I have met with several engines which have been reported as doing the same thing, and it is invariably found that the wheels are out of square, that is, the crank-pins are more or less than 90 degrees apart, or some of the crank-pins are bent, which amounts to the same thing in effect. I believe the slipping is caused by the resistance of the side rods preventing the engine from running as freely as the train, and the train then pushes her down hill. This might easily be verified if a revolution counter were placed upon the engine.

Montreal, Can. R. ATKINSON.

[If the side rods or any other part of the engine binds or runs hard, it would tend to retard the motion of the wheels, and cause them to revolve *slower;* as we understand Mr. Sizer, the wheels slip *ahead* enough so that it is necessary to give the engine sand to stop the slipping; we have no doubt that any defect in the machinery would prevent the wheels from revolving fast enough; but what can cause them to slip too fast?]

Another Dope Receipt.

Editor The Locomotive Engineer:

In April issue of THE LOCOMOTIVE ENGINEER I see our friend A. W. Mason furnishes our boys with a very valuable receipt for cleaning and polishing brass. Bro. Mason's receipt is good, but we think we can improve it a trifle, as we have made the same dope, and used it and experimented on it; find we can do better work with the following

1 pint sperm oil.
½ ounce camphor gum, pulverized.
¼ ounce oxalic acid, pulverized.
¼ ounce arsenic.
2 ounces fine emery flour.
Tripoli to thicken to a paste

Place the sperm oil in a can or bucket, set it over a fire, bring the oil to a slow boil; place the camphor gum and oxalic acid in the hot oil, stir until entirely dissolved, when add tripoli emery and arsenic; use tripoli enough to make a thick paste. This will always stay as a paste and not get hard. Our reason for not using sperm candles is they make the dope hard. Emery flour is better than bath brick. Bro Mason furnishes a good receipt, but our experience is that for hot and cold brass the enclosed is better.

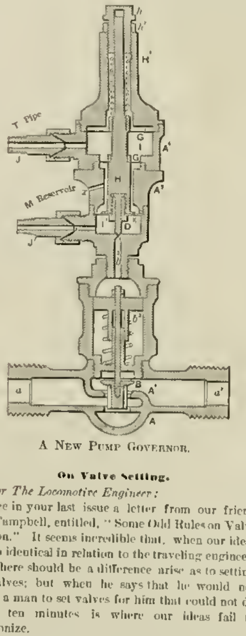
Denver, Col. CACTUS

The Lake Shore Accident and the Sweeney Air Compressor.

Editor The Locomotive Engineer:

In your article in April number about the Lake Shore accident near Buffalo, you say that "after the conductor stopped the forward part of the train he jumped off, and, seeing the danger, signaled the engineer to go ahead, the engineer tried to release brakes, but could not." I suppose that the conductor did not close the valve, so that when the engineer put his valve handle on the release, his air pressure in main reservoir went through his train pipe and escaped through the open conductor's valve, so that pressure could not be maintained in the pipe or underneath the triple valve long enough to release brakes. If that engine had been equipped with the "Sweeney air compressor attachment" the engineer could at any time release brakes when either standing still or running. You are probably acquainted with the construction of that device, which connects the steam chest and cylinders of an engine with the main air reservoir, and when an engine is in motion the cylinders may be used to compress air. But in the case of the Lake Shore accident, when the train was stopped and brakes set, or as in that case at Spuyten Duyvil, the valve on steam chest could be opened, and full boiler pressure of steam forced back to release brakes, even though there were one or two valves open pressure sufficient could be maintained to keep the brakes released until all danger was passed. After using the Sweeney device in that way there may be condensed steam in train pipe, but if one life is saved it were better even if the whole brake apparatus was destroyed; but the brake is supplied with so many bleed cocks, which, if used immediately after, no injury will be done to the brakes.

Sacramento, Cal. T P SWEENEY.



A NEW PUMP GOVERNOR.

On Valve Setting.

Editor The Locomotive Engineer:

I see in your last issue a letter from our friend Mr Campbell, entitled, "Some Odd Rules on Valve Motion." It seems incredible that, when our ideas are so identical in relation to the traveling engineer, that there should be a difference arise as to setting of valves; but when he says that he would not allow a man to set valves for him that could not do it in ten minutes is where our ideas fail to harmonize.

I would like to sit on a brow of a hill and listen to one of his engines exhaust whose valves were set in ten minutes. You may set *at* them in that time, but it is an impossibility to square them, providing they are out in the least. I think his rules are a little ancient; they are a little Greek—or probably the printer has again made one of his errors in setting the article.

If Mr. Campbell's idea is setting valves by running an engine over in her extreme travel, with steam, of course I concur with him on the ten-minute time; but that is not squaring valves. I also disagree as to the amount of lost motion in an engine's valve motion; let there be any great amount of lost motion in eccentric straps, links, rocker-boxes and valve yokes, and it is an impossibility to square an engine. You may run her over a dozen times, and find different results each time; if you happen to get her right at one point of the quadrant she will be out in another. I have often had engines where a scale and valve gauge were useless, then I would square them to sound, as it would be impossible to square them to measurement.

I claim that squaring a set of valves correct is one of the most important jobs on a locomotive; it may seem very simple to divide the lead or to shorten or lengthen a blade, but that is not all, by any means. How often has it occurred to your valve setter, that when you think you have her correct, her lead right, and she seems to measure square on the crosshead, to use an equal amount of steam on both ends or on both sides of the piston; but when she went out you could distinguish an uneven sound; so you give her another whirl, probably two, before you get her right? I do not say that this occurs to every engine, but it does happen sometimes. I concur with Mr. Campbell when he says it will surprise a superintendent or engineer to take an old engine and square her in ten minutes so she will do the work and haul as many cars as she did in her first days. It must surprise the superintendent very much.

Oakland, Cal. W. D. HOLLAND.

A New Air-Pump Governor.

Editor The Locomotive Engineer:

I send you herewith, drawing of a new air-pump governor of my own design, that has, I think, advantages over any other kind.

In order to make the matter better understood, I will mention some of the objectionable results obtained by the present governors now in use (1) In both the Westinghouse and Mason governors, there is but one controlling pressure connection, and that is in communication with the train pipe pressure.

We will consider that we have started the pump, and the desired train pipe pressure of 70 pounds per square inch has been attained, and the pump stopped, as we have a feed valve in the engineer's valve, which reduces the pressure 20 pounds per square inch between the train pipe and main reservoir, we will therefore have a pressure of 90 pounds in the main reservoir

If, now, we reduce the pressure in the train pipe 8 pounds, as by setting the brake, the pump will start and pump an additional pressure in the main reservoir, until the train pipe pressure is restored to 70 pounds, or if not restored in a reasonable length of time, until the pressure in the main reservoir attains a pressure equal to the pressure of steam carried in the boiler (as with an 8" Westinghouse air-pump, you can pump as much pressure as there is steam pressure actuating the pump). If, now, the pressure in the main reservoir has been allowed to run up to boiler pressure, say 140 pounds per square inch, and if, now, the engineer releases his brake by restoring the pressure in the train pipe, this 140 pounds in the main reservoir equalizing throughout the train pipe and auxiliary reservoirs, will reduce the pressure about 3 pounds per square inch in the main reservoir, on an average train; and allowing our feed valve to hold 20 pounds per square inch, we will still have a pressure in the train pipe and auxiliary reservoirs of 117 pounds per square inch available to set the brake, which is 47 pounds per square inch in excess of desired pressure to be available to set the brake. If now, the brake be set, there would be a tendency to rupture brake rigging and slide wheels flat. This objectionable feature is increased as the steam pressure in boiler is increased; for even now it is not an unusual thing for a locomotive boiler to carry 165 to 180 pounds per square inch.

(2) Again, we will consider that we have our normal pressure of 70 pounds in the train pipe, and 90 pounds in the main reservoir as before. If, now, we use air out of the main reservoir for any purpose, such as ringing the bell, manipulating the fire door, moving ash-pan slides, train-signaling apparatus, car lighting, sand jet, or if there be a leak in main reservoir and connections, then the pressure in the main reservoir will be reduced to that of the train pipe, or even lower, before the pump will start, and when it is reduced that low the brake will drag, as it requires a reduction of pressure in train pipe to start the pump. Therefore, with the two governors alluded to, the air direct from main reservoir is not available for use, and it is not desirable to use air from the train pipe for other uses, as it causes the brake to set and drag.

(3) Now, in my "automatic pump governor,"

I overcome these objectionable features by using two controlling pressure chambers and connections. One as connected at *J*, to train pipe, and one as connected at *J'*, to main reservoir.

We will now consider the same circumstances as in preceding case; we will consider that we have started the pump, and the desired train pipe pressure of 70 pounds has been obtained; we also now have an increased pressure of 20 pounds in the main reservoir as before, which is 90 pounds.

If, now, we reduce the pressure in train pipe, as by setting the brake, the pump will start; supplying to the main reservoir a surplus pressure above the normal (90 pounds), to be available to restore the train pipe pressure and release the brake. But this condition of things is not permanent, during the entire time the train pipe pressure may remain below the normal, 70 pounds, for if it remains so for any length of time the surplus pressure in the main reservoir at length reaches a pressure where it will stop the pump. And since the degree of surplus pressure in the main reservoir necessary to do this depends upon the amount of the reduction of pressure in train pipe, it is evident that the surplus pressure in the main reservoir will not always be the same, but will bear a fixed ratio to the reduction of pressure in the train pipe. That is to say, if a reduction of 5 pounds pressure below the normal in train pipe requires an excess of 2 pounds above the normal in the main reservoir to stop the pump and restore the train pipe pressure, then a train pipe reduction of 20 pounds will require an excess of 8 pounds above the normal in the main reservoir to accomplish the same result. It will be seen that my governor automatically meets the requirements of every case, and stops the pump when, and only when the proper pressure in train pipe and main reservoir have been obtained.

There is therefore no danger of rupturing brake rigging or sliding wheels flat, as no excessive pressure, as cited in the other case, is impossible, and unnecessary pumping, involving waste of steam and wear of pump, is prevented.

(2) Again, we will say that we have a normal pressure of 70 pounds in train pipe, and 90 pounds in main reservoir. If, now, we use air from main reservoir, direct, for ringing bell, etc., as mentioned before, any reduction of pressure, by so using air, will immediately start the pump, *not requiring, as with the other governors, a reduction of train pipe pressure to start the pump*, but will start the pump, irrespective of the train pipe pressure, and will continue pumping until the main reservoir pressure has been restored; there is therefore no dragging of the brakes, and there is always a pressure maintained in main reservoir to successfully operate the brake.

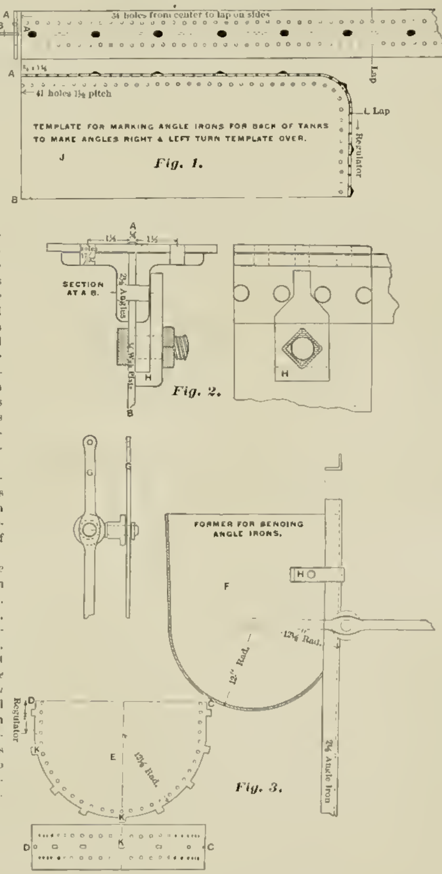
Creston, Iowa.



SYSTEM OF TANK TEMPLATES.

Wants a Higher Court.

Editor The Locomotive Engineer:

Dr. Talmage, in his sermon on "Angelology," paid a glowing compliment to the locomotive engineers, by saying they were "about the grandest men alive." I read that part of the sermon several times, and then called the attention of some of my friends to it, and I want to say that those are my sentiments exactly. I have for some years had a hankering to be traveling engineer, master mechanic, or superintendent of a railroad, so that I might try the experiment of treating the employes with common civility and justice. As it is now on most roads, if a man gets into trouble he gets the grand bounce, whether he is or is not to blame. Several instances of this nature have come under my observation; men with remarkably clean records have been laid off permanently, for some trivial offense, for which they were in no way responsible. This is all wrong, and whenever I hear of such a thing it makes my blood boil to such an extent that my Quaker lineage is forgotten, and I ache to perform the J. L. Sullivan act with some one.

An engineer of my acquaintance, once tried to get past a freight train on a single track; two engines were completely demolished, and three men killed. The superintendent, who happened to be on the train, extricated himself from the wreck, and going to the engineer said, "What are you doing here?" The answer was, "I have orders to be here." Then said the superintendent, "You had no business to run by your orders." No blame could possibly be attached to the engineer—but he was discharged all the same, and the crank who made a mistake in the orders lied out of it, and is still in the employ of the road. There should be some way for an innocent man to vindicate himself, and it cannot be brought about too soon.

I have seen the Swinerton locomotive, felt for the flat spots on the tires, and decided that I had been imposed upon. The runner in charge asked if I expected to find a hex nut for a tire; then he produced a steel straight-edge, and I saw more than I could feel. I have been much amused at the way the daily papers have described this engine as "running by compressed air," "piston rods connected directly to the truck wheels," "a patent balancing device," etc.

The old locomotive "General," of the Western & Atlantic R. R., of Georgia, of which mention was made in the April number, is an interesting relic of the war, and as such should be preserved in the National Museum at Washington, D. C. Let me here suggest that the locomotive engineers of the country chip in and purchase this locomotive, with a view to its preservation as above mentioned. And what is the matter with sending such contributions to the editor of THE LOCOMOTIVE ENGINEER? Don't all speak at once. BAX.

Rahway, N. J.

System of Building Locomotive Tanks by Template

Editor The Locomotive Engineer:

Locomotive builders, whether private or corporate, who have a number of tanks to build of standard dimensions, will find this kink worthy of consideration. *J* is a template to mark angle irons for back and sides of tank; two other templates are required to complete the system, one for semi-circle at front of tank, as shown at *E*, and one for corners in coal bunker, not shown on sketch, as the principle is the same for all three templates; also one regulator to lay off holes in straight part of L's. Template *J* shows one half of tank in width, two angle irons marked one from each side of this template will form angles for top or bottom; the same applies to the other templates. Angles butt together at center of tank, and continue alongside without break to semi-circle at front *c* template *E*. Angles from *L* to be laid off with regulator, using holes marked from template to set regulator. The same applies to angles in coal bunker, to corners from *D* template *E*.

A and *B*, section at ends of template Fig. 1. *C* and *D* cover plate for template *E*. *E*, template for marking front angle irons. *F*, block or former for bending angle irons. *H*, clamps to hold angles in place. *J*, template for marking angles *R* and *L*. *G*, lever with wheel for bending angles. *K*, notches to rivet cover to bed plate.

Templates, as shown, are made from ¼ inch steel, and should be made from material of the same thickness as is used in tanks to be constructed. Web-plate templates may be made any thickness by allowing for same, but cover-plate template should be of same material, as the cover plate is laid off from same regulator as back, sides and front sheets, and any difference in thickness will show in holes when plates are bent. Height of tank will not be a factor. The former for bending angles is clearly shown, and needs no explanation. All that is wanted is a good flange fire where you can get a long heat, or, still better, a small furnace, that would heat about the length you require, which in this case would be about 40 inches, a good size boy can pull lever around. Any shop or R. R. having a standard tank can save cost of formers and templates in the first four tanks made; all parts are interchangeable. A piece can be got out from templates at any time if needed, saving time of straightening out old piece to mark new one; a new piece can be got out and punched while cutting out damaged piece.

It is a good plan to keep a set of templates for sides, back and front sheets, a set means one side sheet, one back, one front, and half of top sheets, top and bottom are the same, except that manhole is left out in the bottom sheets.

JAMES HERON.

Rev. John Brunton, of Pueblo, Col., one of the oldest locomotive engineers in the country, is anxious to correspond with any brother who attended the Baltimore convention in 1855—that was before the day of the present Brotherhood. Who was there?

CONTENTS.

A Modest Invention—100 Miles Per Hour.

It was the writer's lot one day last month to listen to an explanation of a device designed to pull 10 and 15 car trains, at the rate of 100 miles per hour, on the modest expenditure of something like 150 horse-power per day, for 250 or 300 trains.

The United States Pneumatic Railway Co., 607 Chestnut street, Phila., Pa., are the owners of this wonderful device. They have an elaborate set of offices and a 30-foot track on which a car moves back and forth, driven by a steam pump.

The plan is to lay a tube between the rails with a slot in the top; this slot is covered with slides six inches long, and they are moved out of the way of the grip by a track on the car, and closed behind it in the same manner. The grip is firmly riveted to a double-headed piston, packed with leather, one head being in front of the opening, made while car is moving, the other behind. The idea is to set pumps to work to pump the air out of the forward end of the tube and into the rear, thus forcing the piston through the tube and pulling the train with it. The inventor himself explained the device, and his explanation is entertaining, not to say astounding.

He explained, by way of preface, that it cost the P. R. R. over a million of dollars a year for coal, and that the life of a locomotive was but five years at best, and one-third of this time was spent in the repair shop; locomotives had to be repaired after making so many miles, whether worn out or not. His device would not wear out, he could put it on the P. R. R., and pull all their trains between New York and Philadelphia at the rate of 90 miles per hour, by having a ten-horse air-pump every seven to ten miles—he had to run the air-pump he had as fast as it would run to move the little car back and forth while he talked.

How big a tube would he use? Oh, six to twelve inches—fifteen at the outside would pull ten or twelve cars to a train—of course, would have to double the size of wheels under the cars to decrease the friction to what it was now.

How about grades? Oh, grades make no difference at all—you see we have compression on one side and vacuum on the other; when you get a vacuum on anything almost any load can be handled.

About stopping? Why, the easiest thing in the world. Open the valve in the piston, and the air goes through, air from the pipe will supply the air-brakes, but they will not be used, the air going into the vacuum would stop; an express train running 100 miles per hour could be stopped in less than 100 feet—easy enough.

Power was almost nothing; you simply take air from one end and put it in the other, and hitch the trains on as it passes along.

The size of the piston has nothing to do with pulling the train—fifteen inches enough for the heaviest.

It will only cost $10,000 per mile.

No locomotives, or shops, fewer men in train crews, no coal bills, no striking engineers, and 100 miles per hour.

Baldwin Locomotive Works are scared about the thing, and their chief engineer has been there, *incog.* to see if they can't get up something to beat the pneumatic, but they are destined to run against a snag when they get to the patent office.

That is the veriest outline of his explanation. Nothing is impossible with him.

The grade of the track or weight of the trains are not worth figuring on; the area of his cylinder—the tube—is of little importance, the vacuum does the business—stopping and all—we are inclined to believe there will be a great deal more stop than start. This inventor is more fortunate than most of his fellows, he has a company behind him, and people are daily importuned to take stock in the concern. Notices to the effect that stock is for sale are on every hand.

Some of the peculiar locomotives recently turned out have the advantage that they will actually run on the road, they cost more and do less than ordinary locomotives, but they will go; but this scheme has neither novelty or merit, its chief component is the presumption of its projector in ignoring even the first principles of mechanics, setting aside the laws of nature and presuming upon the ignorance of all who come to see his toy.

It is a lamentable fact that such visionary schemes can secure financial backing, while many deserving inventions cannot get a start at all.

The reason is plain, however—a legitimate invention, one that does not make new or destroy old laws of physics cannot offer the dazzling chances of making big money that the wild-cat invention can. The wilder and more unreasonable the scheme the bigger promises it can make, and, the more suckers with money it can take in.

The Polygonal Driving Wheel.

Two months ago we mentioned the fact that the Swinerton polygonal wheel was about to be tried on the elevated road, and that we stood ready to be convinced for or against it on its merits.

The flatted tire were placed under engine 19, a Forney locomotive of the standard elevated pattern, and the sand-boxes left off. The elevated roads in this city are nothing more than iron bridges ten miles long, and the first thing the engine with the flat tire did was to attract universal attention by the noise she made. Then the Swinerton folks said the facets were too long. The engine slipped very badly and it was perfectly plain—after she would slip hard without starting—that she had touched the points between the flat spots only.

The facets have now disappeared from the tread of the wheel, and no difference between that and any other tire can be noticed; still the flat spots can be distinguished by using a straight-edge. The engine has not been able to pull any more cars than the rest, slips just as bad with sand, and worse without, and cannot be declared an improvement or a success.

The company's engine "Onward" has been on the Central of N. J. for some time, and does fairly well, the engineers say that it is because they use the patent sand jet. She has not been able to show a single advantage over other engines, and we will warrant that there is not an 8-wheeler on the road that cannot do as well as she does by taking down the side rods, and putting the same amount of weight on the driving wheels.

The Swinerton driving wheel is an attempt to prove that the amount of surface in contact, instead of the weight or pressure, governs the adhesion of a locomotive driver to the rail. That it should fail to disprove this well-founded law of friction surprises no thinking man—much less a mechanic.

The projectors of the flat facet wheel have never yet satisfactorily explained how the wheel was able to hold to the rail in changing from one flat spot to another, when, according to their own theory, it would have much less adhesion than a round wheel.

On the Ladder.

Three years ago, when the editor of THE LOCOMOTIVE ENGINEER came East to assume that position, he rode from Milwaukee to Chicago on a C., M. & St. P. locomotive, under the charge of engineer James H. Little. This engineer paid very little attention to us, but a good deal of attention to his work, and, consequently, we got to Chicago on time.

About a year afterward the office of traveling engineer was established, and "Jim" was appointed to fill the place, and he has done it so admirably that General Superintendent Earling has just appointed him train master of both divisions of the road out of Chicago. Train master on that road is virtually assistant superintendent.

Railroad managers in the Northwest are beginning to see that practical road men do better in positions of this kind than officers promoted from offices, and better than telegraph operators. Conductors are good, but engineers who have handled the engines and trains are far better, and know what can be done with the power better than any other men on earth.

That good engineers should succeed in places of trust and responsibility like this seems a matter of course. Those who show themselves specially capable of development are the ones who must get the chance when there are places to fill.

As traveling engineer Bro. Little has done a great deal to circulate THE LOCOMOTIVE ENGINEER among the men, and, in a recent letter to the editor on the subject of the work in hand, he said:

"I claim yours is the best mechanical paper published for enginemen, and there is only one improvement I could wish to see, or change to suggest, and that is that you charge $2 per year for it, and make it just twice as large. I hope this change will come in time. I certainly wish it great success and prosperity."

Before another two years has gone by, Jas. H. Little will have written a higher title behind his name than he now has. Ability, energy and common sense keep a man on the ladder once his feet are on the rungs.

A Railroader Gets the Telegraph Prize.

On the 10th of April there was held in this city a national fast telegraphing tournament, at which a large number of experts with the key and sounder took a hand; there was a ladies' class, an old-timers' class, a class *B*, and a free-for all-class *A* for the grand prize, and the championship of America for speed.

The opening address was made by Manager F. Catlin, who, instead of his mouth, used a key and sounder; this brassy speech was well understood by the majority of those present, and rounds of applause greeted each point.

Associated press and other fast senders gathered here to show what they could do, and among the many who stepped upon the platform, there was not a single "plug."

When it came to the final test of speed, and the contestants were pounding out 40 and 45 words a minute it got interesting, until B. R. Pollock, the train dispatcher of the N. Y. & New England road, took his seat—the only railroader in the crowd—and sent 258 words in five minutes. Every one was surprised, and the judges would not decide until Pollock sent 260 words on the third trial, or at the rate of 52 per minute.

Thus does the country railroader come down to the metropolis, capture the big prize and the world's championship, and show the people what men in the ranks are—then go back and hustle "do-nots," and lay the boys out.

J. N. Lauder, Supt. M. P. of the Old Colony road, is building at the South Boston shops a compound locomotive. It will be of the two cylinder style 20 and 29 x 24 The most peculiar feature about it will be the location of the engineer, who will be on the left side; on the Boston & Providence line of this road, the trains run upon the left-hand track, and to change all the signals, switches, etc., would be a great expense, so it is proposed to place the engineer where he can see the signals instead of depending on the fireman to see them; the other engines on this line will also be changed.

Books Received.

SLIDE VALVE GEARS: By Frederic A. Halsey D. Van Nostrand Company, New York Price $1 50.

This little book treats in a masterly way on all the points to be observed in designing slide valve motions It treats almost exclusively on the different forms of valve motion for stationary engines, and is not intended as a treatise on link motion at all. Mathematical formulas are avoided, and all propositions made plain by graphical methods

The author has hit upon a happy idea in making two books in one. There are a number of chapters marked with an asterisk (*), and a beginner can skip these on first reading, the other chapters being elementary and the subject matter continuous, so that young students are not mystified by the use of terms and formulæ they cannot be expected to understand. For those, whose duty it is to design and work out valve motions, this work is invaluable. It is not intended for locomotive engineers

ASKED & ANSWERED.

(26) J. M., Huron, S. D., asks

Which kind of coal can a fireman get the most heat out of—coal that is wet with water or dry coal? I wish you would give a definite answer to this. *A*—You will get more steam from dry coal.

(27) T. D. W., Willard, Tex., writes:

I have charge of a 20x44 Atlas-Corliss engine, running at 70 turns per minute, what horse-power is she? *A*—In order to figure the horse-power we should have to know the steam pressure.

(28) J. W. H., West Superior, Wis., writes:

Please give me a rule for finding the heating surface required in locomotive service per horse-power. I was figuring by your rule the power of the Mason-Farlie engine, and divided the heating surface by the horse-power I could only get, at the most, three square feet to each horse-power Maybe I am wrong, therefore I wish you would set me right. *A*—Your figures are about correct; horse power is not used much in computing power of locomotives, but three square feet of heating surface for one horse-power is a fair average.

(29) E. A. G., Camden, N. J., writes:

1. Please see if my figures for determining weight of load for safety valve are correct 2 Suppose we have a 2" spring, safety valve whose area is 3 1416, pressure 120 pounds, weight of spring and valve 1 pounds, would not the tension of spring have to be compressed so as to be equal by comparison to a dead weight of 372 9920? *A*.—1. Your figures are correct, except that in adding you misplaced the decimal point, getting 159 where you should have but 175.5, and making your answer 58.54 where it should be 63 36. 2 Yes, slightly more, as that weight will just balance the pressure.

(30) W. K. J., Glenn's Ferry, Idado, writes.

In the shop where I am working we are using an old locomotive engine to run the machinery There is a Judson governor on steam pipe, and they are also running the engines with the links out back. Now "A" says that there is no need of hooking links up, as the governor cuts off all steam not needed to run engine. "B" says that, by using governor and running engine with links hooked up, there is a saving of steam or, in other words, is there a saving of steam when using a governor on a link motion engine to run engine with the links hooked up, or cut-off? Which is right? *A*—B is right. By running with links hooked up the engine is using steam expansively—the governor simply maintains uniform speed

(31) E. S. G., Plattsmouth, Neb., sends sketch of a double or balanced throttle having a top $0\frac{1}{4}$" in diameter, and a bottom of $5\frac{3}{4}$", the pressure of the boiler tending to open the lower valve and close the top one, and asks: Will you please let me know in your Answers to Correspondents why a throttle valve like accompanying tracing will work open when using steam? That is, when throttle valve is partially open, it will open of itself *A*—When the double throttle valve is lifted off the seat, the area of the top valve is decreased to the size of the opening under it, which is but $5\frac{3}{4}$, and the steam passing between the seat and the valve tends to lift it Of course all the pressure on the lower valve tends to open; the pressure on the throttle stem is, of course, some, but this is probably more than overcome by the friction of the packing

(32) E. H. P., East St. Louis, asks.

1. If I break a back-up eccentric strap, can I bolt the blade of the back-up to the go-ahead eccentric blade, and take in my full train? 2. My injector won't work, my pump wont shu't off, I am running 25 miles per hour, and must make the next station for the fast mail, what shall I do? I now have three gauges of water 3 What is the proper way to key up rods on a pony? 4. Where can I get a good explanation of valve motion? *A*.—1 No 2. Put on your heater hard enough to prevent the pump getting water by driving it out of the feed pipe 3. If your pony is 4-wheeled connected, put her on the center, key your main rod, and then the side rods, do not key the rods close; side rods should be so easy on pins that they can be easily shaken, but the brasses should be tight in the strap, and keyed brass to brass; be careful not to drive the keys hard enough to spring the brass; if a 6-wheeled engine, key the main connection of side rod first. 4. Sinclair or Forney give detailed explanation of link motion in their books. Alexander's Ready Reference has a plate and short explanation that is very plain. You can find out about extension of the road you mention by addressing some official of the company

(33) L. T., Alexandria, Va., writes

I wish you to enlighten me on the following question in regard to the air-brake. If I understand it right, the air in the train pipe controls the triple valve What I want to know is this: If the air gauge indicates 80 pounds, and you draw 20 pounds off the train pipe, which air from the train pipe escapes in the atmosphere, the air in the auxiliary rushes in the brake cylinder and applies the brake? Now if 20 pounds reduction allows the triple valve its full opening, isn't the brake applied with 80 pounds pressure from the auxiliary? I had an argument with one of our men, who claims that the brake is only applied with 60 pounds pressure; that taking 20 from 80 only leaves 60 pounds for the brake My understanding is, the 20 pounds reduction from the train pipe allows the 80 pounds pressure in the auxiliary to apply the brake. The 20 pounds reduction is from the train pipe, not the auxiliary, which leaves 80 pounds in auxiliary to apply the brake Am I right? *A* You are both wrong The reduction of pressure in the train pipe does not affect the pressure in the auxiliary drum but the air stored there at 80 pounds pressure is obliged to expand into the brake cylinder and in doing so loses a large per cent of its pressure In reducing the pressure in the train pipe to the degree you speak of by service stop, the triple valve does not allow the air in auxiliary drums to rush into brake cylinders full head—it has to pass a very small valve in the slide valve of the triple, and this valve is closed by a spring as soon as the air in the auxiliary is reduced nearly to the pressure in the train pipe, so that, instead of 60 pounds being applied to the brake, there would be nearer 25. The full pressure is only applied in an emergency stop, or when air is nearly all exhausted from train pipe quickly

(34) John Bruce, Ellis, Kan., writes:

1 Will you please let me know through the columns of your paper how to find the radius of the links on an engine? What is the rule, say you had nothing but the links, they being a portion of a circle, is there any rule by which you could determine without taking a point for center, and changing until it would make a circle, which these links are a part of? Is there any difference in long eccentric blades and short ones, in the working of an engine? I heard a runner say he often had to hook the long ones up when running down hill when shut off, as they would tear things up about the valve motion, or run hot if run far. 3. How can I find the stroke of valve and throw of eccentric, and what is the travel of the valve at different points of cut off? *A*.—1. The radius of a link is determined by the distance between the axle center and center of rocker, there is no better or quicker way to find the radius than this, and no necessity for one. 2. Some valve motions jerk so badly when running fast, shut off, that it is better to hook up links some; but this is not always caused by long or short rods—In hooking up you do not shorten the throw of the eccentrics, but the travel of the valve; you allow the eccentrics to move the ends of the link the same, but take off part of the movement of the valve—most of the trouble is there 3. By measuring, if the rocker arms are of equal lengths the travel of the valve is equal to the throw of the eccentric; the throw of the eccentric is the easiest found by subtracting the low side from the high, the remainder being the throw, the distance from the center of the shaft to the center of the eccentric is half the throw Find travel of valve at different cut-off points by measurement

(35) T. J. H., San Bernardino, Cal., writes

1. We will suppose a pressure cock to retain exactly 20 pounds of air in brake cylinder, and engineer, wishing to set brakes tighter, exhausts from train pipe say 5 pounds of air Now how is 5 pounds going to go in brake cylinder against the 20 pounds already in there and make a total of 25 pounds, or will it be necessary to exhaust 25 pounds from train pipe in order to get an extra 5 pounds added to the twenty pounds already in cylinder? 2. Take a brake cylinder 8" diameter with 60 pounds per square inch exerted on piston which moves from cylinder head exactly 1" (we will imagine the cylinder has no leakage groove); this will give a braking power equal to the square of diameter multiplied by pressure per square inch, which equals 3,840 pounds braking power. Now if piston is moved 5" from cylinder head, will you have five times the braking you had in first place or not? 3 Why is saddle pin on link placed back of the perpendicular center of the link? Is there any advantage? If so, what is it? *A*—1. When a pressure-retaining valve is used it does not stop the functions of the triple valve, but simply plugs up the exhaust; when there is a certain pressure left in the brake cylinder the auxiliary is charged again, as usual, and the brake can be used the same as in service. A reduction of 5 pounds in the train pipe will put much more than 5 pounds pressure into the brake cylinder; in this case there is, say, 70 pounds in the auxiliary, and this is turned against the 20 in the brake cylinder, and flows into the brake cylinder until it decreases the pressure behind the piston of the triple valve enough so that the pressure in the train pipe can close it against the pressure in the auxiliary While the pressure-retaining valve is on, the slide valve can be moved to re-charge the auxiliaries without letting off the brake or having the 20 pounds of air have any influence on the triple valve whatever 2 There is just as much pressure on a brake piston at 1 inch from the head as at 5 inches; it is a matter of area 3. Saddle pin is placed back of the link center to equalize the cut-off distorted by the angularity of the connecting rod. See October and November numbers of 1889

Central Railroad of Georgia.

[Editorial Correspondence.]

It is pretty hard to find a place of any size in Central Georgia or Alabama where the trains of the Central Railroad and Banking Co. will not take you, and the concern controls so many roads that it is hardly safe to attempt to enumerate their equipment There are, however, 1,140 miles of road in the main system, this being made up of numerous short lines running in every direction, instead of in a trunk or continuous line

There are 150 locomotives in the service, and 2,300 cars—the company owning and operating their own sleepers This company control the Ocean Steamship Co., and run a line of steamships to New York, Boston and Philadelphia.

The Central Railroad of Georgia is one of the oldest Southern roads, having been chartered in 1835, and the charter of the old Macon & Western, now a part of the system, dates back to 1833, and the main lines of the road have been in successful operation since early in the 40's

The main offices and shops are at Savannah, Ga., where are also the extensive docks of the steamship line

The property of the company is surrounded by a massive brick wall, and the buildings, offices, shops, etc., are put up to stay; there is but very little that shows a temporary arrangement was intended. Brick walks are laid, and heavy walls of brick abound in all the works. We noticed a long-bedded timber planer outside the wood shop, this planer was, perhaps, 30 feet long, and was covered by a canopy roof as long, and some eight or ten feet wide, the brick pillars supporting this roof were about 18x36 inches.

The motive power of the system is under the care of Mr. T. L. Chapman, and the Savannah shops are under the immediate charge of F. H. McGee, Division M M , who was an engineer on the road.

This shop has to do a great deal of the heavy repairs of the ocean ships, and have some heavy machinery for the purpose, but, as a rule, the shop has not much or very modern machinery, and the tool-room is small and gingerly supplied. But the work is well divided up, and the machinery does not make a big display

They have a unique roundhouse, the very best thing of the kind for their climate, but not at all adapted to the blizzard section of the country This house is a complete circle, with the outer wall of brick, on top of this wall the roof is raised up about six inches, for ventilation, and the inner edge of the roof is supported on light pillars set some distance from the inside edge of the roof; there is no attempt at a wall or any enclosure from the inside Of course this makes a very light place to work in, and is cool. There is no need of smoke-jacks, for the smoke and steam have only to follow the shed roof—which is of iron—to escape to the atmosphere It has not snowed in Savannah since 1858.

The only wooden building about the place is the paint shops. The cars have always been red, like the Pennsylvania, but the color is being changed to the dark color used on Pullman sleepers.

Janney couplers are used on passenger, and the Thurmond on new freight equipment.

In the yard there was a large pile of car wheels made in contracting chills; these wheels showed a sharp burr on the face of the thread at every segment block, some of these were as much as $\frac{1}{16}$ of an inch thick at the tread, and from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch high. Of course such work is condemned and refused, and it is hard to imagine what kind of a wheel maker would think that it would do at all. The teeth are too light for gearing, and too heavy for car wheels

The sleepers of this company are of their own build, and are very much like the older Pullmans, but they have one improvement over Pullman, and that is that, when the upper berth is not taken, it is left up

The motive power is good, most of the locomotives being new, and of modern build. Many of the moguls have a "squeeze" brake on the back pair of wheels, a shoe each side of the wheel, brake operated either by steam or vacuum. This scheme may have some advantage in fewer parts, but it must be hard on the side rods.

There are a few old engines in service yet, most of them wood burners, but they are fast going to the wall

Moguls and ten-wheelers are their heaviest engines. Consolidations have not yet made their appearance

For engine trucks they use a heavy wrought-iron framed truck, with outside journal boxes; this is called the Wadley truck, being the design of a former president by that name. The springs are half elliptic, and lie across the truck instead of over or between the boxes. The original design was a swing truck, but trouble was experienced with it, and stops were put each side of the center casting, virtually making a rigid truck of it. By giving this center an inch or so of side play, the center can be shifted by dropping blocks of different thicknesses between the casting and the stops, thus allowing a chance to obviate the evils of flange cutting.

It is claimed that this truck is cheaper than the ordinary truck, is easier to get at and repair, has fewer pieces, and runs a very long time without attention; yet it is not being put under new engines.

There is an extensive brass foundry here, where all the brass and bronze work for the system is done, about 8,000 pounds being melted daily.

There are quite extensive shops at Macon, the grounds and yard being ample as well as the buildings, which are good and substantial; but the shops are poorly supplied with machine tools.

The erecting shop is an old roundhouse entirely enclosed, the immense roof being plastered. It is difficult to clean, as water from a hose cannot be used on it, it is, therefore, jet black. There was considerable work on hand, and several engines in undergoing general repairs. We noticed one getting a very large and expensive patch on the right cylinder There were also several old wood-burners getting changed to coal-burners.

While the machine shop is only average, the blacksmith shop is an extra good one, fires, forges and hammers are arranged in what seems the very best shape, everything is served by cranes, and more special rigs, dies and such tools are in use than in the rest of the entire plant.

These shops are admirably located for the general shops of the road, being nearly in the center of the system, and will, in all probabilty, eventually become such.

The repair track here was full of broken freight cars, like the yard of every road we saw in the South, which shows the cost of breaking in two, and rear-end collisions. It seemed as if we saw enough wreckage on this one trip to pay for the equipment of a large part of the rolling stock with automatic brakes.

There is here a large roundhouse, but it was receiving a new roof, the old iron one having rusted out.

D. M. Gugel, who has been in charge here as M. M. for some thirty years, has just resigned, and Mr. C. F. Thomas, of the E. T , V. & G., appointed to fill his place.

In the Savannah shops it is very hard to prevent the engines, tools and work from rusting; new work will rust in a night on the benches, and paint and oil only seem to lessen, without curing it.

Your representative came to New York from Savannah on the steamship "Chattahoochee," one of the fleet of this company. She weighs 2,076 tons. Some idea of this weight can be had by thinking of fifty-three fifty-ton locomotives in a row She has a compound engine with a high-pressure cylinder, 38x54 inches, and a low-pressure cylinder 74x54 inches, both cylinders being of the same length; ninety pounds of steam is carried. Her coal bunkers hold 204 tons. It is about 750 miles from Savannah to New York by sea, but after we got out of sight of land it commenced to blow, and, if the distance that the boat made *up and down* were stretched out in miles, she would have reached the North Pole instead of Sandy Hook

Unbraked Wheels and Efficient Braking

In another article we have given the facts which show how the Lake Shore accident did happen. It may be of interest to consider a little how it *might* have happened, and how any train running without all the wheels of the cars braked, and with the cars in the rear least effectively braked, is exposed to the same sort of accident. Until the fact was established that in this accident there was no failure of the brakes to hold the rear cars, this inquiry had an immediate interest, which, fortunately, it has lost, now that more of the facts are known. Nevertheless, the moral is still applicable.

In the ill-fated train the weights, braked and unbraked, were about as follows :

FRONT SECTION

	Total weight, lbs	Braked weight, lbs
Locomotive .	110,000	55,000
Tender .	50,000	25,000
Four baggage and express cars .	160,000	144,000
Two day coaches ..	100,000	90,000
Total.... . ..	420,000	314,000

The braked weight was approximately 76 per cent. of the total.

REAR SECTION.

Five Wagner cars..	400,000	240,000

The braked weight was approximately 60 per cent. of the total. These weights are not given as absolutely correct, but we think they will be found very close approximations. It is hardly necessary to say that the difference in the percentage of braked weight of the two parts of the train comes from the fact that but eight wheels out of twelve on each of the four Wagner cars were braked.

Now, had the automatic brakes on all of the cars been operative, what would have happened when the breakaway occurred? The engine, relieved of part of the load, would for an instant have speeded up and made an interval between the two parts of the train before the effect of the brakes was fully felt. This is well known to be what actually happens, even with the quick-acting automatic brake. Then if both parts of the train were equally well braked, they would retain this interval when they stopped. In the exhibition of tests of the Westinghouse train, in the fall of 1887, the distance apart of the sections, when stopped, ran from 22 to 61 feet, and averaged 50 feet. Were the speed high enough to materially lessen the coefficient of friction this interval would be increased. In the case of the Lake Shore train the sections would have separated perhaps 50 feet, perhaps more or perhaps less Then, when the full effect of the brakes was felt, the rate of retardation of the front part, with 75 per cent. of its weight braked, would have been greater than that of the rear part with 60 per cent. braked; and we can readily understand that the first section would have come to a stand first, and a collision ensued, or that the difference in speed of the two sections would have been sufficient to cause a serious wreck

One of the older railroad papers, of recent date, has the above, which we think open to argument.

In the train brake tests cited, the opening between the broken sections occurred principally because the retarding power of the brakes on the rear portion was greater than that of the forward portion, augmented by the fact that the locomotive exerted some pull upon forward part of train, but the main reason being that the locomotive was not braked in proportion to its weight. Where a fully braked train is broken in two an opening is usual, but where the rear of train has cars not braked an opening is not usual—this is proven in practice.

With a freight train of 31 cars, 21 of which had automatic brakes (old-style and quick-action mixed), and running 25 to 30 miles per hour, the writer saw the pin pulled and train parted at the thirteenth car from the rear, this left the rear portion with thirteen loads braked only by three cars, while the forward section had eighteen loads all braked, and the locomotive (not braked); an opening of about thirty-six inches occurred before the hose parted and the brake applied; the rear part of train did not get so far behind the forward part that men could not jump from one car to another, and it gradually closed up without dangerous shock, and the brakes on the forward part of train had to stop the rear part, just as they would have done if the cars had been coupled together. In actual freight service on the Western roads this is occurring all the time with no bad effect, as the brakes being ahead do not allow great enough opening between the sections to cause damage, when the rear section is fully braked it cannot keep up; when it is not fully braked it does keep up, and serious shock does not occur.

Twelve-wheeled cars, with only eight wheels braked, do not allow a train to be stopped quick enough in an emergency, that is a fault. If all this would point to any needed improvement it is to the desirability of braking the locomotive as fully as possible for service, and not emergency.

Worse and Worse.

The *Northwestern Mechanic* has the following explanation (?) of the air-brakes. For getting everything dead wrong, and inventing new forms of brake appliances, it takes first money :

A. L. D , Hudson, Wis , asks: Will you please explain the working of the Westinghouse air brake, also the difference between "straight" and "automatic" air ?

A. As we understand the matter, the Westinghouse brakes are set by springs, and let off by pumping a partial vacuum into the reservoir, thus pulling brakes away from the car wheel. Have not been able to find the exact technical meaning of "straight" and automatic air, but presume the former term is used when air is applied by engineer, the latter when train breaks, thus setting the brakes.

Wonder where they get the vacuum to pump into the reservoir ?

Pedrick & Ayer, of Philadelphia, write us to say that, in view of the orders now on hand, they have decided to place the price of their valve motion model at $70, net.

The Baldwin Works' Compound Locomotive.

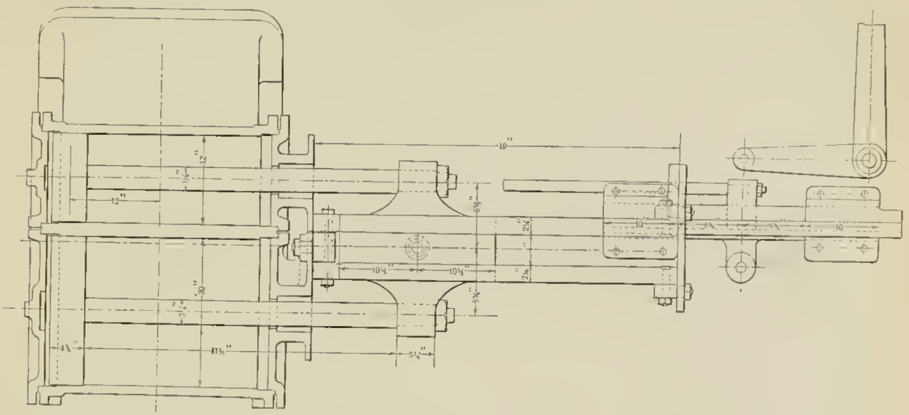
We regret very much that the delay in receiving blue prints prevents us from showing detail cuts of the Baldwin Compound Locomotive on the B. & O road. The cylinders, guides and arrangement for moving the valve, is all we can show.

This engine was built under the patents owned by the works, and was designed to provide a cheap and efficient method of compounding the ordinary locomotive. They use two cylinders on a side, placed one above the other, one 20, the other 12 inches in diameter, and steam is admitted to both through an ingenious double piston valve, located beside the high-pressure cylinder.

Both pistons are fast to a common crosshead, and instead of a rocker the links move a block on a slide—a very simple arrangement.

By this arrangement of parts, very short steam ports are secured, and a receiver is not needed.

The arrangement of guides and crossheads calls for an increased outlay, viz., the cost of two more pistons and their fittings. These are small and comparatively inexpensive. The stuffing-boxes, being fitted with metallic packings, are not serious matters of cost or maintenance. The casting, comprising the cylinder, steam-chest and half-saddle, is of about the same weight as that used on the ordinary locomotive, the exact weight on the truck



of this engine being but 25 pounds more than the ordinary locomotives of the same class, and in every other way is its counterpart. In the connection of two pistons to a common crosshead, the most satisfactory results have ensued. The guide bars and guide bearer are very light, and no heating, cutting or bending has been noticeable in some 20,000 miles of service. A spoonful of oil is sufficient to lubricate them during a run of 100 miles.

All other parts are similar to those of an ordinary locomotive of the same class, not compounded.

The facility with which the engine starts depends upon the admission of steam to the low-pressure cylinder, which is readily accomplished by coupling the two ends of the high-pressure cylinder, and wire-drawing into the low-pressure cylinder. A pressure can thus be obtained, sufficient to start the heaviest trains, utilizing the entire adhesion of the engine without undue strains on the piston rods.

Water caused by condensation in cylinders, the enemy of compound engines in general, is felt to a very slight extent only, so much so that no cylinder cocks are required for the high-pressure cylinders, and one or two strokes clear the low-pressure cylinders entirely.

Relief valves are provided on the low-pressure cylinders to prevent damage in case a careless engineer should get the boiler too full of water, and work it over into the cylinders.

Heavy freight trains, as well as fast express trains, have been hauled with equal success. A piston speed of 1,500 feet per minute has been attained in express service.

As this locomotive has been developed and improved during the past six months, the Baldwin Locomotive Works are now in a position to proceed with accurate tests; comparisons will be made between the compound and the ordinary locomotives of the same class built from the same drawings in all other respects.

The economy in actual practice is so apparent with the locomotive, that an economy of at least 25 per cent. of fuel is expected, and little or no more repairs, while engine is in service, than would be required by an ordinary locomotive.

Some of the papers announce the order of several duplicates of the "J. W. Miller," on the Stonington road, to haul the fast trains there. As a matter of fact, the new engines are about as different from the noted "Miller" as they well could be designed. The "Miller" was designed for hard coal, was 18x24, had a two-inch steam port, two-inch lap and seven-inch travel. The new ones are for soft coal, have deep fire-boxes, 1¼" ports and a reasonable lap and travel. Engines like the "Miller" only come one in a crate

The Homestead Steel Works.

On the 17th of April, Carnegie, Phipps & Co., Limited, through their railroad agents, Coolbaugh McMunn & Pomeroy, of this city, ran a special train to Pittsburgh, to enable a large party of motive power officials to inspect these works, and see how the modern processes admit of the production of boiler plate of uniform quality at the prevailing prices.

The party was under the personal care of Messrs. Coolbaugh and Pomeroy, and consisted of some thirty gentlemen—besides three editors.

On arriving at Pittsburgh the party were met by the officers of the company and escorted to the dining room of the station, where a breakfast awaited them; after breakfast a special train took the party to the Homestead Works, these works are given up entirely to the manufacture of steel plate and structural iron. This plant is new; all the buildings, machinery and processes are modern, and the party were more than interested in the processes until 12 o'clock, when they put their knees under a well-spread board at the hotel of the works

In the afternoon the party were taken to the Edgar Thompson Steel Works, where a specialty is made of steel rail.

This mill is the largest and finest in the country, and produces more rails than any other plant. The work of handling is done almost entirely by machinery, it being almost impossible to follow a bloom from the furnace to the cooling shed, where it comes out a completed rail.

The rails come to the cut off saws in lengths of a little over 60 or 90 feet, and are there cut into 30 foot rails.

We hope at an early day to be able to present a description of these works, and enumerate the figures representing their output

The principal dimensions of the Homestead Mills are given below, and were furnished by the works; the rail mills being larger, will show much greater capacity.

The Homestead Steel Works are located some nine miles above Pittsburgh. They are on the lines of the Monongahela Division of the Pennsylvania Railroad, and the Pittsburgh, McKeesport & Youghiogheny Railroad. The property consists of some 89 acres, of which the works proper occupy about 50 acres of level ground, having a river frontage of 3,100 feet.

The Bessemer department comprises a converting mill 119x73 feet, in which are located six melting cupolas, and two five-ton converters; a blooming mill 178x73 feet containing soaking pits; a powerful blooming train and hydraulic crane for handling ingots, etc., also structural mills 33 inches and 23 inches, which are in a different building, 602x84 feet, having three wings 80 feet deep. In this building there is a 10 inch train for rolling spring steel, rivet rods, etc. The two structural mills are devoted exclusively to rolling steel beams, channels, angles and tees.

The open-hearth furnaces, plate train and finishing machinery are housed in the same building. This is 967 feet long, and is constructed entirely of iron and steel The main building, containing open-hearth plant and plate train—a 119 inch mill, the largest in the world—is 501 feet long, and 86 feet wide in the main span, with a 45 foot wing on each side. The inspecting and marking-out department is 273x43 feet, and the shearing department is 187x86 feet. The open-hearth furnaces are eight in number, a new building is now nearly completed, however, which will contain eight more open-hearth furnaces. This building is about 400 feet long by 200 feet wide.

The furnaces all use natural gas as a fuel, the stacks being placed at the back, and the checker work in the flues pre-heating the air. Charging is done from the general floor level. These furnaces are arranged in pairs, with casting pits between each pair. Nos. 2, 3 and 4 are opposite Nos. 7, 6 and 5 respectively. Between the pairs of furnaces are the ladle cranes, which are directly in the center of the building, and on either side of the cranes are semi-circular pits, capable of taking four sets of moulds. Each pair of furnaces is attended at pits by two seven-ton and two twenty-ton hydraulic cranes, which command the furnace itself, the casting and ladle pits, and the narrow gauge tracks by which the product of the furnaces is removed. At one end of the open-hearth department is a small steel foundry, where special castings for use in the works are manufactured.

The capacity of the open-hearth plant amounts to 7,500 tons of steel per month. This output will be doubled when the new addition is completed.

The slabbing mill is constructed of steel and iron, and is 300 feet long by 120 feet wide, with a 35 foot wing for boilers. Eight heating furnaces and vertical pits 6 feet in diameter and 7 feet deep, are arranged in pairs in the northern end of the building. Two 35-ton hydraulic cranes, fitted with simple hydraulic tackle for gripping ingots, charge and draw these furnaces.

The slabbing train itself is a universal mill. The vertical rolls are of steel 20 inches in diameter, and are driven 50 revolutions per minute, by a pair of 30x54 inch reversing engines, running 100 revolutions per minute. The horizontal rolls are 33 inches in diameter, and are driven by a pair of 40x54 inch reversing engines. This train has already dealt with 48 inch by 48 inch ingots, weighing 38,000 pounds, and is capable of taking a 25 ton ingot 48 inches by 54 inches, and rolling to a section 11 inches by 3 inches. Tables carry the ingot from the roll train to the shear. Tables on both sides of the rolls are run by a pair of upright 10x12 inch reversing engines, and the shear table by a pair of horizontal 8 inch by 10 inch reversing engines. Besides the two cranes for handling ingots at the pits, there are in the mill two sixteen-ton and seven five-ton slab cranes.

The shear power is hydraulic, and operated by the descent of the upper knife with a pressure of 4,000 pounds per square inch (given by two pressure pumps, 65 inch steam cylinder, 10 inch water cylinder, and 8 inch stroke). The shear develops somewhat over 3,000 tons power, and is capable of shearing a 48 inch by 24 inch section. A general pressure in the piping throughout the mill of 500 pounds per square inch is supplied.

All slabs from this mill, before being shipped away or sent to the plate mill, are subjected to a thorough inspection.

In many plate mills the ingots are cast flat, and then rolled down into plate, but here the ingots are cast in the regular large square shape, and are then slabbed down at right angles into thick flat slabs, when they are re-heated and then rolled into plate wide, and can handle plates as high as six tons in weight. Its capacity is 5,000 net tons per month.

In connection with the plate mill is a special set of rolls for bending plates and beams, capable of bending the largest plate that can be rolled in the mill. This department has testing apparatus, and a chemical laboratory.

The system of inspection at these mills is very thorough. The government keeps several inspectors there all of the time, and both by these and the regular inspectors, each plate is inspected both visually and chemically. A record running back for years is kept of every slab, so that the heat, constituents, and everything about it can be told in a very short time.

The shipping department is supplied with sixteen cranes, which place the plates directly on cars on side tracks.

The yard service of the works is performed by three standard gauge engines, and six narrow gauge engines of various sizes. There are nine miles of railroad tracks in the works. In addition to a number of hand and hydraulic cranes in the various shipping departments, there are four 10,000 pound, and two 5,000 pound locomotive cranes.

The yearly pay-roll amounts to approximately $2,000,000, and the number of men employed is about 2,500.

During the visit of the party, the rolls were busy on armor plate for the battle-ship "Texas."

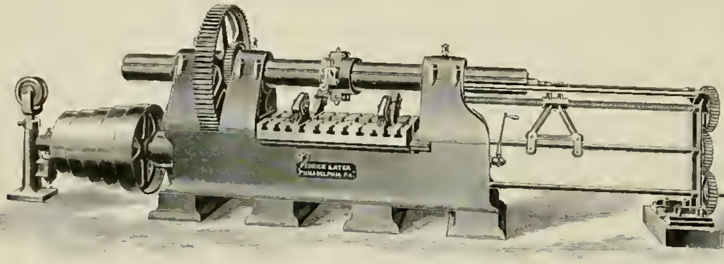
Two hours of the evening were very pleasantly spent in the dining-hall of the Duquesne Club, the entertained shook the hands of the entertainers, and the special train pulled out of the depot for New York.

Each and every member of the party expressed himself as having learned something concerning the manufacture of modern boiler plate, and in the learning a great many hobby-horses and theories got knocked down.

them complete with flanges faced and turned in less than seven hours each; this is very rapid work when the composition of metal for cylinders is considered. They are made of 2,600 pounds of old car wheels, chill and all, tempered with 800 pounds of No 1 charcoal iron, making a very hard, close mixture. With ordinary iron that is often used, the time can be reduced very materially. They do not use facing arms, but place a side tool in regular cutter head, and face off with that.

This machine has just been placed on the market by Pedrick & Ayer, of Philadelphia.

On the 6th of April there was a very largely attended union meeting of train and enginemen at Elmira, New York. The meeting was held under the auspices of Liberty Lodge, No. 242, B. of L. F., and an attendance of over 500 railroad men was the result. The meeting was held with the special object of harmonizing the orders and teaching the true principles of federation. Secret sessions of the different orders were held in the forenoon, and in the evening a public meeting was held at the Opera House. The grand officers of the several orders made speeches, and the whole meeting was interesting and instructive. On the evening of the 7th, a grand ball was given as a fitting wind-up. We have to thank the management of this meeting for a very handsome programme, in the shape of an embroidered harp. This kind of a holiday makes men better satisfied with their lot in life, helps educate them, broadens their views, and teaches the reason and justice and power of fraternity.



in the usual way. This double process increases the strength of the plate, making it more thoroughly wrought and tougher. The high requirements of the government, for whom the firm makes more steel plate than any other, made this extra thoroughness of work and material necessary. The capacity of this mill is 10,000 tons per month.

PLATE MILL.

Ingots were formerly roughed and finished in this mill, but are now roughed in the universal mill to slabs, which are brought by small cars directly to the heating furnaces of this mill. Three heating furnaces, 25 feet by 6 feet 9 inches, are located on each side of the mill, charging and drawing being done by a special hydraulic crane controlled by one man, who is carried about on a seat suspended from the gib.

Re-heated slabs are placed by these cranes on a table of live rollers, which carry them to the mill. The mill is —— feet high. The top and bottom rolls being 119 inches long and 32 inches diameter, and the middle roll 119 inches long and 22 inches diameter, making fifty revolutions per minute. A 42 inch by 54 inch horizontal engine drives the roll train, and screwing down is done by means of a small vertical engine.

From the rolls the finished plates come slowly down a roller table 363 feet long and 5 feet 1½ inches wide, driven by a line shaft and a bevel gearing. An overhead traveling crane runs the full length of the table, so that the plate can be removed at any point, turned over for the inspector on the lower side, or shifted to any part of the table or floor as may be desired. On this the plates are allowed to cool, air having free access below the table, and are inspected above and below, and stamped as to the quality, dimensions, etc , and carefully laid out for shearing. The inspectors examine stamping and marks, and stamp test pieces. From the table plates are rolled on casters to the shears. The casters are small rolls supported on vertical shafts fixed in the floor. The shearing is done by three shears, one with a knife 135 inches long, and two 36 inch knives.

This mill has rolled plates from 3 inches thick, 115 inches wide down to ⅜ inch thick and 117 inches

Leeds' Cylinder Boring and Facing Machine.

The machine here shown was designed by Pulaski Leeds, Sup't of M P. of the L. & N. Railway, for boring and facing locomotive cylinders.

The machine is extra heavy and strong, as will be seen from the engraving. There is not the least tremble or jar on the heaviest work, the bar being 8 inches in diameter, and the bed and housings proportionately heavy. The bar is driven by powerful gears, 4½-inch and 5-inch face, back-geared 36 to 1, and driven by a 5-inch belt on cones, the largest of which is 30 inches diameter, and smallest 18 inches in diameter, with five changes. The feed is changeable by placing change gears similar to lathes for cutting screws. Distance between bearings for bar to revolve in is 4 feet 6 inches, but can be made to meet any requirements.

Table or platen is 36 inches long, with suitable T slots for securing the work. From top of platen to center of bar is 17¼ inches. At the end of the machine, forming a part of cone shaft support, is a sheave to take the weight of bar when drawn out to place cylinder on platen. The table or platen has a sufficient amount of adjustment, and is operated by a screw 2¼ inches in diameter, by a crank from either front or rear end of the machine. When desired, four adjustable saddles to receive cylinders are furnished, which have movable parts, operated by screws and wrench to facilitate placing cylinders in position for boring. When once set machine is all right for other cylinders of same size

At the Louisville shops of the Louisville & Nashville R. R. Co., this machine has been in practical operation for some time, boring 20-inch cylinders 33¼ inches long, counterbore 2⅜ inches long, finishing

E. M. Roberts, who has been for some years master mechanic of the Ashland Coal and Iron Company, at Ashland, Ky., has been appointed master mechanic of the Georgia Division of the E. T , V. & G., at Atlanta, taking the place of C. F. Thomas, who has gone to the Georgia Central. Mr. Roberts is a young man who has already made his mark in the railroad world.

Many heavy locomotives are now being built at an average cost of about six cents per pound—cheap enough.

This has been a hard winter on steam heater men.

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 240,000 cars. This includes 140,000 freight cars. Orders have been received for 80,000 of the improved quick-action freight brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

E. L. ADREON, MANAGER. JOHN B. GRAY, AGENT. C. C. HIGHAM, GENERAL SUPT.

THE AMERICAN BRAKE COMPANY,

NEW YORK OFFICE, 160 Broadway, JOHN B. GRAY, Agent.

THE WESTINGHOUSE AIR BRAKE CO., Lessee,

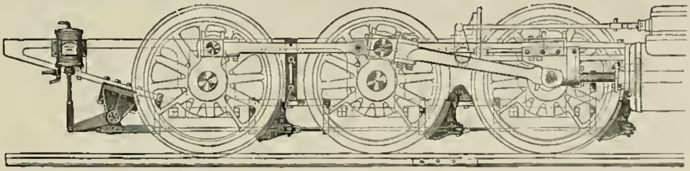
CHICAGO OFFICE, GRAND PACIFIC HOTEL.

MANUFACTURERS OF

LOCOMOTIVE BRAKES.

GENERAL OFFICE, ST. LOUIS, MO., U. S. A.

BRAKES Made to Order for any Special Form or Class of Engine.



All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear and Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM, AIR or VACUUM.

DIXON'S

GRAPHITE

PIPE JOINT

GREASE,

For Steam or Gas Pipes, Bolts, Screws, Etc.

Far Better and Cheaper than Red Lead.

Makes a tighter joint than red lead, that can be opened with perfect ease many years after.

No longer any necessity for

BROKEN PIPES, STRAINED TONGS or LEAKY JOINTS.

Put up in 1 lb., 5 lb., 10 lb., 25 lb. & 50 lb. packages.

☞ Send for Illustrated Catalogue containing more information concerning Graphite and its uses than is in print elsewhere in any language. ☜

JOSEPH DIXON CRUCIBLE CO.,

JERSEY CITY, N. J.

THE "LACKAWANNA" LOCOMOTIVE GREASE CUP

Specially adapted for use on

CRANK-PINS, GUIDES, ECCENTRICS, AND OTHER BEARINGS.

A POSITIVE FORCE FEED WITH PERFECT REGULATION.

Pressure on Grease can be instantly released by hand, without wrenches or screws. Engineer can see at a glance whether Feed is on or off. Tested on locomotive crank pins in hard daily service.

In regular use on the Erie & Wyoming Valley R. R. (with but one filling each week), the Suburban Rapid Transit R. R. (N. Y. City), and other roads.

Our "Lackawanna" Compound, specially recommended for these cups, is not affected by heat or cold, having worked successfully at 30° below, and 95° above zero.

LACKAWANNA LUBRICATING CO.,

SCRANTON PA.

THE SHACKLETON SYSTEM

— OF —

HEATING PASSENGER CARS.

THIS SYSTEM utilizes the live or exhaust steam from the locomotive. Steam is conducted through the cars by pipes placed under the roof. Vertical pipes connect the overhead steam pipe with branch pipes that extend through the large water pipes at the floor level, and heat the water in these floor level pipes.

These large pipes are connected at either end of the car diagonally with radiators. Vertical steam pipes also connect the radiators with the overhead pipes.

The surplus water being drawn up into a reservoir that is exhausted by steam is utilized in the closets.

Under the car, or at one end, is placed a boiler for use in heating the water when the car is detached. With this system there is no drip. Pipes are quickly drained; perfect ventilation; uniform heating of all the cars in a train, entire safety.

The Shackleton Car Heating and Ventilating Co.,

JOS. SHACKLETON, M. E. Gen. Mgr.

BOUND BROOK, N. J.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

ECLIPSE LUBRICATING OIL COMPANY, L't'd.

MANUFACTURERS OF EVERY PRODUCT OF PETROLEUM.

Main Office: FRANKLIN, PA. Refineries: FRANKLIN, PA. OLEAN, N. Y. ERIE, PA. OIL CITY, PA.

PERFECTION BRONZE

is the best Journal Bearing Metal in the world. Genuine Babbitt and Anti-Friction Metals.

EASTWOOD WIRE M'F'G CO.,

BELLEVILLE, ESSEX COUNTY, NEW JERSEY.

"LITTLE GIANT" INJECTORS

WITH ADJUSTABLE TUBE.

SUITED TO EVERY SERVICE. POSITIVE, CONVENIENT AND DURABLE.

BOILER WASHER AND TESTING DEVICE.

Uses warm water, avoiding injury, and facilitates raising of steam.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III, NO. 6. NEW YORK, JUNE, 1890. $1.00 per Year or 10c. a copy.

Historical Locomotives—The Grasshoppers.

There are very few railroad men who have not heard of the famous "Grasshopper" locomotives on the Baltimore & Ohio Railroad, but few of them have ever seen one. They have, however, been in use longer than any other locomotives ever built—some of them having been in the service more than fifty years—and still pegging away.

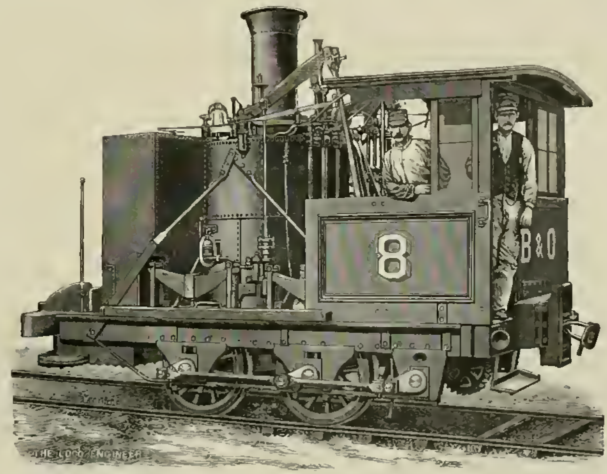
The B. & O. offered a prize, in 1831, of $4,000 for the most approved engine to be delivered before June 1st, 1831, and $3,500 for the next best. The specification read as follows:

"The engine, when in operation, must not exceed three and a half tons weight, and must, on a level road, be capable of drawing day by day fifteen tons, inclusive of the weight of the wagons, fifteen miles per hour."

The firm of Davis & Gartner, York, Pa., furnished for this trial the first "Grasshopper" locomotive, named the "York." It was designed by Phineas Davis, a watchmaker by trade. As you will see, the upright cylinders were placed close to the boiler, and the cross-head was connected to the walking-beam by double connecting rods, and from the ends of the beams rods were connected to cranks on the crank-shaft, and the power transmitted from that to the drives by connecting rods. The walking-beams were hinged on top of the boiler, and their peculiar motion—resembling the motion of the rear legs of a grasshopper—gave them their name; men on the road used to call their running "walking." The original Grasshoppers had a rotary fan to urge the fire, and the exhaust was into the atmosphere.

This picture was made from a photograph taken about five years ago in the yard at Wilmington, Del., and now in the possession of Wm. Wright, general foreman of the P. W & B. shops there. It shows just how the Grasshoppers of to-day look—for there are quite a number of them still at work; the above subject herself still switches at Mount Clare shops, near Baltimore.

An English syndicate recently offered $4,000,000 for the Baldwin Locomotive Works. The works are well worth three times that amount.



THE GRASSHOPPER LOCOMOTIVE.

Two of a Kind.

It is worth notice that the very engineers that kick the hardest, and ridicule the most, and condemn the "machinist runner" the loudest, are the very roosters that think they can file rod brasses, reduce eccentric straps, and line up guides better than any machinist alive. "Machinist runners" do not do road work as well as men with road experience, and are just as poor men for engineers as "engineer machinists" are for repairs and general shop work. What both ought to do is to know what the other needs, but not how to do the other's work. If more machinists could recognize the fact that locomotives ought to be put up so as to stand hard usage at full capacity for twenty-four hours at a stretch, with the engineer caring for nothing but to use the engine to make time, and more engineers could be made to recognize the fact that the joints of a locomotive should be loose ones, that the machinists know enough to close up eccentrics straps so as to be loose at the right place, and that they should be able to adjust wedges, rods and valve motion better than any engineer, the better it will be. Six weeks of firing for the aspirant of the title of "machinist runner," and six weeks as helper for the engineer who knows so much about repairs will cure the most aggravated case.

The R. I. Locomotive Works are building three compounds for one of the Brooklyn elevated roads.

The Longest Lay-off.

It is no uncommon thing for enginemen to get a lay-off of from ten to ninety days for sins of commission or omission. Some of the eastern roads,—notably the Pennsylvania—give very long suspensions, where other roads would fire a man bodily, and sue him for trespass if he walked across the right of way. There is to-day an engineer running out of the city of Philadelphia, on one of the P. R. R. lines, who was once laid off for *ten years*—most anybody would as soon be discharged. He was a good man, but had made a mistake. He went to work on another road, and at the end of his suspension came back and took his old place, and has held it down ever since.

The B. & O. have some hard runs for their fast trains; on one division they have a grade of 117 feet per mile for 17 miles, and they want to get trains of from six to eight cars up there at the rate of 35 miles per hour. This work would call for an engine developing something like 1,500 horse-power—a pretty big locomotive. The great difficulty of a job like this is the same as with Hobson's horse, that was not able to make a mile in two minutes "because the distance was too great for the time." There is now on this grade a magnificent Baldwin 10-wheeler with cylinders 21x24, a 66-inch wheel and 160 pounds of steam. This engine will probably come as close to the desired time as anything on wheels—but it is a big contract. Here is a job for the Strong—can she do it?

There are few heavy passenger locomotives in this country that are on long, fast runs that keep their driving-boxes cool. From 7x8 to 8x8 is considered a fair driving-box bearing, while 8½x10 is above the average. In England many are made from 12 to 15 inches long. With the fire-box on top of the frames it ought not to be a very serious problem to properly hang the springs on a 15-inch box—and our big passenger engines would doubtless be better for the big bearings.

The P. R. R. are equipping the entire system with a steam heater arrangement of their own.

Simple Lessons in Drawing.

By Orville H. Reynolds.

EIGHTH PAPER.

Our previous lessons have been figures of two dimensions, viz.: length and breadth, drawn on a surface of like dimensions. We will now take up the delineation of solids—figures of three dimensions—length, breadth and thickness.

The drawing of solid objects will require more than one view—two, and sometimes three—in order to show the object to be represented, this depending on its simplicity. If of a complicated design, however, it may require not only three views or elevations, but many sections taken through such places as will tend to make it clearly understood, the point through which the section is taken determining whether vertical or longitudinal.

The views of an object which it may be necessary to show are a front view, called a front elevation; a side view, called a side elevation; and top or bottom views, called plans. These several views, when determined by projections, are known respectively as vertical and horizontal projections, thereby showing their relation one to the other by their position on drawing.

It now becomes necessary to know how to arrange these different views with reference to their relation to each other, and the reason why they are so arranged. To project is to throw out or forward. Orthographic projection is that projection which is made by drawing lines from every point to be projected perpendicular to its plane of projection.

In descriptive geometry the projection of a point on a plane is the foot of a perpendicular to the plane, drawn through the point.

In accordance with the principle here advanced we may take any solid, as a cube $D\ E\ F$, Fig. 52, and, projecting in space a number of points (all surfaces are supposed to be made up of points), be able to delineate the object truthfully on a horizontal plane.

Fig. 52 represents three planes of projection, each at right angles to the other; these planes are designated A, B and C. Let the cube be shown on plane A, then plane $D\ E$ of cube is horizontal, and planes $D\ F$ and $F\ E$ are vertical; the sides of the cube are therefore parallel to these planes of projection.

If now dotted lines are drawn from the angles of the cube perpendicular to the planes of projection, as from D to D and E to E', the surface $D\ E$ is projected on the plane of projection C, and we have a plan view of the cube. Projecting D and F on plane A, we have the front elevation, a projection of the surface $D\ F$.

On plane B we project in like manner $E'\ F$, and get the projection of plane $E\ F$, which is the side elevation. We now have three views of the cube delineated on a horizontal plane—front view, side view and plan.

It is plain that, if vertical lines $F'\ G$, $E''\ H$ and $D''\ J$, $F''\ I$ be drawn to intersect plane C, and horizontal lines are drawn from these intersections, that the plan $D'\ E'$ will be delineated from the projections of front and side views without any reference to cube $D\ E\ F$ whatever.

In like manner the surface $E''\ F''$ may be found from the other views by projecting lines $G\ H$ from $D'\ E'$ and lines $K\ L$ from $D''\ F''$.

The cube is taken in this case for an example because of its simple form. Three views are not necessary to show this figure, it being evident that if we know one dimension we know all, but the principle applies to all figures of three dimensions.

Let us suppose the planes of projection as shown in Fig. 52 to be hinged at $M\ N\ O$, and turned in space, as indicated by dotted lines, until they occupy the position shown in Fig. 53, thus bringing all the views to one common plane or surface, as would be the case when shown on the drawing-board. We find the proposition made in the beginning of this paper, "that the projection of a point on a plane is the foot of a perpendicular to the plane drawn through the point" to be verified, it being obvious that if the **T** square be placed on sides $D'\ F'$ on the elevation, that it will pass through corresponding points on the plan, etc.

In Fig. 54 we have the projection of a hexagonal prism in the form of a six-sided nut. Draw the line $A\ D$ and center lines $C\ D$ and $E\ F$, taking intersection of center lines for a center, and with radius equal to side of the hexagon describe a circle. From points $E\ F$, with same radius, describe four arcs, cutting the first circle; connect these points by straight lines; describe another circle to represent the hole, also a circle within the sides, to represent the chamfer or bevel of corners, and the plan of nut is complete.

The front elevation, a vertical projection, is now to be constructed. It is shown resting on base line $A\ B$, therefore must be in a plane vertical to the base line, then lines projected from points $E\ G\ H\ F$ through the base line will give the true location of these points.

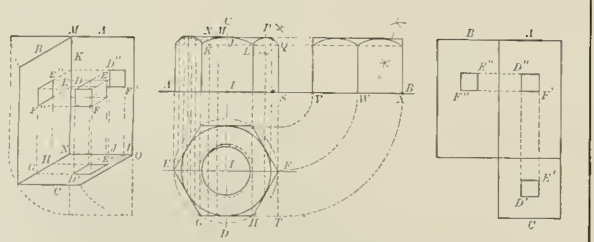


Fig. 52. Fig. 54. Fig. 53.

SIMPLE LESSONS IN DRAWING

The height of the figure, which is the thickness of nut, may now be laid off above the base line.

The chamfer on the vertical projection is now to be drawn in order to complete this projection. With radius $I\ J$ describe arc $K\ L$, which is the curved edge of the face as seen at its true size, this face being parallel to the vertical plane.

The other two faces standing at angles to the plane of projection do not appear like the one just shown, although exactly like it in fact.

The correct method by which to draw these two curves as shown foreshortened, is to find points through which to draw the curve as it appears, and is as follows: Divide one-half of the line $G\ H$ into any number of equal parts, as three, and from these points project lines through arc $K\ L$ at $M\ N$; next divide the side $E\ G$ of plan into twice the number of parts laid off on $G\ H$; from these points also erect perpendiculars; draw horizontal lines from $J\ M\ N$, cutting these perpendiculars on arc $K\ L$, when points in the curve are found which are to be traced by templet, taking in as many as possible always.

There is a practical method for drawing these curves as shown foreshortened, which is also applicable to other curves, whose office is merely to give a finish to the object, as in the case of the chamfer, executed as follows: Bisect the side of plan as at O, from which erect a perpendicular through front elevation at P; find the center for a circle which will pass through the three points $L\ P\ Q$ at R (see Fig. 40, seventh paper), and with radius $R\ L$ describe the arc. This method, with the compasses, answers all purposes, with the advantage of quick execution.

While the two views or projections of the nut are sufficient to truthfully show the object, there is still one more elevation to be delineated if we show three distinct views of the solid upon the plane of drawing-board. This third view is the side elevation, the side E of the plan will be taken to show in elevation. Draw horizontal lines from top, center and bottom of plan, cutting the perpendicular $Q\ S\ T$; take on the compasses the distance $S\ U$ for a radius, and describe an arc from S, cutting base line $A\ B$ at V; draw arc $S\ F$ to W, and $S\ T$ to X; from points $V\ W\ X$ erect perpendiculars to top line of front elevation, after which draw the arcs at top by the practical method. We now have a side elevation projected from side F in the plan, giving three views of the nut; these views showing the object perfectly, no sections of it are required to simplify what is already plain enough.

One word by way of advice: Do *not* leave these hints until the principles conveyed in the lesson are understood; they are not so difficult but that determined application will smooth over the rough places.

Their comprehension at the outset is all vital where success is desired.

One of the Oldest.

William Galloway died at Baltimore, Md., early last month, aged eighty-one years. He was the first regular railroad engineer in this country, and the oldest in point of service in the world, having been connected with the Baltimore & Ohio road for fifty-four years. Before the locomotives appeared, and when the cars were drawn by horses, Mr Galloway became the car dispatcher at Mount Clare Station.

When the Baltimore & Ohio completed its tracks to Washington, Mr. Galloway was put in charge of Lafayette Engine No. 13, and he ran between the two cities forty-six years. In all his service he met with but two accidents, in both of which his engine was thrown from the track. He was never sick in fifty-four years, and he missed his trip only four times, when something was the matter with the engine. He left ten children. Several of his sons and one of his grandsons occupy good positions in the railroad service. In 1887 he was retired with a pension, and since that time he lived quietly.

The engineers on the island of Cuba have always taken considerable interest in The Locomotive Engineer, and Chief Engineer Walter S. Phelps of Bueno y cia Estates, raised a club two years ago, that has recently been renewed with additions. Mr. Ernesto Villsanna, general foreman of the R. R. shops at Guantanamo, is spoken of as one of the brightest mechanics in his line, having had charge for five years, and been appointed in full charge when but nineteen years of age. Mr. Villsanna could, no doubt, tell us something interesting about the care of locomotives in the West Indies.

The Baldwin Locomotive Works have recently turned out a compound locomotive for South America. The machine is their four-cylinder design, such as is used on the B. & O., except that the low-pressure cylinders are above the high-pressure ones. This plan, it is believed, will cause less trouble from condensed water than the other.

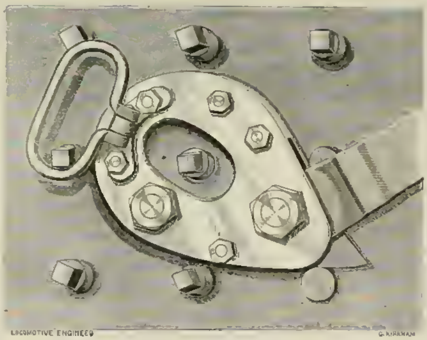
A company has been formed here to introduce the automatic vacuum brake, now so much used in England and Australia.

A Stay Bolt Cutter.

The accompanying engravings show in perspective and detail a very handy and efficient stay bolt cutter recently designed and patented by John Bersch, a railroad mechanic at Kingston, Pa. This cutter is small and easily handled by one man, and cuts off a stay bolt without straining the threads or loosening the bolt, and entirely prevents splitting the bolt, often done in breaking off a stay when not properly "nicked" with the chisel. This cutter leaves a clean sheared head to rivet down.

The sectional cut shows the bottom plate and all the moving parts; the two parts marked "rest" are merely pieces to hold the two main plates apart, so that the cutter and lever works between the plates. This sketch shows only the bottom or main plate, the top plate is shown in the engraving. The plate as shown above is regulated in thickness as regards the length you want your stub to remain for riveting, if ¼ inch leave plate ¼ inch thick, if $\frac{3}{16}$ make plate same as cutter cuts just over top of plate; the spring pulls cutter back in position for next bolt, when bolt is cut off. It requires about a 5½-foot lever, and then it is readily worked, at the rate of from 4 to 8 per minute. The sectional cut is just half size; the tool weighs 9½ pounds, with a stub lever six inches long. The long lever is a socket for the stub, making the tool easier to handle.

No difficulty is found in cutting ⅞ and 1 inch bolts with this device. Any further information will be furnished by the inventor.



STAY BOLT CUTTER.

The Greatest Locomotive Ever Built.

"Your pictur' of that big ingine of Cushing's reminds me of the story of the big ingine built for the New Orleans & Fiddler's Green Railroad way back in '56—she was the biggest ever built. Why, she was—what? Never heard of her? Well, now!" and the old-timer took a fresh chew of fine-cut and looked at the editor with pity.

"Well, then, here goes. In '56 I was down on the O. & M., a broad gauge road—six feet. Well, of course the men there were from all the roads then running in this country, but just at the time I speak of the road was under a manager from the Erie, and he brung down a lot of Erie engineers for some new ingins we got—at that time the Erie was the crack road of America—well, them Erie men kept mostly by theirselves, and were continually talkin' about the big ingines on the Erie.

"Nothing could be done or nothing could be got, but what they'd say it was *almost* as good, or as big, or as fast as something on the Erie.

"At one place on the road we all had to put up at a big boarding-house, and every evening them Erie men would sit and tell lies about the big things on the Erie, till we all got plumb sick of it.

"There was one runner there of the name of Hen. Burrows, that had more quiet fun in him than you ever see; he could tell anything with a perfectly straight face—well, Hen just made up his mind to bust up that Erie bragging, so one night he just put it up that none of us was to act surprised, or let on that we didn't believe all he said and he would tell a bigger ingine story than the biggest liar the Erie ever raised—an' he did.

"After supper we all set around the stove smoking and bragging on our ingins, the Erie men were at one of the tables listening to a new man from there, who was telling about some new 30-ton Hinkleys the Erie had just put on the road, when in comes Hen.

"'Boys', says he, 'I'm goin' to leave you, going back to run the big ingine on the N. O. & F. G.'

"'What road is that?' says one of the Erie fellers.

"'Never heard of that road and the biggest ingine on earth?' asked Hen. 'Well, *where* does that Erie road run to, anyhow? Ain't there no newspapers up there? Why, there ain't a child in the South as don't know all about the New Orleans & Fiddler's Green road and the big ingine.

"'Gentlemen, I had the honor to run that ingine from the day she was finished to last fall, when she went into the shop.

"'She was built to haul the big fiddle from Fiddler's Green to New Orleans and back, besides playing it while there.

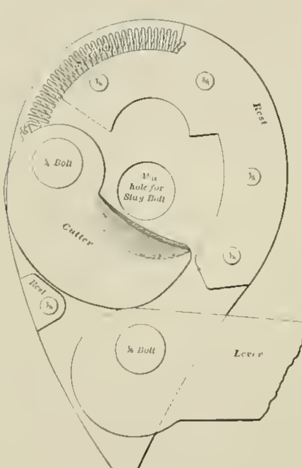
"'Talk about your Erie ingins', says Hen., lookin' around from face to face as he refilled his pipe, 'why, they ain't got one with a boiler big enough for her pump-barrel.

"'She was five stories high, and two counties and a township long.

"'She had drives a hundred and nine feet high—not counting the tire.

"'I don't just remember the size of her tank—wan't never down to it but once—but it took seven miles of the Mississippi River to fill it.

"'She had forty-two acres of grates.



STAY BOLT CUTTER, DETAIL.

"'Why, we us't to clean her flues by runnin' an old Erie engine with a snow-plow through 'em.

"'There was 80 firemen and 112 coal passers, and the men on duty was chained to the brake staff to keep the exhaust from suckin' 'em into the fire.

"'Erie? Why, good Lord, man, that ingin run 33 miles and stopped for water to every exhaust.

"'There was a regular bridle path on the running-board, and the man that went out to oil the valves rode horseback.

"'She had a valve travel of three-quarters of a mile, a four months' lap, and it was an hour and 'leven minutes between exhausts.

"'Onc't, when we got to New Orleans, the head fireman hollered up the speakin' tube for me to come down to the ash-pan deck, where ten or twelve of his men were working the steam hoes, cleaning out the ash pan, he said there was a big clinker just back of the front damper that the hoe wouldn't move. Well, sir, we went in there and there were 'leven broad-gauge Hinkleys that she had picked up in crossing other roads.

"'At the Mardi Gras last year they coated 38 flat cars with rosin, and used 'em for a bow to play the big fiddle. I played by notes set up like mile posts along the track—'bout a mile and a half apart—they was made of boiler plate, paper notes would tear all to pieces, the vibration was so hard.

"'A year ago this month, one awful wet night I was taking a hundred and ninety-six five-story cars of cotton up Snake Hill grade, when I had to go down the gangway a couple of stories to turn steam onto the ingin that moved the pet cock to the pump, and she got out of sand and slipped for a couple of minutes till I got back and shut her off, and, what do you think?—she had piled 80 miles of iron right behind the train—had to lay new track 80 miles out of New Orleans and chain it to the trees.

"'The bell weighed 19 ton, and her whistle could be heard in Memphis.

"'Had to use wood in her—when using soft coal the smoke obscured the sun, chickens went to roost, and crops wouldn't ripen.

"'It took 900 gallons of oil to oil around—used to put it on with a fire ingin.

"'If you knocked the fire out of her Saturday night there would still be smoke coming out of the stack Tuesday morning—it was so far from the grates to top of stack.

"'Machinists used to crawl into the cylinder cocks to set out her packing.

"'It took four barrels of oil to black her stack.

"'Gentlemen, her sand-box held 30 car loads, it took 1200 men three weeks to wood her up, she used more water every trip than this road does in a year, and it took more steam to fill one of her chests than the Erie road ever made. Why, dummit!' says Hen, stoppin' to light his pipe, 'think of a crosshead weighin' 29 tons, making a stroke every four months, and a main rod sixteen hundred and——'

"'Say, Captain,' says one of the Erie men, 'let's all have suthin,' and from that day out I never heard an Erie man telling about any thing big on that road."

Some experiments were recently made at Altoona to test the safety of the Frost dry carbureter system of train lighting. A carbureter was charged and then heated in a forge fire, hammered flat under a steam hammer, and otherwise treated very roughly, and all without serious consequences. The Frost light is fast gaining ground, and is a very successful train light—requiring no station plant. The only great precaution necessary to be observed in its use is not to charge the carbureters at night.

We are indebted to the Jos. Dixon Crucible Co., of Jersey City, for a bunch of lead pencils comprising every variety supposed to be needed by an editor. There are hard ones, soft ones, blue, black and mixed, but the ideal editorial pencil is not made by this company—or any other. We want a pencil that can spell and knows how to put in the proper proportion of commas and semicolons.

This year the Engineers Brotherhood will hold their annual convention at Pittsburgh, and the firemen, who meet but once in two years, hold forth at the Golden Gate.

A New Power Hammer.

One of the most useful and money-saving tools that can be put into a railroad shop is a good power hammer; for all ordinary repair work they are better than steam hammers, as they require no extra help, the smith himself controlling the stroke with his foot.

On this and page 105 will be found engravings of a hammer recently designed by Alexander Beaudry, the inventor of the well-known dead stroke hammers, and the forging presses that bear his name.

This hammer is built on an entirely new principle, and is of a particularly strong and handy design. The anvil block sets on a separate foundation, and is in no way attached to the frame of the hammer; the shaft, however, passes through a large hole cored in it.

The pillars form the frame of the machine, house all the working parts, and are themselves the guides for the head.

The hammer head, which weighs 400 pounds, is supported by a belt 3½ inches wide by 1¼ inches thick that passes through it and is fast to a parallel motion supported on springs, as shown in detail drawing. The head is counterbalanced by a weight in the wheel on the right side of the tool. The lever *a*, shown in this motion, being linked at each end, can be moved up or down without throwing its center out of line up or down.

There is an eccentric on each side of the frame having a 3-inch face and a throw of 6 inches, these give the motion to the head, six inches positive stroke, and about the same extra caused by the throw of the head and spring of the belt and its supports. The stroke of the hammer is controlled by a treadle that operates a belt-tightener, and can be instantly changed from a 2-pound blow to an 800-pound blow. The speed of the shaft should be 200 revolutions per minute. The belt pulley is 5½ face by 18 inches in diameter.

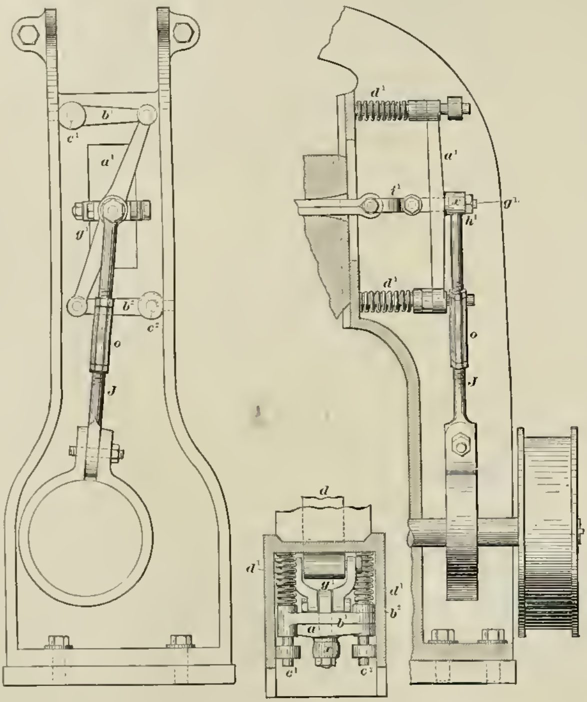
The anvil block is 28 inches high, the anvil and hammer head are removable and held in place by wedges.

There are no small parts to the tool, there is little to get out of order or to wear enough to affect the working quality of the tool, and the machine has a number of advantages over a helve hammer, especially where but one can be had. The blow is direct and square, like a steam hammer, and dies can be used as readily as in a drop hammer.

Beaudry & Co., 70 Kilby street, Boston, Mass., are the builders.

At the Baldwin Locomotive Works there is an elaborate restaurant where dinner is served to a large number of their workmen. The place is carefully kept, and good meals are furnished at a very low cost—so low, in fact, that no one can afford to carry a cold lunch.

The P. R. R. are equipping the entire system with a steam heater arrangement of their own development.



DETAILS, BEAUDRY'S POWER HAMMER.

Heat, Motion and Work, and their Units of Measurement.

By F. F. HEMENWAY.

FIRST PAPER.

The modern steam engine is a machine in such common use that it fails to excite attention. We do indeed give passing notice to something out of the usual order, as when engines of unusual power are placed in a steamship or elsewhere; but how few of us ever stop to think how much that enters into our daily lives is due to the genius of the men who have saddled and bridled steam for the every-day use of humanity. For the civilization we enjoy, we are indebted to the steam engine more than to any other agency; more than to all other agencies. Without it the civilization of the present day—or anything approaching it—would be impossible. It spins the thread, and weaves the cloth we wear; it fashions the furniture we use, and weaves the carpets we walk on; it annihilates distance, and places in our hands the products of the most remote countries; it carries us to and from the scenes of our daily labor, and though most of us cannot own a carriage, the steam engine enables us to travel with a convenience never dreamed of before its common use, and at a cost so moderate that the poor may now enjoy what the rich could not enjoy before its advent. It does all these things and a thousand beside that eclipse the wonders of Aladdin's lamp. Yet so gradually have the blessings of the steam engine been brought to bear upon civilization, so slow and steady has been the advance of steam, that there has been no place for wonder. We do not marvel at the rising and setting of the sun, or at the progression of the seasons, because we have been accustomed to these changes from our infancy. For similar reasons we do not marvel at the changes wrought by steam. Those men who have brought the steam engine to its present state of perfection have done more, a thousand times more, than all the conquering armies of the world, yet how little we know of them. The immediate change from the rigor of winter—from the frozen streams and frosty atmosphere to midsummer, would set every tongue in motion, and yet the change in human affairs, wrought by the advent of the steam engine, is just as marvelous.

I am not here to sing praises to the steam engine, or to those who have perfected it. But it is interesting, and instructive as well, to go back and briefly glance at progress in the use of steam. We see the well-nigh perfect steam engine of to-day, and if we were to see it to-day for the first time, reason would teach us that it was not always so nearly perfect. We should intuitively know that it was the result of persevering labor.

It is impossible to say how many thousand years ago men boiled water, and saw the vapor rise and float away in the air. And as some writer has pointed out, they could not have failed to observe that this vapor exercised force in escaping from the water, and making its way into the atmosphere. Here, then, was an essential fact that might lead to the conception of the steam engine. This steam, imperfectly confined, would lift the cover, perhaps a stone, from the vessel containing the water. It would do work. If it would do this work, it could be made to do useful work. That would be the natural line of reasoning. Why, then, did it require so long a time to put the knowledge of the fact that this vapor from boiling water contained the essence of motion, to useful purposes? It was because the utility of the knowledge of a fact depends so much upon concurrent knowledge. If some one, two thousand years ago, had conceived the steam engine of to-day, there was no one who could have built it. And it was not conceived, because no one could build it. Suppose it had been built, there was no use to put it to. There was no such association of ideas as rendered the conception of the steam engine possible. We can, to-day, conceive of many things fashioned from metals, because we know these metals exist, and because we know there are those skilled in putting them into the desired shapes. But if the knowledge of how to extract these metals from the ore, and to fashion them, did not exist, then we could not conceive of these things. It would be useless for one man to know much unless there were others who knew a good deal. It may appear, at first thought, strange, but it is nevertheless true, that every one in this world is interested in helping his neighbor to knowledge. If we get much ahead of the general knowledge of the world, we are, in the estimation of the world, cranks. The world will always be full of cranks, and their lot is not a happy one. But we are talking of the steam engine.

Something like two thousand years ago, Hero, of Alexandria, we are told, made the first steam engine. You have all seen pictures of Hero's engine, so I need not speak of its construction, further than to say that it contained the germs of the steam engine of to-day. It was not very much like a modern steam engine, but it contained within itself, what would, with our present knowledge of everything else besides the steam engine, have speedily become a thing of levers and shafts, and other accessories. But in Hero's time, there was not in the world the concomitant knowledge to bring this about. This lack of knowledge in others, so necessary to supplement what Hero knew, was mainly due to the fact that, in his time, those who worked did not think. They were not expected—were practically forbidden to think. Between the men who worked and those who thought, or thought they thought, there was as wide a distinction as can well be imagined. And this distinction prevented anything coming of Hero's demonstration of the utility of steam as motive force. Nothing ever came of it until this sharp distinction between working and thinking was broken down; until the philosopher, as a class distinct from the rest of humanity, practically disappeared; until men who looked at the utility of things, and who could both plan and execute, began coming to the front in the material affairs of the world. Hero's conception remained a toy until this change in human affairs came about. And but for this change, it would still be a toy. You may divide up labor as much as you will; you may assign this part to that one, and another part to another one, but you can never succeed if you separate brain from muscle. Without in some degree the ability to plan, there will never be the skill to execute; in even a more pronounced degree is it true that, without the skill to execute, the wisdom to plan will be wanting. The world is prosperous to-day because of this combination, and it is to this combination that the wonderful advancement in the arts and sciences is due. The history of every nation in the world will sustain this proposition. For thousands of years it was sought to work out some other civilization than that based upon a condition of general intelligence; but the effort was a failure.

When the time came that man was conceded the right to work and think in combination, the working mechanic turned his attention to the steam engine. Thomas Newcomen, a working blacksmith, added a cylinder in which a piston moved steam-tight, and John Cawley, a plumber, made some minor improvements, and the toy of the philosophers became a machine, valuable for the industrial purposes of the day.

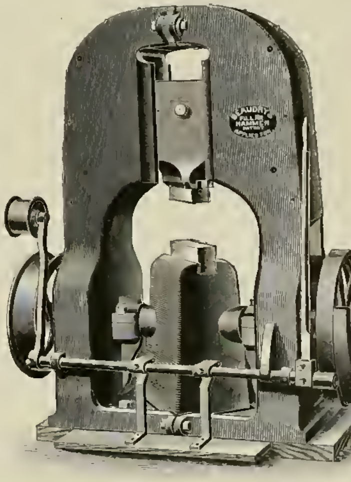
The fact worthy of note is that this, the first really great advance towards a practical steam engine, was made by plain working-men who thought. There is a lesson in this that should be valuable to each of us, and especially so to the younger men. The lesson is too plain to require elaborating. The men of science were outdone by the man at the forge. Thos. Newcomen's habit of fashioning iron to a useful purpose induced thought in a practical direction, instead of on severely scientific lines. The plain blacksmith distanced the ornate philosophers, because he knew more things that were useful than they knew. He was wiser than they, if we value wisdom by what it can accomplish. He was not trained to think as the philosopher thinks. He had trained himself to think in the rugged school of experience, where the best training comes from. One can imagine—almost see—Thomas Newcomen in the glow of his forge, thinking out the problem of that cylinder and piston that ought to have made him more famous than he is.

So on, from the time of Newcomen down to the present time, the advances towards the science of steam engineering have been made by plain workingmen; men who wrought with their hands and thought with their brains

But you do not care to hear the history of the steam engine, and the men who perfected it, nor I to repeat that history. It would not be essentially different from the history of a thousand other things that have helped the world along in its progress. The history of all these things brings to the front, what, according to common acceptation, are workingmen. Science has played a remarkably small part in the material progress of the world we live in. What I purpose, is to say a few words about getting mechanical work from coal, which is something that most of you practice during your working hours, and no doubt think a good deal about during hours you are not at work. Because the steam engine occupies the place it does occupy in the world's economy, and because the practical side of a question is always the important side, this question of getting useful work from coal is one of the most significant questions of the day.

It seems to the uninitiated a simple matter to shovel coal into the furnace of a boiler, supply the boiler with water, and use the resulting steam, but you who do this, know that to do it right, to do it so as to get the best attainable results, is very far from being a simple matter. On the contrary, you know that it is an exceedingly complex matter; a matter about which the wisest will always find something to learn.

We are continually being told that the process of getting mechanical work from coal is an extremely wasteful process. In the sense that it is possible to utilize but a small percentage of the latent energy of coal, as useful work, this is true enough. But



BEAUDRY'S POWER HAMMER.

while there is great loss of useful effect in the steam engine and boiler that cannot, in our present knowledge, be avoided, there are other losses that can be materially modified In order to see how this may be done, it is necessary to see what these losses are.

HEAT.

What the engineer has to do with first, last, and all the time is heat. Its production—speaking in a popular sense—and its utilization, are what mainly concerns him from the time he shovels the coal into the furnace till the exhaust steam escapes into the atmosphere or into the condenser. We speak—and properly enough—about the economical production and use of steam, but water—steam—is only a means to an end. It bears about the same relation to the subject that the harness does to the horse that pulls the load. For various reasons, one of which is that it is about the most common thing in the world, water is the best medium known for transferring the heat in the furnace to the place where it is utilized as motive power.

It was only a few years ago, as time goes, since heat was considered a mysterious *something* that insinuated itself in some equally mysterious way between the component atoms of matter, with the result of increasing the temperature of bodies and bringing about the phenomena known to be due to heat. This idea of heat was that of the ancient philosophers, who, after they had decided upon a thing, gave it but little consideration, for fear they might be called upon to reverse their opinion, thereby acknowledging that they were not infallible—a fear that happily does not exist at the present time. In the times of these old philosophers—the good old times we hear so much about—all investigation and pretty much all thinking was done by those who were trained to think, that is, by those who were assumed to be trained to think. It was not supposed that those who worked were capable of doing their own thinking, to say nothing of thinking for others. These old philosophers had a patent on mental effort, and when it came to things of practical value, they made a rather sorry mess of working their patent.

One of the first to see the inconsistency of the old-time theory of heat, was Count Rumford, and he was led to some experiments by observing the heat generated in the process of boring cannon. Any one of you who have ever drilled a hole in metal, know that the metal as well as the drill is heated, and that the duller the drill—the less freedom with which it cuts—the greater the heat. He was followed by other observers, the observations leading up to the present theory of heat. According to this theory, or, as we may say, scientific fact, because it has been demonstrated beyond doubt—premising that all bodies are composed of atoms almost infinitely small, too small to be seen by any means at our command—heat is simply motion of these atoms, and temperature, as indicated by the thermometer, is the measure of the intensity of that motion. For example, we communicate heat to a piece of iron, and we say the heat expands it, it grows longer. This is because the more violent vibration of the atoms demand more room in which to vibrate. The atoms of iron are held together by a force called cohesion—a force about which we know but little. And if we heat the iron sufficiently, there is war between the cohesive force and the force of heat, and the vibration of the atoms becomes so great as to separate them, so that the iron is melted and cohesion is in part—not entirely—destroyed. More heat will entirely destroy cohesion, and the molten iron becomes gas. Now, to bring this iron from a solid to a molten condition, and then to drive it off in the form of a gas, requires work, and this work is done by the heat that is applied To be brief, because we are getting onto ground that cannot be covered in a few letters, to bring about these changes in the piece of iron, required that the atoms of iron be put in motion, and the greater the change the greater the motion required. The atoms of the iron were never at rest, because they were never absolutely cold, which is a temperature very much lower than we know anything about by observation. In driving them off in the form of gas, we have increased the intensity of their motion, and hence their temperature. I notice the example of the piece of iron, because its three states, a change from one to the other, requiring the application of heat, and involving motion, lead up to the present understanding of the fact, that motion of any kind is the result of heat, in other words, that heat and motion are substantially synonymous terms; as Tyndall puts it, heat is a mode of motion.

WORK

Work is motion against resistance When heat is communicated to a body, the immediate result is work, because the motion of atoms is resisted by cohesion, and generally otherwise. But what we want to compare heat with, is another kind of motion, that is, motion that brings about mechanical results, as, for example, the motion of the piston of a steam engine against whatever opposes that motion. Without, perhaps, the best possible authority in the world for doing so, we will, for the sake of getting on common ground, call this motion of the piston of the engine against opposing force, mechanical work Let us see what this is and what it is not. If, by means of a lever, you try to raise a weight, but do not succeed, you may call it hard work, but mechanically speaking, no work has been done The weight has not been raised, and to do work there must be motion. If you pick up a weight from the floor you do work, because you raise that weight against resistance. But you may hold it at the height to which you have raised it for a week, and in so holding it you are doing no work, as we speak of work in a mechanical sense. The point to be noted here is, that to do work there must be motion, and that motion must be against resistance If you block the drive wheel of your engine so that the pistons cannot move, and then bring the whole boiler pressure to bear against the piston, no work is done, because there is no motion of the pistons

Now, we can, and do convert the vibratory motion of the atoms of a substance into what we term work—that is, motion against palpable resistance. That is just what is being done wherever there is a steam engine in operation. And that is all that is being done Then this work, that is, the equivalent of it, must go back again to heat. It has gone from heat, in the furnace of the boiler, through the engine, into work, and if we had means of tracing it, it has again appeared as heat, in whatever has resisted that motion. When you find your journal-box warm, some of it is there, and so on all through the connection between the engine and the machinery it drives, or the train it pulls, and the air that machinery puts in motion

Suppose we screwed down the pillow-block bolts of a stationary engine, until with full steam it would just run itself, then we should find the principal part of the heat we had converted into work right there.

The law of heat and motion is one of those natural laws that we cannot change. Motion, that is work, results from a change in the temperature, and while this change is taking place, we can couple on our little endeavors and get them pulled along a little ways.

We may take, as a familiar example of the transformation of one kind of motion into another kind, a shaft being turned in its bearings against the opposition of friction and attached machinery. In the shaft is tangible motion against resistance, and heat—atomic motion—will disappear from whatever is doing that work of turning the shaft just in proportion to the work required It requires a definite amount of heat to do a definite amount of work, as we might be sure would be the case from a consideration of the fact that all that is done is to change one kind of motion into another kind. In the work of turning this shaft, the motion we call heat has disappeared in one place, and appeared in another place as another kind of motion If we could follow the transformation further, we should find this motion of the shaft appearing again as heat, in whatever had resisted the revolution of the shaft All the heat that is utilized in moving the piston of a steam engine—all the heat of which the motion of the piston is an equivalent—could, if we had the means of following it up, be accounted for in whatever has tended to stop that motion. Out of these changes of motion between its two forms—motion of atoms and motion of bodies—we get useful mechanical work

It is well to impress these facts upon our minds. There are those who say the engineer has no occasion to bother himself about them. If he never aspires to do more than shovel coal and open a throttle valve in a perfunctory manner, it may not make much difference. But the engineer of to-day is not satisfied with this. He wants to know *why* he shovels coal and opens throttle valves. He expects to study steam engineering apart from running a steam engine. He expects to invent and improve steam engines. And aside from the question of pecuniary gain, the engineer has a desire to understand things for the sake of understanding them, just as much as the doctor or the lawyer has.

An Interesting Report.

An interested reader of THE LOCOMOTIVE ENGINEER sends us a little scrap of history in an enumeration of the locomotives in use on the

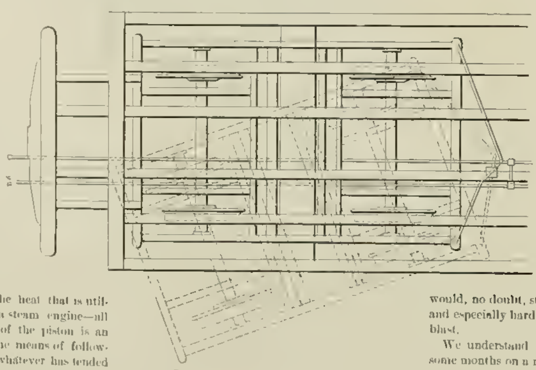
Copy of Fifth Annual Report Pennsylvania R. R. Co., for the year ending 1851. Phila., Jan., 1852

Pennsylvania R R. forty years ago. At that time 26 locomotives composed the entire power of the great road that now has on its own lines proper over 1,500 locomotives, and on the "systems" controlled by it, perhaps as many more.

Many of our older readers will, no doubt, recall many experiences with some of these old mills.

John Player, Sup't. M. P. of the Wisconsin Central, has completed designs for a new compound locomotive, and has received permission to build one at the Waukesha Shops. The design is of the 4-cylinder, tandem style.

It would be a blessed good thing if the eight-hour rule could be applied to some of our engine and trainmen who are making 24 and 36 hour runs.



DERAILING AIR-BRAKE APPLIER.

The Philadelphia & Reading are putting down a track tank on their Bound Brook division, and intend to run their express engines through to New York. No other straight and level piece of track located near the middle of the division being found, the tank will be laid on the long bridge over the Delaware River at Trenton Junction. The track tank and scoop were invented and first used by Ramsbottom, in England, some twenty years ago.

Derailing Air-brake Applier.

The accompanying sketch shows the general arrangement of a device arranged to automatically apply the air-brakes in case of derailment—a drop of four inches for any wheel being enough to open the cock and apply the brakes; also opening a cock in the signal hose, and blowing the whistle in the cab. This device is the invention of W. Edward Maher, Gen'l M M. of the Charleston, Cincinnati & Chicago R. R.

We will have to decline to publish questions about the horse power of stationary engines, when the matter simply calls for a little plain figuring. We have over a dozen such letters on hand now. On page 51 of the current issue will be found plain and simple directions for finding the horse-power of any engine—figure it yourself.

The Great Eastern Railway, of England, publish a monthly list of "farm houses and country lodgings to be let." This list tells the name and address of the landlord, size and description of lodgings, rent, and distance to nearest station, and distance of station from the cities on the line. This is done to build up a big suburban traffic.

A little black oil in your injector occasionally will keep down the formation of scale, and lubricate the packing so that all the handles will move easily.

A New Feed-water Heater and Purifier.

The cuts on page 107 show very plainly the plan proposed for heating and purifying feed water by Wm. W. Sutcliffe, of New Orleans, La.

Water is fed into the lower chamber and runs through a chamber filled with coke, called the filter chamber, and from there to the upper chamber and through the internal pipe to the boiler.

Mr. Sutcliffe thinks he will be able to utilize a great deal of heat now thrown out of the stack unused, and that in passing the feed water through a bed of coke the heat will separate and deposit on the coke a great deal of the scale-forming substances in the water How often the small quantity of coke that can be held in the stack will have to be changed will depend upon the quality of the water.

This heater is probably as good as any heater in the market, but has not overcome one of the principal causes of trouble with front end or stack heaters, and that is the formation on the pipes etc., when the feed is shut off, of sulphuric acid that rapidly eats out the pipes and sheets. Many of our older readers will remember the trouble from this source with the Magoon heater, which was a coil of pipe in the stack. The inside pipe would, no doubt, stand on a wood burner, but coal and especially hard coal, would eat it off like a sand blast.

We understand the device has been in use for some months on a road out of New Orleans.

In reply to inquiry of correspondents, we would say that the St John cylinder packing is a cast, snap ring packing, the rings being of peculiar form. It is, and has been for some years, in use on the Western Maryland Railroad, and is in general use on stationary engines.

The new cars of the Central Ry. of N. J. are lighted with the Pintsch system of gas light; tanks of compressed gas are stored under the cars. The new lamps of this system are very handsome ones.

Correspondence

Why the Black Hand Moves.

Editor The Locomotive Engineer:

In your April number the answer to J. W. Peterson, Boone, Ia. (2) does not seem to make the matter quite clear. I enclose one of W. A. B. Co's. pamphlets explaining the new valve. By referring to this it will be seen that in moving handle to emergency position, the port *j* comes over equalizing port *g* in valve seat, and permits air to feed from main reservoir to space *s*, where of course it shows on black hand of gauge. This is more marked when handle is not put at once to extreme emergency position. J. H. McFERRIN.

Topeka, Kan.

[This is practically just the explanation offered in April number: if handle is thrown to emergency very quick, the equalizing of pointers does not occur; if moved slow enough the port is in connection long enough to cause the movement as mentioned by our correspondent.]

Two Air-brake Problems.

Editor The Locomotive Engineer:

In looking up the air-brake subject, as I find it in practice, and on examination of the construction of its parts, and comparing notes with the condition of things as described by Mr. J. E. Phelan in THE LOCOMOTIVE ENGINEER of Sept., 1888, and later in book form, "Air Brake Practice," which is said to be correct, and intended for instruction of engineers and others. Will you call attention to where he says, on page 35, that the emergency check valve is held to its seat when train line is charged? It reads, "After emergency valve is worked open, then pressure in train line unseats check valve and flows directs to brake cylinder."

How does maximum pressure keep check to its seat, while a reduction in train line will lift check against spring, which is between emergency valve and check? Is it not held open by train line pressure, and closes only when train line pressure is removed? Also on page 69, in referring to slide valve in emergency position, "It allows air to flow from train line to brake cylinder, at the same time opens *larger opening* from auxiliary reservoir to the brake cylinder in addition thereto." On examination of slide valve, I find the opening at the top of "emergency port" to be considerably smaller than the feed "service" port. Can he figure to get more air out of the oblong opening on face of valve than will go in at the top? Also, why is it made so?

J. R. ALEXANDER,

Pittsburgh, Pa. Engineman P. R. R.

[The emergency valve on the new, quick-acting triple is composed of two valves and a piston. The lower valve seats against the train pipe pressure, and is held to its seat by a spring that also holds the upper valve against its seat; the train pipe pressure tends to *lift* the lower valve and to close the upper one. The upper valve is opened against the train pipe pressure by the slide of the triple admitting air above the piston of the emergency; this done the air in the train pipe lifts the lower check, and rushing past the upper one, enters the brake cylinder; as soon as there is as much pressure in the brake cylinder as in the train pipe—or a little before—the lower valve is seated. Train pipe pressure can open the lower check, and does, but cannot open the upper one; it must be opened from the top.

The service stop valve of the triple has a small opening at the seat (in the large slide valve), the port does not entirely govern the amount of air admitted, in going from "service" to "emergency," the oblong port is brought into communication with the passage to brake cylinder. It is made oblong so that it will give a full opening on the passage, in case of slight variations of movement. Mr. Phelan's conclusions are correct, unless it be in the statement about the larger openings for emergency.]

How I Set Valves in Ten Minutes.

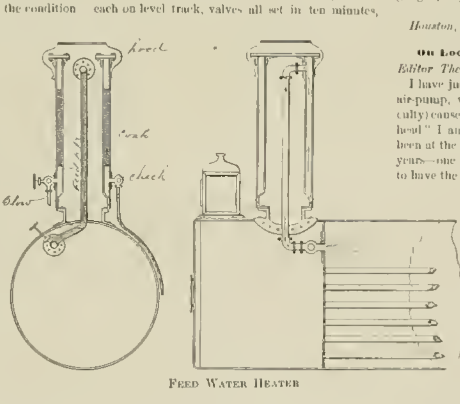
Editor The Locomotive Engineer:

In answer to our friend Mr. De Sanno, I would state to him, as regards the oblong hole in eccentric blades, the building shop of Baldwins always does it, and for this simple purpose, they set their valves by this oblong hole, and I assure you when their engines leave the shop, are about as perfect as valve motion can be made.

Now, the two round holes I mention with hammer-fit bolts are to keep meddlesome engineers from altering blades, for the same reason that eccentries are keyed on shaft—now will any one answer why this is not a good idea—and as I said before, a simple liner put in stationary gib or shoe, as commonly called, will always keep your valves square, and lead about same as when she came out of shop.

Now, I have not the time to write this up as I would like to, but will explain as best I can for the benefit of our friend Mr. Holland, of Oakland.

Now, Mr H., I would be pleased to have you sitting on a hill, and hear one of my little engines, 11 x 16, mogul type, Dickson make, coming up the hill with 12 standard loads 40,000 lbs. to the car—grades 70 feet to the mile, or 35 cars of 40,000 lbs each on level track, valves all set in ten minutes, and the rocker arm meets her equal vibration about on time. Well now I want you to catch on, if possible for you to do so on my poor writing, and if you do, you will say I am correct on the ten minutes, and I will take my longest way.



FEED WATER HEATER

Now understand that squaring a valve and setting one are two different things. I am telling now how to set valves when they are square, that is, suppose your valve sets over both ports square, and your valve rod is proper length, and to cut it short, all rods are proper length, except eccentric blades and eccentrics out of place.

Now to begin with, we will commence on right side of engine engine has plenty of lost motion.

Now take center—first put reverse lever in front notch, pinch her back until rocker arm moves, then pinch her ahead until you catch center dead, then make your mark with your gauge on valve stem. Then put reverse lever in back notch, then pinch her ahead until rocker arm moves, then pinch her back to catch dead on center, mark valve stem, scratch a letter B on your back-up mark, or letter F on forward, so you will remember your mark. Then go on left side, come ahead a quarter turn, proceed with that as you did right side, then come back to right side, catch centers as you did before. Remember if you are working in forward motion you must pinch her back until rocker arm moves, in that way you catch up all lost motion; now go back to left side, come ahead a quarter of turn, and proceed as before. Take your lap marks on valve stem, get a pair of fine point dividers, get the center of your lap marks, put your dividers in center mark, set them to one of your scratch marks, throw them around and make scratches with them, then put your two tram marks together, and whatever the difference is, the eccentric blade will want to be lengthened or shortened one-half that, that you can tell by looking at marks on valve rod; then you have them divided up even, now if your eccentric is wrong, you will move it until your tram drops in center punch mark at the end of lap, not in center mark.

Now this is my ten minutes racket. I have used up my ten minutes in setting valve, and have told my man what to do; go off, attend to other business, but Heaven only knows when he will get through, if he has to chip off back end of blade and cut the three holes out

Now I guess you will catch on to the ten minutes and the lost motion; this all on setting valves, setting and squaring valves are two different things.

As to gauging a valve without taking steam chest cover off, I expect is an old chestnut to our friend H, a good many shop and road men. You must know how much outside lap your engine has, then put two parallel strips on your guides, take a true two-foot square and set your rocker arm center with the square, then take valve gauge and mark valve stem, for example, if your engine has ⅞ lap, set your dividers ⅞, and mark valve stem with dividers, forward and back, take off steam chest cover, and you will find out you have them about properly gauged, if your valve stem is the right length.

E. A. CAMPBELL

Houston, Texas. Supt. M. P. and Mach.

On Locating Trouble in an Air-pump.

Editor The Locomotive Engineer:

I have just had a little experience with a six-inch air-pump, which (after I had overcome the difficulty) caused me to say to myself, what a "chucklehead" I am, to be fooled like this, after having been at the head of this air "dispensary" for ten years—one of the wipers said he thought I ought to have the "slack" in me taken up. I thought the suggestion a good one, and gave him a "snipe" for it. Now, for the benefit of some of your readers who are in the same business that I am in, and who have not had much experience, I will explain how I came to be fooled.

Engine 582 (N. Y. C. R. R.) runs from, or rather between Rochester and Charlotte, and as there is no one in Rochester to repair air-pumps, this and all other engines doing the same work are sent to Syracuse when air-pumps want repairing. This engine (582) came down in the afternoon, and the engineer wanted to get back as soon as possible, so I had to hurry to get her done, so he could get home before dark, and in my hurry I failed to locate the difficulty promptly. The first thing I did was to take off the top head, and found everything all right there, then I examined air valves, and found lower discharge valve worn out, the other valves were all right, and after examining air piston, to be sure it was tight, I put in new discharge valve, put on air cylinder head, and turned on steam, the piston went up to end of stroke and stopped—then I stopped, and scratched my head, and was soon lost in deep meditation, but not long—I went at it again, and removed the reversing cylinder cap to see if the reversing piston had performed its duty. I found it had—another pause. Then I removed the reversing valve cap, and—tumbled. The piston did not raise reversing valve enough to exhaust steam from top of reversing piston, and allow main steam valve to reverse; now what is the reason the piston don't raise the reversing valve? I have it, one of the reversing valve plate bolts was loose and sticking up, and if my head had been properly constructed I would have discovered it when I had the cylinder head off, all this I said to myself while taking off the cylinder head the second time

Well, after almost blistering my fingers, I finally got the head off, only to find that the cap bolts were right where they belonged. I did not get discouraged or mad, but kept at it until I found what caused the trouble, it was this On again taking off the air cylinder head, and removing air piston, I found a small piece of brass on top side of air piston, which was thick enough to prevent the piston traveling its full stroke, and moving the reversing valve far enough to exhaust steam from top of reversing piston, which would allow the main steam valve to perform its duty.

Now, if I had taken time to think, I would have discovered what the trouble was sooner than I did, and would have saved myself a great deal of unnecessary labor, for I have had the very same thing happen before. But I don't get fooled again on that.

Syracuse, N. Y. W. F. RELYEA.

Suggestions for Reverse Lever.

Editor The Locomotive Engineer:

Enclosed please find sketch and suggestions for new kink in reverse levers. There is an idea prevalent with some railroad men that a finely graduated quadrant or sector for a locomotive reverse lever is just the thing; well, perhaps it is, if valve gear could be kept in first-class condition and without lost motion, but, as this condition of things is impossible, why cling to these ideas in locomotive construction? Now, fellow railroaders, did you ever see a finely graduated quadrant that had been in use any length of time that did not have a lot of teeth or sections broke out? If so, what good is this fine graduation in locomotive valve motion? I claim that it is something that cannot be maintained in the wear and tear incident to locomotive service. Again, look at the general condition of the ordinarily graduated quadrant, what a rattle-trap condition some of them are in! And when the reach rod is connected to the side of the lever the condition of things is still worse, and, with the latch and notches badly worn, and two or three off-sets in the reach rod, it is a sad state of affairs for the man who runs the engine; and with a dry valve seat it has a tendency to make a man forget he ever went to Sunday-school.

There is an effort made to repair some of these troubles by dove-tailing a new section in and upsetting the latch, but it is not a good job when done, these sections get loose and drop out of one bar of the quadrant, and it happens to be our fancy notch that makes more trouble. It is in view of these troubles, and how best to get rid of them, that prompted me to send the enclosed sketch. I propose to make the quadrant of a single bar (like the Baldwin), drill a hole through wherever you want a notch or pocket, then counterbore from the top, and fit in a hardened bushing with a taper hole through it (make a fair driving fit); the size of the lower end of the taper hole is less than the hole drilled through the bar, as that leaves a chance to hack the bushings out for renewal.

The latch is made of one-inch square steel, with the lower end turned taper to fit the hole in bushing, and to be hardened. This is a quick, cheap latch to make, and, with the bushings, can be kept in stock. If a bushing gets worn in the hole, knock it out and give it a quarter turn, or change it with one of the back-motion bushings; by giving it a quarter-turn it takes up some of the slack by presenting a good side to the latch. If you will notice, nine out of ten of the builders place the latch in the rear of the lever, with no way to take up the lost motion in the latch but a set-screw. We may put in as many liners as we please, but the point of the set-screw must take the thrust of the lever, which has a tendency to pull ahead.

I propose to dovetail a strip of steel in forward edge of lever, and give the latch a hardened bearing to ride on. To take up wear I use a small wedge held in place by a set-bolt screwed into the wedge, the hole through the clamp to be slotted same as set-bolt in wedges. Another use for hole through quadrant is it allows all dirt to pass through without filling up the hole. Reach rod connections with lever should be made with a jaw to get a square pull on lever. Would make bar 1¼x1¾; counterbore, 1½ diameter by ⅜ deep; drill inch hole through bar; taper hole, 1 in. top, ¾ bottom. Fig. 1 is side view, Fig. 2 is view looking through *A B*. This lever is not patented—use it if you want to.

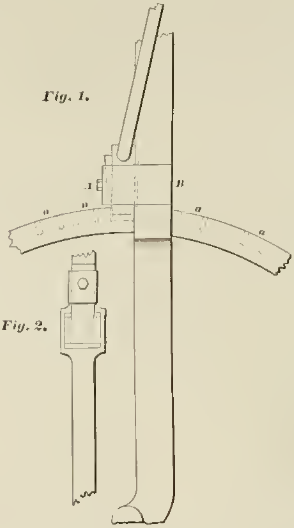
Corry, Pa. W. DE SANNO.

What Big Engines Will Do.

Editor The Locomotive Engineer.

As you are perhaps well aware, the N. Y. Central & Hudson River R. R. have always used eight-wheelers in freight service, and have simply increased the number of trains when business was lively; this was pretty good for engineers, as more of them had to be employed, and many a fireman got a chance to run a few months in the year.

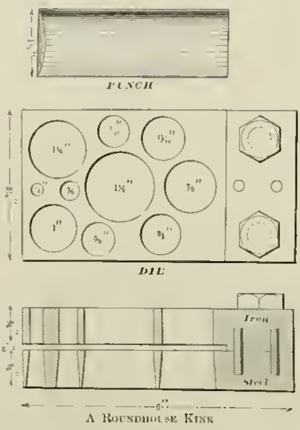
There is no doubt that this was not economical



SUGGESTIONS FOR REVERSE LEVER.

management, however, for some months ago the company put in service some very heavy moguls on the division west of Albany, and in the month of January there were hauled 252 trains less than in that month the year before, yet there were pulled 10,000 cars more. How's that? A good many will feel disposed to kick, and say that this all tends to do up engineers, but I do not.

Every machine device or system that will allow more work to be done for less outlay is a benefit to workingmen, as more will be done.



A ROUNDHOUSE KINK

The road I am on needs one big reform, however, and that is the shortening of the hours that freight men spend on their engines, 24, 36 and 40 are not uncommon, the first being a regular thing—it is too much.

Most of the men here are in favor of federation, and think when it does come that the possibility of a strike will be very dim. W. E. ANDROS.

Albany, N. Y.

A Question for Discussion—A Roundhouse Kink.

Editor The Locomotive Engineer:

To promote discussion among the boys I will propose a simple question. What would be the course to pursue if an engine broke a side rod or side rod pin, if the valve motion of the same is connected to one pair of drivers, and the main rod to another pair, as there are engines so designed, and in service—the elevated road engines in New York being a sample? Would the engineer be obliged to leave his train or not?

I enclose a sketch of a very useful tool for roundhouses and for shop repairs. As a general rule, roundhouse jobs are done in a hurry, and liners are cut out for closing eccentric straps, guides and similar work about the engine with an old cold chisel, and quite often a part of the liner turns over or doubles, and, twisting the part of machinery on which it is used, causes accidents and breakdowns. By using such liners, the engineer will soon find his eccentric strap or guide bolt loose, and by tightening it in a hurry, so as not to lose any time, the result will be a hot eccentric or guide—all on account of a rough liner and the hurry. Enclosed sketch is a plan and sectional view of a very cheap and handy tool, and if once used you would not like to be without it.

The lower plate is of steel, and is the cutter; the upper one, of iron, is simply the guide for the punch. There should, of course, be a full set of cupped punches made for the cutter. You can cut tin, iron or rubber, and save a good deal of time, besides doing neater work than the usual plan of cold chisel work. O. G. BRETTING.

Sedalia, Mo.

The Methuselahs of the Railways.

Editor The Locomotive Engineer:

All men are liars—only some have gone right on up to be 33 degree liars, while the great majority seem satisfied with the third degree.

Railroading and lying go together just like a young couple—affinity for one another.

It's a mighty powerful kind of Christianity that will keep an engineer from making the record of his pet engine 50 seconds out of 59. Nought is next to nine—that's near enough.

The average of us would come right home from the funeral of Ananias, and pull out a $28 watch and swear that it hadn't missed a tick for two years, and we never touched the regulator in our life.

But the biggest lies are about age—age lies are always carried in stock, same as a dinner-pail, overclothes or gall. It has been for years a habit of many railroad men and officials to gauge what a man *could* do by how long he *had* done it. If a man was a good man with air-brakes, they say "he o'rt to be—handled it for eighteen years on the Q."

Men who have run less than two years are considered as cub apprentices by those who have run five. An "old-time rocks" is the ideal. Experience is a good thing, but I don't believe it is necessary for a man to always make his own, any more than it is necessary for him to touch off a can of powder to see if it will explode—other people's experience with powder is conclusive with me.

You put the best man on the road in for round house foreman, master mechanic or superintendent, and the first year or so he will refer to the time he ran an engine or train, as so many years—always counting the odd months over as a full year. In a couple of years, and especially in talking to new men or young ones, he will include in that time the brief period of his existence when he was braking or firing, and in ten years he will set back the date till the time he remembers how a train of cars looked—and he will tell it so often and so honestly that he will believe it himself. Now I don't suppose this is any news to you—guess when it comes to a lying match you won't get the booby prize—but I want to call your attention to it, and just say it was started to make life tolerable to young men, does no harm, and just a little good. I want to warn the boys to not bring it home with 'em, however.

The other night we had company, and Mrs. A. had just been telling how we had to git married while my train waited, and I had to go right out with a train of soldiers (I am going to have a pension out of that yet, see if I don't), which was all facts. Well, half an hour after I was telling a railroad story, and incidentally mentioned gettin' married, and reached back, as usual, kind of familiar like, for a date, overreaching just enough to fix the wedding in the year Mrs. A. was born. She jumped the track right there, and spoiled the whole story.

Away back in '78 (I came mighty near saying '58—that's when I went firing) I was performing as roundhouse foreman (twilight foreman), and had occasion one night to hustle around for an extra fireman for an express train. The only material available was a young fellow, recently employed, who was on the switch engine; he had had a couple of years' experience on some other road, or roads, I believe. His head was a small collection of other little accessories attached to a large bump of talkativeness. The engineer was the oldest on the road; ran the first engine; deacon in the church, and a good man. Old Frank would no more tell a lie, knowingly, than fly, but, like all other railroaders, his memory of dates was a little offish, and about twice a year some of the older citizens had to tell him that it was the *charter* the road got in 1835, and not the *first* engine, which came in '47.

Well, the next night the express came up on time, and as old Frank put his finger prints and name on the register, I asked him "how that young fellow done."

"Young feller?" says he, with a pitiful look at me. "Young feller?" "Why, John, that man has fired for two years on every road in North America, some on most of 'em in South America, and all the principal ones in Europe, Asia and Africa, and a little in Australia and New Zealand. Young feller? why, man, he's a hundred and ninety years old according to his own figgers, don't call him no young feller."

JOHN ALEXANDER.

A Time-saving Wheel Truck.

Editor The Locomotive Engineer:

To those of your readers who have many engine truck and tender truck wheels to change, the following description of a wheel truck we made here will be of interest, I think. Take a piece of sound oak plank, 2⅝" x 16" x 37"; 10" from one end cut a hole in the center of plank, which will let pass through the top end of a common 6' screw jack. This hole should be cut so that the jack will stand in a perpendicular position when the plank is at the angle shown at *F*, Fig. 1. Then have forged an axle of 2" x 2" iron, bent in form of *A*, Fig. 1, turn the journals 1⅛" x 3¼". The center part of this axle should be flattened to about 1" x 2" to admit of the bolting over it of the piece of boiler steel *B*, Fig. 1. This plate is of ⅜" steel, 8" wide, and bent in the form of *B*, Fig. 1. This is bolted to the bottom side of plank over the axle with ⅝" bolts, as shown at *F*. In bolting this plate to plank I used four pieces of ½" x 1½" x 12" iron, one of which passed over each end of the steel plate. The other two pieces were let into the top side of plank flush. Each end of the steel plate takes three bolts, which also pass through the iron pieces mentioned. Then I put a ⅝" bolt through the plank and each end of the iron bars, just at the edge of the steel plate. This plate should be very securely bolted to the plank, as it carries almost the entire weight of the load. The carrying wheels shown by the dotted lines *F*, Fig. 1, are 8" in diameter, with 2¼" face. The small lead wheel is 4" in diameter, with 1¾" face. This wheel is let into the center of plank near the end, as shown. For this we used a friction roller for tender truck, which had the journals cast on. For boxes we took an old pair of hand-car boxes, and bored them out to suit. Now, on each edge at the end of the plank which carries the lead wheel, I bolted a steel piece slotted as shown at *C*, Fig. 1. These were made of ½" x 3" steel—made them of the broken top leaf of a driving spring—these pieces are fastened to the plank with 1" x 5" square-headed bolts, which pass through the slots, and screw into the plank, the same as lag screws. These steel pieces must move easily backward and forward on the bolts.

In order to have the truck carry wheels from 28" to 33" in diameter, I made two jack heads. The one marked *D*, Fig. 1, is used when 33" wheels are to be loaded. The one marked *E*, Fig. 1, for 28" and 30" wheels.

To load a pair of wheels on this truck, proceed as follows: Run the truck under the axle, and push it forward until the forward end of plank strikes the inside edge of wheel flange, this will push the ends of slotted steel pieces back flush with end of plank. Then place the jack head directly under axle, this brings the front end of the plank square with wheel flange. Then by raising jack, wheel No. 1, Fig. 2, will be raised first, for (if the truck is made to these measurements) when the truck is placed in position described above the jack head will be 1" nearer to wheel No. 1 than to wheel No. 2. Raise wheel No. 1 until, by pressing down on it, wheel No. 2 will be raised above the top edges of slotted steel pieces, when they can be pushed out under the flange of wheel No. 2, which (when pressure is removed from wheel No. 1) will drop into the notches in steel pieces, and the wheels will rest in a parallel position, as shown.

We find that two men, by pushing on wheel No. 1, can run a pair of wheels thus loaded any place in the roundhouse.

I had two pine planks made 4" x 14" x 53", and hinged them together, and faced the top sides with No. 16 sheet-iron, along the outer edges of each plank on the top I screwed a piece of ⅜ x 1" iron, the entire length, to prevent the truck from running off. If these planks are placed across the pit and spread out, a pair of wheels can be run out and in on them nicely.

If any one of your readers will build a truck of this description and try it, I am positive that they will like it, as two men can take out and put in a pair of wheels in half the time three or four men can do it without the truck, and do it, too, without danger to themselves.

L. C. HITCHCOCK,
"Soo" R. R. Foreman.

Minneapolis, Minn.

A TIME-SAVING WHEEL TRUCK.

Slipping Drivers Going Down Hill.

Editor The Locomotive Engineer:

I would say that I run an engine that did slip, and I give her sand, and she stopped. We had been running down hill about a mile from where I shut off. There is another engineer on this road that she's done the same thing with. I have been going forty-five miles an hour, and have her slip up, and I shut off steam, and she would slip till I give her sand. I have let her go eighty rods sometimes before giving sand. Why is it that she will slip so long after shutting off steam?

JAMES A. NUTE.

Nashua, N. H.

[We wish our correspondent would give us all the particulars noted when this slipping occurs. What is the grade, size and style of engine, weight on drivers, etc.? What causes the engine to slip after steam is shut off is more than we can see. All the pushing of the train would exert itself at the axle, and in no way tend to slip the drives ahead. If there is any one who has noted similar diseases in locomotives run by them we should be pleased to hear from them.]

W. E. Maher, Gen'l M. M. of the C., C. & C., is having ten ten-wheelers, 19x24 cylinders, built at Baldwins.

The Question of Federation.

The flood of correspondence on federation *pro* and *con* we shall have to decline—if it were all published it would fill the paper. Federation will become universal in time; in fact, is now in full operation, except the engineers. The argument against the engineers' special committee, for not getting up an original plan of federation, is useless. Suppose they did get up a new plan, who would they federate with? They have only the choice to join the present federated body or stay out of it. They can't "federate" alone. It would seem as though an organization strong enough to secure valuable "agreements" would be better able to renew and enforce them than ever if their numbers were doubled. A general who has taken a fort with an army of 5,000 men does not usually surrender it because he has been, reinforced by 50,000 The question is not whether or no we want federation—federation is here. The question now is, shall this magnificent array of organized railroad men fill the chairs of their supreme council with men of brains, men who know enough to be reasonable, honest and just; men who will be firm yet gentle with their strength; men who will meet rail road officials on common ground, and become so grand a board of arbitration that the railroad strike will be forever dead; or will they let the council become an autocratic ring of agitators and hoodlums who will make the orders behind them the clubs to show their authority, and the sewers to convey their spleen against "capital"? We have confidence in the good judgment of American railroaders when they "sit down to reason together," and believe that the present high character of the supreme council will be maintained.

A Hard Hit at Mr. Webb.

In a long report of an accident on the London & Northwestern road, in England, the *Railway Herald*, of London, says:

"The London & Northwestern Company has always been backward in the adoption of any improvements not suggested or introduced by the chief locomotive engineer of the line. It was only a short time ago that its faith was pinned to the Clark & Webb chain brake as the best possible. Driven from this position by circumstances over which it had no control, it adopted the simple vacuum as its next fetish, and failing to obtain salvation through that, *adopted* the vacuum automatic to its requirements, or prejudices.

"To argue, as was done before the coroner and the Board of Trade Inspector, that the driver should have had his train under the control of his hand-brake, is practically to admit the unreliability of the form of vacuum brake with which the train was furnished, and is in itself a strong condemnation of the company for its employment."

The same trouble is experienced in this country to some extent, not in the adoption of brakes, but of other appliances, and on many of our big roads an invention has to be "improved" to be adapted to the needs of the service—often cutting out the lights, liver and backbone of the invention proper, then when it fails condemn the inventor or the makers.

Some American Inventions that were First Adopted in Europe.

It is pretty generally acknowledged now, that the shifting link motion was first made and used by W T James, in the city of New York, about the year 1832; it was condemned in this country, but adopted at once by Geo. Stephenson, and became known as his invention. Mr. Rogers was the first American builder to appreciate its merits and persist in its use on his locomotives.

The Allen or double-opening valve—one with a passage through it to increase the steam opening—was invented by an American, Mr. Allen, who tried in vain for years to impress its merits for fast locomotives upon American railroad men, it was no sooner introduced in England when it became a general favorite, and is yet known as the "trick" valve. Here it is just coming into general use—long after the patent has expired

The English roads used the brick arch with success for a long time before it came into anything like general use here. Yet it was invented and introduced by Geo. S Griggs, on the Boston & Providence road, a great many years ago.

Don't Run the Risk.

An engineer is usually commended for sticking by his engine and trying, to the last moment, to stop his train. It was reserved for a coroner's jury in this city to find that one poor fellow of this stamp lost his life "through his own neglect."—*Phila. Ledger.*

Try to stop if you have time, but get off anyway You can put the brake on as you fall off—if the engine has no brake, get off quick. Meeting grim death with your hand on the throttle is no honor. The wives and children of many a railroad hero of this kind are in need of bread to-day Be a hero to your own family.

Some excuse is perhaps necessary for the present issue of the THE LOCOMOTIVE ENGINEER; it has been thrown together hurriedly, and shows a dearth of original matter. The editor has been nearly half the month at the bedside, the bier and the grave of an only child; a man cannot write when his heart is full of sorrow, and his brain seared with grief, when the noonday sun seems dark, when the flowers and the grass seem dead and dry, when the songs of the birds seem like funeral dirges, and the words between the lines upon the paper fade dreamily away before the misty gaze, and seem to disappear in long rows of little graves.

A statue has just been erected in Newark, N. J., to the memory of Seth Boyden, one of the ablest mechanics of the first half of this century. His inventions and discoveries were many and varied; among them, patent or glazed leather, malleable iron, nail machines, the machine for making split leather, and a cut-off for steam engines, the first one controlled by the governor. In 1837 he built for the Morris & Essex railroad the "Orange," the first locomotive built in the State of New Jersey. He introduced the present outside connected engine, being the first to discard the crank axle. Seth Boyden was born Nov. 17th, 1788, and died March 31st, 1870.

It would make considerable difference in your pay check—if you run by the mile—where your run was. The English mile, as you know, is 5,280 feet, but the standard mile of different nations varies greatly, there being no less than 32 different standards; the shortest is the Chinese, which is but 1,887 feet, the longest is the Hessian, which stretches out for 58,500 feet. The miles of all countries except China, Lithuania and Russia, are longer than the English mile.

Some of the roads out of Pittsburgh get their coal delivered on the chutes at 85 cents per ton—not much of an excuse for the motive power officials to experiment with compound locomotives or valve motions. In the extreme southwest or Mexico, where coal sometimes touches $10, any device that will save five per cent. of the fuel would be worth taking pains with.

The big U. P engine illustrated last month was one of some 40 built Baldwin's Cookes' and Rome have all furnished engines of that size recently.

Books Received.

LOCOMOTIVE ENGINE RUNNING AND MANAGEMENT. A Treatise on Locomotive Engines By Angus Sinclair, Secretary American Railway Master Mechanics' Association, etc. John Wiley & Sons, New York. Price, $2

This work is one of the best known and appreciated of all the works published for enginemen. Its popularity is shown by the fact that it has reached the fourteenth edition in less than six years In the present edition Mr. Sinclair has almost a new book, having taken out much that was of little use and replaced it with fresh matter of practical value. He has elaborated and extended the chapters on combustion, and has a chapter of questions and answers for the examination of engineers and firemen.

The chapter on radial and other odd forms of valve gear has been cut out, and standard practice in the matter of valve motion more fully covered and explained

The articles on air-brakes are brought up to present practice

This is the only book ever written about "running" locomotives, and its main value is in the excellent chapters on road service about the break-downs, emergencies, etc. No engineman should be without it in his little collection of useful books.

ASKED & ANSWERED.

(36) Statistics, Washington, asks:

What are the railroads of the United States worth—the whole system complete? *A*.—Estimated at nine and a half billions of dollars.

(37) W. S., Laulsbaugh, Oakville, Md., asks:

What is meant by consolidation and shifting locomotives? *A*.—A consolidation locomotive is one having eight wheels connected, and a two wheeled truck. A shifting locomotive is one used for switching.

(38) O. C., Boston, Mass., asks:

Is it possible with the modern sight-feed lubricator, with double feed (one drop-glass for each cylinder) to "feed across," or both glasses show feed and both feeds go to one cylinder? *A*.—On many kinds it is, and is a serious fault. Name the maker.

(39) C. E. B., Groton, Mass., asks:

Who invented the variable exhaust? *A*.—Ross Winans used it on some of his earliest locomotives. He secured a patent, and sued many builders and railroads for infringement, but it was proven that it was used some years prior to Winans by the Hackworths, in England.

(40) F. S. S., Charlestown, Mass., asks:

Is the automatic brake used much in Great Britain? *A*.—Automatic brakes are fitted upon about one-third of the rolling stock in Great Britain, part of this being air and part vacuum. Non-automatic brakes, both air and vacuum, are quite common, yet many roads run without continuous brakes, and a great many cars have no brakes whatever.

(41) M. R. B., Alexandria, Va., writes:

1. I have eighty pounds of air with handle in full release position. I take eight pounds out of train pipe; what is pressure in brake cylinder per square inch? 2. If I have eighty pounds and take out twenty pounds, what is pressure in brake cylinder per square inch? 3. When engineer's brake valve handle is moved from full release to emergency notch and left there, why is it all of the air does not escape out of train pipe? All of these apply to brake valve of '88. *A*.—1. About twenty pounds. 2. If you reduce train pipe pressure twenty pounds by the service stop exhaust, it would probably apply the brake full, giving about fifty pounds per square inch on the piston head. With the new quick-action triple valve, and a twenty pound reduction through emergency, you could get in the neighborhood of sixty pounds on the piston. 3. The air will all escape from train pipe if valve is left in emergency stop—the gauge is shut off and does not show the reduction.

(42) F. J. C., Oswego, N. Y., asks:

Could an engine run with her back-up eccentric rod broken by weighting bottom on link? Heard it was done by putting piece of rail two feet long at the bottom. Also let me know is there any difference in length between go-ahead and back-up rods? *A*.—It is barely possible that an engine could be moved as you say, but it is not safe or practical. It takes a long time to fix up, and there is little if any use in it—unless the back-up eccentric rod broke on an engine already on one side, and it was necessary to get in. This question is like the one, "How to run with both front cylinder heads knocked out," the answer being to stop up both front ports so as to clear the valve and the piston. You might just as well tell a man on the road to make two new heads. The answers given in this column are intended to cover general practice. There should be no difference in length of blades, yet they are sometimes varried in valve setting, to secure the best results at some one point of cut-off.

The "Engineering News" on Air-brakes.

The *Engineering News*, of this city, thinks we were wrong in trying to point out that it was wrong in blaming the engineer for not being able to release the brakes in the Hamburg disaster. Speaking of our statement that it was impossible to release the brake, as long as there was an opening in the train pipe, it says:

"Our contemporary forgets that there are two kinds of conductor's valve, both of which have their advocates, and both of which are largely used. One of them, the older form and the one still most largely used, stays open only so long as held open. On its release it becomes instantly possible for the engineman to release brakes in the usual way. The other style is a plain cock, which, if once opened, stays open until closed by hand. We understand that this last style was *not* in use in this case, but whether it was or not makes no difference, because the facts are that in the Lake Shore disaster the engineer failed to place his brake valve on lap when the conductor's valve was pulled open, and so lost all the air from the main reservoir through his own valve. He was, therefore, clearly in fault in any case, since he had no right to assume that the conductor's valve would be left open, even if it was not of the self closing type."

If, as our contemporary assumes, the conductor's valve was pulled open, and allowed to close, the engineer's valve would have kept supplying air to the train pipe, and the brakes would probably have released before a stop was made under ordinary circumstances. It is plain that the conductor was frightened, and he did not hold on to that self-closing valve very long. It looks as if the conductor's valve was one of the sort that stay open, for had it been a self-closing one, on so short an application, the air could not have all escaped from the engine drum, especially if the valve was in feed position. This *instantly* business in releasing air-brakes when once set, does not work. If it is proven that the engineer did not put his valve at lap, it will show that he did not understand the true nature of the stop, and how necessary it was to release quick—he is not to blame for not being able to see in the cars, and behind the train. We would call the attention of our contemporary to a railroad rule almost universally in use in this country—and not a bad one either—which instructs the engineer to open his valve and assist in making a quick stop when he feels the brake go on from the train—it being assumed that something is wrong. If this rule is in force on the Lake Shore, the engineer can be blamed for not doing more instead of less to make a stop where the final crash came.

Again our contemporary, in explaining its statement that after the first break there was much air in the auxiliary drums that could have been utilized for braking, it says:

"Our contemporary also asserts, with much confidence.

"'It was impossible to release those brakes, when set at Dunkirk by the first break, without (restoring the pressure in the train pipe, or) bleeding out *all* the air in the brake cylinders and auxiliary drums. So long as there was a pound of air in the auxiliary drums and the train pipe was open, the brakes would set.'

"There is a little appendage to the brake-gear known as the 'four-way cock,' which our contemporary has apparently forgotten, but which makes the above statement untrue. We did not assume this four-way cock to have been used."

On the quick acting brake, those built since 1887, there is no "little appendage" in the shape of a four-way cock, and the brake cannot be changed or cut out. On much of the old equipment the handles of these cocks have been removed or are wired up to prevent men from meddling with them. Brakes are used to stop the cars when in motion, and it is plain enough that if the four-way cock was used to retain "air available for braking," the cock would have to be turned by hand to use it, and as the cock is under the car, it cannot be reached.

This idea of putting the power to apply a continuous brake into the hands of the trainmen, and then blaming the engineer for not being an antidote for all their mistakes, is wrong.

Some Information About Interlocking Switches and Signals.

The Johnson Railroad Signal Company, of Rahway, N. J., have recently issued a catalogue of their interlocking signal appliances, and in the preface of the book tell a great deal that is of engrossing interest to those interested in signaling. The catalogue is a large book, very fully illustrated, and one that should be in the possession of every office of the operating departments of railroads. We quote from it as follows:

The credit of the introduction of interlocking signals in the United States is due to Messrs. Toucey & Buchanan, of the New York Central & Hudson River Railroad, the former, general superintendent, and the latter superintendent of motive power. These two gentlemen very early saw the advantages of concentrating switches as much as possible so that they could be worked from a central point and protected by a much smaller number of signals than would be necessary if a signal was placed for every switch. They devised an interlocking machine, and the first one was fixed at Spuyten Duyvil Junction, in New York City, in 1874, and remained in service until 1888. This machine compares very favorably with the earlier machines used in England, which was the birthplace of interlocking signals.

The Pennsylvania Railroad was also early in the field, but they sent to the well known firm of Saxby & Farmer, of London, England, for a complete machine, etc., with signals and connections, which were sent over and fixed at East Newark Junction on the New York Division, being put into service on February 11, 1875, where they are now working.

In 1876 Messrs. Saxby & Farmer sent a very complete model of their system of interlocking and block signals to the Centennial Exhibition in Philadelphia. This exhibit did more, perhaps, than any other one thing to acquaint railroad managers in this country with the systems of interlocking and block signals, which were then extensively used on European railroads.

Very shortly after this, the elevated railroads of New York were built and equipped at the most important points with the Saxby & Farmer machine, manufactured by the Jackson Manufacturing Company, of Harrisburg, Pa., who had purchased the patent rights for this country.

The slow progress of the introduction of interlocking, up to the year 1887, was due partly to a want of knowledge of its advantages and partly to the serious depression of trade which was felt so long.

The advantages of interlocking may be classed under two heads:

I. Increased safety.

II. Increased facility in the handling of traffic at busy points.

Increased safety is assured by working each system of switches and signals from a central point, the mechanism for operating such system being so arranged that, so long as the apparatus is kept in good condition, movements taking place under the sanction of the operator, as expressed by the lowering of a signal or signals—and no other movements can take place without such sanction—are secure against collision from conflicting directions, and disturbance of the switches traversed by such authorized movements.

Much of the increased facility that may be obtained depends upon a good lay-out of tracks as well as of the signals. When switches are arranged so as to obtain the greatest number of movements with the least possible running, much more rapid handling of trains can be obtained with safety by one man who handles all switches and signals from an elevated point, where he can see each movement and anticipate each requirement, than by a number of men who have to run from switch to switch to throw them.

One can best realize this by watching the movements of trains at Grand Central Station, New York, Broad Street Station, Philadelphia, or the Boston Yard of the Boston & Albany R. R., and comparing them with those at other busy places which have no interlocking.

The introduction of interlocking signals and switches has not always been a complete success, for obvious reasons, viz.: faulty arrangement of tracks and incomplete signaling. The existence of either or both these conditions will, of course, mar the complete efficiency of any system, and if, from desire to economize or other reasons, systems having such faults are introduced or allowed to remain, satisfactory results can scarcely be expected.

It is very satisfactory to all concerned in good signaling to know that an increasing number of roads are alive to the importance of having a properly equipped signal department. Several important roads have appointed signal engineers whose duty it is to superintend the construction of new work and maintain it in good condition afterwards.

In making these appointments it is well to secure the services of men of some years' experience, because although signaling may appear to be very simple and is so in small plants, there are so many intricacies in large ones (and every road will have some such), that nothing but long and varied experience can fit a man to fill the position satisfactorily.

There is something about signals very fascinating to the inventive faculty, and the application for patents, and the patents granted for signaling devices, must approximate very nearly to the infinite number of car couplers and rail sections. While it is very laudable to desire to improve signaling devices, it must be remembered that there is great economy in uniformity, and changes should not be made unless some decided advantage is gained.

The experience of twenty-five years has pretty conclusively shown among other things that the semaphore signal is the most satisfactory type of signal; that switches and locks should be worked by pipe; that facing switches should be fitted with facing point locks; that facing point locks should be duplex, *i. e.*, so arranged that, in the event of the breakage of connections, the plunger of the lock cannot be thrown into the wrong position of the switch; that two lines of wire should be used to each signal; that signal blades should be so constructed as to go to the danger position in case of breakage of connections anywhere between the operating lever and blade; that wires to distant signals should be automatically compensated; that iron plates should be fixed under switch points to keep the track accurately to gauge; that plungers of facing point locks should not be pointed; that cranks and pipe compensators should be fixed on foundations firmly imbedded in concrete; that all side tracks connected to main tracks should be "trapped," *i. e.*, have a derailing switch to prevent cars coming onto the main track until the switch is set for the side track; that a signal should be given for every train movement; that high signals should only be used for main running tracks; that separate signal posts should be used for each track running parallel or converging; that one post with one or more blades (various systems are in use for indicating the route open) should be used for diverging tracks; that it is a most dangerous and reprehensible practice to displace or disconnect any part of safety appliances, such as detector bar, switches, switch locks, machine interlocking, except in cases of absolute necessity, and then only temporarily and under proper protective conditions, such as padlocking the switches affected, issuance of caution, notice and employment of flagmen at the positions of danger; that all ground connections should be well drained and all the appliances kept clean.

The points on a railroad where the most train movements are found are usually chosen to introduce interlocking signals, but an exception to this rule is found at grade crossings and drawbridges, of which there are so many in this country. Most of the States some years since passed laws compelling railroad companies to bring their trains to a full stop before crossing a drawbridge or a grade crossing. These laws have been found very irksome, not only on account of the cost of an unnecessary stop, but from the delay caused by stopping passenger and heavy freight trains. This has been very clearly pointed out in some of the reports of railroad commissioners.

For a simple grade crossing protected by 4 derailing switches, 4 home and 4 distant signals, the most simple form of interlocking answers every purpose, and great efforts have been made to reduce the cost to as low a figure as possible. It must be remembered, however, that no matter how simple the interlocking, it should be arranged to be perfectly safe under all circumstances, and easy to maintain in good condition so that one man will be able to properly maintain several crossing towers. In the struggle to introduce cheap appliances, too little attention has sometimes been given to a proper factor of safety. There are crossings now being used with the derailing switches worked without a facing point lock or detector bar. This should absolutely be prohibited, as innumerable wrecks have occurred through the throwing of a switch under a train, and one of the most disastrous accidents that ever occurred was caused in this manner, before, however, the facing point lock was in general use. It must not be forgotten that a derailing switch is a facing switch, which ought to be avoided as much as possible consistent with proper handling of traffic. One of the first conditions, then, in connection with derailing switches should be to make it impossible to give a clear signal with the switch open or partially open. With ordinary interlocking this is improbable, but not impossible. The only absolutely certain method is by working the signal by means of the last movement of the plunger of facing point lock. A switch detector, however, worked by the home signal connection, may well be accepted as sufficiently certain, but without this a crossing should not be considered absolutely safe. In this connection we may consider the working of switches and locks by two lines of wire, which is far less costly than pipe, but which is open to objections that should be clearly stated and understood. It has been demonstrated that switches and locks can be worked by means of continuous wire, and they are certainly easier for the operator. But it is equally certain that perfect means have not yet been found to automatically counteract the effects of the stretching of the wires caused by varying strains. Adjusting screws are furnished and answer perfectly well when handled by competent men, but just at those places where wire-working switches are likely to be used, competent repair and maintenance men are least likely to be found. While, therefore, we are prepared to connect switches by wire, and have the most perfect appliances in the field for so doing, we recommend the pipe connections solely because they are more easily kept in order. The wire-working can be made perfectly safe, except that, when from any cause they become too slack to throw the switch, the operator is usually not sufficiently skilled to know how to tighten them to do their proper work. A passenger train may be standing waiting for the signal which the operator is unable to lower, owing to the imperfect action of the switch. He becomes excited, and instead of going to the switch to ascertain the trouble, he will wave his lantern for the engineman to come ahead, which the latter will frequently do, and so derail his train. This has happened several times.

A great many efforts have been made to work and lock a switch by means of one lever, and various devices are in existence for accomplishing that purpose. We believe we have the only movement that does the work perfectly and in a thoroughly satisfactory manner. We have accomplished this by giving a long initial stroke to the pipe connection, which thereby reduces the power of the operator for rupturing them by giving him less leverage. At the same time, by using our anti-friction pipe carriers, the force required to move the connection is much lessened, and finally the switch and lock movement itself is so designed as to give the minimum of resistance in its proper work, and the maximum for rupture. With this device we claim that switches can be worked with greater facility than those having a separate lock lever, and as safely. When a connection becomes broken the operator knows it through his switch detector, which prevents the signal from being lowered unless the switch is properly home.

Our devices for working signals and switches from the center of a drawbridge are now so complete, that not only do we obtain as perfect working as from ordinary towers, but no trouble is experienced from the changing position of the draw due to expansion and contraction, and the movement caused by passing trains. It very frequently happens that switches are located near the end of a drawbridge, and the use of a machine fixed in the center of the draw and worked by the draw tender saves the expense of switchmen at one or both ends of the draw. It is very essential, however, that the connections be so arranged as to require little adjustment and be easily kept in good order. Due allowance should also be made for the jarring to bridge couplers, caused by trains passing on and off the bridge. All these requirements are met by the appliances furnished in our system.

SOME SNOW PLOW TRIALS.

A fruitful source of danger to trains is the misplaced switch which is continually causing disaster, and which can almost invariably be avoided by the use of distant switch signals. It is absolutely certain that, with facing switches unprotected by a signal, these accidents will continue to happen in the future, as they have done in the past. It is not an expensive matter to have these signals, and they can be arranged to be fixed in connection with any kind of switch stand. We have been unable in this issue of our catalogue to illustrate distant switch signals.

For roads not having sufficient traffic to warrant the use of distant switch signals we can furnish padlocks for the ordinary switch levers so arranged that the switchman cannot take out the key of the padlock until the switch is set and locked for the main track. For switches also that are too far from a tower to be conveniently worked, we have a key locking arrangement, by means of which a key must be taken from the tower to open the outlying switch, and until the key is brought back to the tower no signal can be given for a train to proceed in the direction of the switch, and of course the key cannot be brought back until the switch is set and locked for the main track. This method is a slow, but very safe arrangement.

It very frequently happens that a signal tower is located at or near a street crossing, in which case it is decided economy to work the gates from the tower, and they may be interlocked with the signals or not, as may be found most desirable. This is very often found much more convenient, as well as safer, than having a separate man on the ground, who is liable to raise or lower his gates at the wrong moment, and besides, cannot see approaching trains so well as the man in an elevated tower. The ordinary lifting gates may be used, or swinging gates which close against the street in one position, and against the railroad in the other, so preventing cattle, etc., from getting onto the railroad when being driven over the crossing.

Various devices are in use for notifying enginemen of the position of signals during foggy weather. The most usual method of doing this is to place men at the signals with torpedoes, which they fasten to the rails according to the position of the signal. Unless this is done, or some automatic system used, trains will necessarily be delayed. So far as we know, nothing has yet been put into service that gives complete satisfaction, although numerous inventions have been made.

It is the custom in France to attach a torpedo to each home signal, so arranged that when the signal is at "danger" the torpedo is on the track, and when the signal is at "clear," the torpedo is withdrawn clear of the track, so that only when an engine or train runs past the signal at danger is the torpedo exploded. It is often important to know if an engineman has overrun his signal, and this will give some indication, but not certain evidence, as there is nothing to prevent an operator throwing his signal to "danger" during the passage of a train, and so putting the torpedo on the track in front of the wheels.

The Palmer torpedo signal is in use to some extent, and has given, so far as we know, general satisfaction. It works with the home signal as described above, but the instrument is arranged to hold five torpedoes, and when one is exploded another takes its place until the five are exhausted, when the box has to be filled again.

Some efforts have recently been made to introduce an illuminated blade for signals, so as to show a night signal as near as possible like the day signal, but so far these efforts have not been very successful. The idea of illuminating the blade is quite an old one, and has been extensively tried, but never with enough success to displace the usual lamp showing red for "danger" and white for "all clear." Notwithstanding that some objections can be raised to this method of night signaling, the fact remains that if accidents do occur through its use they rarely or never come to light, and tens of thousands of these signals are in service and have been for years.

It is quite probable that, could equally good results have been obtained by colors for day signals, color instead of position would in all probability have been chosen. With a sky background the position signal by day shows perfectly, but unfortunately we cannot always obtain a sky background, so that it is impossible to give an equally good signal for all places. Ordinary observation will convince any one that a day signal may much more easily be passed unobserved than a night signal. The improvement needed, then, is not in night, but in day signals.

In considering the question of position signals for night, we need to be careful not to be allured into its adoption for the sake of conforming to the principle adopted for day signals. It is quite reasonable to have one principle for day and another for night; and unless it can be shown that there are important grounds for change other than mere uniformity, it would seem to be undesirable to make a new departure from an old established system which has worked so well in the past.

What are the advantages to be gained by introducing illuminated blades instead of the different colored lights, that would warrant railroad companies to depart from present usage? They perhaps are more distinctive, but certainly are not so arrestive as a strong light through a good red lens.

Are they less expensive in first cost or to maintain? On the contrary, in both they will exceed the present methods. Will they retain the same uniform state of illumination? No; they are more liable to derangement, and more difficult to keep from becoming dim and obscure. Are they more desirable because of color blindness? No; color blindness can readily be detected, and precaution should be taken to remove men from a position they are unfitted for.

Trains carry colored lights in their rear, and the misunderstanding of such would lead to accidents.

It may be said that their chief advantage lies in the fact that they differ from other lights about cities, more than the old systems.

Let us examine this. What is there in it? On the surface it is striking. Are not enginemen conversant with the road they run over? Do they not know the location of all their signals, and can a light be added to or taken from the systems through which they pass without being detected by them? If so, we are in a sorry plight, because neither system gives us security. Lights may be extinguished, and the rule which says, "*The absence of a signal where there should be one must be taken as a danger signal*" presupposes knowledge of the positions of all signals which govern the movements of the enginemen, and if one fails to observe the absence of a signal where there should be one, great risk is certainly incurred. Where is the danger in additional lights along the route, either transitory or fixed? If of the same color as the railroad's safety light it can only be misleading through the extinction of the proper signal light and occupying its position. If of the same color as the railroad's danger signal the worst that could happen would be slight delay. The idea of street lights being mistaken for signal lights by a railroad engineman is far-fetched and imaginary and does not rest upon good grounds.

As the proper working of any kind of mechanism depends to a great extent upon the condition in which it is kept, we furnish a few general rules for maintenance which have received very general approval.

In our mechanical devices we shall endeavor to keep to one standard as much as possible consistent with a due regard for decided improvements.

Snow Plow Battles.

During the past winter the fall of snow in the Rocky and Sierra Nevada Mountains has been something enormous, and every known device for keeping the railway lines clear have had an excellent chance for trial.

On the Central and Southern Pacific early in the winter both the Rotary and the Cyclone plows were in service, and had as large contracts as it is usually safe to take with snow plows of any kind. In this matter of handling snow by machinery the Rotary has the advantage of several years' experience, while the others are comparatively new.

The illustrations here shown are from instantaneous photographs, and are true representations.

Fig. 1 shows a Rotary after it had backed out of a cleared siding at Cascade, Cal. The cut shows the successive layers of snow and ice. The snow at this point was so deep that the top had to be shoveled off in order to give the plow room to throw the snow, it was so deep it was above the chute.

Fig. 5 shows this plow at work in the siding, throwing a solid stream of ice and snow clear over the main track.

Fig. 6 shows the plow at work in the great Cascade cut, and delivering snow on top of a 30 foot embankment.

Fig. 4 shows the cut after it was opened, and gives some idea of the battles the Central Pacific has had with snow. Late in April there was a great contest between the "Rotary" and the "Jull" plows on the Alpine division of the Denver, South Park & Pacific. This line over Alpine pass in the Rocky Mountains is operated only in summer, and had been closed for over four months. The snow was deep and hard, and the many springs in the mountains had flooded the tracks and frozen hard. This was the first great trial of the Jull, and a hard one. The road is narrow gauge, very crooked and very steep, and this plow—which projects 15' 4" ahead of the front axle—was very hard to keep on the track. Much trouble was experienced in getting her over the line 155 miles where there was no snow, and the first round she had with a 8-foot bank left her off the iron, as shown in Fig. 2.

SOME SNOW PLOW TRIALS.

The conical auger seemed to run all right, but the plow could not be kept on the track, and some difficulty was experienced because the plow could not throw the snow on either side of the track without stopping to change a heavy gate at the top, as shown in Fig. 3.

Fig. 7 shows the Rotary making eight miles per hour through four feet of solid snow on this division of the road.

It was unfortunate for the "Jull" that it was not first tried on some straight and level road, instead of on one of the hardest in the country.

The work of the Rotary plows has proven the feasibility of handling snow by machinery, and their excellent work on all the western roads this winter will no doubt still further introduce them.

These cuts and this data were furnished by the Leslie Brothers builders of the Rotary plow.

A Great Brake Trial.

The governments of South Australia will decide upon the adoption of automatic continuous brakes this year, and, to better enable their mechanics to decide on the best, will hold a great public test in September, under the following conditions:

1. Any brake entering into this competition must be continuous and automatic in its action, and capable of being applied by the driver or guard. 2. The engines, tenders and trains shall be similar in all respects. 3. The trains shall consist of not less than fifty vehicles of mixed classes. 4. The trials shall be made on the narrow gauge lines. 5. All engine and tender wheels, except the leading bogie wheels, shall be braked not to exceed 95 per cent. of the working weight on each wheel. 6. All other vehicles in the trains shall be braked with one block to each wheel; the brake block pressure on each wheel not to exceed 100 per cent. of the weight on that wheel when the vehicle is empty. 7. The brake mechanism used in the trials shall be such as is intended for general use. 8. With the exception of the addition of the brake rigging, the standard construction of the government stock shall not be interfered with. 9. Competitors shall design their own brake rigging, and be responsible for the method of application to the stock. 10. The trials shall be made with brake blocks hanging ½ in. from the periphery of the wheel. Tests will afterwards be made with blocks hanging 1 in. from the wheel, in order to show the efficiency of the brake with half-worn blocks. 11. The consumption of coal and water of each engine on trial shall be taken. 12. Each competitor shall be allowed to select his own trainmen from the South Australian Railway service. 13. Each competitor shall be allowed three days' private trial with his train in complete form before the competitive trials take place. 14. Before the trials are made the board must receive a written assurance from each competitor that his train and brake are complete and to his satisfaction. 15. No competitor will be allowed to interfere with, alter or repair his train during the progress of the trials, except with the written permission of the board. 16. The whole cost of fitting up the train shall be borne by the competitors, in accordance with the resolution passed by the house of assembly: "That a board of experts

be appointed to inquire into the respective merits of the Westinghouse, vacuum and other brakes, and practically try the same, if necessary, at the cost of the respective manufacturers or competitors, with a view of recommending which is the most suitable for adoption on the South Australian railways." 17. The brake trials shall take place in the first week in September, 1890. 18. Any persons desiring to compete under these conditions must signify their intention in writing to the board on or before April 30, 1890.

The Great "Tip" Question.

The chairman of the London & Southwestern goes even further than Mr Laing, of the Brighton, in his remarks on this subject to the general meeting of the shareholders, held on the 7th inst.

When questioned by Sir William Vincent as to the notice threatening dismissal to any servants taking gratuities ever being acted on, and asking if even the directors themselves did not tempt the men to transgress the rule, the Hon. Ralph H. Dutton had to admit that the regulation has been withdrawn.

By this admission Mr. Dutton practically admits that his company allows its customers to supplement the unduly low wages of its servants by public charity—for it is nothing more or less, and we shall, probably, in a short time see notices displayed in the stations, "Please remember the porter, he only gets 15s. a week," or, "Kind friends, the booking-clerk has a wife and three children to keep on 18s. per week."

There seems, latterly, to be a tendency arising amongst those who control our railways, to make extra charges for all the comforts and conveniences which have hitherto been considered to be included in the fares charged to their customers, as witness the proposed charge for an electric light by which it is possible to read, on the District Railway. Perhaps we shall hear next that the same company, in conjunction with the Metropolitan, has fitted trains with cylinders containing compressed oxygen, from which by putting a penny in a slot their unfortunate passengers may be enabled to obtain a supply sufficient to travel safely through the suffocating fumes of their ill-ventilated tunnels.

We do not in the slightest degree wish to divert the welcome addition to the wages of the underpaid and overworked railway men afforded by the liberality of the public; but we do think it a mean and despicable action on the part of a body of well-to-do employers to deliberately underpay their servants and leave them to depend upon the charitable contributions of their customers to pay the difference.

Besides this, the taking of "tips" on the part of men is destructive of their self respect Those who are acquainted with the men working on the railways in the United States and the Colonies, know that the offer of a "tip" would be taken as an insult, and might possibly be followed by a knock down blow from the indignant conductor or baggage man

Why should not the same independent spirit exist on our railways? The answer comes promptly, "Because the pay of the men is not sufficient to support them."

The question then arises as to how the present system is to be altered, and we reply, by paying the men fair wages for their work. "But," it will be argued by railway managers and others who want all the plunder for themselves, "the companies can't afford it." "Then," we would reply, "charge higher fares", the public would be as willing to pay a small extra charge to the company as to tip the servants, provided that they were sure that the latter duly reaped his proper share of the money.

The fact is that our railway companies are one and all seeking to give the least amount of service to the public for the greatest amount of money, and at the same time extorting the greatest possible amount of labor from their servants for the smallest possible remuneration.—*R'y Herald* (*Eng.*)

[So far as we know, conductors of trains in this country do not take "tips," and train baggage men seldom get the chance, but baggage men and porters at large stations not only get them, but ask for them; at some of the North River ferry-houses in this city the porters will ask for a tip before they take a trunk off a carriage boot. Not long ago a baggage porter at the Grand Central station put a trunk on a carriage for us, and stepped to the door saying, "Can't you give me something for handling your trunk, sir, *I get no salary.*" This, of course, was not true, but the tip was wanted just the same. Porters on our Pullman sleepers receive but $15 per month, make long trips of from four to ten days away from home, and—live on tips The tip business is growing in this country; it is degrading to the service, and ought to be stopped, and the cause and the remedy are plainly stated by our English contemporary above. We are sincerely sorry there is not as much of the insult and knock-down business here as our friends across the pond give us credit for.]

Quite a Change of Officials.

On the first of June Geo. W. Cushing resigned his position as supt. of motive power of the U. P., and was succeeded by Harvey Middleton, of the Santa Fe. John Player, of the Wis. Central, takes Mr. Middleton's place. Mr. Player's successor has not yet been named.

SOME SNOW PLOW TRIALS.

Pedrick & Ayer, of Philadelphia, have issued a neat catalogue of the Richards open side planer, the manufacture of which they have recently undertaken; this is one of the most ingenious and convenient tools devised in recent years for planing iron, a very small machine doing very large work, the tool traveling and the work standing still; anything that can be got up beside the tool can be operated upon. The circular shows the tool at work on numerous difficult planer jobs.

They Lead the Procession.

Horace Lovering, of the Maine Central, has sent in a list of 160 subscribers, the largest club of the year so far. Geo. McCombs, of the Duluth, South Shore & Atlantic, is a good second, with 143 to his credit. Both say they are not through yet.

The first of a series of articles on Heat, Motion and Work, and their Units of Measurements, which appears on another page, will be found of engrossing interest to all who have to do with the steam engine in any form. The articles are extracts from a paper read by Mr. Hemenway before an engineer's club in this city. The facts are stated in such an interesting way, and the illustrations are clothed in such plain raiment, that any engineman can understand them. Mr. Hemenway has the reputation of being one of the best steam engineers in America; he came up from the ranks, and knows how to explain mechanical subjects for the masses. Read the articles.

The estate of F W. Richardson, Troy, N. Y., have recently issued a very neat and complete catalogue of their balanced valves, relief valves, valve springs, valve motion models, etc. The catalogue contains a great deal of information about balanced valves. We notice that they are now branding all valves made by them as "made only by estate of F. W. Richardson," this being done to get rid of bearing the blame for failure of many mongrel balanced valves that are called Richardson.

Send us notices of promotions and appointments of enginemen or machinists to foremanships, traveling engineer, master mechanic or engine dispatcher positions. This paper tries to aid its patrons to rise in their profession, and knows of no better way to help them than to record their successes in that line. Promotions from the left to the right side we count as a matter of course, if we tried to record them, there would be little else in the paper

There are still in use on the Bristol & Exeter Ry., in England, two of the Pearson express locomotives, built in 1867, having a single pair of drives nine feet two inches in diameter They are said to have made ninety miles per hour.

George Francis Train has just completed a trip around the world in 67 days, 13 hours, 3 minutes, and 3 seconds, not counting a 24 hour stop in New York. He says he can make it in 48 days, and will try it in October. So much for steam.

The Richmond Cedar Works of Richmond, Va., intend to change their pole road track to iron or steel, and want about 12 miles of thirty to thirty-five pound rails, old or new. Also engine and cars, narrow or standard gauge.

One of the most interesting things a man can keep is his time books or stubs of trip slips. History thus compiled day by day is worth looking over long years after.

A man is under indictment in England for stopping a Great Eastern express train between stations to get on. In this country he would be elected a director.

Wm. H. Miller has been appointed Master Mechanic of the Columbus, Hocking Valley & Toledo Ry., in place of J. S. Patterson, resigned.

We will pay five dollars for a copy of the sixth annual report of the Master Mechanics Association. Who has one to spare?

There were 30,038 tons less steel rails made in England last year than the year before.

There is a locomotive on the London & Northwestern road that makes 800 miles per day; she is run by three crews.

President M. E. Ingalls, of the Chesapeake & Ohio Ry., will deliver the opening address at the Master Mechanics' Association on the 17th.

It is some days since anything abnormal in the locomotive line has come forward. As the barber says—next.

Last year there were 1,139 people killed, and 10,981 injured by railroad accidents in Great Britain.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S

HIGH VISCOSITY. HIGH FIRE TEST.

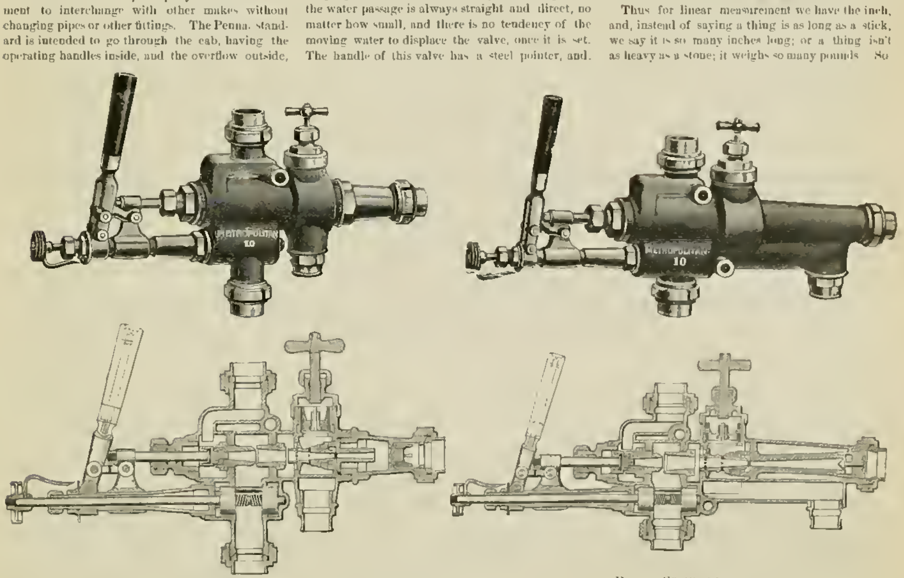
VOL. III, NO. 7. NEW YORK, JULY, 1890. $1.00 per Year or 10c. a copy.

The Metropolitan, Re-starting, Locomotive Injector.

The accompanying engravings illustrate a new re-starting injector recently placed on the market by the Hayden & Derby Manufacturing Co., of 111 Liberty street, New York City.

The two styles are alike, except in length, and this difference is made principally to suit the instrument to interchange with other makes without changing pipes or other fittings. The Penna. standard is intended to go through the cab, having the operating handles inside, and the overflow outside, end of the body, which prevents the paint from being burned off the injector, and makes it much easier to keep clean.

The water valve or "lazy-cock" is of an entirely new design, as is plainly shown in the sectional view, the stem terminates in a right and left-hand screw, and when it is revolved it moves two cylindrical plugs to or from each other, by this arrangement the water passage is always straight and direct, no matter how small, and there is no tendency of the moving water to displace the valve, once it is set. The handle of this valve has a steel pointer, and.



N. Y. STANDARD. METROPOLITAN INJECTOR. PENNA. STANDARD.

while the N. Y. standard is intended for use where the overflow pipe is wanted inside.

There is no primer or small starting valve of any kind, nor is it necessary to operate the starting lever slowly to prime the instrument; when it is desired to start the injector, the lever is pulled wide open, and the instrument will go to work at once, and will automatically re start—as soon as working conditions are restored—if the water splashes away from the feed hose or the injector "breaks" from any other cause. The instrument is made of brass and bronze, except the long guide for the cross-head, that also carries through its center the spindle of the water-regulating valve, which is made of malleable iron, and the handles, which are of hard rubber. The water passage is very direct and large, and the steam is introduced at the extreme back by use of a series of marks on the guide, the runner can adjust the valve very closely, and keep it in one place, the handle, coming back as it does, makes it very easy of access. The overflow valve is large, and has its guides or wings in a chamber above the seat, is easy of access, easy to grind in, and too large to wear much in service

Special pains have been taken to make the tubes removable for repairs, no matter how bad the water is. The seat and valve of the main steam valve, or ram, are made of nickel, are hard, will not corrode or stick together, and wear much less than brass.

The manufacturers of this injector have been something like a year testing it, and overcoming defects, it is now in use on the Central Railroad of N. J., giving good satisfaction.

Heat, Motion and Work, and their Units of Measurement.

BY F. F. HEMENWAY

SECOND PAPER.

In order to measure things we must have

UNITS OF MEASUREMENT

Thus for linear measurement we have the inch, and, instead of saying a thing is as long as a stick, we say it is so many inches long; or a thing isn't as heavy as a stone; it weighs so many pounds So when the mechanical theory of heat was accepted, it was necessary to establish a unit by the use of which quantities of heat could be measured. The thermometer measures the quality—that is, the intensity of the heat—but not the quantity Here again, water is the best medium, and the

UNIT OF HEAT

was fixed as the quantity of heat that will increase the temperature of one pound of water by one degree, the water being at a temperature just above freezing. The reason why the temperature of the water is fixed—Rankine makes it 39.1—is because the quantity of heat varies slightly at different temperatures. But the variation is so slight as under ordinary circumstances to be of little importance The most we care for now is to understand what a unit of heat really is. A pound of water is a definite—a measurable quantity—so is a degree on the Fahrenheit scale; then, although we cannot handle a unit of heat, it is still, by comparison, a definite quantity.

THE UNIT OF WORK.

The unit of work is the foot-pound; it is the amount—the quantity—of work required to lift a weight of one pound to a height of one foot against the force of gravity. This unit is used to measure motion in any direction against resistance. Now it will be readily understood that, to make the knowledge of heat readily available for calculations, it was necessary to establish the exact relation between the unit of heat and the unit of work, and after much experiment it was found that one unit of heat was equal to 772 units of work.

This is something worth thinking about. We can afford to give it a little more attention, even at the expense of recapitulation, let us do so. A unit of heat is the *quantity* of heat required to raise the temperature of one pound of water one degree. By comparison we can get a fair idea of this quantity without being able to see it. A pound of water is—near enough for present purposes—one pint; not a very large quantity. And a difference in temperature of one degree in this water is not appreciable to the touch. If you took this pint of water at a temperature of 30, you could hardly put your hand in it and remove it without increasing its temperature by one degree. Put the water in a tin basin and burn a match under it, and you might increase its temperature one degree. A pound of coal is a small lump, yet it is capable of yielding from 12,000 to 14,000 units of heat. From the foregoing we can see that a unit of heat is a very small quantity indeed. Yet if all this heat was usefully expended in doing work it would raise a weight of one pound to a height of 772 feet, or a weight of 772 pounds to a height of one foot. This 772 foot-pounds is called the mechanical equivalent of heat. What this really means is that one unit of heat will perform 772 units of work.

ENERGY.

Energy, in mechanics, is the capacity for doing work, and is usually considered as divided into two kinds, viz. Kinetic, or actual energy, and potential, or possible energy. If a body is moving at a given velocity it possesses actual energy, and the amount of this may be determined by a consideration of its weight and velocity. For example, a cannon ball of a given weight projected at a given velocity, possesses a definite amount of actual energy, because it will do a definite amount of work in being brought to rest. The fly-wheel of a steam engine contains actual energy because it will do work in being stopped, or in having its motion reduced.

Potential energy is the possibility of doing work possessed by a body. Thus, if the same cannon ball were carried from the ground to the top of a building, it would possess potential energy with reference to the ground, because it would do work in falling.

ENERGY OF COAL.

Coal, which is the most common fuel in use, possesses the possibility of heat, and heat is motion of one kind. According to strict definition it would not, perhaps, be correct to say that coal possessed potential energy, still, if one were to say this were so, it would not be easy to successfully dispute the statement. To return to the cannon ball, its potential energy is due to the fact that it has been carried away from the ground, in carrying it away work has been done, and, of course, heat has been expended. When we let it fall it will render an exact equivalent for the work done in raising it. The cannon ball lies inert at the top of the building, but if we release it, it falls to the ground, and in falling does the work that has been done in raising it.

Now take a lump of coal weighing, say, one pound. It is before us inert, but, like the cannon ball at the top of the building, it possesses the possibility of producing heat, which heat may in turn be converted into motion against resistance. The action of the sun—the heat—has gone on for years storing up possibility of energy in this lump of coal; carrying the cannon ball to the top of the building stored up the possibility of energy in it.

COMBUSTION.

We liberate the heat stored up in the coal by combustion, which is a chemical combination productive of heat. There is a material difference between a chemical combination of substances and a simple mechanical mixture of substances. Thus the two gases, oxygen and nitrogen, unite, mechanically, to form air, and in air we find without difficulty the properties pertaining to both these gases. Substances unite chemically when they have affinity—that is, chemical attraction—one for the other, and the result is a compound entirely unlike either of the substances entering into the combination. Certain substances, each harmless in itself, may chemically combine to form a high explosive or a deadly poison.

In all chemical combination heat is evolved, but the combination may be so slow that the heat is not noticeable. But in combustion, as we speak of it in burning coal, the combination is rapid, and the heat evolved is correspondingly intense. This combination is that of oxygen and the combustible matter of the coal, which is largely carbon. The heat resulting from combustion is believed to be due to the violent clashing together of the atoms of the combustible matter and the atoms of oxygen, in their intense efforts to unite.

The chief constituents of coal are carbon and hydrogen. What is called a pure anthracite coal contains about 92 per cent. carbon, 2 per cent. hydrogen, 1 per cent. oxygen, 2 per cent. water and 3 per cent. ash; and, since carbon predominates—in fact, forms nearly all the combustible in the coal—we may for present purposes consider all the combustible matter as carbon. It has been experimentally determined that the combustion of a pound of pure carbon will yield 14,500 heat units, and as the combustion of hydrogen, weight for weight, yields rather more than four and a fourth times as much heat as the combustion of carbon, we may conclude that a pound of the purest obtainable anthracite coal will yield 14,500 heat units. Let us put it at 14,000. The problem that concerns you as engineers and firemen is how to set this heat free, and how best to utilize it in moving the piston of the engine back and forth in its travel.

It will be interesting to think of the equivalent in mechanical work of this little lump of coal. It contains 14,000 heat units, each equivalent to 772 units of work, altogether $14,000 \times 772 = 10,808,000$ feet that the heat of this small piece of coal would lift a weight equal to its own if all the heat it contained could be applied to that purpose; this is more than 2,000 miles. It seems almost incredible, yet it is no more than the realization of the full mechanical equivalent of the heat in the coal.

Let us see what work we get from this coal in actual practice. In steam plants as they go, and in every-day practice, if we get a horse-power on the consumption of two and a half pounds of coal per hour, the result is considered very good. Some plants may be doing as well as this, but very few better, and many worse. Now let us take this same one pound weight and use an engine requiring two and a half pounds of coal per horse-power per hour to raising it to a height of 2,000 miles, or equivalent work. Suppose we raise this weight to a height of 2,000 miles in one hour of time. A horse-power will raise 33,000 pounds one foot high in one minute, so it will raise 1,980,000 in one hour. Dividing 10,808,000—the number of feet in 2,000 miles—by this, shows us that it would require five and a half horse-power exerted for one hour to raise this pound weight to a height of 2,000 miles. At two and a half pounds of coal per horse-power there would be required thirteen and three-quarter pounds of coal to do what work there is heat enough in one pound to do. In this instance, viz.: with an engine using two and a half pounds of coal per horse-power per hour, between 7 and 8 per cent. of the total heat efficiency of the coal is utilized. It will readily be understood that with the largest and most efficient of steam engines—those doing a horse-power on about one and a quarter pounds of coal—the greater part of the heat goes to waste.

HOW LOSSES OCCUR.

In order to save it is necessary to consider how losses occur. Let us start first at the boiler. Combustion, as we have seen, is a chemical combination of combustible matter and oxygen. In chemical combinations definite quantities unite. If too much of one substance is present the surplus is rejected. In the combination of carbon and oxygen, called combustion, one pound of carbon unites with two and two-third pounds of oxygen, the result being carbonic acid gas. Air is composed of the two gases, oxygen and nitrogen, nitrogen largely predominating, so that, to get the two and two-third pounds of oxygen required, we must have about twelve pounds of air. This is assuming that all the oxygen is utilized. In practice this is not the case, so that it is necessary to supply about twenty-four pounds of air to the furnace for every pound of coal burned. Not only is the oxygen we use largely diluted with the nitrogen, that is of no use in supporting combustion, but we admit about twice as much air as we use the oxygen from. The nitrogen is inert, but its presence is necessary to dilute the oxygen. We know that the gases as they enter the chimney are hot, as we use the term, and that all the heat they carry away to the chimney must come from the coal. Hence we can readily see that all this surplus air that goes through the furnace, and the nitrogen of the air from which the oxygen has been used, carry away part of the heat of the coal, heat we are trying to utilize as motive power. There is loss here—in part necessary loss, and generally in part unnecessary loss. Let us see what this loss is.

The Boyden Air-brake.

One of the most interesting exhibits at the Master Mechanics' Convention was that of the Boyden air brake. This company had a complete equipment in operation, the engine attachments, including driver brakes, and ten complete brakes. In the Boyden the driver brakes are worked "straight" air while the train is automatic, or the driver brakes can be operated automatic with the train, or left inoperative, or the driver brake can be held on while train brakes are being re-charged. The general plan of the brake is not far different from the Westinghouse, the air is supplied by a pump—a very neat and simple one, by the way—is stored in a large drum, and the cylinders, auxiliary drums, pipe and hose connections are very like, if not exactly like, the Westinghouse.

The quick-action triple valve is altogether different, but similar in action. The brake, as shown in this equipment at least, is very much quicker both in application and release, it being possible to recharge the auxiliaries before the air is exhausted from the cylinders.

The engineer's valve is a large 3-way cock, and all the positions for the different combinations of the combined straight and automatic are made by ports in the plug of the valve.

The train brake cannot be changed from automatic, and is entirely interchangeable with the Westinghouse. It is in use on the B. & O.

A testing machine, just completed by the Phenix Iron Co., of Phenixville, Pa., is said to be the largest ever built. It is designed to test full size bridge members up to 55 feet in length, and to strains up to 2,000,000 pounds, either in tension or compression. Water pressure of 720 pounds per square inch is applied to a cylinder 5 feet 6 inches in diameter and 5 feet stroke. The general style of construction is similar to the machine at the Union Bridge Works at Athens, Pa. The cylinder is cast steel, and without the heads weighs 28,000 pounds; the other parts, crossheads, etc., are correspondingly massive.

The Rogers Locomotive Works are very busy on large orders. The Central of N. J. have just received from them several more for their fast express runs; these are 19 x 24, 8 wheelers, weighing upward of 100,000 pounds.

Editor J. N. Corbin, of the *Union Pacific Employes' Magazine*, Denver, Col., was a welcome caller at our den this month.

The B. & O. have ordered 1,000 box and 2,000 coal cars, the box cars to be equipped with air-brakes.

An Old Knight of the Drop Hook.

Some time ago John Brunton, of Pueblo, Col., asked through this paper if there were still alive any of the other engineers who were delegates to the Baltimore Convention, Knights of the Footboard, in 1855. He sends us an interesting letter, an outline of which we print below

"... I saw in THE LOCOMOTIVE ENGINEER your name as one of the delegates to the Baltimore Convention. I was one of the delegates sent from the Camden & Amboy R. R., and resided at South Amboy, N. J., then, as now. I have been continually employed since July 1, 1842, first as fireman, then engineer, up to 1863, then as roundhouse foreman, in which capacity I am still employed.... James R. Smith, now of Newark, N. J., was a delegate from the N. J. R. R. and Transportation Co. I have railroaded now 48 years; we have but one man still in the service who is older, Geo. Vernon, who has been at it for 51 years.... I fired the John Bull in 1842, the first locomotive in the State of N. J. I afterward ran her at different times. I had the honor to run the special that carried the Prince of Wales over the C. & A. road, and ran the engine that carried the last President's message that was taken to N. Y. in that way before the final adoption of the telegraph. I was one of the first to run a locomotive burning hard coal successfully; the engine had a single driver eight feet in diameter. I ran this engine three years without a blower.... I was sent to the Chicago Exposition of Railway Appliances in 1883 to run the John Bull around the grounds—she was the oldest locomotive in the world, capable of holding steam, having been built by Stephenson in 1831."

JOHN SEXTON.

The Johnston Electric Train Signal Co. have put up a new factory at Woburn, Mass. They will make other electrical devices beside their train signal.

Railway Accident Statistics.

The following statement for the year ending June 30, 1889, was compiled in the office of the statistician to the Inter-state Commerce Commission, and presented to the National Convention of Railroad Commissioners in Washington, May 28, 1890:

The figures given below make an exhibit of the number killed and injured under the three heads: "employes," "passengers" and "other persons." They further show the classes of accidents, and the loss of life and injury to persons resulting from each. A summary of these facts is given in the table which follows:

RAILWAY ACCIDENTS FOR THE YEAR ENDING JUNE 30, 1889.

KIND OF ACCIDENT.	EMPLOYES Killed	EMPLOYES Injured	PASSENGERS Killed	PASSENGERS Injured	OTHER PERSONS Killed	OTHER PERSONS Injured	TOTAL Killed	TOTAL Injured
Coupling and uncoupling cars.	300	6,757		...	...	.	300	6,757
Falling from trains and engines	493	2,011		.	.		493	2,011
Overhead obstructions..	65	296			.	..	65	296
Collisions.	167	820	107	145	37	48	311	1,313
Derailments	125	655	28	389	29	69	182	1,113
Other train accidents	189	1,016	26	247	522	515	737	1,778
At highway crossings	24	45	3	10	110	634	137	695
At stations	70	690	26	296	228	472	324	1,166
Other causes	630	7,729	130	754	2,915	2,397	3,671	10,880
Total .	1,972	20,028	310	2,146	3,541	4,135	5,823	26,309

The railways of the United States carried 472,171,343 passengers during the year covered by this statement, from which it appears that one passenger in every 1,523,133 was killed, and one passenger in every 220,024 was injured. For the year 1888 the rate of casualty in England to passengers from railway accidents was one passenger in 6,942,336 killed, and one passenger in 527,577 injured. In judging of the above figures it should be noted that passenger mileage for a given number of tickets sold is much greater in the United States than in England, a fact which mitigates somewhat the severity of judgment upon railway management in the United States disclosed in the above comparison.

In order to appreciate the above exhibit of casualties to employes of railways, it is necessary to know the number of employes liable to the various sorts of accidents recorded. The total number of railway employes in the United States is 704,736, which, for the present purpose, may be divided into trainmen, switchmen, flagmen and watchmen, and other employes. The number of employes in each class, as also the casualties to each class, is given in the following statement:

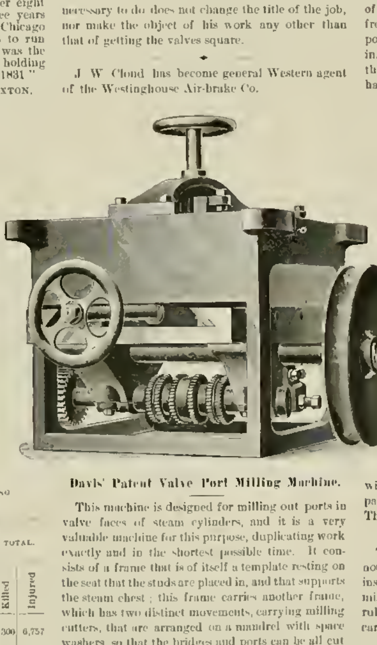
CASUALTIES TO EMPLOYES.

Class of employes.	Number	Killed.	Injured.
Trainmen	137 334	1,179	11,301
Switchmen, flagmen and watchmen	38,344	229	2 155
Other employes	517,820	536	6,360
Unclassified	16,238	28	214
	704,736	1,972	20,030

—*Ry. Age.*

Squaring valves, setting valves, and running them over all mean the same thing exactly. When a mechanic is sent to do this work he may only have to move a blade on the strap, or he may have to move all the eccentrics—what he finds it necessary to do does not change the title of the job, nor make the object of his work any other than that of getting the valves square.

J. W. Cloud has become general Western agent of the Westinghouse Air-brake Co.



Davis' Patent Valve Port Milling Machine.

This machine is designed for milling out ports in valve faces of steam cylinders, and it is a very valuable machine for this purpose, duplicating work exactly and in the shortest possible time. It consists of a frame that is of itself a template resting on the seat that the studs are placed in, and that supports the steam chest; this frame carries another frame, which has two distinct movements, carrying milling cutters, that are arranged on a mandrel with space washers, so that the bridges and ports can be all cut to dimensions at one operation; the inner frame is fed down into the cut by the hand-wheel and screw shown on top, and is fed the length of the ports by the hand-wheel at the end of machine. It is operated by a rope belt similar to that used for driving drills, etc. The machine is much lighter than the cylinder, and can be readily placed in position, using the stud holes to attach to, for that purpose. Built by Pedrick & Ayer, 1001 and 1003 Hamilton street, Philadelphia, Pa.

George W. Cushing, lately superintendent of motive power of the Union Pacific, has located in Chicago, his address being box 336. Mr. Cushing does not intend to quit railroading just yet, and will enter the field when suitable opportunity offers.

The popularity of the little book on "Air-brake Practice," by J. E. Phelan, cannot be explained better than by stating the fact that the first edition of 2,000 has been exhausted, and a second edition is now in press.

A Cheap and Handy Latch for Baggage and Express Car Doors.

On the large side doors of express and baggage cars on the Old Colony road they use a very neat and cheap fastening or latch. Bolted flat against the inside of the door there is a steel spring, about two inches of which terminates in a hook that closes over a strip secured to the frame; this catch has a curved end that allows the hook to ride over the strip in closing. Over this spring catch is a plain curved handle, such as used for a thumb latch on doors; this is hung on single rivets, up and down, that allow the handle to move or swing an inch or so. One of the ends of this handle has a projection that extends out under the spring at right angles to the handle, and when the handle is pulled to open the door, this projection swings up and pulls the spring catch out of the plate on the frame.

The whole thing is cheap and substantial

Filling "A Long-felt Want."

The average man has wrestled with the problem of carrying postage stamps without having them, from innate perversity, glue themselves to his pocket-book, or whatever receptacle he places them in. But his wrestling has been unsuccessful. Now the Mason Regulator Company, of Boston, Mass., has stepped into the breach and issued a neat little case, by the use of which stamps can be carried in a pocket-book with the assurance that a fellow can find one loose when he wants it. By enclosing a postage stamp to the company, the case can be had by anybody.—*American Machinist.*

We have one of the books, but the long-felt want is still empty—want stamps to put into it.

On the C. & O. road a great many castings are plainly marked with the pattern number, size in inches, and weight. A front end door marked in inch-and-a-half letters "No. 301, size 50 in., wt. 345," does not look as neat as a plain door, but it admits of no mistakes in repairs, etc; still in a case like the front door the mark could just as well be inside. The plan would save lots of trouble if used extensively in car repairs.

When the N. Y. C. & H. R. gets through changing the numbers on its locomotives, those numbered below 250 will be switching engines, those from 250 to 700 passenger, and all above that, freight engines. The road owns over 900 locomotives.

The B. & O. have put up one of the popular notices, "No drinking on or off duty—no re-instatement, under any circumstances, after a dismissal on a proved charge of drunkenness." This rule will be pretty general in five years. Will you care?

Francis C. Lowthorp, who recently died at the age of 81 years, is credited with being the inventor of the turntable. He was a civil engineer, and long a resident of Trenton, N. J.

The magnificent instruction car of the Westinghouse Co. has been on the Pacific coast since February, having made 23,000 miles from then till June 1st. It is now in Mexico.

The P. & R. now rate their new 50,000 coal cars as a car, two of the old style eight-wheeled cars, and four of the four-wheeled "jimmies" are now rated as a car.

E. F. C. Davis, lately superintendent of the Reading Coal and Iron Co., has become general manager of the Richmond Locomotive Works.

The Amalgamated Railway employes of Australia are agitating for eight hours.

The Plug Engineer.

When Angus Sinclair first struck a job on a prairie road in Iowa, he was put to stopping and starting an old scrap heap on a branch—in local railroad parlance called "the plug run."

It was not long before the townspeople got the fever from the boys and called it the "plug run." Then the boys abbreviated it to "the plug," and everybody followed. Sinclair was known only as "the engineer of the plug," as were also the other trainmen, each according to his station.

One Sunday evening, our friend Sinclair was out with a party of young people taking in the town—had his best girl along—and they strayed into a church where the colored people were having a revival.

The party of young folks sat quietly in the back seats eating peanuts, until at last the hat was passed, it went around and came back to the earnest old exhorter in charge with but a few sorry pennies, which he emptied on the pulpit, and, leaning over the altar of hope, handed the hat back to one of the deacons, saying, "We has to hab a little mo' dan dat, pass it agin, an' don't forgit de white brudders in de back ro',prehaps da gib sumting."

Again the hat came around, and the embryo secretary of the Master Mechanics Association chipped in a quarter.

When the hat got back to the front, the old dominie picked the quarter out from among the pennies, and holding it up between his thumb and finger said:

"De engineer ob de plug gibs a quarter. Lord bress de engineer ob de plug!"

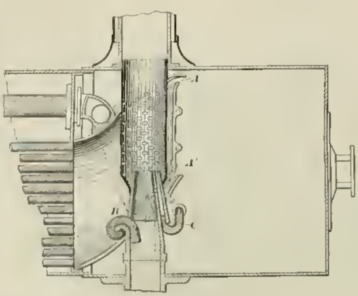


Fig. 1.

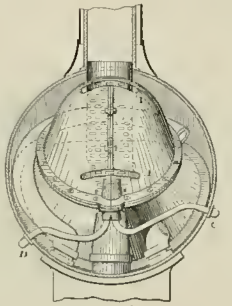

Fig. 2.

HOUSTON'S ARRANGEMENT OF LOCOMOTIVE SMOKE-BOX.

Dead and on Duty.

Engineer Murphy, of the P. & R., was in charge of one of the Wooten fire box express locomotives pulling a West bound passenger train on the Bound Brook line, on the evening of June 3d. In this class of locomotives the fireman is located back of the fire-box, and the engineer ahead. The fireman noticed, when nearly half-way over the division, that the engineer was not making customary signals, and was running at a very high rate of speed, so he climbed over the fire-box to the cab, and found the engineer dead—his head nearly severed from his body. Murphy had been killed by the spout of a water crane—some of these cranes in use on this road not being automatic in returning to position.

Suppose that this fast train should have kept on until it caught a train ahead, crashed into it and killed a lot of passengers. The verdict of the company, the coroner and the public would doubtless have been that the engineer was drunk, or asleep at his post.

The fireman on this engine laid his comrade's body down as best he could, and ran the engine over the road, making all the connections and causing no delay. He was the right man in the right place.

A Little Fuel Test.

Early this month Master Mechanic Van Brunt, of the Pennsylvania & Northwestern Railroad, conducted a ten days' experiment with three new Baldwin consolidation locomotives, to see what effect the Smith exhaust pipe had on the coal pile.

The engines are all alike, haul the same trains over the same track under exactly the same conditions, except that one has Smith's exhaust pipe. The grade is 105 feet per mile for eight miles, all the rest 85 feet per mile.

Engine 18 consumed in ten days 130,700 pounds of coal, and ran 1,105 miles, averaging 118 pounds per mile.

Engine 23 consumed in the same time 113,500 pounds of coal, and ran 1,030 miles, averaging 110 pounds per mile.

Engine 24 (with Smith exhaust) consumed 92,400 pounds of coal, and ran 1,139 miles, or on an average of 82 pounds per mile.

This is a saving of about 30 per cent. of the fuel, and, if anything like it can be maintained the year round, it would pay for a great deal of attention to the pipe.

We have heard lots of good reports from this pipe, and but one complaint—it stops up.

A very small percentage of the fuel burned would pay for cleaning out the pipe two or three times a week. Any nozzle will stop up.

A Joke on the Company Doctor (?).

"Flat-wheel Thornton" runs a train on a big road that has a hospital fund and company doctors.

Flat wheel got his name from a slight limp caused by the use of an artificial limb, though few knew that he wore such a member.

Flat-wheel was "forninst" the hospital fund, and always allowed his monthly deduction for that fund with a bad grace and a hard kick, he never missed an opportunity to declare that the work done by the company doctors was no good, and that the fifty cents off his pay was robbery.

There were lots of other men who thought as "Flat-wheel" did, and finally the company made membership in the hospital scheme voluntary—if you wanted it come and say so, if not, nothing would be taken from your pay. Flat-wheel did not take stock, and had kicked so long that he kept right on kicking, forgetting that he "wasn't in it." One stormy night the switcher ran him down in the yard, and cut off his wooden leg, and the boys took him home. On the way he conceived a revengeful joke on the company doctor; he would send for him, post haste, to amputate his leg—make him earn his money. The doctor was telephoned for, and told to hurry, as Jim Thornton had his leg cut off.

Hastily gathering up his instruments he went to the home of Flat-wheel, who laughed loud and long as he advised Doc. to get an axe and a spoke shave, and make a nice job of it

When pay-day came around the laugh was on Flat wheel—there was a deduction of $25 for professional services of company's physician.

Flat-wheel did get the $25 back, but it cost him $50 for cigars.

Houston's Arrangement of Locomotive Smoke-box.

The device here described is the invention of Chas. Houston, an engineer on the Central Railroad of New Jersey, and is in use on engine 145, belonging to that company. Engineer Houston did not start out to prevent sparks, his idea was to improve the draught enough to admit of the use of a larger nozzle, and thus allow the engine to do more work on a given expenditure of fuel—a subject which enginemen, as a whole, do not worry over much. Houston thought that the many angles and curves that the gases had to pass through to get from the flues, under the diaphragm to the front, through the netting back, and then into the stack, must create friction, and call for a sharper blast up the stack to finally draw them off, than if they traveled in a more direct line. He studied up what little there is known of the laws of induced currents, and found that a continuous jet of steam would move a much greater volume of gas or air through a given orifice than a much larger intermittent blast.

Having secured permission to test his ideas on his own engine, a device similar to the one here shown was put upon the 145, last winter. Experiments developed faults that called for modifications until the present form of front is now used.

A steel hood was made that would cover the flue sheet at one end, and was curved and tapered just enough to fit tight up at the base of the stack, this allowed the gases to travel in the most direct route to the open stack, making no unnecessary crooks and turns

The nozzle stand enters the hood as shown and was at first tried a third higher, but the lower nozzle does much the best.

The perforated sleeve is all the netting there is, and the openings in this are an inch by a quarter of an inch.

At *A* and *A'* there is an opening into the hood for the passage of large sparks; they of course follow the outside of the curve in making the turn. At *B*, Fig. 1, a small pipe enters the nozzle stand and turns around it, directing its jet out of the lower opening at *A'*; this is to throw out such cinders as lodge at the base of stand, and are too large to go out through the screen. At *C* and *D*, Fig. 2, is shown the arrangement of air pump exhaust and blower pipes. They enter an opening in the nozzle stand, and will stay where they are placed—this would be a good thing in any front. Fig 2 is a front view of the device, the front above the nozzle can be taken off for examination, or to clean the nozzle or screen. It will be seen that the steam pipes are entirely outside of the hood, and their leaking will not affect the steaming qualities of the engine.

Engine 145 is an 8 wheeler, 18 x 22, with a 5½ foot wheel, and rather a small boiler; hard coal is used in a fire-box 9 feet long and 36" wide; she originally had a pair of 3" nozzles, and was changed to a single nozzle 3⅞" in diameter; since this device has been used, the nozzle has been opened to 4¼". The engine is on express runs, making 138 miles of fast time every day. One noticeable improvement is the even way the fire burns, being alike all over the box, the engine runs 101 miles without using a poker or slash bar. In May, '89, with standard extension, this engine ran 3,744 miles, using 129 tons of coal; in the same month this year she ran 3,864 miles, using 115 tons of coal, and on one trip daily hauling a five-car train, where last year it was four cars, but it is fair to say that in the meantime the engine has been overhauled. One thing about the device, it can be applied with equal facility to a short or an extension arch—the 145 had an extension and it was left on.

The principle of the device seems good and reasonable, and the inventor has not claimed to save all the fuel and most of the oil; his device is cheaper to make and repair than an extension diaphragm and nettings, and he runs with a larger nozzle doing more work on less fuel

Some Early Valve Motions.

SYSTEM OF TWO FIXED ECCENTRICS.

Two eminent French engineers, Messrs. E. Flachat and J. Petiet, made some experiments with locomotives as early as 1842, and in their report described all the then well-known forms of locomotives in use in European countries. In 1846 their work was translated into English, and a copy of that work is before us as we write. Most of the enginemen of to-day know very little about early valve motions, even so recent a thing as the "hook motion" having become ancient history. All the engines built prior to 1840 were inside connected ones, and the engravings—which were made in 1846—show the throw of the crank. The plan for reversing a locomotive engine where a single eccentric on a side was employed, never became very popular, on account of the complication arising from the angularity of the connecting rod, and the eccentric rod itself. Of course in this form the valve traveled full stroke all the time, as did also all the other forms of hook motion, but this was afterward remedied by the introduction of the "independent cut-off"—another valve riding on top of the main valve.

In Fig. 1 is shown one form of the single eccentric plan, the main rod is not shown, but the throw of the crank is shown as down and moving in the direction of the arrow, the eccentric rod was held up by a roller on the arm of a tumbling shaft that was let into a slot in the forward end of the rod, the rod terminated in two hooks, top and bottom, these hooks were spread wide apart at the ends, so as to catch the pin at any point of its travel and bring it to the bearing at the center of the V.

As it now stands, the lower hook is engaged with the pin in lower end of rocker; to reverse, the lever on the tumbling shaft was pulled back; this raised the roller *G*, and lifted the hook from the pin *D*, in lower end of rocker, and engaged the upper hook with the pin at the upper end, thus moving the valve for the reverse motion. Fig. 2 shows the plan used by a Mr. Cave, a prominent designer of that time; it differs very little from the plan in Fig. 1, except in detail; he used a much shorter eccentric rod, and advanced the eccentric to increase lead for forward gear, but the motion was distorted thereby. He used a loop on top V that admitted of a lighter form, and the doubled-hooked head was raised and lowered by a hanger, much as the present link is.

One peculiarity about this form of motion was that the engine was direct acting when running in one direction, and indirect when moving in the other.

On the first of June the Pennsylvania Railroad Company voluntarily advanced the wages of all its employes on the Southwestern Pennsylvania branch from 10 to 15 per cent. The increase equalizes the wages of the Pennsylvania road employes on all branches.

The B. & O., and the Central of N. J., are having cars built for a vestibuled express between this city and Washington, to be known as the "Royal Blue"; the cars will be painted blue—the engineer will be blew (up) if he don't make the time.

Report on Compound Locomotives, M. M's. Association.

The slight experience America has had with the compound locomotive, although elsewhere there are between six and seven hundred in successful service, so contracts the possible field to be covered by a report on the subject assigned to us, that we, of necessity, must go beyond the limits of this land and of this association for the major part of our facts; and in expressing opinions and conclusions, are compelled to take for granted a fair acquaintance with its modern literature, giving the experimental results of trials carried on outside the American continent.

To commence with—and as a help in the direction of narrowing the province to be covered by this report—we would suggest for discussion the following questions, viz.: 1st. Is increase of boiler pressure an essential element in the success of compounding? 2d. What gains have followed compounding? 3d. What are said to be its losses? 4th. What, per engine, is the increased first cost of compounding? and 5th. Does the saving more than balance this cost? 6th. What are American conditions for locomotive service, and can the compound locomotive meet them? 7th. Is it an essential defect of the compound that it must be short of starting power? 8th. Give a brief summary covering some details and peculiarities common to compounds.

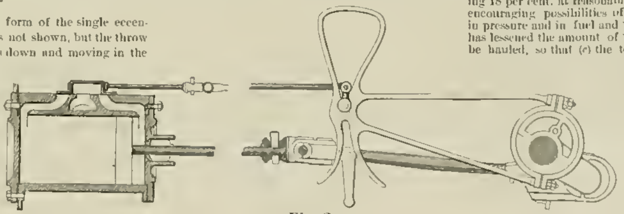

Fig. 2.

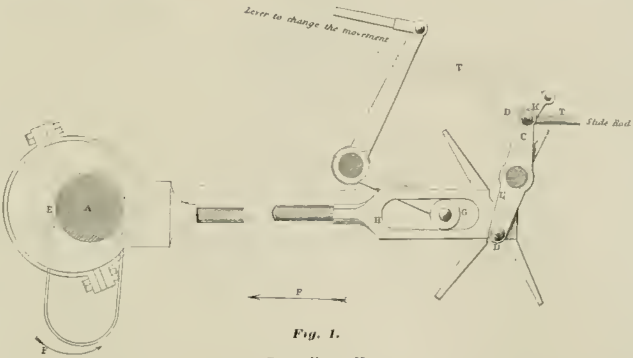

Fig. 1.

SOME EARLY VALVE MOTIONS.

1st. Is compounding of any value without increase of boiler pressure? This query is due to the repeated assertion that in compounding there was not, and could not be, an economy in steam consumption, except the boiler pressure be decidedly increased, raised to 170 lbs., or even higher. The results of the experiments of Mr T. Urquhart, locomotive superintendent G. & T. Railway (South-east Russia), contradict this statement. The trials cover a period of ten months, in the same class of service, with simple and compound engines practically of the same weight, and all with pressures of 135 lbs., and they show for the compounds a general average saving in fuel of 18 per cent.

Apart from this solution of the vexed question of pressure, Mr Urquhart's experience is unusually interesting, because the experiments were carried out in cold weather, with oil fuel, which has a more uniform heating quality than soft coal; and the delivery of the fuel into the fire-box was almost automatic, thus practically getting rid of the "personal factor," for which it is always necessary to allow in comparing special and brief experiments.

Mr. C. Sandiford, of the N. W. Railway, Lahore, India, reports a 13½ per cent. economy with unaltered, but still lower, pressures, viz., 120 lbs., the saving being the same whether the steam was used in two or four-cylinder (tandem) engines.

These results will not surprise those who are familiar with exactly parallel cases in other forms of steam engineering.

Do not misunderstand us to say that there are no economies in higher pressures. There are wide possibilities with high temperature; and the many published figures, from recent trials, stoutly confirm our opinion. But under this leading heading, the committee wished to emphasize the fact that compounding, at ordinary working pressures, has its own value as an economizer of steam, without keeping hid the sister fact that higher pressures give an additional possibility. And it should not be forgotten that very high pressure steam has, so far, only been fully utilized by passage through more than one cylinder.

Higher pressures and very early valve cut-offs, for simple engines, have had a fair trial on many of our railroads; nevertheless, to-day initial cylinder pressures above 150 lbs. are rare; and we believe that when boiler pressures higher than 160 lbs. are retained, it is with the object of making the boiler a reservoir of power for starting and grade climbing, rather than with a confirmed faith that very early cut-offs lower the fuel bill.

The Saxony Railroad report increasing their boiler pressures for simple engines from 8½ to 12 atmospheres (say from 120 to 175 lbs.), without resultant economy, whereas 212 lbs. has not proved too high for convenience or economy in the compound practice of the P., L. & M. Railway (France).

2. *What gains have followed compounding?* (*a*) It has achieved a saving in the fuel burnt averaging 18 per cent. at reasonable boiler pressures, with encouraging possibilities of further improvement in pressure and in fuel and water economy. (*b*) It has lessened the amount of water (dead weight) to be hauled, so that (*c*) the tender and its load are materially reduced in weight. (*d*) It has increased the possibilities of speed far beyond 60 miles per hour, without unduly straining the motion, frames, axles, or axle-boxes of the engine. (*e*) It has increased the haulage power at full speed, or, in other words, has increased the continuous H. P. developed, per given weight of engine and boiler. (*f*) In some classes has increased the starting power. (*g*) It has materially lessened the slide-valve friction per H. P. developed. (*h*) It has equalized or distributed the turning force on the crank pin, over a longer portion of its path, which, of course, tends to lengthen the repair life of the engine. (*i*) In the two cylinder type it has decreased the oil consumption, and has even done so in the Woolfe four cylinder engine. (*j*) Its smoother and steadier draught on the fire is favorable to the combustion of all kinds of soft coal; and the sparks thrown being smaller and less in number, it lessens the risk to property from destruction by fire. (*k*) These advantages and economies are gained without having to *improve* the man handling the engine, less being left to his discretion (or careless indifference) than in the simple engine. (*l*) Valve motion, of every locomotive type, can be used in its best working and most effective position. (*m*) A wider elasticity in locomotive design is permitted, as, if desired, side rods can be dispensed with, or articulated engines of 100 tons weight, with independent trucks, used for sharp curves on mountain service, as suggested by Mallet and Brunner. One such engine of 80 long tons is now under construction.

3. *What losses are said to have followed compounding?* (*a*) In some particular types, as actually proportioned, a loss in starting power of from 15 to 20 per cent. However, loss of power in starting cannot be said to be a defect in the principle of compounding. (*b*) An increase in the number of parts. They are few and plain in the two-cylinder engine, entailing little outlay in first cost or in repair. (*c*) A possible, but, this committee thinks, not probable increase in the cost of repairs to the boiler, per pound of fuel burnt, if higher pressures are used. Positive information on this point is difficult to obtain. (*d*) An increased cost of repairs to the engine per mile run. This item is not yet large enough to be measurable, after three years' continuous service in the plainer forms of the two cylinder compounds. (*e*) A larger percentage of failures on the road, due to greater

complication and size of parts. (*f*) Increased reciprocating weights on one side, either not balanced, and so increasing the deflection of the engine, or, if approximately balanced, the balance weight doing injury to the roadbed, etc. The two last sections seem to be pure suppositions, which, after search, we find no evidence to sustain. (*g*) Want of variability or adaptability to wide extremes in speed, and to amount of work to be performed; so that a large compound does not work as cheaply when hauling light loads, or running without load, as a simple engine does.

It is not proved that a compound, working properly throttled, that is, with steam wire-drawn, may not have actually, as she theoretically has, a wide and economical adaptability. So that if the compound, like any other motor, be not as economical when exerting low power as when exerting full power, it probably will use less steam than the simple engine of same weight, working under similar conditions of light haulage duty.

However, the one thing certain about "American conditions" is that no large portion of our motive power does run lightly loaded, and until we have a wider experimental experience, it is not recommended that all locomotives, doing branch and local light service, be built compound.

4th. What is the increased first cost per engine? M. V. Borries has published figures giving cost. In speaking of his own design of engine, he says they can "be built 2 to 5 per cent. cheaper than single engines of the same power—not of the same maximum tractive force, because this power depends upon the boiler, which might be 10 to 15 per cent. smaller for the compound engine. If the same boiler is kept, as is commonly the case, the compound engine would be some 2 or 3 per cent. heavier, and 4 or 5 per cent. more costly than a simple one; but, with properly dimensioned cylinders, 10 to 15 per cent. more powerful than the latter. For equal work the compound engine would always be the cheaper engine." Mr. E. Worthington says: "The intercepting valve and copper pipes forming the receiver, and the patterns for two different sizes of cylinders, are the chief items which raise the cost of a two-cylindered compound locomotive; while engines with three or more cylinders have additional parts, which considerably increase their cost. In engines with four cylinders, the tandem system is cheaper than the receiver system. Tandem cylinders are, however, objectionable, because the pistons are difficult to examine; but the receiver system is ready of access, and affords an opportunity of heating the intermediate steam by circulating it among the waste gases of the smoke-box; and, by isolating the high-pressure and low pressure cylinders, an advantageous difference of temperature is maintained between them.'

"The cost of constructing a number of two-cylindered locomotives does not greatly exceed that of the same number of ordinary engines. The cost of three-cylinder locomotives may exceed that of simple engines by $1,000 to $1,250 each."

The cost of changing simple to two-cylinder engines need not exceed $250 to $300 each, if the expense of drawings, patterns, and templates be divided over a series of engines. The additional cost of building a two-cylinder engine, with receiver, etc., as used by the M. C. Railway, or the ingenious form of four-cylinder engines, as used by the B. & O. Railway, need be little, if anything, over $200 (excluding royalties), or say from 2 to 2½ per cent. increase on the cost of a simple engine.

5th. Does the saving more than balance the increased first cost? If, for convenience, the fuel saving be taken at 17 per cent., or ⅙, and the gross consumption at 900 tons per year, with coal at $1.50 per ton, the decrease in the annual fuel bill is but $225. Certainly not a wide margin to cover contingencies. If, however, at first only the more powerful engines are compounded, whose consumption averages 1,200 tons per year, and coal, as is common, costs on tender $3 per ton, the saving on fuel is $600, or two cents per mile on a mileage of 30,000 per annum. As this amount would cover not only reasonable interest on first cost, but also allow for about 33 per cent. increase in total expenditure for motive power, repairs and renewals, the saving is certainly enough to permit a possible, but, we think, not a probable, largely increased cost of engine repairs, and yet have a margin of saving on the final balance sheet to the credit of the compound.

6th. What are "American conditions" for locomotive service? Can the compound engine meet them? We have given this section a large amount of attention, because it has so often been said that the compound must, to be successful on this continent, be adapted to suit American conditions, and your committee naturally were desirous of fully understanding these conditions. They have not been specified by those making the assertion, and we must reluctantly confess to having failed to identify, much less define them, so that after a long, unsatisfactory chase, they appear to us to be somewhat mythical. If any member can, and will, specify them, he will confer a favor, at least upon the committee, if not upon the association.

If an American condition be large starting power, then the Malett two-cylinder and all four-cylinder engines easily have cylinder power in excess of their adhesive weight. If American conditions be ability to do satisfactory work on a second rate or third-rate roadbed, or simplicity of construction, or easy accessibility of parts, then these conditions are met by any two-cylinder engine, or by the B. & O. Railway four-cylinder engine.

Apparently neither climate nor men are factors in this equation, as compounds are a success in the hands of ordinary enginemen in partially civilized countries; and in hot climates, as well as in Russia, under conditions of low temperature and snow, as trying as those ordinarily met with inside of 51 degrees, the present northern limit of our railway belt.

7th. Is it an essential defect of compound locomotives that they must be short of starting power? Certainly not! The starting power of the Malett type is at least equal to that of a simple engine of the same weight, and its cylinder power can easily be made to exceed it, by allowing more than half boiler pressure in the large cylinder for the first few revolutions. In the V. Borries, Worsdell, Pitkin and other two-cylinder types and the Lepage three-cylinder engine, their starting power (as Prof. Woods has graphically illustrated), at 170 lbs., may be greater than that of a simple engine at 150 lbs., having cylinders of the same size as the high-pressure, *during the first half revolution*, but that after this the power (at low speed) of the compound diminishes to 80 or 85 per cent. of that of the simple engine. This conclusion is modified and improved by the knowledge that all two-cylinder engines originally designed as compounds have, or should have, their small cylinder larger than the cylinder of the simple engine of corresponding weight or duty.

It is possible, with the Lindner or equivalent form of starting valve—and a painstaking engineman—to get about 90 per cent. of the starting power of a corresponding simple engine. The Webb type of three-cylinder engine (except with the low-pressure crank dead on center) has cylinder power enough to slip both pairs of wheels, and no higher starting power is desirable. What may be called the opposite form of three-cylinder engine (the Sauvage type), with cylinders of approximately the same diameter, as used on the Northern Railway of France, has ample starting power, because the full boiler pressure is admitted direct to the two low-pressure cylinders. In fact, if desired, the locomotive can be continuously so worked, viz., as a simple engine. Tancem and other forms of four-cylinder engines are not wanting in starting power. The B. & O. Railway engine in starting, with a gear as simple as the water tap gear, puts the small piston practically into equilibrium, and thus admits high-pressure steam to the large cylinder.

A mean effective pressure of 90 lbs. in a simple 18x24 in. engine will start a train of 18 coaches on a level in a lively fashion, and a compound can easily give the equivalent of that total pressure without being over-cylindered.

Going back to the two-cylinder style of engine, with automatic intercepting valve and limited size of cylinder, it would seem as if all of them were capable of getting into motion the load they were designed to haul at full speed, so that their limitations are that they do not get away quite as smartly, quite as noisily, or with the same tearing effort on fire and fire-box as do certain simple engines that waste both fuel and steam in starting. The comparative difference in time or distance required by this class of compound to attain maximum speed has not yet been shown by experiment, but is probably less than is generally supposed.

Mr. Urquhart, desiring to settle the question of the tractive power of simple engines altered to compound, with one cylinder unchanged, and with boiler pressure unchanged, carried out tests, using both indicator and dynamometer, and he reports that at a speed of 10 miles per hour the compound passenger engine suffered the following diminution, viz.: In first notch, 42 per cent.; in second notch, 28 per cent; in third notch, 17 per cent.; in fourth notch, 7 per cent.; and in fifth notch, or full gear, 5 per cent. And a similar test of the freight compound showed, in the first notch, 27 per cent. loss; in the second notch, 17 per cent.; in the third notch, 10 per cent., and in the fourth notch, or full gear, 5 per cent. He goes on to say that, for all practical purposes in full gear a 5 per cent. difference, at this speed, may be neglected.

(*Concluded on page 134.*)

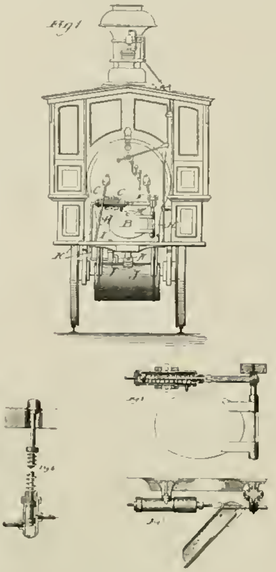
Fire Door Opener

On this page will be found drawings of a device recently designed and patented by David Hawksworth, of Plattsmouth, Neb., for opening and closing the fire door on locomotives, without requiring the fireman to use his hands.

Fig. 1 shows it as applied to a locomotive. Fig. 2 shows interior of cylinder, door closed. Fig. 3 is a plan, showing door partly open, and Fig. 4 is a detail of the operating valve.

Air or steam is used, but air is preferable, as it requires no exhaust piping.

Fig. 4 shows the push button, which is located in the deck, so as to be convenient to the fireman's foot; when the latter wishes to open the door, he pushes down the button as he brings his scoop into position; this moves the valve on lower end of stem that admits air to the cylinder over the door, and the air pressure swings the door by means of the rack and sector shown. When pressure is relieved, the spring on stem of button rod moves it up, exhausts the air from the cylinder, and the spring within it closes the door. The whole scheme is easily understood from the drawings.



FIRE DOOR OPENER.

Correspondence

The Old-time Engines of the P. R. R.

Editor The Locomotive Engineer:

In looking over the list of old P. R. R. engines in the June issue, I see the name Penrose; unless there were two engines of this name, am quite sure she was a Wm. Norris—will not be certain. The engine Heisley was a diminutive four-wheeler, she was the first engine to pass through the big tunnel west of Altoona.

The writer at that time was wiping engines at Altoona; one Saturday afternoon the R. R. Co. gave all hands a trip up to the tunnel; we had one coach, and the locomotive York, the crack engine of the P. R. R., and engineer John Stevens at the throttle. The F. K. Heisley had a party at the west end of the tunnel; the York was too large to pass through, as things were in an unfinished state, the Heisley, being very small, came through. The year I have forgotten, but the Logan House was being built at the time. Perhaps some old P. R. R. man can give dates. The engines Blair, Mifflin and Indiana were crank-axle engines, with six-foot drivers in rear of fire-box, a pair of smaller wheels forward of fire-box, and a four wheeled truck under front end. President Taylor went over the P. R. R. in a special pulled by one of these engines, at a speed of sixty miles an hour. The locomotive Harrisburg spoken of was an old Baldwin half-crank, with engine and tender on one frame. Wm. Nichols was Gen. M. M. at the time we made the trip up to the tunnel.

Cause of Locomotives Slipping in Going Down Grade Shut Off.

Editor The Locomotive Engineer:

I notice another article in your issue for June about locomotive driving wheels slipping while running down grade *after steam has been shut off*, which you supplement by saying, "What causes the engine to slip after steam is shut off is more than we can see. All the pushing of the train would exert itself at the axle, and in no way tend to slip the drives ahead."

My theory is this. The locomotive itself (not including the tender) is *very much heavier* than tender, or any one of the cars; the tendency of the locomotive on down grade (being so much heavier) is to run away from the train even after steam is shut off. The train, therefore (tender included), on a down grade, is not pushing the engine, but pulling back on it. I am speaking, of course, of locomotives without brakes on drivers and in support of my theory will say: First, that a locomotive with train of empty cars running down grade would slip more than with train of *loaded cars* running down same grade.

Second, that same locomotive running alone (or running "wild," as they say), down same grade would not slip drivers at all.

The "slipping," therefore, is caused by the backward pull of the train, or rather forward and heavier impetus of the locomotive, checked by the slower impetus of its following cars.

Your correspondent James A. Nute says he gave his engine sand and she stopped slipping; and he adds, "We had been running down hill about a mile from where I shut off." I understand from this that the engine had been running down grade about a mile before she slipped, then he "gave her sand, and she stopped." This would seem to confirm my position. As the impetus of the locomotive increased, the strain or pull on the locomotive increased until she "slipped."

J. H. BURRELL, JR.

Philadelphia, Pa.

[Our correspondent is wrong in presuming that a heavy load will run faster on a down grade than a light one. If they were of the same size a light load will run as fast as a heavy one; the heavy load will require more braking force to stop it in a given distance, however.

It is well known in practical railroading that on a long down grade a locomotive cannot run away from a train—if the train has time enough, and no brakes are applied, it will catch the locomotive every time. Suppose the engine did exert a pull on the train all the time, and the train held it back, there is nothing to cause the wheels to revolve ahead faster than the movement of the engine called for; they are held in close contact with the rail by the enormous weight piled upon them, and it would be impossible to make them slip on the rail by any propelling or retarding power applied to the axle. Besides this, the moving parts of the locomotive tend, by their friction, to retard the forward motion of the wheels. We do not pretend to say that this slipping does not occur, but, if it does, the cause will be found in the running gear or counterweights.]

A Subject for Discussion—"Herding" Cars.

Editor The Locomotive Engineer:

What is the matter with all shop and road men, that they do not let us hear from them once in a while? I just think your paper is the only chance I have ever found where all the boys can sail through without running on a snag. Now, boys, hoist your sails and let us hear from you on any subject. This paper seems to be open to all classes of railroad men.

I would like to hear some old and young railroad men's opinion on the train dispatcher. Is he a good investment to a railroad, or is he an expensive luxury?

The H. & T. C. transfer runs close to my office; they have a pretty good hill to climb and a very sharp curve. They have recently got one of Baldwin's large size sixty five ton engines, six-wheeler; she is very powerful; they have to wait at about 5 P. M. for S. P. trains. This engine is run by a Texas raised man; he remarked to me yesterday evening that he could put more cars up that hill than any four men could "herd"—that is what the Texas boys call switching cars here. Ask one of the yard men what he does on the road and he will tell you he is "herding" cars.

Houston, Texas. E. A. CAMPBELL,
S. M. P. & M., H. E. & W. T.

Some Difficulties in the Way of Campbell's Plan of Valve Setting.

Editor The Locomotive Engineer:

Mr. Campbell's pointers are hardly to the point; as his explanation of squaring valves would properly belong to the lathe and planer, and is not squaring as understood in railroad parlance. If we divide one revolution of the wheel into four equal points, and the engine exhausts at each one of these points sharp, she is called square; of course, we don't intend the four exhausts to be all on one side. We can hear engines every day that have a square exhaust nozzle and a three-cornered exhaust, and others with a round nozzle and square exhaust, and when some of the three-cornered ones get to slipping, it is hard to tell which is the off cylinder. Of course, the idea of the round holes is good, but your man is going to chip them out, what then? Your pointers on gauging a valve have a proviso; to wit, *if* the valve rod is the right length. Norris used to build engines with an inclined cylinder, but with the back end of the chest and seat the highest, so the square business would not work in gauging the valves in that case. Now, if this talk imparts no information to the reader, it does put a fellow to thinking. W. DE SANNO.

Corry, Pa.

A Good Job for the Engineer who can make a Locomotive Slip When Steam is Shut Off.

Editor The Locomotive Engineer:

One of the engineers on the Boston & Albany says that he has been coming down one of those steepest grades, and get to going so fast that the drivers would stop revolving and slide on the rail; he said it never happened on a dry rail. He would whistle for brakes and they would slack up, and then they would revolve again. This was before air-brakes were thought of. I asked him if the lead truck wheels slid too; he looked at me as much as to say: What a pity! and free schools in this country too!

I have been offered a new job since I wrote you before. One of the owners of a large shop here saw my sketch in last month's, and if he could get that engine that I run he says his fortune is made; he says he would disconnect the tender, put the engine on some of the heaviest steel rails, put bumper timbers at each end, have the flange turned off the back drivers, put jacks under each corner, grease the rail, fire her up, then I am to open the throttle, get her to slipping, then jack her up, then I shut off steam, dump the fire, and let her go Gallagher. They are to run the shop days, run the dynamo nights for the electric lights, have it so she can be oiled running; when they want to stop drop on the rails, give her sand. He says if she will slip for half a mile after being shut off, he don't see why she would not run till she broke down, if you have it fixed as above.

Worcester, Mass. JAMES A. NUTE.

How an Engine Can be Run with a Back-up Eccentric Rod Off.

Editor The Locomotive Engineer:

I am a constant reader of your valuable paper. I say valuable, because I have been running a locomotive a great many years, and have taken all the mechanical papers, and find this one far superior. All engineers should take it, as it is just what they need. It will help them in their daily labors, as it has helped me.

I see in the Questions and Answers, one asked by F. J. C., Oswego, New York, "Could an engine run with her back-up eccentric rod broken?"

I have on two occasions had the same happen me. It happened when I was hauling a mixed train; I had my full train, part passenger and part freight. After stopping I put her in back gear, and put a rope through the bolt-hole in link, then lashed it to the bottom of the pump where the feed pipe connects on; lashed it tight—it took but a few minutes—then proceeded to my journey's end, making my running time twenty miles an hour with my full train—and the engine worked well. A pump is not a necessity for this purpose; any part of the engine that is below the link. At the end of my journey I did some switching. This looks a little fishy, but it is the truth. When I wanted to back I would reverse, and send the fireman out and push the valve on the center, which could be done easily when in back gear; then she would perform the same as running with one side; pressure on valve would hold it central. There is one thing about doing this—they must be sure and have the engine in back gear at time of lashing; if not, it will not work. This, I am sure, will work to a charm, and in regard to backing she will do first-rate. L. S. SPRING.

St. Stephen, N. B.

Another Engine that Slips.

Editor The Locomotive Engineer.

In reply to your request, on page 100 of June number, I will send you the following as my experience with engines slipping when steam is shut off. It was with a 36-ton, Brooks engine of the ordinary eight wheeled type, 17-inch cylinders; do not know the weight on drivers; this engine would slip badly when running at high speed with steam shut off. Slipping could be stopped by hooking reverse lever up to center notch, also by using sand, but this was not advisable, as the slipping was so hard that the using of sand was apt to do damage to rods and pins. My way of accounting for it, was too much counterbalance in the front pair of drivers. The front pair had just the same amount of counterbalance when engine was built, but one wheel had been broken and replaced by another of a later pattern, which had a considerably heavier balance block, which gave a heavier counterbalance on one side than the other. After considerable study about the matter, I decided to call the attention of the master mechanic to the matter, expecting he would think I was getting some very foolish notions into my head, to report such a seemingly impossible thing as this. I did so, and told him what I thought was the cause of it. He agreed with me as to the engine's having too much counterbalance in front pair of wheels, but did not think it would cause the slipping. In order to test the matter, he reduced the balance weight on the heavy wheel down to about the same as the other wheels, and the trouble immediately ceased.

I think your paper a long way ahead of any one I have ever read, and of great value to engineers, firemen and shopmen, and well worth twice the price charged for it. WM. BOSLEY.

Mattoon, Ills.

[It seems strange that if this slip was caused by bad counterbalancing that the slipping could be stopped by hooking up the reverse lever. Most of those who report trouble of this kind claim, however, that proper adjustment of the counterbalances have cured the disease.]

Switch Targets.

Editor The Locomotive Engineer.

While this is a subject of vital interest to engineering and all classes of trainmen, they hardly ever discuss it or make any recommendations in regard to adopting a uniform system. On some lines three or four kinds of switch targets are used; lots of the switch levers for main line switches have no targets at all, sometimes one style is used for a main line switch at one end of a yard, and for an inside switch at the other end.

Some years ago we used to see the target set one way at a main line switch for "all right," at the very next station it would be the same way for the side track, so that an engineer or trainman was obliged to keep track of the difference in his mind, or get off the short rail. The more enlightened and systematic way of to-day don't permit that, and an attempt at uniformity is the result. It can be easily adjusted by selecting the best kind of switch stand and target in use on that particular road, and using them for main line switches, relegating the poorer kinds to inside switches and yards.

Then a more important point is, that a switch target should show a *positive* signal that the switch is set for the main line. The engineer should have a little notice that the switch is right or wrong before he gets close enough to see the rails. This he does not get when the target sets edgeways to him, when the main line is clear. The roads that show the edge of the target or no target at all when the main track is clear, say that a target is not of much use to a man on a fast train, but some of them have a clause in their rules which makes an engineer responsible for knowing that the switch is all right before he passes over it.

If the target on a switch moved by a crank, as most of them are at this day, shows one certain shape as well as color when switch is set for the main line, it is also in the line of safety to have a different shaped target on the side of the first one, which points out definitely which siding is connected with the main line. Colors are apt to lose their brilliancy, so they will not always prove a sure guide, when the target is covered with sleet and snow the *shape* of it is the only satisfactory guide.

Some of the roads in this State have a standard switch target, which shows positively the position of the main line switches, whether open or shut, and they can be easily distinguished from the inside switches. Several roads use a large white disk from 11 to 24 in diameter, the side is visible when main line is safe, if kept painted it shows a long way off either day or night. On one side of this is a siding signal, which is 10" to 18" long with a fish tail end, which is seen when switch is set for the siding, painted the danger color, bright red. This siding signal points the same way as the switch crank for a stub switch, and the opposite way for a split, so an engineer knows into which siding he is going. When the edges of all main line switch targets are set towards the engineer when switches are shut, he takes everything for all right, and in a manner, goes it blind.

However, the split switch is gradually crowding the dangerous "stub" off the main line, before long a fast passenger train will not be run over stub switches at a high rate of speed. If entrance switches at stations have targets and lights a little higher than the rest of them, they are better land marks. The ideal switch target is one which moves to danger before the switch is opened, and stays there till it is closed. It has not been made yet, but would be certain and cheap, but it will get here—some day. C. B. CONGER

Lansing, Mich.

Keeping an Engine Clean.

Editor The Locomotive Engineer:

A locomotive fireman always has lots of scouring brass, blacking boiler butt and smoke arch, cleaning domes, jacket, windows, cab and other work, and the easiest way would be the best, providing it was the best looking when done. Now I, for one, would like to hear from brother firemen through THE LOCOMOTIVE ENGINEER on this subject. I will give my experience, and hope to hear from others. The ways are old to many, still I think some will find it new. For cold brass I use oxalic acid (quite strong) and tripoli on a piece of waste, then wash it off with water (this prevents making the brass hard), then rub with lantern oil and tripoli or Putz pomade, wipe that off and polish with lamp black, in this way you get a good polish easily. For hot brass I put a little lantern oil with the acid, which prevents sticking of tripoli to brass. I have used tripoli, lard oil, and Putz pomade all over engine, also tripoline and matchless polish. I am going to try the recipe in May LOCOMOTIVE ENGINEER.

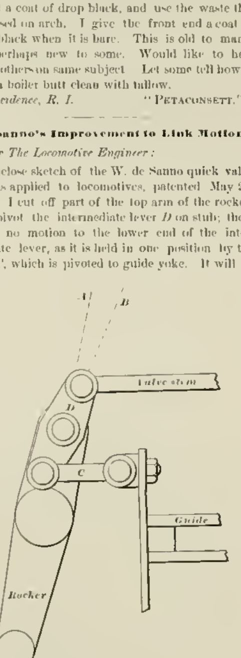
For polishing dope on smoke arch, I use one quart boiled oil, one gill drop black, half pint varnish, half pint Japan, three gills raw oil, all well mixed. To use: Take piece of waste, wet it with water, rub it full of soap, squeeze it hard, and then fill it full of the dope and rub on arch with one hand, and, with a piece of clean waste in the other, wipe over it, this will make it black and glossy, and will not gum up but very little; you can keep your arch right down smooth, with very little oil over the iron; and when it rains you do not have the arch all peeled up in places, but the rain washes it *all* off. Then take a piece of sand or emery paper and rub it down, and put on the dope; use the piece of waste that you wipe off arch with on boiler head, and wipe that over with clean waste afterwards. I use the dope to black the domes same way as on arch; I use tallow on stack and on outside of cab, wash cab inside with soap and water, and wipe dry; on windows I use whiskey (hydraulic jack) and tripoli. This dries quickly and wipes off clean. On the jacket I potash first, then wash off with a hose, then tallow, then wipe off tallow dry. When it storms I tallow jacket, and when it is over wipe it off with waste and lampblack. When a boiler head is gummed up badly I take a hose and give it lots of cold water, then it peels all off clean. Emery cloth it, then give it a coat of drop black, and use the waste that you used on arch. I give the front end a coat of drop black when it is bare. This is old to many, but perhaps new to some. Would like to hear from others on same subject. Let some tell how to keep a boiler butt clean with tallow.

Providence, R. I. "PETACONSETT."

De Sanno's Improvement to Link Motion

Editor The Locomotive Engineer:

I enclose sketch of the W. de Sanno quick valve gear as applied to locomotives, patented May 27, 1890. I cut off part of the top arm of the rocker, and pivot the intermediate lever *D* on stub; there being no motion to the lower end of the intermediate lever, as it is held in one position by the link *C*, which is pivoted to guide yoke. It will be



DE SANNO'S VALVE GEAR.

seen that the intermediate lever gives a quick motion to the valve, as it also increases the travel.

In applying this device to an old locomotive, the extreme notches in the quadrant must be blocked up, and the links worked at what would be equivalent to full stroke or travel of the valve by the old method, and the valves re-set to suit the new order of things; it is also likely that the inside lap would have to be increased with this motion, that being left, however, to the judgment of the parties using it. W. DE SANNO.

Corry, Pa.

Lubricators that Feed Across.

Editor The Locomotive Engineer:

In looking over this months' paper, in Questions and Answers I notice O. C., Boston, Mass., 38, wants to know if it is *possible* for double feed lubricators to feed across, to one cylinder or the other, I would say that I have had a little experience of that kind on an engine on the road where I am employed; it is a Seibert oiler, double glass, upfeed; it worked to all outside appearances as nice as one could wish, but the left-hand cylinder groaned continually. I asked the foreman if it was possible for both feeds to go the right hand side; he smiled, and asked me if I did not know that it was impossible, as there was a separator in the T at back of oiler. I told him I knew there was a bridge of brass in a good many places that was not effective. The result was that oiler was taken apart, and what we found was the oil hole in feed pipe to left hand side at the union was plugged solid, the engine had been running that way two months; all the oil that side got was put in through release valve on front of steam chest; after that we had no trouble.

Plainfield, Ct. NEW ENGLAND

Some New York Central Engines that Slip Even with the Main Rods Down.

Editor The Locomotive Engineer:

I am glad the "slipping driver mystery" has been brought to your notice, and hope we shall hear more about it.

Mr. James A. Nutes' article leads me to infer that his engine was slipping when he shut off steam, and continued to slip (until he gave her sand), which is a very common thing on a slippery rail. Now the problem I would like to have solved is this: What causes an engine to slip when no steam has been used to start her slipping, while running along, say twenty-five miles an hour? This subject of "driver slipping" is not new on the New York Central, for I have heard engineers tell about it, ten years ago, and they are men whose integrity cannot be questioned.

John Hutchinson says when he was running old 85 on the Albany division, she would slip her drivers after she had run along a mile or two without using steam, so that he thought she would strip herself. This matter has met with much ridicule on this road, but I believe if men would study the subject before they express an opinion, it would not appear so ridiculous to them. I have heard engineers say, less than five years ago, that it would be impossible to discard the pump and run with inspectors; and to-day those same engineers say they would not give one injector for all the pumps they ever used—they may change their mind about engines slipping too.

Now, Mr. Editor, here is something to "bite" on, and I presume, when some men see it, they will say the man that told the "yarn" is "off," and the man that wrote it is "offer," but I don't care, I believe the man that gave me the following facts, and his name is Joe Norman. Engine 121 is a Schenectady engine with 62" wheels and 17"×24" cylinders; she has solid side rods weighing 250 lbs. each, her drivers have each four pieces of counter balance cast into them about half the length of spoke; weight on drivers about 25 tons. This engine was built for freight, but was equipped with air-brake and put in passenger service, and runs between Syracuse and Niagara Falls via Auburn branch. Charley Thomas and Ed. Shaffer double crew on her, and both are familiar with her slipping. A short time ago Shaffer went to California and Norman took his place, and here is what Norman says. Shortly after he took the engine, and while coming down one day, he heard an unusual noise, and asked his fireman what he thought it was. The fireman said, "Oh, that's nothing, she is only slipping." Joe looked at him with astonishment and said, "Slipping *be darned*; you must think I'm a farmer," and in order to convince him, the fireman stepped over and gave her sand, and stopped her slipping; Joe was convinced. The next trip Joe made on her she blew out a rivet, so he had to dump her and be towed in, and after getting under pretty good headway, *and while being towed, she began to slip worse than ever.*

Mr. Norman and fireman are both willing to make affidavit that the above facts are true. Now for the purpose of getting up a little discussion, I will give an opinion as to the cause of this engine 121 slipping with "main rods off." In the first place, she is a very slippery engine, and I believe that the momentum of the drivers, after the engine had attained a certain rate of speed, was sufficient to cause them to slip, especially if she struck a slippery part of the track, and, too, with main rods off, there was much less resistance to the wheels, which allowed them to slip with greater ease than if the main rods were left on; then again it might be a twisted shaft that caused the slipping. Let's hear from some one else on this subject.

Syracuse, N. Y. W. F. RELYEA.

Squaring Valves and Rocker Arms.

Editor The Locomotive Engineer:

When I see or read of one of those elastic men, that can always do a thing in about one third the time that it would take a man who is simply flesh and blood, without elasticity, I find it hard to refrain from attacking some of their wonderful *sayings*—for observation has convinced me that they are not *doings*.

Your contributor, Mr. E. A. Campbell, makes the statement in the April number, that he would not allow a man to set valves for him that could not do it in ten minutes, and further adds that lost motion has nothing to do with the engine working well.

Such broad statements, without some qualification, could not come from one who regards the truth essential to progress.

I waited patiently for Mr. Campbell's 10-minute method of valve setting, or "squaring"—as he seems pleased to put it in the June number—and found it similar to a "seven-hour system in grammar" that was published several years ago—too much India rubber in the statement.

You will notice he only does a part of the work necessary to the squaring of the valve, and leaves the rest for some poor machinist to do. Also, that he concluded to square the valve by the eccentric blade, and not by the shoe (or dead wedge as sometimes called), as he suggested in the April number, and quoted in the June number.

Now he does not state how long he will be in testing the work of the machinist; perhaps he intended to leave that for the machinist, so as to help him out on the 10-minute business, or he may regard it unnecessary to try the valve again, presuming that he can guess exactly how much to move the eccentric blade and make her square.

Any man familiar with the link motion will tell you that when the length of blade is to be changed it is not safe to change it, and not prove your work, unless the work be new, and one is familiar with just that particular design of engine.

Mr. C. is inconsistent when he finds fault with the slotted holes in blades, and says they are made without them to keep meddlesome engineers from altering, and in another breath tells them to square the valve with a liner back of the shoe. Such managing tends to make meddlesome engineers.

Now in my opinion a good engineer—one who knows enough about valve motion to let it alone, unless he has the necessary tools and ample time—would never attempt to monkey with his engine, but would endeavor to locate the defects, and report same to proper persons. And if Mr. C would like to keep his hair from turning white, and not be troubled with indigestion, he would have no other engineers in his employ.

Again. He gives us a rule for "gauging" a valve without taking the steam chest cover off, which cannot be relied on in all cases; certainly is not correct for engines having inclined cylinders whose valve seat is not parallel with the center line of cylinder. Such engines are in use to-day, and Mr. C. could not square his rocker arm in 10 minutes by that method on such an engine. It is to his credit that he winds up by advising us to take off steam chest cover to examine the work done in that manner.

If Mr. C. would either make or buy a good valve motion model, and then put in a few hours of rightdown honest study of the link motion, he would not be so liable to blunder into trouble that he does not "have time" to clear up, as he states in the June number of THE LOCOMOTIVE ENGINEER. A line drawn through the center of rocker box and upper rocker arm pin should be at a right angle to *valve seat* when valve is in its central position, or center of valve seat, and a simple method of obtaining this is to lay a straight edge on valve seat, that is long enough to reach the rocker arm, then by using a square in connection with straight-edge, the rocker arm can be set at a right angle to valve seat. Now make a small prick-punch mark on and near top of rocker arm, and use tram from this point to another point on frame, and you have an accurate method of squaring rocker arm without removing steam chest cover but once.

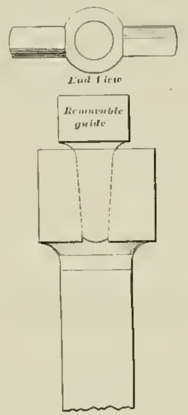
Some Kinks in Shop Tools.

Editor The Locomotive Engineer:

There has lately been going the rounds in various forms, new and improved "guides" for counter boring. Some have straight shank and set screws, and some screw in the counterbore, but the best that has ever come under my notice is one used at the P. W. & B. shops at Wilmington, during Mr. Gordon's reign, and probably in use yet. It is often called for in repairs, and the work of changing guides or "tits" is almost nothing. The sketch will show the whole thing in a nutshell. The counterbores, whether they be flat or round, are reamed to a standard taper to receive the guides, and they fit, and fit central every time, not being pushed out of place with a set-screw at the side, as some are. A pin hole through them makes an easy way for removing, or they can be forced out by a pin in hole just behind the shank, as many Fox lathe centers are.

The sketch shows one in place, also an end view of a flat counterbore. By having a number of guides and counterbores any repair shop can call itself well equipped in that line.

Another tool that I have been using lately will perhaps be of interest, as it is a rapid and easy cutting tool. I recently took a cut on a 20-inch lathe, driven by a 2-inch belt, which was ⅜ of an inch deep, and when a 2-inch belt will pull a ⅜ cut it shows that the tool must cut very easily and makes a shearing cut. Baldwins use this form of tool almost entirely and find it superior for ordinary



COUNTERBORE.

LATHE TOOL.

work to the old-time "diamond point" which has held its own for so many years.

The sketches will show the idea, and each can easily learn to grind it so as to cut the easiest. For repair work or any work where time is an object, this tool will be found particularly useful.

Philadelphia, Pa. FRED H. COLVIN.

What Causes This Heating?

Editor The Locomotive Engineer.

I am running a Hinkley mogul with a common valve, no patent attachments at all, but has relief valves in front of steam chest, this engine came to me from the main line. She is on what is considered a fast express freight. The road is hilly and very crooked, and I have to run with closed throttle in some places. The first night I ran that engine I noticed she was blowing through valve seat and cylinder packing on left-hand side, also considerable groaning there. When I had got about twenty miles out I noticed an unusual noise in cylinder when running by gravity. I opened the throttle again, all was as usual, Seibert oiler was working all right and I got over the trip without further trouble. That day I bored holes in the exhaust pipes under saddle, to let off the water that accumulates in such places. That night I had a repetition of the night before, only worse, the lever commenced to yank, the valve to chatter, the cylinder sounded as if everything was smashed inside of it, and under the engine the fire flew lively. I called for brakes and stopped. I honestly thought I had picked up something from the track when I saw the fire fly. I looked that engine over, tried all journals to see if everything was cool, but could not find anything wrong about her, so I called off brakes and started. When I shut off again the same noise and fire flying took place. After I had run about two miles I opened throttle and it stopped, then I knew where it came from, or I believe I do; the junk ring was riding on the bottom of the cylinder, the follower head was the colors of the rainbow, the cylinder was scored all around, the valve seat was cut, and very rough. I summed it up this way—first the engine has got a Seibert oiler, double feed, a common valve and relief valves in steam chest, oil allowance one pint to seventy-five miles. When working steam, with what oil she got, the steam served to lubricate her enough to keep things quiet, when shut off, release valve drops, the oil comes down through oil pipe in vapor, strikes the top of the valve, the steam is condensed by coming in contact with cold air from the release valve, drops in recess of the valve and stays there, none goes to cylinder at all, for cylinder shows red rust all around. I claim the cylinder got over-heated by junk ring riding on lower part of cylinder, forming a gas which exploded and showed fire underneath through the holes I made in exhaust pipes. I talked with the older men, and, as usual, they said it could not be. Now I am of the same opinion as at first, regardless of older runners. What is your opinion?

Plainfield, Ct. NEW ENGLAND.

[It looks very much as if the trouble came from the absence of oil. Red rust in the cylinder and cut surfaces would seem to substantiate that theory. If the trouble is on one side and not on the other it would seem to indicate that the oil was not delivered on that side. Disconnect the oil pipe at the chest and see if it feeds. Your piston packing may be follower bound and help in the cutting process, but it is intended that the bull ring, or junk ring, should ride on the bottom of the cylinder and carry the weight of the piston—more oil, better oil, or at least *some* oil will doubtless help you.]

Equalizing Pressure on the Double Air Gauge.

Editor The Locomotive Engineer:

I can answer question in regard to increase of pressure on train pipe gauge when using emergency stop. If the valve is moved suddenly to full emergency stop position it will cause a sudden jump of train gauge pointer, but the increase of pressure will be slight; now move the handle of valve slowly until the exhaust through the emergency port blows strong, you will notice pressure on train pipe gauge will equalize with main drum pressure; this is caused by the small feed port in rotary valve coming in communication with equalizing port, allowing air from the main drum to flow into service stop drum equalizing the pressure. To prove this, take out rotary valve, plug up small feed port, replace valve, put handle in full release position, pump up pressure and use emergency stop; the gauge will then show no increase of pressure.

ENGINEER ROCKY MOUNTAIN DIVISION,

Missoula, Mont. NORTHERN PACIFIC.

Standard Size for Axle for Heavy Tenders.

The master mechanics have adopted the standard M. C. B. axle for 60,000 pound cars for heavy tenders, thus avoiding the carrying of two sizes in stock that must of necessity be almost identical. This axle tapers, without curve, from just back of the wheel fit to the center.

The committee report in favor of 300 pounds per square inch of contact as a safe load for the journal. The size of this standard axle bearing is 4¼x8 inches, which gives 225 pounds per square inch for a heavy tender of size specified in their circular, which they describe as one well able to carry 3,600 gallons of water and 16,000 pounds of coal.

CONTENTS.

The Pay of Master Mechanics.

As a rule, master mechanics keep their jobs longer than superintendents, trainmasters and other transportation department officers, but they do not begin to get the pay that the latter do.

There are a few roads that pay a reasonable salary to a superintendent of motive power, but we believe it safe to say that the average pay of master mechanics throughout the country is not above $1,800 per year, while a majority of division master mechanics receive a third less.

If these men held jobs that required little work, or no particular knowledge of mechanics, there would be some excuse for the stingy pay; but the position requires a good man, a hard working man, one who is able to handle men, to accomplish much with cramped financial resources, who can get along with little material, and run his shop short-handed and equipped with ancient tools.

The master mechanics of the country are made of the better class of engineers, machinists or draftsmen, and ought, at the very least, to receive as high salaries as the best men under them—there are very few master mechanics who get as high pay, month in month out, as their own engineers. This not only lowers the officer in charge to a level with his men, but takes away some of his self-respect, and does not raise his dignity with those under him.

The management of our roads have squeezed at our motive power departments so long that the injustice and unreasonableness of expecting so much for so little has become second nature to them.

Of course an engineer making $140 per month cannot afford to give up his run to worry over a master mechanic's job for $90 or $100, so a less capable man takes the place, and the standard is lowered just the difference between them, and the service suffers.

As a class, there are no employes of our railroads that earn and deserve better pay than the master mechanics, and the picayunish little checks they get ought to be a shame to the management.

A manager or superintendent who received the same pay as conductors or brakemen would not be counted as much good—and he ought not to be much good. What is true of one department is true of another.

There is not a road on the American continent that can afford to have a wooden-sheared lathe or a seventy-five-dollar master mechanic in its shops; both show bad management and dangerous equipment of the vital part of the passenger carrying department.

A Death Trap and Its Victims.

On May 30th a local train connecting the city of Oakland, Cal., with the ferry-boats for San Francisco, plunged into an open draw bridge at Webster St., Oakland.

The engine, tender and one car went into the draw where the water was deep, and thirteen out of the forty odd passengers were killed.

This bridge is 100 feet long, over a stream 20 feet deep, and the trains approach it at a high rate of speed from a curve. When the bridge is open, the bridgeman is supposed to signal the trains by sticking a red flag in the end of a tie.

If the railroad wanted dead passengers instead of live ones, and deliberately planned a trap to catch them, they might go a great way and hunt a long time before finding a better device for execution than this bridge.

It seems that the usual primitive plan of stopping at each drawbridge was not even followed, they put out a red flag—if the watchman thinks about it—and the trains run fast over a bridge, carrying a passenger train every thirty minutes, and being constantly opened for the passage of vessels.

The least that could have been done was to stop for the bridge, and, if this was a rule and the engineer did not stop, he is guilty of a crime and should be punished; but, even though this rule was in force, it does not clear the skirts of the company—they had not provided this dangerous spot with proper signals—distance signals that must be set at danger before the bridge can be opened, and a derailing switch to throw the engine off the track if the engineer ignored the signal. These are modern safeguards; they are not expensive nor untried, and any road that crosses drawbridges without them should be held responsible for every life lost.

The coroner's jury, as usual, blame the engineer, and mildly remonstrate against the primitive signal system that caused this accident.

They find that the deaths were caused by the criminal negligence of engineer Dunn, and add:

"We find engineer Dunn guilty of manslaughter. We also find that the railway company does not take sufficient caution to signal trains when approaching the drawbridge."

Are you living up to all the rules about dead stops at draws and road crossings?

Some Continuous Brake Statistics.

The English Board of Trade, to whom all railroad accidents in Great Britain are reported, and who officially investigate all fatal accidents, have recently published a statement of the reported brake failures for July to December, 1889. This report shows that trains equipped with Westinghouse automatic ran 23,325,198 miles, and had charged against it 359 faults. The automatic vacuum was used on trains that ran 40,272,589 miles, and had 331 faults charged against it. Clark & Webb's automatic ran 911,048 miles and failed 3 times; the same company's non-automatic brake made 918,564 miles with two faults. The plain vacuum was on trains running 12,036,390 miles with 52 failures, and the Westinghouse straight air-brake ran 773,885 miles without a fault. This is 64,973 miles to one failure for the automatic air, 121,670 miles for the automatic vacuum, 231,469 for the simple vacuum, and 773,885, without a fault, for straight air.

These figures show that there were 76,407,162 miles run by braked trains in Great Britain in six months—rather large figures.

Every time a brake fails to stop a train at the right time and spot is called a fault, which is an erroneous deduction—the man often fails. Human beings are not always sure, neither has there yet been built a device for any purpose not liable to fail.

Two Kinds of Management.

A recent meeting of railroad men was held in Philadelphia, at which a grievance was introduced by representatives of the Baltimore & Ohio road, showing that the train employes of the Pennsylvania Company received larger pay for the same service performed by them. The committee stated that on through runs between Philadelphia and Washington on the Baltimore & Ohio, conductors in their fourth year received $4.12 per round trip; baggagemen, $2.25, and brakemen, $1, while on the Philadelphia, Wilmington & Baltimore, conductors receive $6, baggagemen, $2.75, and brakemen, $3. On the division between Philadelphia and Baltimore, the Baltimore & Ohio conductors receive $2.90 per round trip, baggagemen, $1 61, and brakemen, $1 29, while on the Pennsylvania, conductors receive $4.24, baggagemen, $2.60, and brakemen $2 36.

The Secret of Fast Time.

The White Star steamship "Doric" has just returned from a trip around the world; she steamed continuously without slowing or stopping for 77 days, 6 hours and 50 minutes; making 28,000 miles. This is considered fast work, yet the speed is but little over 13 miles per hour, slow speed, even for a freight train. One of our modern passenger engines making 60 miles per hour ought to get over the distance in a little less than 20 days. It is rather doubtful, however, that if there was a continuous system of railroads around the earth, the average traveler would get around the globe in less than 77 days. There are so many stops and slow-downs in railroad trains as now run. The secret of making time is to keep going—get away from stations, and move.

The first steamboat on the Mississippi River was the New Orleans, built at Pittsburgh, in 1811, by Nicholas J. Roosevelt, from plans furnished by Robert Fulton.

Car Platform Gates.

There is one little improvement on passenger cars that is coming, and is deservedly popular where used, and that is the platform gate. By using a light iron gate on each side of the platforms there is no danger of people being blown or thrown off while passing from one car to another; by keeping the gates closed on one side, passengers are prevented from getting on or off trains on the wrong side, the habit of getting off on the wrong side, to avoid the crowd, has cost many a man his life; this danger is double on roads having more than one track. On double-track roads the company that does not use gates on passenger car platforms, is not furnishing its patrons with the best modern safety appliances.

On the Ladder.

J. McNaughten, Master Mechanic at Livingstone, Mont. T., for the N. P. Co., has been appointed Supt. of Motive Power of the Wis. Central, in place of John Player, resigned. Mr. McNaughten is a rising young mechanic, yet in the early 30s.

Angus Brown, M. M. of the Yellowstone division of the N. P., goes to the Montana division in place of J. McNaughten, and General Foreman Gardner, of the Missoula (Mont.) shops, has been promoted to be Master Mechanic at Glendive.

ASKED & ANSWERED.

(43) E. H., Manchester, O., asks:

What do you mean by a "floating box" truck? *A.*—A truck in which the journal boxes are free to move up and down in jaws or pedestals.

(44) J. D. B., Greenville, Texas, asks:

What operated the Creamer brake—steam, air or vacuum? *A.*—The Creamer brake was operated by a coil spring which wound up the hand-brake staff.

(45) Crow, St. Paul, Minn., asks:

What is the standard length of the new hook coupler? *A.*—The Master Car Builders' Standard Janney Coupler is 30 inches long for new cars, and 28 inches for those placed on old cars.

(46) Fireboy, Middletown, N. Y., asks:

What effect on the fire would a good blower have if the smoke arch door was open? *A.* No perceptible effect; the blast would induce a current of air up the stack, but the air would be supplied from the nearest and easiest source, which would be the open door of the arch.

The U. S. Circuit Court of Georgia has granted a perpetual injunction restraining the officers of that State from collecting taxes on sleeping car companies doing business in the State. The comptroller general had a bill against the Pullman Co. for $32,000. This will give a black eye to several State taxation boards, who have been figuring to fleece Pullman. The Pullman Co. will pay their taxes in Illinois and Michigan, where their works are located.

The New York, Lake Erie & Western Railroad Company has let a contract to Neafie & Levy, of Philadelphia, for a new ferry-boat to run between New York and Jersey City. The boat will be 230 feet long, 38 feet beam, 62 feet wide over the guards and 16 feet depth of hold. It will be a double-screw boat, with a propeller at each end, much on the plan of the Bergen, of the Hoboken ferry. The engines will be of the compound type.

The Order of Railway Conductors repealed their anti-strike laws at the recent Rochester convention, on account of the pressure of the new order of the Brotherhood of Railroad Conductors, and the other orders. Now several of their lodges have thrown up their charters, and the Reading have ordered their employes to quit the order—they are out of luck.

The business of the Santa Fe road has increased $2,489,326 in nine months, from July, '89, to March, '90.

The Master Mechanics' Meeting.

The twenty-third annual convention of the American Railway Master Mechanics' Association was held at Old Point Comfort, Va., June 17th, 18th and 19th. This association has a membership of 363, including most of the best known master mechanics in America. At Fortress Monroe, or Old Point Comfort, there is a fort and a hotel, so the usual welcoming speech by the mayor was not possible, and the welcome address was very neatly delivered by M. E. Ingalls, president of the Chesapeake & Ohio road, who reviewed a great deal of the interesting history of the immediate surroundings.

Within sight of the meeting-room the great fight between the Monitor and the Merrimac took place on March 8th, 1862; in front is the battery on the Rip-Rap, behind, the walls of Fortress Monroe. President Briggs made a hit in his speech; it was received with great satisfaction, and was the subject of much comment and congratulation. We have space but for two paragraphs, the first showing something of the work of this association, the second a just tribute to the rank and file under the command of the members of this society, and showing from whence the whole army has been recruited.

"The great diversity of territory through which our locomotives travel would seem to prevent anything like national uniformity in construction, severe grades demanding features in the engine not required over prairie country, and other special forms provided for use in special localities; but when we travel through our country and see the different locomotives at work we cannot but be struck with the great similarity of these powerful machines, and we feel a glow of pleasure in the knowledge that the existing uniformity and excellence has been attained more through the labors of this association than from any other influence. This thought inspires us with confidence in our progression, and we look forward to our annual convention in the full security of individual improvement as members, and enlarged and enlightened service for the companies we represent.

"As we contemplate the immense work that our locomotives have been made to perform in the transportation of the harvests from the prairie to the seaboard, in the movement of all living and dead freight, creating cities, establishing markets, breathing life and civilization, making the 'desert even blossom as a rose,' let us not forget the grand army of faithful engineers and firemen to whose care these vast machines are entrusted; an army of men larger in numbers, stronger in discipline, richer in intelligence and higher in bravery, than any Alexander could ever boast. These men, largely recruited from humble life, form a perpetual monument to the mothers who gave them birth, true type of our American womanhood, who sent her boys to school and struggled so often with poverty and privation that her children should have every opportunity for gaining knowledge, and who, by a lifetime of devotion, has encouraged and fortified us all in the development of our progression."

The secretary's report showed a membership of 363, of which 15 are associates, and 14 honorary members. During the year 18 were dropped for non-payment of dues, 3 resigned and 3 died; one of these, H. M. Britton, was one of the organizers of the association, and for several years its president. The circulation of the annual report was shown to be 1,317 copies.

The treasurer's report showed a total receipt of $3,174.52 during the year, and a balance on hand of $1,080.67.

A change in the constitution was made, providing for the use of written ballots without nominations.

The association has about $7,000, known as the "Boston Fund," and Mr. Setchel, the custodian of the fund, introduced the following resolution, which was unanimously carried:

"*Resolved*, By the American Railway Master Mechanics' Association in convention assembled, that a committee of three members, consisting of J. N. Lauder, John N. Barr and Angus Sinclair, be, and are hereby appointed, empowered and directed to confer with the trustees or other proper officers of the Massachusetts School of Technology of Boston, and Cornell University of Ithaca, N. Y., and the Stevens Institute of Technology, and arrange and report a plan at our next annual meeting for the investment of the principal and interest of the Boston Fund of this association in one or more scholarships in one or both of these institutions, and submit the same for the approval of the association. The benefits of said scholarships to be for such time as may be directed by the association as a prize to the sons of members who shall exhibit the most valuable attainments and skill in the development of locomotive mechanics.

"And be it further *Resolved*, That notice is hereby given that a vote will be taken at our 24th annual meeting to so appropriate said fund."

The first paper read was the one on compound locomotives, which was of considerable length and of great interest. The committee made research far and wide, and presented reports from all the compound locomotives in America, as well as the results of experiments made in England, France, Russia, Saxony and India. The report was considered the best one read, and is published in full in another column, to which the reader's attention is directed.

One paragraph of their report may be of especial interest to those of our readers who took part in the discussion on the "full throttle" subject. We quote:

"Putting emphasis on this truth will not frighten those who are familiar with the fact that wire-drawing is common to-day with our best enginemen. And it may be here noted that the *imperative necessity* for this so-called "crude practice" is the full explanation for the slight use in modern locomotives of screw and other finely divided reversing gears. This statement opens up the whole matter of cylinder condensation, but it is too large a matter to be properly treated in this report.

"However, such modern experimenters as Westinghouse, Kennedy, etc., prove that wire-drawing the admission into cylinders of large surface and small volume is more economical than valve cut-offs at less than 50 per cent. of the stroke."

The next report was on the efficiency of the link as compared with other valve motions; this paper was long and interesting, and contained valuable data on the various forms of valve motion, and while some show a slight saving in fuel all were expensive in repairs.

The committee express regret that they had no report of the utility of the Strong valve gear but publish the following from Ross Kells, of the Erie:

"We have only made one test of locomotive equipped with a valve motion other than the link, and that test was to determine which of the two designs was the most economical on the basis of coal consumed per ton per 100 miles. We found on this test that our regular link motion locomotives were fully as economical on coal, and much more economical on maintenance of valve gear."

Almost every one knows that it was under Mr. Kells on the Erie that the Strong was tested and the elaborate report compiled by her owners showing her superiority over ordinary locomotives.

The report concludes as follows:

"Nowhere is the 'survival of the fittest' more pronounced than in railroad practice. The history of valve motions and devices to improve the link motion, and those that were to supersede it (?) would fill volumes. Many have been theoretically correct, and very promising, but, after the crucial test, have resulted in failure; and the link motion remains in almost undisputed possession of the field.

"It has been urged against the link that it is not a scientific or true mechanical motion. This may be true, but the fact remains, that fairly good results are obtained from it; that it will take more punishment in the shape of rough usage and neglect, and cost less to make and repair, than any other valve motion now being experimented with on locomotive engines.

"In conclusion, your committee are of the opinion that there has not been brought to their notice a valve motion more efficient for all-around work, and general utility, than a well designed link with large bearing surfaces—assisted in its work by steam passages and pipes of generous dimensions—free from sharp turns and bends—giving the link plenty and hot steam to distribute, and, most important of all, not crippled at the very end by a contracted exhaust nozzle."

The committee on the subject of placing fire-boxes above the frames presented a report in which they say:

"In summing up, the evidences prove that with the fire-box above the frames the combustion is very much better than when between the frames; and larger nozzles may be used, thereby lessening the objectionable back-pressure upon the exhaust. Cheaper fuel may be used, other things being equal. More water space around the fire-box may be had, and the sides of the furnace may be inclined sufficiently to take advantage not only of the greater efficiency of the heating surface, but giving the water a better chance to circulate. We also have more space for the ash pan, and can hang it higher to keep it out of the snow and away from the driving boxes. The rigid wheel base can be shortened. It gives better clearance for eccentrics and straps. It makes a better proportioned boiler, when found necessary to increase the diameter of boiler shell or to lengthen the fire-box. The fireman can work his fire to better advantage, and the weight of engine can be more evenly distributed upon the wheels. The cost of keeping up the expansion braces is very much less, and the frames can be taken down and replaced at a very much less expense of time and money, than with the furnace between the frames. Soft coal as well as anthracite is now being used in fire-boxes above the frames."

They asked to have the subject continued, so as to be able to get comparative reports on experiments now going on.

The subject of the relative value of steel and iron axles was continued, the report presented not being satisfactory to the committee. The best part of the report was a sensible letter from John Hickey, of the Milwaukee, Lake Shore & Western road, which says:

"In considering the diameter of a driving axle, we must be governed by the capacity of the cylinder, the boiler pressure, and the diameter of the wheel, as well as the weight per journal. In other words, the diameter of driving axle should be proportioned to the power of the engine, like other parts of the machinery, and this being the case, it will be entirely safe for any customary weight. The diameter of the driving axle therefore should be of such size and strength as to meet the power of the piston, rather than be simply to resist the weight brought upon it. As there is but little difference in the strength of the best quality of iron and a quality of mild steel suitable for axles, there should be little or no difference in their respective diameters when used under like conditions. For engine truck axles, my experience has been that the journals should be of such size as not to permit a greater load than three hundred pounds per square inch of bearing, and that the diameter of journal be not less than 55 per cent. of its length. This rule will hold good for all bearings of railway rolling stock, except locomotive crank-pins and driving axles, the size of which must be in keeping with the power of the locomotive. The wear of journals of course depends on the weight per unit of bearing in contact, and the material of such bearing; a clear hard brass giving less wear for a given number of miles than softer metal. All other things being equal, we find but very little difference in the wear of steel and iron axles."

The committee on brick arches in fire-boxes, report strongly in favor of their use, and recommend as the best manner of supporting the arch:

"First, Freedom from any danger to those constantly employed about the engine by failure of parts, such as are sometimes attended by the use of circulating pipes. Second, One that can be quickly and cheaply, yet substantially put up and maintained, and that is in a measure protected by the arch from the action of the fire. Third, One that will allow the bricks to be removed and replaced with greatest ease and least possible damage, and that will give easy access to the boiler tubes, tube sheet and crown sheet when bricks are removed, and we think that these several conditions are nearer met by some of the methods known as the 'angle iron and stud supports,' and we believe that the best features of some of these might be combined and worked into a support that will meet the requirements of the general service. We are not prepared to recommend the abolition of the circulating pipe, but we suggest the serious consideration of a safer and cheaper method for supporting brick arches than is obtained by their use.

"We desire to call attention to the large number of arch bricks broken in transit and by handling after they are received. This is especially the case where bricks are hauled long distances and when shapes are flat, long and heavy. It has occurred to us that some suitable means might be adopted to strengthen the brick by having iron rods made up in the moulds in such a manner that, should the bricks become cracked or broken through their section, they would be held together and could be utilized, and as soon as exposed to heat in furnace, they would fuse together from the effect of accumulated slag, etc."

The committee on best form and size of axles for heavy tenders define a heavy tender as one carrying about 3,000 gallons of water and 16,000 pounds of coal, and recommend the master car builders' standard axle for cars of 60,000 pounds capacity. This axle is of the following dimensions: Length over all, 7' ½"; between centers of bearings, 6' 3"; collar, ⅝"; length of bearing, 8"; dust guard bearing, 2"; wheel fit, 7¼"; fillet between bearing and collar radius of ¼", between bearing and dust guard bearing, ⅝"; between dust guard and wheel fit, ⅛". Diameter at collar, 5¼"; bearing, 4¼"; dust guard bearing, 5¼"; wheel fit, 5⅝"; behind the wheel the axle is 5¼", with a straight taper to the center, where it is 4⅞".

Committee on subject of preventing corrosion of water tanks recommend the use of good metallic paint, and care of enginemen in using water on coal, but some of the members reported good results from lessening the area of the top sheets exposed to water, and damp coal and cinders. Several roads do this by taking off the flange, and substituting a railing on the larger part of the back of tank, running the back flange across ahead of the manhole; the sloping of the top of sides toward the coal pit also helps, and the entire absence of mouldings around the bottom of the tank prevents corrosion there.

The committee on exhaust nozzles, who were given the rather large contract for finding the relative sizes for nozzles and steam passages in proportion to the size of cylinders, reported that they could find no proportion. They cite the functions to be filled by a successful nozzle as follows:

"It must create draught enough on the fire to make steam, and at the same time impose the least possible amount of work on the pistons in the shape of back pressure. It should be large enough to produce a nearly uniform blast without lifting or tearing the fire, and be economical in its use of fuel." And add:

"After two years of experiment and research your committee has come to the conclusion that, owing to the great diversity in the relative proportions of the cylinders and boilers, together with the difference in the quality of fuel, that any rule which does not recognize each and all of these factors would be utterly worthless. . . .

"The principal question on which the exhaust nozzle practice of the country splits is whether the pipe shall be double or single.

"Those using the double pipe claim that in this way only can the exhaust from one cylinder be prevented from adding injurious back pressure on the other, while the advocates of the single nozzle urge that the use of the exits requires that neither of them shall be central, and consequently the exhaust will not produce the maximum effect, while the single exit, being in the axis of the stack, will produce the maximum effect, and can, in consequence, be made larger and reduce the necessary back pressure.

"Your committee regard neither of these opinions as correct without some qualification. We have found that there is very little difference in the back pressure in either plan, and this is entirely a question of design. So true is this that it is impossible to determine, from the card alone, which type of nozzle is used."

The experiments seem to prove one fact that is not generally known in regard to back pressure on the opposite piston when using a single nozzle.

"Your committee has in some instances reduced the height of bridge to much less than half that of pipe, with no increase of back pressure, and are of the opinion that the most vital point in the design is that the area of each of the two pipes—where they combine—shall in no case exceed that of the final exit, and the indications, so far, are that this area can, with advantage, be made decidedly less than the final one; how much less we do not know."

They leave the subject as follows:

"In view of these facts, your committee feels itself incompetent to advise any plan to determine the size of exhaust nozzle in proportion to any other part of the engine or boiler, and believes that the best possible practice is for each user of locomotives to adopt a nozzle that will make steam freely and fill the other condition named, best determined by an intelligent use of the indicator and a check on the fuel account."

Which is about the landing place of everybody else who investigates the nozzle business very deep. The committee was ordered enlarged and continued for another year.

The committees on testing laboratories, the car coupler question and on the purification and softening of feed water did not report, and were continued.

The committee on subjects for the ensuing year reported the following, which are interesting ones:

1.—Washing locomotive boilers. Methods in use causing the least delay. Washing effect on plates of fire-box while retaining heat from the brick arch. Situation of washout plugs. Describe plan for washing out with hot water.

2.—Best material for locomotive crank-pins, and proportions for same suitable for engines having cylinders 17, 19 and 18, 20 inches in diameter.

3.—Comparative advantages of operating locomotives with different crews on the first in and first out plan, and that of confining men to certain engines; the latter not running a greater number of miles than can be rendered by their regular crews. Discuss any improvements in the method of running engines.

4.—Examination of engineers and firemen in their duties relating to the use of fuel, care of a locomotive, and ability to meet disorder or disability of machinery. To what extent practiced and best plan of conducting same.

5.—Locomotive rods, connecting and parallel. Suitable material for and best form of. Relative merits of solid ends, and those constructed with straps, bolts and keys.

6.—Office dials, most convenient for showing condition, location, in what service, and repairs required, etc., of all engines.

7.—Relative economy and safety of using eight-wheel and mogul type of locomotive for freight and passenger service. It is suggested that the members of this committee be authorized to interview any member or members of the association on this subject, and that it be the duty of all members so required by the committee to appear before them and answer such questions as may be asked. Such questions and answers to form an appendix to the report of the committee.

8.—The subjects of best form of brake shoes for locomotive and tender brakes; the object to find out the wear of flanges on wheels and increase of mileage between turning.

Officers for the following year are: President, John Mackenzie, of the Nickel Plate; 1st vice-president, John Hickey, of the M., L. S. and W.; 2d vice president, Wm. Garstang, of the C. and O.; treasurer, O. Stewart, of the Fitchburg, and secretary, Angus Sinclair, of the *Car Builder*, were re-elected.

NOTES.

The supply men distinguished themselves in the entertainment of the ladies.

Vice-President Griggs stated that his experience with the brick arch dated back thirty-four years. Mr. Griggs' father was the first to use the arch, in 1857.

The next convention will in all probability be held at Cape May, but the hotel that gets to be headquarters will have to guarantee to have a good room for every member who wants one—and that is right.

There were a good many G. A. R. badges worn by the members, who argued peaceable subjects with men who argued against their former visits to the South with guns. Mr. Meehan, of the Queen and Crescent, was one of the engineers on the Merrimac when the Monitor gave her her fatal stab.

One of the best arguments presented in favor of the use of the brick arch was that brought forward by Mr. Mehan, of the Queen & Crescent. He said the arch did more to prevent over-firing than anything else. A fireman cannot make steam when the box is filled with coal up to the arch, and will soon learn that a thin enough fire must be carried to allow of free combustion under the arch.

One of the last acts of the meeting was to adopt a resolution that all committee reports should be delivered to the secretary before May 1st, and printed and mailed to each member before the meeting. If this resolution be carried out to the letter, and no subject discussed that was not so sent out, it would seem as if it might admit of the discussion of the various subjects without reading the papers. Every member ought to be interested enough to study up every subject on the list with which he comes in contact.

Noon hour discussion on topics proposed by members are always interesting. Mr. Forney called out a good many theories, opinions, and the results of observation in his question as to the safety of a pony truck at high speeds. The pony truck is not far different from the leading wheel or single truck as used in Europe on the fastest locomotives in the world. Where the rigid wheel base is not too long the pony truck seems to be safe at any speed, and certainly allows of a better distribution of weight than the four-wheeled truck.

The ride about the city of Richmond was very interesting indeed. The old State house—the first capitol building built in America—is still in use, and contains many interesting relics, for instance, the first iron stove brought to America. It looks more like a Chinese altar than a stove, but it warmed the capitol long years before stoves were introduced. The site of Libby prison, Belle Isle, the oldest house, and the church and pew from which Patrick Henry made his famous speech against the oppression of England, in which he said: "Give me liberty or give me death," all attracted attention.

The excursion over the C. & O. to Richmond was enjoyable, and the visit to and banquet at the Richmond Locomotive Works appreciated. These works are busy on their special lines of machinery; they are building two heavy engines for the C. & O. with cylinders 21 x 24, and ten for the R. & D. 20 x 24, and are rebuilding several; they had four of their pole road locomotives on the erecting pits, and stationary and portable engines were to be seen everywhere. The engines and boilers of the battle ship *Texas* are being built here, and there was a great quantity of heavy pieces in the various departments. The works have just got into the new addition, and any quantity of material, in all stages of manufacture, is piled up everywhere, the new tools are of the best makes and heaviest patterns.

During part of the session, two men sat side by side, whose railroad history would read like a novel, one was John Y. Smith, inventor of the vacuum brake, who served as supt. of machinery of the military railroads of the United States during the civil war, the other was John O'Brien, who served as a master mechanic under the stars and bars, and who took charge of the mechanical end of the enterprise when Stonewall Jackson made his famous raid into Maryland, and captured 38 locomotives on the B. & O., and took them south across the country. Mr Smith was a man of nearly 50 years of age when the war broke out, and had had experience from the very birth of railroads, having at the age of seven been a boy in the shops of the great George Stephenson. Mr. O'Brien was but a boy of 20 or 21 when Fort Sumter pulled down her flag. Mr. O'Brien is still in active service as master mechanic of the Petersburg road at Richmond, while Mr. Smith has long taken matters easy on the fame and fortune he made with his brake, yet he has always been a busy man, and has to-day a new invention in the shape of an exhaust pipe, on the plan of his vacuum-producing apparatus in the brake, that bids fair to be a very useful device. There is no jet black hair on either of these heads now, but all the white ones are honored ones, and no one thinks of giving one more credit than the other for his services—because each did the work allotted to him in the best manner that he was capable of.

Simple Lessons in Drawing.

By ORVILLE H. REYNOLDS.

NINTH PAPER.

The projections of a hexagon nut, as shown in Fig. 54, by which we have three views, and the reasons therefor, were made in harmony with the principles of projection, as explained in its accompanying paper, mention is made of this fact because the process, as touched in that case, is in strict accord with the teaching of high authority. There is another method, however, which has special features to recommend its use, as will presently be shown; a method adopted by draftsmen by reason of a readier understanding of the relation of one view to the other.

By a reference to Fig. 54 we find the top view of the nut placed under the front or side view; this would not be a serious objection in this case, for the view explains itself, but instances occur in practice when it does not make itself clear, as, for example, when top and bottom views are both drawn, and there is such a similarity as to create a doubt of which is top or bottom, making necessary an inscription to cover the situation.

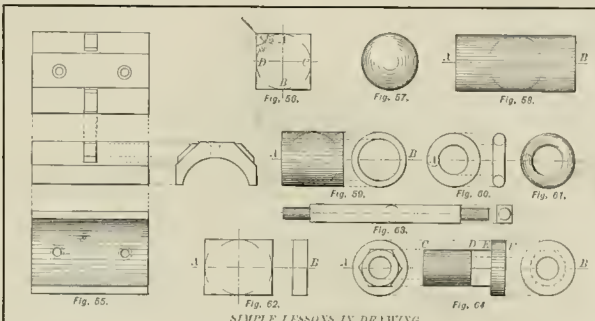
The arrangement of views in Fig. 55 is such that can be no question as to what they are meant to represent. Here the different views are placed on the side from which they are supposed to be taken, as the top view placed at the top or over the side view; the bottom view placed at the bottom or under the side view; and ends arranged at the ends they represent.

The views thus shown are each on the drawing in the proper position to be easily understood, having the advantage over the first method of shortening the construction lines, in projecting the several views from the side view.

This will be clear by referring once more to Fig. 54, where the front elevation is projected from the plan; the lines of projection are shown passing across the front view, which, while serving their purpose, tend to mystify rather than make clear their object; these objectionable features are not present in the method by which Fig. 55 is constructed, for we project directly from one view to the other without passing the lines of projection across the different views.

This method we will use in preference to the first, it being essentially a shop method, while equally as correct as the first.

In general, the side elevation should be drawn first, and the other views projected from it, but this should be decided by the view that has the most detail.



SIMPLE LESSONS IN DRAWING.

All the views of a drawing should be placed in the same position on the paper as the object represented would occupy when in service, so that it would not oblige one consulting the same to stand on his head in order to bring the view right side up. Let the top of the object be drawn so that it is uppermost on the paper; any other position will only bring vexation, of which there is quite enough, without any superhuman effort on our part to woo it.

While it is desirable to show an object in all its parts, and as plain as possible, judgment must be used in drawing those views only really required to that end, therefore, the fewer views shown that will accomplish this result the better.

One view of a cube, Fig. 56, tells the whole story; as does also one view of a sphere when shaded, as in Fig. 57. One view of a solid cylinder explains itself if made to show the length, but then only when line shaded, as in Fig. 58, the one view showing the length, and also that it is round.

When a hollow cylinder is represented, then two views are necessary, as in Fig. 59, when the line shading may be omitted. The dotted lines *C* and *D* represent diameter of the hole, and are projected by placing the T square at the upper and lower edges of the hole on end view, and dotting the lines through side view. To draw Fig. 59, set the compasses to the required radius, and describe two short arcs at any place on the paper, and try with the scale or rule if the arcs are of the correct diameter, if found so, describe the circle at the point selected for the end view; this will represent the outside of the cylinder, repeat the operation for the inner diameter of cylinder by taking the correct radius for same, and the end view is completed, from which the side view can be readily projected with the T square, as explained for the dotted lines.

The trial arcs made with the compasses are necessary, in order to get the circles of a correct size, for the reason that it is largely a matter of guess to take off a radius from the scale or rule, the compasses being liable to overrun or fall short of the graduations on the rule at the first setting; it is easier, therefore, to rub out the trial arcs if wrong, than to erase a complete circle.

A ring cylindrical in section, Fig. 60, is drawn to show the side view, first by setting the compasses as above, to describe the inner and outer circles, when the edge view is drawn by laying off the thickness with the compasses set to half diameter, and describing two semi circles at top and bottom, which shall be tangent to lines projected from top and bottom of side view; perpendiculars erected tangent to these semi-circles give the edge view in outline. The semi-circles at top and bottom of edge view should be taken on the compasses and continued as dotted lines, in order to show the section of the piece, or these dotted semi-circles can be omitted, and a dotted circle shown instead, as at *A* on side view.

This figure would also explain itself without the edge view, if line shading is employed, as at Fig. 61.

An ordinary rectangular object of uniform thickness can be shown in two views, as Fig. 62; these views showing the length, breadth and thickness, arcs for these dimensions to be described from the center line *A B*, as in preceding examples, horizontal lines tangent to the arcs are first drawn with the T square, passing far enough beyond the ends to form the top and bottom of edge view when perpendiculars erected with the triangle, cutting the other arcs, and intersecting the horizontals, will complete the figure.

Fig. 63 represents a square object with a journal on each end, now it is evident that, with the side view alone, and given in outline only, it would be impossible to tell whether the pieces were round or square; when, however, the end views are shown, all is at once clear. The end views can be omitted in this case, if the journaled ends are line shaded as shown, the shading showing that the ends are round, while the body is known to be square from lack of it.

A hollow piece with a round collar at one end, and round body at the other, with a hexagon shaped portion under the collar, is shown in Fig. 64.

The center line *A B* is to be drawn first, on which describe diameter of the collar, also diameter of the hole at *B*; at end *A* of center line describe a circle for the hole, also a circle for the collar with compasses set to those sizes from the other end view. The hexagon across the flats is shown the same size as diameter of end *C*; it is, therefore, delineated by using T square to draw horizontals at top and bottom, and 60 triangle for the remaining sides.

The side view is now to be projected from the last end view completed, first lay off the several lengths, as from *C* to *D*, *D* to *E*, and *E* to *F*, erecting light perpendiculars at these points; the side view can now be completed with the T square, projecting from top of collar on end views to *E F*, and from top of hexagon to *C E*; the center line making the corner of hexagon at the center of the figure; following down with the T square, the bottom outline is made, showing whole of side view, the three views furnishing all information required.

Let us now see if the drawing of this figure can be simplified. If the side view is drawn first, and line shades as shown, then no end views are needed to make the shape understood.

If end view *B* is drawn with the hexagon, and small end shown by dotted lines to bring out the hidden portions, then making end view *A* will be a waste of time, because the side view and end view *B* tell us what we want to know.

Again we can omit the end view *B*, making the end view *A* and the side view answer all purposes.

The side view and two end views made just a plain outline drawing without any line shading on round portions, is perhaps the neatest, and after all the clearest arrangement of this figure; however, there is no better practice than to try the different ways to show the figures as here suggested, not forgetting to imitate as closely as possible the shading of the round portions.

The shading of round surfaces tends to bring them into sharper relief, and, as hinted, if done with care will save making an end view in many cases.

In mechanical drawing the light is supposed to come from the upper left-hand corner of the drawing, as shown by the arrow in Fig 56, which leaves the top and left-hand side in the light, and bottom and right-hand side in the shade.

Round surfaces thus represented come to have a distinct individuality, and are quickly recognized.

A hole is shown with a heavy line at upper left-hand surface, as in Fig. 59.

An end view of a cylinder would be shaded as shown on bottom right-hand edge of same figure. In round surfaces the upper side of side view is shaded somewhat the lightest, because exposed partially to the light, while the bottom surface is darker because in the shade.

The light and heavy lines have the effect of bringing a drawing out clearer cut than they otherwise would be.

Illinois Central Strike.

As we go to press there is a general strike of yard and trainmen on the Illinois Central road. The trouble seems to be local, and not to affect the various organizations of these men as a whole—federation keeps the orders out of trouble here.

A very obnoxious superintendent by the name of Russell seems to have caused all the trouble, and the men demand his removal; this the company's manager refuses to do. They have reinstated those discharged by him, but this does not appear to satisfy the men.

It is a pretty hard matter to decide just how far men are justifiable in carrying a matter of this kind, but there is a limit, and the Illinois Central men are pretty close to it. A man that will try to accomplish anything on a road where all the men cordially hate him has no judgment, and does not look to the interest of the road he pretends to serve—Mr. Russell should resign forthwith and seek new fields.

That class of minor officials who think that to serve the company they must fight the men, are too numerous, and will have to retire; and that class of men who think that, by concerted action, they can decide who shall be their officers, and who shall and shall not be dismissed the service, must also retire.

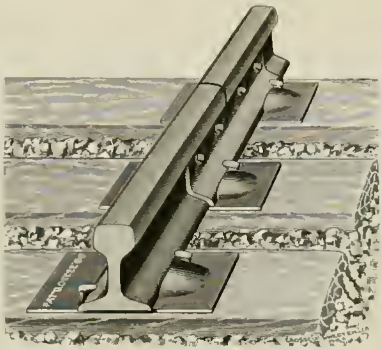
Before Mr. Russell's employment on this line, he held official positions on two other lines running out of Chicago, and the employes of these two lines have notified the I. C. men that they will strike to help them, rather than see Russell win; which goes to show that Mr. Russell is of about the kind and caliber he is represented to be. While the war goes on, thousands of dollars worth of perishable freight is rotting on the side tracks, and ten thousand of passengers are discommoded.

Baldwins are building twenty-five locomotives for the N. P. They will be equipped with the Boyer speed recorder—a device attached to the truck axle.

The Snow Plow Question.

Before the snow plow trials on the Central Pacific road last winter the management had determined to abandon their expensive snow sheds over the Sierra Nevada mountains, and trust to the new plows, but have now ordered all the sheds put into thorough repair. The trials satisfied the managers that, as yet, the sheds are the most reliable. The Cyclone Plow and the Rotary both did fairly good work in the heavy snow, but it would take a million dollars worth of them to keep that road open all the time during another such blizzard. The Jull plow will never do anything until the enormous overhang of the auger and hood is cured; the Cyclone plow has done good work, but has developed some little defects that can be cured. The principle on which it works is good, and its inventor has sense enough to see that it is not perfect and is trying to make it so, asking the practical railroad men of the country to help him. The Leslie plow is doing as well as any of them, but is the oldest, and has been changed a great deal to bring it up—during its first and second winter it was as faulty as any. The perfectly reliable and satisfactory power plow for our Northern lines has not yet been built, and a fortune awaits the builder.

The St. Paul, Minneapolis & Omaha road have an engine in their transfer yard at St. Paul with cylinders 24x28.



An Improved Tie Plate.

The illustration on this page shows an improved tie plate which has no projecting spurs in the wood, and which takes the thrust of the flange upon all the bolts in the plate instead of on the outside spikes; this is done through the medium of the pressed shoulder on outside plate. This plate has a long spike hole through the plate inside the rail; this hole is on an angle from the rail and admits of the inside spike being driven tight against the rail, regardless of variations in width of rail.

These plates prevent the rail from cutting into the ties, and are of especial value in yards where lots of heavy switching is done. On the Western and Southern roads, where soft wood ties are in use, they ought to greatly prolong the life of ties. For further information address C. D. Halsey, Ass't Eng'r M. W., Penna. R. R., Jersey City, N. J., who is president of the Shoulder Tie Plate Co.

A specimen tire and axle has been added to our office museum by the Midvale Steel Co.

The Great Western Railroad of England have on exhibition at the Edinburgh exposition the seven-foot gauge express locomotive, "Lord of the Isles," built in 1851. This engine has 18x24 inch cylinders, a single pair of drivers 8 feet in diameter, a double truck in front and a pair of trailing wheels behind, all having 4-foot wheels. This class of engines were so efficient for express that they were built in this way up to 1881.

Report on Compound Locomotives.

(*Continued from page* 126.)

8th. General.—A recent press notice credits Mr. Webb with an attempt to reduce first cost, by throwing away the valve gear for the low-pressure cylinder, and using in its place a single loose reversing eccentric; in other words, with an attempt to use an invariable cut-off for the large cylinder. And such practice is not unreasonable if it from the first be acknowledged that the compound is designed for doing a maximum specific duty with high economy, and, therefore, the valve gear cannot be, and is not, arranged for a wide variability of service.

This intention in design most clearly marks all those engines using but one valve or one valve stem to distribute the steam to both high and low-pressure cylinders; such, for instance, as the Vauclain piston valve, the Woolfe hollow D valve, and the Dunbar single valve stem. In the two first-mentioned most ingenious valves, the release of the high-pressure cylinder must be at the same moment as the admission to the low-pressure, or it is no actual release, and the cut-off in the low-pressure cylinder marks the exact point when compression in the high-pressure cylinder commences, there being no appreciable "receiver" capacity in the valves themselves, large as the passages through them have to be. There is, then it, is clear, little elasticity of adjustment in such valves and gears. The cut-off being early in the small cylinder, it must be early in the large, and, as a result, the compression in the small cylinder is enormous. Thus the conclusion is again brought home to us that the control of the compound, when small horse power is to be developed, must be chiefly through the throttle wire-drawing the steam, and thus reducing the initial pressure.

Putting emphasis on this truth will not frighten those who are familiar with the fact that wire-drawing is common to-day with our best enginemen. And it may here be noted that the *imperative necessity* for this so-called "crude practice" is the full explanation for the slight use in modern locomotives of screw and other finely divided reversing gears. This statement opens up the whole matter of cylinder condensation, but it is too large a matter to be properly treated in this report.

However, such modern experimenters as Westinghouse, Kennedy, etc., prove that wire drawing the admission into cylinders of large surface and small volume is more economical than valve cut-offs at less than 50 per cent. of the stroke.

There are some constructive details and peculiarities about compounds that may deserve special mention. For instance, it is judicious to put safety or relief valves on the low-pressure chest or cylinder, but they should be so located or guarded that in case they came into action they should not smother the engineman with steam, and obscure his vision. All types do not require water taps on both cylinders, but most receivers should be so drained. If an intercepting valve is used, a reducing valve is not required, and if an intercepting valve is not used, there must be a valve to give independent exhaust direct to the atmosphere from the high-pressure cylinder. The weight of evidence, so far, is in favor of the use of an intermediate receiver. Such a device effectually isolates the cylinders, so that each retains its distinctive temperature. The general practice of drying the intermediate steam by putting the receiver in the smoke-box has much to recommend it. Copper pipes, set close to the curve of the smoke-box, are not cumbersome or much in the way; and if it be desired that the feed-water also be heated in the smoke-box, the large receiver pipes need not interfere with the details of such an arrangement. Receiver capacity cannot, under our limiting conditions, be too large. It should never be less than 1½ times the volume of the high-pressure cylinder, and two or more volumes are desirable, because, with a liberal receiver, the steam supply to the low-pressure cylinder is more uniform in pressure and amount, the re heating or drying of the steam is more thoroughly done, and "the drop" in pressure between high pressure final and low pressure initial is less detrimental to steam economy.

If one side of a compound should break down, the other side can be run as a single cylinder engine, if the failure is not due to a total collapse of the cylinder on the side to be blocked. And in a tandem, as in a simple engine, the failure on one side may be a total collapse without its interfering with the use of the other side as a single engine.

J. DAVIS BARNETT,
JOHN PLAYER,
H. D. GARRETT,
F. W. DEAN.

Mr. Wallace, who is introducing the Partington metallic packing in the United States, is meeting with marked success in the way of having the packing intelligently tested by a number of our largest lines. An article of merit only needs a fair test.

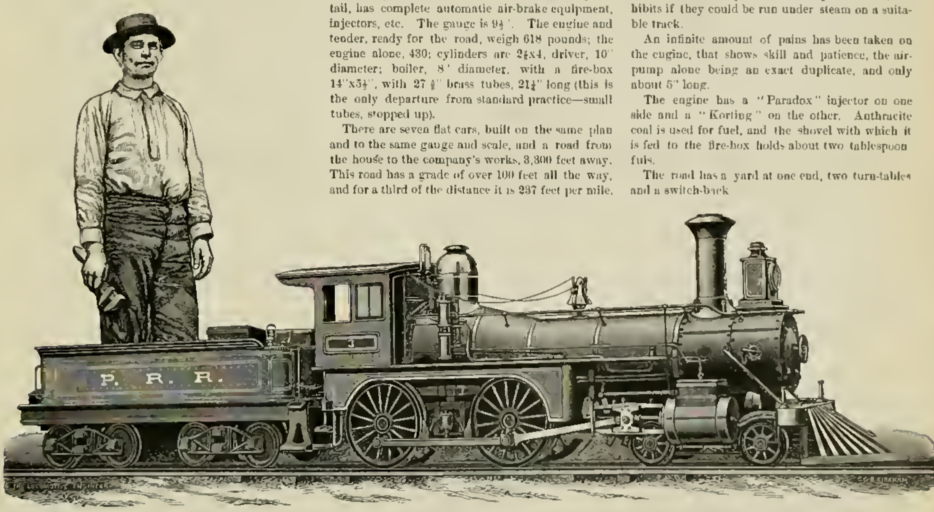
THE LOCOMOTIVE ENGINEER.

DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III, NO. 8 | NEW YORK, AUGUST, 1890. | $1.00 per Year or 10c. a copy.

The Smallest Locomotive in Service in America.

The illustration on this page represents and gives some idea of the proportionate size of a very small locomotive, yet one capable of doing considerable work. As will be seen, the engine is an exact copy of a standard P. R. R passenger locomotive, but is just one-sixth of full size.



GULLIVER AND THE LILLIPUTIAN.

Some years ago Daniel Coxe, a son of one of the firm of Coxe Bros. & Co., who own and operate extensive coal mines at and in the neighborhood of Drifton, Pa., took it into his head to build a locomotive. Probably the notion came there from his ancestors, as he is the grandson of Richard Norris, the once famous builder of American locomotives. As he had access to tools and material in the company shops this was not hard to do, and he soon turned out a rather expensive toy, yet one that sharpened his appetite for something better. A year or two afterward No. 2 was made. She would move under steam—and that was about all.

Young Coxe made up his mind to build another locomotive that should be just like a large one, excepting as to size, and see if it would not do work in proportion to its size and weight.

A very neat little shop was fitted up at home, with a planer, shaper, drill and several lathes, and work commenced, building exact to standard drawings, only on a scale of 2" to the foot.

He then secured the services of A. J. Beltz, a machinist with a bent for small work, and whose picture is shown beside the engine.

In 1887 this engine was turned out, and a road built for her, and she has been in use there ever since, making between 2,500 and 3,000 miles.

The engine in the picture is perfect in every detail, has complete automatic air-brake equipment, injectors, etc. The gauge is 9½". The engine and tender, ready for the road, weigh 618 pounds; the engine alone, 430; cylinders are 2⅝x4, driver, 10" diameter; boiler, 8" diameter, with a fire-box 14"x5½", with 27 ⅝" brass tubes, 21¼" long (this is the only departure from standard practice—small tubes, stopped up).

There are seven flat cars, built on the same plan and to the same gauge and scale, and a road from the house to the company's works, 3,300 feet away. This road has a grade of over 100 feet all the way, and for a third of the distance it is 237 feet per mile.

The entire line is equipped with semaphore signals, and the regulation Lehigh Valley switch-stands and targets. The rails are the lightest rolled, and much too large for the engine. They are 8 pounds to the yard.

A cushion that fits the top of the tank allows the runner to lay partially upon the tank and partly on the first car, the cab being just about large enough to get a man's hand into with comfort.

With four or five men on the cars the little mill soon gets up a speed that makes you want to keep up your legs and look out not to strike passing objects. She has taken twelve persons over the road at once.

With 140 pounds of steam the engine started from a dead stop and ran 2,500 feet to a dead stop again, in 1 min. and 40 sec.—over 20 miles per hour.

The engine does no particular good, perhaps, is of little use, you may say, yet it teaches a lesson in what can be done if done well. There are no bent wires or makeshifts for the engine; there is nothing on a big engine that is not to be found on this, and she does work just in proportion.

Mr. Coxe now has another and slightly larger engine nearly completed. She is modeled principally on the "Class K" engines of the P. R. R., and he expects to exhibit both of them at the coming world's fair. They would be very interesting exhibits if they could be run under steam on a suitable track.

An infinite amount of pains has been taken on the engine, that shows skill and patience, the air-pump alone being an exact duplicate, and only about 5" long.

The engine has a "Paradox" injector on one side and a "Korting" on the other. Anthracite coal is used for fuel, and the shovel with which it is fed to the fire-box holds about two tablespoonfuls.

The road has a yard at one end, two turn-tables and a switch-back.

The smallest road we know of that is open for public business is the two foot-gauge road of the Monson, Maine, Slate Company, which is six miles long, and hauls six tons of freight per car, doing a business of 9,000 tons in 1888, and carrying 4,200 passengers.

A person seeing young Coxe and his little engine sailing along up through his father's orchard would think for a moment that he was looking into the big end of an opera glass, at a Pennsylvania construction train on the other side of a wide valley.

Down South many of the old timers refer to the blocks placed over driving-boxes, in case of a break-down, as "Confederate springs." During the war springs were not to be had in the Confederate States for love or money, and as fast as they were broken in service, blocks of wood took their places, and were nicknamed "Confederate springs."

Ft. Wayne Shop of the P., Ft W. & C. Ry.

(Editorial Correspondence.)

The general shops of the Ft. Wayne road are located in the city of Ft. Wayne, Ind., and are quite extensive, and as modern as usually found in shops of their age.

The buildings are of brick, substantially made, and, while there are a few old tools, most of them are modern and up to date.

PIECE-WORK.

Here, as at many other of the Pennsylvania company's shops, most of the work is done by the piece, and this alone brings out a great many short cuts and hurry processes that cheapen the work and get it out of the way. Piece-work has many advantages and some disadvantages, and is, no doubt, more valuable where manufacturing is done than in repairs; but I am not going to discuss its merits and demerits. I went after

SOME KINKS.

There is no plate planer in the shop, yet they plane plates of any size. This is done by an attachment to a large planer. An old planer table was set up beside a large planer and leveled with its bed; then the cross-rail of the old planer was securely fastened on two brackets bolted to the end of the table, and the head carrying the tool-post fitted to it. When a boiler plate is too large to be placed on the planer table it is fastened upon the old, stationary bed, beside the planer, and the tool on the end of the big planer table travels along and trims the sheet as wanted. This tool does nice work, does it well, and for two cents per foot, as against ten or twelve cents for hand work. They have invented and are using the best form of

SIDE PLATES

for taking up lateral motion in driving boxes and axles I have ever seen. Instead of making the plates of iron, cutting them in halves and tap-bolting or riveting them to the hubs of drivers with copper, they make them of phosphor bronze, in one piece, without bolts. They turn a recess in the side of wheel center, as shown in sketch, making an inclined shoulder as at 1, and a similar shoulder on the axle as at 2. In half a dozen places around this circle they chip off a piece of the inclined shoulder, as shown at *a*; this keeps the plate from turning around. This turning once done never needs touching again to fit new plates. The wheel center prepared, the axle is set perpendicular, and the outside of the circle built up with clay, and the place poured about ⅛ of an inch above the finished size with a good quality of phosphor bronze. As this cools it shrinks and binds solidly against the two inclines 1 and 2, which holds it solid against the hub, and the notches prevent its turning around. All that is necessary is to put the wheels in the lathe and face off this plate. It wears well, and can be very cheaply replaced, and there are no bolts or rivets to work out and cut the box. When one of these plates is struck with a hammer it sounds like the wheel center itself—it is there to stay.

LIVELY WORK

There are no slow moving machines here. Milling is done with a generous cut under a solid stream of water. Rods, guides, guide yokes, frames, etc., are sent to the machine shop just as they come from the steam hammer, and without any attempt at finishing up by blacksmith. In the room devoted to axle work and bolt cutting all the bolt cutters have been speeded up, the double-head bolt machines are cutting on an average 1,500 bolts per day as against 700 before speed was changed. On all this class of work they use a special brand of cottonseed oil that they think especially good.

CHEAP WORK.

In this room car axles are turned for 20 cents each, which is the cheapest I have heard of.

TURRET-HEADED LATHES

are employed on small iron work that is got out in large quantities and in duplicate, and, of course, the price is kept way down.

THE BLACKSMITH SHOP

is especially well equipped, and there seems to be more ingenious tools here than in the rest of the shop. Special dies for almost every piece forged are in use, the bolt forging machines being made to turn out bolts of peculiar patterns and pins with keyholes all punched out at one blow. They make crown bar bolts that are finished under the head on a taper, and so nicely that they go into the boiler without machine work or copper washers; the tools for this work are very ingenious, insuring as they do exact uniformity in the work turned out. On the

GUIDE YOKES,

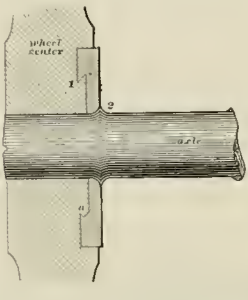
which are large, and slotted for the main rod, they save time and money by cutting the iron out of the solid, and making three welds in it instead of bending the yoke, as is usual. The welds are at each corner, and at its center under the boiler, very little work is done aside from the welds until they go to the machine shop.

THE PLANING MILL

has recently been re-arranged so that every piece of timber does through it for all work, no material having to go back once it is in the mill. All the tools are served with hoods, and exhaust fans take out shavings and sawdust, the sawdust goes to a house for its storage and the shavings go by another system of piping to the boiler-house, or the dust-house, as wanted.

CAB-DOOR KINK.

All the front doors of their cabs open out and swing from the outside corner. On the corner of the cab, and extending ahead about four inches,



there is a cast-iron bracket that holds a plug of soft rubber for the door to strike against; the door is held open by a long hook that drops into one of a series of holes in an angle-iron fast to the inside of the cab below the side window. When the door is wide open this rubber has to be compressed in order to hook it open, and this keeps the door from rattling. Right in the center of the glass of the front door, and about on a level with a man's eyes, there is a little glass some four inches wide and extending across the door, that is in a frame of its own and hinged from above to swing out. This is used to admit a little air without many cinders, and for the men to reach out of to clean snow off the glass.

AIR WOULD BE BETTER.

For driving the cylinder boring bar, valve seat, planer, etc., a small engine is used and steam is taken from a system of pipe for it. The use of steam calls for the piping away of the exhaust and the use of hot pipes where every leak is noticeable and annoying. Compressed air would be cooler and cheaper to use, as it can be carried long distances in rubber hose, requiring no pipe work, the exhaust taking care of itself, and allowing of the moving of the engine.

THE BOILER SHOP

is pretty well arranged and busy on Belpaire boilers, a form now much used by the Pennsylvania Railroad.

ENCOURAGE INVENTION.

This company encourage their men to improve tools and processes, and there were several new devices in course of erection that I shall write of in good time. When a device is gotten up by one of the men that seems to have merit it is tried, and if found good, adopted. The company pay for having it patented, and often a good bonus for its use as well; then the inventor has the patent to dispose of to other roads.

A CAR DRAFT GEAR

was recently invented here by General Foreman Graham, and is now being applied to all freight cars built. G. H. Judy has charge of the blacksmith shop and can well be proud of his special tools. George L. Potter, the master mechanic in charge of this shop, is a young man and one of the many bright graduates of the Renovo (Pa.) shop.

J. A. H.

Helping the Engineer.

No good fireman ought to let his engineer do any repairing on the road that he does not have a hand in, and learn how it is done. There should be a feeling of fellowship and a disposition on the part of both men to see that all the work to be done about the engine is done well and to the best advantage. A fireman should be willing to help pack or oil around, or the engineer be willing to help clean the fire when in a hurry on the road, and his own work is done.

Of course the fireman will help the engineer more than the engineer will the fireman—one is anxious to learn the business, the other is supposed to have learned it.

It often happens that a particularly helpful fireman will entirely spoil an engineer who is so built that his constitution will stand considerable rest. "Follow me around with a wrench and the tallow pot," is an old gag used to illustrate their ways.

The writer has in mind a rather young runner, who got so bad this way that he needed a porter to wait on him, his firemen were asked to do everything, and they finally began to figure to get changed off—particularly as the engine ran by this man got to steaming badly. We had one bright boy firing on the road that cured the restful runner in one trip.

Harry was rustling for steam pretty hard, and was tired, having done all the oiling, switching and other work on the trip. When well out on the road, about the middle of the division, the engineer took a chew of plug, and smiling at the sweating youth, who was worrying over the position of the pointer, said for the tenth time:

"Son, you are younger 'en me, git me a drink, won't yer?"

Harry slid off his box, slammed in three or four shovels of coal, set his shaker bar on the stub, took down the wash bucket, drew it brimming full of water, put the tin cup into it, and set it over in front of the eagle-eyed steersman, saying:

"Just help yourself, I'm awful busy now."

The Pennsylvania's New "Class P" Engines.

The P. R. R. have just turned out another series of the "Class P" engines, such as illustrated in our issue of December last. These have a larger cab than the ones shown, which was badly needed, the piping has been arranged a little better, and they are more comfortable. A man can take off a plate on the back board of the cab and pack the throttle, which is easier than taking off the cab, which almost seemed necessary before.

The greatest change is in the location of the engineer's brake valve, which has been placed on the fireman's side and connection made to it by a reach rod and a couple of bell cranks—this is a doubtful improvement. There seems to be a prevalent idea that this valve must be on the boiler-head somewhere. The Erie plan of placing it below the footboard, with the stem extending up like an old-fashioned lazy cock, and carrying the handle and stops, is a cheaper and better arrangement than this.

The cylinder cocks and sand valves are operated by good-sized and conveniently located levers on the side of cab.

The ash-pan slides on the last series, operated by rack and pinion, have not been a success, as they stick and become inoperative.

Simple Lessons in Drawing for the Shop.

By ORVILLE H. REYNOLDS.

TENTH PAPER.

It is not always the case that an object can be shown thoroughly and clearly by the elevations and plan alone, even when hidden parts are made as plain as possible by means of dotted lines. Often it will be found necessary to resort to sectional views, as hinted in a former paper; indeed, it will be preferable to make the sectional views, rather than have the drawing confusing by too many dotted lines, as is too often the case.

An intelligent use of sectional views goes far toward making a drawing easily read and understood. A section is intended to show the interior of a body, and is a longitudinal section when cut lengthwise through its center in either a vertical or horizontal plane; a cross or transverse section when cut through crosswise. When sections are made at different angles they are said to be oblique.

These terms we are not tied to in practice, however, since a section can be, and often is referred to as a section on any line, as A B, etc. It is, therefore, a matter of no special consequence whether the section is longitudinal or transverse in most cases, so that the letters of reference convey the information of where the section is taken from.

Fig. 65 represents a crosshead of a locomotive engine having guides of four bar type. The plan or top view is drawn first. The center line A B having been drawn, describe arcs on each side of it, representing lines to be drawn with the T square. The lengths can then be laid off, beginning with the ends, after which draw the keyway, then the solid end through which keyway is shown, and finish the view by drawing the pin or journal, and the half collars next to the pin. The plan thus delineated is complete.

Next project the end lines of plan to any point below the view to form the ends of the next view, the center line of which is to be drawn at a convenient distance from the plan, as at C D. Describe on each side of center line arcs to represent the thickness of crosshead, and draw with T square to intersect lines forming the ends. This outline as shown would represent a side elevation if completed, but the question here presents itself, Will a side elevation show what is wanted as clearly as a section?

When it is considered that a front view is to be drawn, and that it will show the wings of the crosshead as well as a side view, we can decide that a side view can be dispensed with, and substitute for it a sectional view.

After an examination of the plan, it will be evident that the center line A B will be the proper place from which to take the section, for the reason that it will give more detail in the section than any other point that could be chosen, it showing the diameter and taper of hole for piston fit, and also the width of keyway with its taper, which would not be the case if the section were taken elsewhere; therefore the line A B shall be the place at which the plan is supposed to be cut.

All points lying in the same vertical plane on the plan may now be projected to the sectional view. The points to be projected are, the edge of half collars, the center line of journal E F, the inside end of piston fit, and large and small ends of keyway. The taper of hole for piston fit is next laid off each side of center line and drawn, the points projected for top and bottom of keyway then connected, leaving the front line square with the center line, and the rear line slightly angular for the draw of key. Nothing now remains to complete this view, except to describe at the intersection of lines C D and E F, the circle for the pin or journal, and the semi-circle for half-collars, after which the portions supposed to be cut are section-lined with the 45° triangle.

We have here a longitudinal vertical section representing the crosshead as it would appear were it to be cut on the line designated, and the upper half turned toward us so as to bring into view the cut surface.

The front view is next drawn by projecting from the plan the lines representing the width of the crosshead, both of the top and wings, after which the center line K L is to be drawn, and from which the thickness of body and wings is to be laid off. At the intersection of center lines, the circles representing the large and small diameters of the piston fit are to be described, and the front elevation is completed.

To still further illustrate the subject, let us make one more section. Supposing the crosshead to be cut on line I J; this will give us a transverse section looking toward the journal.

In order to draw this section, produce the top and bottom lines of longitudinal section a convenient distance, also the center line, and erect a perpendicular at such a distance from the section already made as will bring the proposed section in the same relation to the one made as the latter is to the plan. This suggestion is made so as to have a well-ordered arrangement of views, and should be observed in all cases when grouping views.

The thickness having been determined when the top and bottom lines were projected from the first section, we will take for a center the intersection of center lines, and setting the compasses on the plan at intersection of the center lines, take the distance over wings, and transfer the same to proposed section; then take length of journal from the same point on plan, and transfer that dimension also, lastly take the radius of journal, and lay off each side of center line. All that now remains to complete the view is to use the 45°-triangle for the section lines.

The crosshead, as represented, is supposed to be complete and ready for service. The pattern maker would regard the drawing as showing finished dimensions, and in making the pattern would allow for shrinkage and finish; by finish is meant the material to be removed in the turning, planing and boring.

After the casting is made, the operation of "laying off," or putting on the lines for the guidance of the lathe and planer men, is identical with the drawing of it, except that in one case we make our lines on paper with a pencil, and in the other make them on the iron with a sharp scriber, after the application of chalk to the rough surface. The surface plate will take the place of the drawing table, and the try square and surface gauge will do duty in place of the triangle and T square. The results are the same in both instances, with a trifling difference in the method of their attainment.

The center lines are the points from which all dimensions are to be laid off, same as when making the drawing.

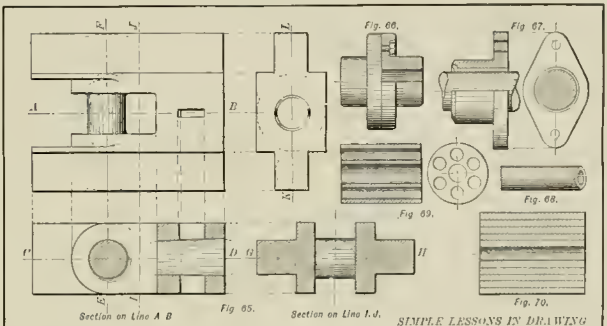
Intersection of center lines at sides forms the centers on which the journal is to be turned, intersection of center lines at end locates the center of hole for piston fit, the core of which, by the way, should have a piece of pine neatly fitted, having a tin center, from which to describe the circle representing the hole for piston. From this center another and larger circle should be described, by which the crosshead is set true in the lathe when boring the hole. This last operation, and laying off the keyway, is deferred until the crosshead is planed in many cases.

Much latitude is taken in the matter of sections, as, if it is desired to show the interior of merely one special part on a drawing, it is done by showing it cut away at the particular place to be represented, and not carry section through the whole plane where shown. A reference to Fig. 66 will convey the idea. Here we have a flanged coupling for shafting, shown with one-eighth of the figure cut away, giving enough detail in the one view to make its construction plain, as is sometimes done when the parts are shown assembled or in position, thus saving a detailed drawing of the object.

Fig. 67 represents a piston gland, with all details complete in a half-longitudinal section. Here we have the cast-iron body, with a brass bushing, and piston rod shown broken. The front elevation shows section lines where the hole should be. Now, as a section is meant to represent a cut or broken solid, those lines are intended for the broken piston, and not the hole.

Instances are recalled in which the holes have been cross-hatched or section-lined, but no argument is needed to show up the practice as a failure and misleading.

The view of a broken tube, in Fig. 68 shows an oblique section. The principal use of view like this is to show that it is a tube, or hollow. If it were not broken at an angle, and if no end view was shown, it would look like a solid cylinder, as made, it tells at once what it is.



SIMPLE LESSONS IN DRAWING

Fig 69 is a section and end view of a cylinder, with perforations in the direction of its length. A transverse section would show just the same as the end view, therefore it is not necessary. The longitudinal section and end view give all information needed.

In Fig. 70 is shown a number of concentric bands in sections, the section lines running in opposite directions on adjacent sections. A good effect is brought out if the 45° triangle is used on alternate sections with the 60°-triangle between.

In order to avoid a shabby appearance in a sectional view of this or any other kind, it is well to exercise care in drawing the lines to the edges of the respective sections, being quite sure that the pencil or pen does not pass by the outline of section.

In the spacing of section lines there will be found a big field for practice. While it is of no consequence how much the spacing of lines may differ on adjoining sections, they should be at a uniform distance on each individual section.

The United States now produces 26 per cent. of all the iron ore that is mined, 26 per cent. of all the coal, 30 per cent. of all the pig-iron, and 32 per cent. of all the steel that is manufactured. The world's annual production of iron ore is placed at 53,280,000 tons, of coal, 462,000,000 tons, pig iron, 24,869,000 tons, steel, 10,513,000 tons.

At the Brooks Locomotive Works.

The Brooks Locomotive Works, at Dunkirk, N Y., are the only works of the kind in this country, unless it be Cooke's new shop, that are all on the ground floor. These works were established over 20 years ago by H. G. Brooks, who for many years before had charge of the motive power of the Erie; in fact, the Erie shops were at first used, and afterward purchased from the road.

The shop room seems ample, except in the foundry, which is very crowded, but plenty of ground is at hand for extensions when needed; a new tank shop is now being put up over the old one.

The machine shop is well supplied with tools, most of which are of late design, the heavier ones being well served with cranes.

They have recently put up a large combined miller and slotter, imported from England, that is a very fair illustration of what use "combination" tools are in a manufacturing business. One side at a time is all that can be used, the tools are "combined" on one base, not to do work together, and to change from miller to slotter or *vice versa* is a job requiring more time than needed to transfer the work to another machine twice over. The machine was doing nice work as a slotter, and most of the gears and other extra paraphernalia of the miller part, rested quietly against a post out of the operator's way. This is the day of special tools, and not combinations. This kind of a tool might be a nice thing for some small, isolated railroad that had a little of each kind of work to do.

The different kinds of work in these shops has been separated into different rooms and buildings, so that there is little confusion, and tools for certain work are close to each other. There is a separate shop where cylinders are finished, where frames are made, one for rod work, another for tanks and the same for trucks.

The boiler shop is well supplied with tools and has a very large traveling crane, having a bridge 80 feet in length. Hydraulic riveters and some steam riveters are used, but these will soon be replaced with hydraulic tools; many of the heating forges, such as rivet forges, are heated by oil, which gives a clean, hot blaze, free from sulphur and dirt

A very elaborate hydraulic plant has recently been added to the works; water is supplied under several hundred pounds pressure by a compound pump, and will be used for every purpose where it is practicable. This plant was made by the Dunkirk Engineering Company.

The blacksmith shop is nicely arranged, every fire has a large hood, and the smoke-pipe makes a turn and enters an underground flue connected to the stack; draught is created by exhaust fans. By this arrangement there are no obstructions overhead, and cranes and trolleys have full swing.

There is here a very nicely arranged case hardening furnace, designed by Mr. Brooks, and a great deal of case-hardening is done; equalizers are milled out where spring hangers come and case-hardened; in fact, any and every piece subject to wear that can be case-hardened is so treated.

There is a separate building in the yard, isolated from the others and having no windows; this is for the storage of templates, of which there is a great accumulation, as templates are made for all work.

The tool room is well provided with tools, especially grinding tools, and all reamers, twist drills, taps, dies, and lathe tools, are made here, they claim a saving of 50 per cent in the matter of twist drills alone. All lathe and planer tools are ground to gauge by use of a Sellers' tool grinder, and no trips are allowed to the tool dresser or the grindstone.

The shops are full of work, so full that no orders are taken for this year's delivery, and it is a noticeable fact that they are building no "specification" engine—that class of work where the order calls for just such a bolt and such a thread in each particular place. All the engines going up are Brooks engines.

On some of the larger boilers a double row of rivets is used in the mud rings, clear around; butt joints are avoided in longitudinal seams and triple riveted lap joints used.

Unless otherwise ordered all engines have the Morse balanced valves.

On their tanks they extend a narrow flange around the front of each tank head at the gangway; this makes all the water that comes ahead on the top of tank run into the coal space instead of the gangway.

The drawing room is pretty well crowded just now and larger quarters are being planned.

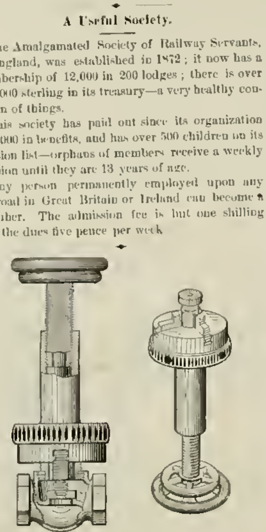
In the office building is the famous Brooks Technical School, not only free to every apprentice boy in the shop, but obligatory—he must attend. Books, drawing material and teachers are furnished by the company entirely free; all the boy has to do is to attend. Three years of apprenticeship and schooling generally turns out a mechanic who is able to take hold of a foremanship or other position of responsibility, with some show of going to the top. This free school is an inducement to the better class of boys, and the result is that the works secure the services of intelligent and earnest workers. Their apprentices are drawn from nearly every State in the Union, and one boy from England and another from Cuba were pointed out to us.

A Useful Society.

The Amalgamated Society of Railway Servants, in England, was established in 1872; it now has a membership of 12,000 in 200 lodges; there is over £70,000 sterling in its treasury—a very healthy condition of things.

This society has paid out since its organization £60,000 in benefits, and has over 500 children on its pension list—orphans of members receive a weekly pension until they are 13 years of age.

Any person permanently employed upon any railroad in Great Britain or Ireland can become a member. The admission fee is but one shilling and the dues five pence per week.



A New Valve Reseating Tool.

The accompanying cuts show the design of a neat and handy tool for reseating valves, that seems to possess especial merit as a tool on locomotive repairs. Being portable and small, it admits of being carried to an engine and adjusted without taking a leaky valve off, and is applicable to angle or globe valves, and will work equally well at any angle or in any position.

The body of the tool is a small chuck with three expanding jaws, the face of the jaws being threaded so as to engage with the threads in a wide range of sizes of valves. These jaws once in the threads of the valve, hold the chuck true without possibility of cramping. The extension on top of the chuck carries a feed sleeve that feeds the tool down, by one handle—the smaller of the two handles shown—and this sleeve carries a spindle free to turn. The top of this spindle carries a hand wheel, and the bottom a cutting tool or rose bit, this tool, being removable, a variety of sizes and shapes can be used.

After adjusting the tool on a valve it is but the work of a moment to make a new seat.

The address of the inventor is, Charles L. Morse, Athol, Mass.

Wanting to Know that which is Other People's Business.

The Central Railroad of Georgia recently sent out a personal record sheet, that for gall and impertinence is fully up to the standard, if not a little ahead of it. Here are some of the questions.

1. Full name?
2. Born? In what city or town, State and month, day and year.
3. Height and weight?
4. Married or single?
5. Residence of family or relatives?
6. State of health?
7. State if insured. In what companies, and for what amounts?
8. State if eyesight and hearing is good or defective, and how?
9. State experience, if any, in railroad service other than this road, giving capacity of service, time, and with what road?
10. State if discharged from service, as above, cause, and from what road?
11. State where last employed, capacity, time and cause for leaving?
12. Give names and address of parties to whom you refer?
13. Were you ever employed by this road, when and in what capacity?
14. Were you ever discharged from this road, for what cause, and when?
15. Will you study the rules governing employes on this road carefully, keep posted and obey them? If not promptly furnished with a copy of rules, will you apply to the head of your department for them at once?
16. Do you know that bridges, including highway bridges, and tunnels, overhanging roofs, etc., on this system, are too low to clear a man standing on a box car?
17. Do you know that there are many structures adjacent to the tracks on this system, and particularly bridges and tunnel walls, water tanks and spouts, overhanging roofs, wood racks and platforms which render it unsafe to climb up or down the side of a box car while the cars are in motion?
18. Do you know that the coupling and uncoupling of cars is attended with great danger, in spite of all precautions of the company; that the company hauls the cars of other roads as well as its own; that drawheads are of different heights, sizes and patterns, and that some cars have dead blocks and others not, and that altogether there is great lack of uniformity in coupling and buffing apparatus?
19. Will you abstain from the use of intoxicating drinks while in the service of this company?
20. Will you keep away from the places where it is sold, and lend your influence to help others do the same?
21. Are you now, or have you at any time, been disabled from any cause?

There is also a "minor's release," the parents releasing and forever acquitting the company "from any liability for damages for any injuries which may be sustained by said minor while in its employment." The release also provides that the company "may pay all wages and other moneys" to the minor.

Some of the questions are all right, and should be answered as a matter of record in case of accident, but numbers 2, 3, 4, 6, 7, 10 and 11 are private matters, and concern the company no more than does the color of the subject's great grandmother's hair.

Questions 13 and 14 should be matters of record on the road.

Questions 16, 17 and 18 are damaging confessions of the maintenance and use by this company of death-traps, and the answering in the affirmative of these questions was intended to put the responsibility of death or injury from the causes mentioned upon the victim of these traps, rather than upon the company. If there are railroad commissions in the States traversed by this road, this should be a pointer for them—some changes and repairs are needed. The minor clause is a sneaking plan to avoid damage, should a minor be killed by some of the traps set by the company. It would look much better for this great corporation to ask the men to point out such places as would not clear men on top of cars, etc., that they might put them in safe working shape, than to ask the men to take all the risk, and hold the company blameless.

The Central has evidently got some official with very little to do.

The temperance questions are all right enough, but how much better number 20 would look if it read "Will you keep away from places where it is sold, and assist and emulate all the officers of the company, by individual example, in helping others to do the same." Probably the very official who schemed up this clause drinks more liquor than the average of his men.

The men on this road very properly declined to answer some of these questions, and the company has withdrawn them—and it is well they did. The men now ought to demand that some of the traps set in their paths be removed—the road is dangerous enough at best.

Engineer Benj. Hurst, of the Erie, died last month; he had been an engineer for 51 years.

A Big Engine.

The largest Corliss engine ever erected has recently been turned out by Hick, Hargreaves & Co., Bolton, England. This engine is a double one, each cylinder developing 5,000 horse-power; it is of the vertical type and stands 48 feet high. It will drive a dynamo 45 feet in diameter, supplying a current of 20,000 volts. Some idea of the size of this engine can be had from the sizes of minor parts; the bolts through the straps of the connecting rods are *nine* inches in diameter.

Cause and Effect.

The passenger and freight agents lay awake nights to devise schemes and excuses to cut rates below living figures, and then the stockholder—who, like the storied Jew, must have his pound of flesh—demands retrenchment in the shape of a cut in pay, shorter hours or a reduction of the shop force.

The men who own most of the stock of American roads seem to pay very little, if any, attention to the condition of their properties or the management into whose hands it is placed, so long as they pay dividends.

After a season of "economy" and "retrenchment" of this kind a change of managers and a cessation of dividends has to be had to get the property back into a fit shape to operate and restore in the public, confidence enough to get them to ride over the lines again and pay fare.

A Compound Design.

Geo. L. Flertz, of Detroit, sends us a sketch of plan for compound locomotive, recently patented by a Pennsylvanian, in which the low-pressure cylinder occupies the place now occupied by cylinder of a simple engine, and the high-pressure is located back of it, the crosshead playing between them on a common piston, and asks an opinion on it, especially for 10-wheeled engines.

The design is complicated and entirely impractical; the pair of cylinders could not be got into a space of less than 8 feet fore and aft, and the high-pressure cylinder is in the way of the main rod, requiring an offset in the crosshead and crank-pins, long beyond reason. Such an engine has more parts, greater weight on truck, extra valve gear, extra steam piping, would cost much more to begin with, cause enormous friction and wear, and consequently cost more for running repairs—a worse arrangement could hardly be devised.

An Improvement in Car Seats.

The ordinary reversible back seat has had a pretty long run on American roads, because of its reversible adjustment, but it has a number of disadvantages that are well known.

In the first place the back has to be light and strong, is limited as to height, and being hinged to the seat ends, it cannot be taken out for cleaning. Seats are reversed in order to throw two together either for parties, or for the baggage or feet of hoggish travelers. On the western trunk lines running through cars over 1,000 to 2,500 miles of road, there is a great temptation to make beds of seats by removing and changing seat cushions.

The invention here illustrated consists of stationary standards supporting fixed backs, while the seat itself is reversed by swinging it on its support, and using the opposite back, as plainly shown in the drawing.

The backs are double, and upholstered on each side, and can carry a head rest such as used in reclining chair cars, the back can be inclined either way by the use of notches shown on the standard, and can be lifted out of its place to be beaten and cleaned.

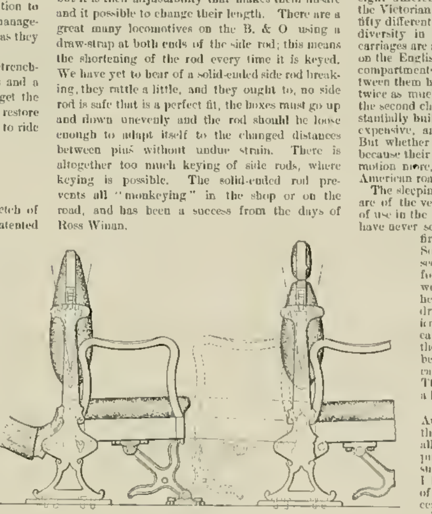
The swinging seat is held at the center and front by its supporting link, and at the back by the foot-rest.

This arrangement secures to each passenger a degree of privacy not possible with the reversible back seat, as it admits of his riding with his face to the front or rear without facing his neighbors. It provides a better head-rest and less draughts. It effectually prevents the putting of feet on opposite cushions, and makes a seat in which both the back and seat cushions are removable for cleaning.

This seat has just been patented by Geo. W Cushing, of Chicago, Ill.

Side Rods.

Not long ago a fireman was killed on the B. & O. on account of a broken side rod, and, in a claim for damages by his relatives, several good arguments were brought up to show that the company did not use a good or safe rod. There is no doubt that a strap rod would be all right if keyed solid, and the right length at the start—and left alone—but it is their adjustability that makes them unsafe and it possible to change their length. There are a great many locomotives on the B. & O using a draw-strap at both ends of the side rod; this means the shortening of the rod every time it is keyed. We have yet to hear of a solid-ended side rod breaking, they rattle a little, and they ought to, no side rod is safe that is a perfect fit, the boxes must go up and down unevenly and the rod should be loose enough to adapt itself to the changed distances between pins without undue strain. There is altogether too much keying of side rods, where keying is possible. The solid-ended rod prevents all "monkeying" in the shop or on the road, and has been a success from the days of Ross Winan.



The Cheapest Extension Front.

At the Wilkesbarre shops of the Lehigh Valley road they put on a complete extension front for the small sum of $40.

This extension is of cast-iron, half-inch thick, having a flange at the back edge on the inside, on very large boilers the same casting is used by placing the flange on the outside.

The extension is rounded neatly at the front corner, showing no joint, having no bolt heads and requiring no front ring. The door lugs being cast on, all that is necessary is to put this casting on a boring-mill, face the back end and the door joint, and drill the bolt holes in the back flange, or these can be cored in.

The front is about 18 inches long, presents a clean and neat appearance, does not crack as bad as a separate front, and is cheap to apply and replace, as, if broken, there is some return in the shape of iron for the cupola.

This front ought to be a popular one on account of its cheapness for repairs; it is but very little heavier than a wrought front of the same length, and not as heavy as the average one of 24 or 28 inches.

The coal mines under the city of Wilkesbarre, Pa., recently caused a settling that dropped part of the Lehigh Valley machine shops some twenty inches. The walls have been patched up, and are now safe, but they look a little "offish."

Some Notes on Australian Railways

Henry George has been writing some interesting letters from Australia to the *Standard*, of this city, from one of which we clip the following interesting facts:

The Australian colonies are separated from each other, not merely by tariffs. They also have the additional protection of differing railway gauges. The New South Wales railways are built on the standard English and American gauge of 4 feet 8½ inches. Queensland, on the north of New South Wales, has adopted the narrow gauge of 3 feet 6 inches; Victoria, on the south of New South Wales, has the Irish gauge of 5 feet 3 inches. The only intercolonial line of unbroken gauge now existing is that between Melbourne and Adelaide, which is 5 feet 3 inches in both colonies. South Australia began to build on this gauge, but afterward (on the score of economy) changed it for the narrow gauge of 3 feet 6 inches, and so, at a short distance from Adelaide, her own lines break gauge, thus necessitating the transshipping of passengers and freight for Broken Hill, and all points at any distance in the interior

On the South Australian railways some twenty-eight different patterns of engines are in use; on the Victorian railways there are, I am told, over fifty different patterns. There is also considerable diversity in New South Wales. The passenger carriages are also of different styles, but generally on the English model, with first and second-class compartments in the same car—the difference between them being in the upholstery. They charge twice as much for traveling in the first class as in the second class The roadways are well and substantially built—so substantially as to be needlessly expensive, an American might sometimes think. But whether because the carriages are lighter or because their springs are not so good, one feels the motion more, it seems to me, than is usual on the American roads.

The sleeping cars on the New South Wales lines are of the very earliest Pullman model—long out of use in the United States—so long, in fact, that I have never seen anything of the kind there The first sleeping car I entered in New South Wales, which was at night time, seemed to me a rather grotesque and forlorn parody on the sleeping car as we know it. And this impression was heightened when I found that to get a drink of water one must go, not to an ice filled refrigerator, but to a water bag carried on the rail on the platform of the car But these sleepers are really better than they at first look, and one can travel very comfortably in them. The charge for the night is 12s 6d, for a low berth and 10s, for an upper berth.

The particular interest which these Australian railways have for me is that they are all public property and are all built, maintained and managed on public account by public officials. The subject is such an interesting one that I hope to have an opportunity to speak of it more at length hereafter but this is certain—that the State management of railways is, in Australia at least, such a success that no one seems to dream of resorting to the system of corporate management.

Enlargement of Baldwins.

The Baldwin Locomotive Works at Philadelphia are the largest in the world, but are going to be much larger.

The old erecting shops on Broad street, south of the present office, will give place to a new shop of modern design with "saw-tooth" skylights, and two traveling cranes, each capable of lifting 100 tons, and will extend almost to Fifteenth street, having a frontage on Broad street of 158 feet and on Buttonwood street of 306 feet.

Adjoining the erecting shop a four-story machine shop will be built, running from Buttonwood to Spring Garden streets, a distance of 208 feet, and from Fifteenth street to the new office building, 227 feet.

The office at the southwest corner of Broad and Spring Garden will be extended 47 feet, making the total dimensions 167 feet.

In order to make these improvements it will be necessary to remove seventy-five houses, destroy two courts running off Spring Garden street, one on Fifteenth and another on Buttonwood street The works are crowded with orders.

The office of John W Cloud, secretary of the Master Car Builders Association, has been moved from Buffalo, N. Y., to 974 Rookery Building, Chicago, Ill.

Haberkorn's Air-brake Governor and Triple Valve.

The accompanying engravings represent a car governor and a triple valve, devised by Mr. T. H. Haberkorn, lately master mechanic of the Fort Wayne, Cincinnati & Louisville road.

Mr. Haberkorn started in some years ago to supply the passenger equipment of his road with some kind of a brake that would interchange with the Westinghouse, and thus admit of other roads handling their cars into Cincinnati, the company being, or claiming to be, too poverty-stricken to buy the Westinghouse brake.

His experiments led him to supply a complete automatic air-brake equipment that was satisfactory, and which is still in use on the road. His air-pump has the reversing rods outside, and is not unlike the Westinghouse in appearance, doing the same work in the same way. His engineer's valve is a 3-way cock, but having graduating ports, and arranged to work the driving brake with straight air, and either independent of, or in connection with the train brake. We hope to show up all these devices in good time, however.

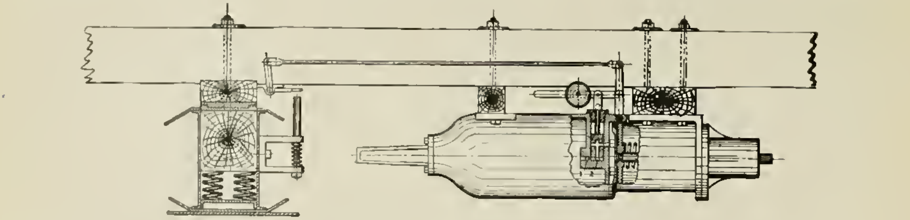
The most interesting and important invention of Mr. Haberkorn is his automatic car governor—which is applicable to any other automatic air-brake. This device is shown as applied to the combined drum and cylinder of his brake—it is really in the pipe connecting the drum and the cylinder.

This governor brakes the car according to its load—the true principle—and prevents the sliding of wheels on empty cars—an object long sought, but generally in the shape of additions to the triple valve, or in safety valves, very wasteful of air. The valve is simply a straight plug fitted nicely into a hole, and carrying at the groove near the top a scarfed, leather packing ring that is set out by the air pressure under it, and entering from the hollow stem; the plug has a hole drilled from the bottom, and a cross-hole that allows air to pass from the auxiliary drum through the plug to the brake cylinder, as shown by the ports; when the pressure of air from the drum is admitted, through the plug, to the cylinder, it soon equalizes, and the pressure under the plug tends to raise it, and will do so unless it is held down; if it raises, the cross-hole in the plug passes the feed port to the cylinder and shuts off the supply of air—no matter how much the triple valve may be offering to the brake cylinder.

The governor valve is held down by a weighted bell crank, as shown, the weight being adjustable by a set-screw in the side of the ball. The valve has no seat and does not bottom at all, but rests on top of its case upon the shoulder of the forked connection to the bell crank.

Suppose, now, you take an empty car and find that you want to brake 70 per cent. of its weight in order to do the most efficient braking and be in no danger of skidding wheels, and you find that, say, 20 pounds is the maximum pressure you want. You set the weight so that the valve will raise at 20 pounds, and that car will not be overbraked in service, and requires no farther attention. But when this car is loaded, it is not only desirable, but necessary to apply more braking force, and, consequently, more pressure. This is done by use of the bell cranks and levers shown, which simply hold down the safety valve. The short arm of the governing valve bell crank is connected by a rod to a second bell crank, located on a shaft attached to the sills of the car over the truck. This shaft also carries an arm, so set that in being depressed it will strike a pin located on the truck frame proper. Now, when a load is put upon the car the springs of the truck are depressed, and the arm of the bell crank shaft will strike the projecting pin on the transom of the truck, and will cause a pull on the rod, and thus the holding down of the governor valve and the admission of more air to the cylinder.

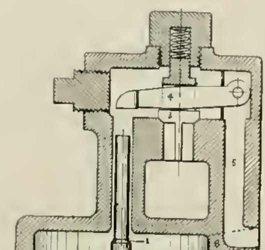
The plug valve is filed off slightly just below the cross hole that admits of a slight leak of air to the cylinder when the valve is not held down solidly, and which slightly increases the pressure when only a partial load is on the car. The spring on the pin in the lug on truck transom is quite stiff, and only operates when the car is overloaded, and by compressing prevents breakage to the bell cranks and rod.



AIR-BRAKE GOVERNOR.

This governor has been in actual use, and seems to do its work well, admitting of the application of the brakes on a loaded car to the full capacity, but effectually preventing the overbraking of empty cars.

There are enough flat wheels scrapped on every road in the country each year, from the sliding of wheels on empty cars, to put this device on them twice over. There are no packed or ground joints, and nothing to wear out. The port marked 1 is the supply port from drum, and 2 leads to cylinder through the governor valve.



TRIPLE VALVE.

Mr. Haberkorn's triple valve is a very simple one, as shown by the engraving, it has very few pieces, no sliding valves, and no packing rings. The valve case is about half the size of the Westinghouse; the main valve is a plain, winged valve, with a graduating spindle on top; it slides nicely in the case without packing. The train pipe connection is under the valve, which sets vertical, and forces it up; in doing so it passes the feed slot 7, and the air, passing around it, flows into the auxiliary drum through the port shown in dotted lines and marked 6; this port and the port to the cylinder are side and side on the flat side of the valve case to the right, and when bolted to the side of the auxiliary drum, cover the ports marked 1 and 2 in the cut of governor. While the valve remains in this position the valve 2 is against the seat above the valve, preventing any air from going above it, and the extension of the stem lifts the end of the lever 4, and thus the valve 3 that opens free communication between the brake cylinder, the port 5 and the atmosphere, through the large port.

Now if the pressure below the large valve be reduced slightly it will move down, closing the feed port 7 and the exhaust valve 3, and admitting air from above the valve and in the drum to flow around the graduating stem, and through the port 5 into the brake cylinder. when the pressure above becomes slightly less the valve will move up until it meets the resistance of the spring above the exhaust valve, which is reinforced by the pressure upon the exhaust valve itself, closing the feed port, and holding the pressure on. When emergency is applied, and a very heavy reduction made in train pipe, the large valve travels clear down, withdrawing the graduating plug 1 entirely from the feed port, and admitting the full pressure of air to the cylinder at once.

This valve has very little friction, moves easily, and is simple; it has been doing satisfactory service for some years, both alone and mixed with other air-brake cars.

The Haberkorn Air-brake Co., Ft. Wayne, Ind., are the builders, and have twenty-five sets of their brakes set up and at work in their shop, that seem to fill all the requirements of automatic air-brakes.

The Grand Lodge of the Brotherhood of Locomotive Firemen will convene in biennial session, on the 10th day of September, in the city of San Francisco. The 400 delegates to this convention will be well received on the coast; western people take to organizations. The firemen are composed principally of young, vigorous men, and their Grand Lodge has the reputation of being the finest looking body of men that meet in convention. Lieut-Gov. Robinson, of Canada, said at Toronto, that they eclipsed in personal appearance the picked troops in the British army. Before federation was consummated it was deemed advisable to change the name of the order, so as to include all enginemen in the title, and there is little doubt that it would have been carried out at this convention. It is not considered essential now, and the scheme will probably not be pushed.

The Engineers' Brotherhood will meet in October in the city of Pittsburgh, Pa. A very large attendance can be counted on, and when it comes to discussing the federation or no federation question, things may be warm and interesting.

The new "class P." 8 wheeled passenger engines on the P. R. R. have wider cabs. On the last lot they had to pick out their thin men to sit beside that Belpaire fire-box.

When you write for publication, always write on one side of the paper, and sign your own name; if you do not want it published, just put it under your *nom de plume*.

Correspondence

The Boyden Air-brake.

Editor The Locomotive Engineer:

In looking over your Number 7, issued for July, 1890, on page 122 I note, under the head of Boyden Air-brake, on the last line of the article, you state "It is in use on the B. & O." I would be obliged to you if you would correct the same, as this brake is not in use on the B & O., except on four cars, on which the application is entirely experimental.

Respectfully, G. B. HAZLEHURST,
Acting General Supt. M. P.

Baltimore, Md.

[The editor has been given to understand that the brake was in use as stated, and with this idea repeats the assertion in the July issue. When we are misinformed we are glad to know it.]

Radical Cure for Lubricators that "Feed Across."

Editor The Locomotive Engineer:

I am an old Mossback. I do not believe in cylinder oil, I like good old tallow; I do not believe in the sight-feed lubricators; steam when kept good and dry is the best lubricator that can be used, put a little tallow in cylinders when you shut off, going down hill.

If "New England" tallowed his cylinders from the cab he would not have had any trouble as he describes.

Let us hear from everybody on sight feeds and cylinder oil.

Texaline, Tex. "OLD MOSSBACK"

Big Engine—Slipping—Vacuum—Brakes—Electricity.

Editor The Locomotive Engineer:

In reading the June number of THE LOCOMOTIVE ENGINEER, I see where W. E. Andros, on page 108, says that big engines have no tendency of doing the engineers up; will he please give us a little more explanation of what he means, and I will show him how big engines have done us up, and done us up badly, too.

I read so much in your paper about engines slipping with steam shut off. I never had any to slip as I read it, but I had them to lock and slide on a bad rail for ten or fifteen feet, until the train would bump the engine, and then the wheels would revolve as nice as could be; this was on a grade of only sixty feet to the mile. I know how the vacuum brake works; will some one please tell me how the automatic vacuum brake works, and also did any one ever experience any electricity about an engine while it was blowing off steam?

Baltimore, Md. OLD TIMER.

On the Care of Cab Brass.

Editor The Locomotive Engineer:

I notice in nearly every issue of your valuable paper some fireman giving receipts for polishing and scouring brass, blacking boiler heads and front ends, scrubbing cabs, etc.

I would like to give these firemen a receipt that we have down in this part of the country, and that is, don't scour at all; black all the brass, keep engine wiped clean, and she will make the time just the same.

We have large engines, weighing from forty-five to sixty-five tons, in both passenger and freight service, and when a fireman has stoked away from five to eight tons in 130 or 140 miles on passenger, and from ten to fifteen tons on freight, we think he has earned his money.

I would like to hear from some one who has a receipt for a black paint or varnish that can be applied to cold brass and will not blister or scale off.

We have all found from experience that hot brass can be turned a jet black by applying a little signal oil and water occasionally. Let us hear of some way by which railroad officials can be prevailed on to abolish this everlasting scouring and scrubbing.

Mattoon, Ill. FIREMAN

The Mystery Solved at Last.

Editor The Locomotive Engineer:

Engine 170, a Roger, consolidation, 20x24, weight 110,000 pounds, on the Henderson division, L. & N., used to slip, without steam, when going down hill. As engines are run "chain-gang," most every man here has run her and had the same or similar experience. She would slip on a dry rail but was worse on a wet one.

One's first thought was a broken equalizer or spring, or that side rods had gone. Some thought she was about to strip herself and would get back on the tank. Sand would generally stop it.

She never did this until she had been overhauled, and the foreman said her left main tire was left ⅛ of an inch larger than the others—by mistake—and was positive that caused the trouble.

I have known this difference in size of tire to exist on other engines and they didn't slip.

Now if that was the cause why didn't she slip on every down grade?

She would sometimes make a round trip and behave all right and again she would have several "fits" in a day or night.

Fritz, our favorite German machinist, and a good one, said it was because she was turned out on Friday. H. DIV

Nashville, Tenn.

Is It Caused by the Side Rods?

Editor The Locomotive Engineer:

I have just been reading W. F. Relyea's account of engine slipping without using steam, and would like to inquire of him if the engine slipped before solid rods were put on her, and what the difference in weight, if any, is between new and old rods?

Have also read Wm. Bosley's account of same trouble, where it was caused by counterbalance being too heavy.

It has occurred to me, after reading both articles, that the solid rods on the engine Mr. Relyea mentions may be heavier than the ones that were originally made for her, and would work in the same manner as an excessive counterbalance. Am I right or wrong? WM. P. ARNOLD

Chicago, Ill.

[There would be little difference in weight of solid and loose strap rods. Mr. Relyea's idea is, that slipping is caused by excessive or uneven counterbalance, such as would be caused by a twisted axle; the particular point he made was that the engine slipped while being towed in with her main rods down.]

The Most Reasonable Explanation of Cause of Slip When Shut Off.

Editor The Locomotive Engineer.

Though the reports which have appeared in your columns lately of engines slipping ahead while running down hill without steam savor a little of the uncanny in railroading, yet I offer the following suggestion of a possible cause, which can be worked out in cold figures by any one having the time.

Your correspondent, Wm. Bosley, stated in your last issue that his 17" 8-wheeled Brooks engine slipped badly going down hill at 45 miles per hour, after receiving a new main wheel which had an excessive counterweight, and also that this slipping ceased entirely when the excess of counterweight was removed. This statement is close enough for my hypothesis.

"Nosing," as it is sometimes called—the side swinging motion so familiar in the cab—is due to a horizontal couple produced by the joint action of counterweights and reciprocating parts tending to turn the whole engine about a vertical axis passing through its center of gravity, and is all transmitted from the wheels and axles by a greater or less forward and back motion of the driving-boxes. In a case of excessive counterweight in one wheel on an axle both ends of the axle will travel forward and back, relatively to the engine, very rapidly at 45 miles an hour.

When a driving-wheel is over-counterweighted, its rotation about its center is exactly on the same plan as the whirling of a ball about a center to which it is attached by a string, as the center of gravity of the wheel is not at its center of rotation. Now take a ball or chestnut tied to a string and whirl it as in boyhood and notice that, if you reproduce the horizontal back and forward motion I have mentioned, the ball can be rotated at great speed. Each counterweight in a pair of driving-wheels produces this motion for the wheel at the other end of its axle—and I think the testimony goes to show that the energy developed is sufficient to skid the wheels. As I say, it can be calculated. Of course this energy is supplied by the train shoving the engine down hill, and its expenditure can be shown to act as a brake on the train. Set some brakes on your train and see if slipping does not cease.

Mr. Bosley also said that pulling reverse lever to center stopped slipping—when lever is in this position lap keeps both ports closed, and in a balanced valve very little steam or air can pass into steam chest past edges of valve. In this condition air is drawn through cylinder cocks in quantity, and, as it cannot escape, soon both pistons are working against heavy back-pressure, such that the wonder would be if wheels were not locked to slide without turning. E. H. MUMFORD.

Detroit, Mich.

A New Way to Rate Loads for Fly Runs.

Editor The Locomotive Engineer:

Hearing a conductor bragging about a "fly run" he made with a ten special, calling it a "picnic," I asked the engineer about it—not supposing, of course, that he helped to make the "picnic" run; he said:

"It was a pretty good run, and I guess it was a picnic for the conductor—the fireboy found him asleep in the doghouse at Arena. The 'picnic' I had was not so easy. The last trip in, I asked the boss for some extra tender brasses; and just about that time Jim, the car repairer, came along, and told the boss that all the hand cars used one kind of brasses, and that just mixed the thing up, so what did he do but throw on a lot of old Roger brasses that wouldn't fit the 218—as she has no M. C. B standard axles, and, to make things worse, that new man in the office got an idea that in giving a 'special' orders, it must be a mile for each car, we had forty loads, and the dogon fool gave us a forty mile order, I just had to fan them, and the first thing I knew, one of the tender-boxes got hot, and the fun commenced. Every stop we made, the fireman would have to oil around, while I poked dope and dirty waste in that tender box, for I couldn't get one of them brasses in, and that is just the way we had to monkey along all night to get over the road."

I wonder if that dispatcher won't get a patent on that new load and speed chart of his.

Fly runs are generally made on the tail end of the train, but let a poor run be made on account of hot boxes, poor dispatchers or any other cause, and it's the engineer—but I guess most of the boys have been there. W. DE SANNO.

Corry, Pa.

Not a Hero.

Editor The Locomotive Engineer:

Noticing in your June issue an article under the heading, "Don't Take the Risk," I would like to give you my experience. On March 7, 1888, I was pulling passenger on the Cincinnati Southern, between Oakdale and Chattanooga. I was running about 45 miles per hour, when, just before I struck the switch at Lorraine, Tenn., I noticed the switch rail point, which was a spring connection, sticking out about *a mile*, it looked to me. I barely had time to slap on my air and made a break for the gangway, but before I reached it she turned on her side with the tank, baggage car and two coaches on top of her. The last thing I remember was seeing the ground going past pretty fast, about one inch from my nose. I got a great send-off in the daily papers for "sticking to my post," and saving the lives of a hundred passengers. There were only seven passengers on the train—a pumper, traveling engineer, one passenger agent, one supervisor, and three section men, and if the parties who wrote me up in the paper had seen me hustling to get off, they would never write up another engineer who "stuck to his post" and "risked his life to save his passengers." I would rather be a live coward than a dead hero. BOB M.

Colorado City, Col.

Which Way do They Slip?

Editor The Locomotive Engineer:

I have been taking your paper about two years, and take great interest in some arguments found therein. In these arguments a man finds food for thought, that otherwise he would never, probably, have thought of at all. In several issues past I have noted opinions of different persons as to cause of engines slipping while running down hill. *If* such is the case, why is it? I would like to ask one question of these men who claim that one thing or another causes it. I have been trying to get it into my thick head which way they mean the word "slipping" to be construed—wheels revolving faster than speed of engine calls for, or, so to speak, nearly stopping or entirely so? In my opinion the slipping of drivers *ahead* is in such direct opposition to natural laws as not to apply to this case, probably I may be quite mistaken as to their meaning

Reading, Pa E A G

[It is claimed that the engines mentioned slip their drivers *ahead*, while running shut off—just as they would if steam was used.]

Some Observations on Bad Steaming Engines.

Editor The Locomotive Engineer.

I have been firing several years, and, like all other men of my calling, my greatest dread was a "bad steamer." I was on several of them, but always with the same engineer, and guess I never would have struck a free steamer if Ben hadn't gone away to get married, and I got onto the extra list. I suddenly found good steamers—even some of the hard old pills I had hated before.

Then I began to inquire into the "cause why," and to observe I soon found that the way water was supplied to the boiler had almost as much influence on the steam gauge as the way coal was supplied.

I found that the men who were "even pumpers," who kept the water at about the proper level, supplied it evenly, increasing the feed for heavier work, and decreasing it for lighter work, generally ran good steaming locomotives.

I also found that the men who slap on the squirt full head on starting out, and shut it off when they have three gauges in the stack, have poor steamers.

I pray for the former and play for the latter—pray that I go out with the one, and play I am sick when marked up to worry with the other.

Philadelphia, Pa. B B. B.

Some Facts About the "Neversink" and Another Early Locomotive that Exploded.

Editor The Locomotive Engineer:

The enclosed letter will explain itself. It goes to confirm my statements, leaving the cast-iron stay bars unsettled. The Dr. Lardner referred to was charged at that time in the newspapers with not confining himself strictly to scientific affairs, and possibly was in error as to the cause of the explosion. J Bourne.

Newton, Kas

JOHN BOURNE Dear Sir: Having read some articles by you in the May number of that most excellent paper, THE LOCOMOTIVE ENGINEER, to which I am a subscriber, I write to state that you are correct as to the explosion of the "Neversink."

That engine was an 8-wheeled combined, built by Baldwin for the P. & R., and it exploded Thursday, Jan. 14, 1847, near Mill Creek Bridge a short distance above Manayunk. The *Railroad Journal* for January, 1847, contains a full account of the accident.

Regarding the explosion of the Norris engine to which you refer, the engine was named "Richmond," was one of a pair built for the P. & R by Norris Bros., Phila., 1844, and exploded near Reading, September 2d, 1844, killing engineer, two firemen and the conductor.

This explosion occurred during a violent thunder storm and was supposed to have resulted from the engine having been struck by lightning

It was investigated by a celebrated engineer and scientist, Dr. Dion Lardner, commissioned by Norris Bros., and I have before me an elaborate copy of his report. It was most satisfactorily proved that the engine was well built and that the cast-iron stay bars (although a faulty plan of construction) had nothing to do with the accident. The boiler iron was subjected to tests and found A1, pumps worked perfectly, and the engine drew easily 700 gross tons, a large load for such an engine, having cylinders 14½ x 20, drivers 46", and weighing but 36,925 with wood and water The mate was the "Atlantic" I write this thinking it may be of interest, and hope to have Mr. Hill publish the full account of it.

Chestnut Hill, Pa. HENRY L. NORRIS, JR.

How a Train Runs Down Hill.

Editor The Locomotive Engineer:

I notice an article in your July number, signed J. H. Burrell, Jr., in which he states that the tendency of the locomotive on a down grade is to run away from the train, and that the train holding her back is the cause of the slipping of the drivers after steam is shut off

I well remember of an instance of a freight train running away on the Jamestown road between Dayton and Gowanda. I think the distance is eight miles, and the grade 132 feet to the mile. Engineer Walter Russell was running the engine, and the speed was so great that it was with difficulty that he could keep his feet or hang on, and he stated at the time that the engine was running about as fast as it seemed possible to run, but every few seconds the train would give the engine a push which increased her speed.

I think there is a good deal of imagination in regard to the engine slipping after steam is shut off. I ran an engine over twenty-five years, and can say that I never remember or knew of my engine slipping her drivers after the throttle was shut off and the steam had left the cylinders, unless she was reversed.

Any engineer will tell you that, especially on freight trains, after shutting off steam they can feel the engine fall back on the train, and the buffers will always come together on a heavy down grade.

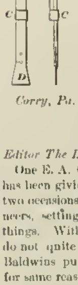
W. H. H. WEBSTER.

Chatham, Ont. U. S Consul.

Making an Engine Steam with a T-Square.

Editor The Locomotive Engineer:

Enclosed please find sketch of jig for setting exhaust nozzles; and in nine cases out of ten where crooked nozzles prevent an engine from steaming this jig will remedy the trouble. Take two pieces of pine 1¼x¼, and of proper length, put bands around making a slip joint tight enough to stay where put; in lower end put in sheet brass fish tail *D*, square with the center line of gauge. Clean off top of nozzle, set gauge on central, and see how the point ranges with center of cone, fore and aft and across, if it does not range central face off bottom joint of nozzle (not exhaust pipe) until it is right. For double nozzles the gauge must be used right and left, and it will make a straight shot every time. It is not patented



Corry, Pa. W. DE SANNO.

On the Old Subject.

Editor The Locomotive Engineer:

One E. A. Campbell, Supt. M P. and Machinery, has been giving his opinions quite freely on one or two occasions recently in regard to traveling engineers, setting of valves, lost motion and other things. With all due respect to Mr. Campbell, I do not quite agree with him when he states that Baldwins put hammer-fit bolts in eccentric blades for same reason that eccentrics are keyed on shaft, viz., to keep meddlesome engineers from monkeying with those things. Eccentrics are keyed on shaft, and hammer-fit bolts are put in eccentric blades to keep them secure in place in service. Mr. Campbell does not have much faith in the ability of locomotive engineers, it seems; I wonder what he pays his engineers per day.

I would like to be "sitting on a hill," and behold one of the little mogul type 11" by 16 hauling thirty-five loaded, 50,000 pounds capacity cars. I just imagine that he would need to give her more "lost motion" in the shape of another "little mogul." She might sound square through after the ten-minute racket. When I see engineers and firemen sitting about roundhouse telling about fast runs and great steamers, I have some suspicion that such men are a leetle disappointing when out on the road, this often applies to others besides engineers and firemen. From ten years' experience running a locomotive, I am in favor of a good, reliable traveling engineer; one that understands his business thoroughly will save thousands of dollars to a railroad company yearly, while the sort of man that some roads employ will never save anything. I am not in favor of lost motion in valve motion or running gear of locomotives.

Pittsburgh, Pa. J. J. CLAIR.

Explaining an Explanation.

Editor The Locomotive Engineer:

I suppose I will have to be a little more explicit on my ten-minute racket of valve setting for the benefit of our friend Mr. C. F. Richmond, as I feel a little aggrieved that he should think that I would deviate from the truth when I am penning these articles for the benefit of my fellow-men and not for a financial consideration. I will tell it in another way, and I think he will catch on, and if he does not, just tell him to call on me if he is a subscriber for this paper. I will take pains to show him that I am perfectly truthful in my statement.

Take a valve gauge about two feet long like this

Gauge your valve with it, make center-punch mark on your steam chests, base or any part of cylinder that is stationary, then gauge your valve stem back of knuckle, if rod has one. Any way, gauge the length of gauge; in this way you only have one tram or gauge to handle; then take your wheel centers from main rod as it rises and falls with uneven track, but every time after main rod is run you always have to take center over; now in this way you only have to take centers on one side and use travel on the other. Now, Mr. Richmond, do you catch on? You misconstrue my meaning about using liners on shoes; if you do this you have to alter parallel rods, and all this is more trouble than chipping out holes in eccentric blades of old engines.

You are off on the inclined engines; you get the length of valve rod the same as straight cylinders; if not you could not throw her out of gear.

I simply told you as regards to gauging valves to take off steam chest cover, to prove my assertion in case you doubt it. E. A CAMPBELL,

Houston, Tex. Supt. M P & Mach'y

Speed of Heavy vs. Light Trains.

Editor The Locomotive Engineer:

In your July issue you say that Mr. Burrell, Jr., "is wrong in presuming that a heavy load will run faster on a down grade than a light one."

It seems to me that Mr. Burrell, Jr., is right, and "ye editor" on a wrong tack, for it seems to be shown on all sides, from the boy and his sled to the freight train, that a heavy load will run faster, other conditions being equal, than a light one.

A heavy man on a heavy bicycle coasts away from the "spider" on his "light roadster" every time, and the same seems to hold good in all cases. If there is no difference, why does the D & H. C. Co. grade their gravity tracks so as to give the "empties" a steeper incline than the "loads" to acquire the same speed?

I suppose you will cite the case of the two falling bodies of unequal weight, and you *may* be right, but it doesn't seem so to me, as rolling down and dropping down do not appear to be just the same kind of a dose. O. H RIDGWAY.

Swampville, Pa.

[In a vacuum a light weight and a heavy one of equal size will fall at the same speed. In the air the heavy one will gain slightly on account of the resistance of the air On a railroad grade, a heavy car of exactly the same size of a light one would meet the same resistance from the air, but would have more force to overcome it, which would give it an advantage, but it would lose on account of increased friction due to its load. The reason that a train of light cars will keep up to a heavy locomotive when drifting down hill, is that much of the force of the locomotive is expended in moving the machinery. The friction is much greater on the locomotive than on the cars, weight for weight. The D. & H. Canal Co.'s gravity road has a steeper grade, in some places, for empty cars than for loads, and on this grade cars will run faster. There is no particular attempt to make them travel at a uniform speed with the loads. The loads are *hauled* up the main grade and let run down short inclines to another hoisting plant. The line provided for empty cars is long, and so arranged that the cars return all the way by gravity, and as they arrive at the place of starting their line must be of a less grade than the up line, worked by engines, with *drops* between to gain distance. Men often imagine that a loaded train runs faster than a light one because it takes more force or a longer time to stop them. The braking force must be in proportion to the weight as well as the speed. Of course, when a very high speed is attained, the resistance of the air acts as a brake and tends to slow down the light car more than the heavy one, if their areas are the same.]

A New Fire-door Deflector.

Editor The Locomotive Engineer:

Enclosed sketch shows an improvement made to a P. R. R. "Class O" fire-box door, now being tried on Engine No. 1053 for some time, and showing very good results.

Fig. 1 shows a vertical section of the door closed, Fig. 2 the position of liner when the door is opened, and Fig. 3 the liner itself.

I use the standard casting for fire-door and liner, and hang the liner on two eye-bolt hinges, as shown at *a a*, placed a little above the center, so that it can swing freely. On the top of liner a finger, *b*, extends above, so as to come in contact with ring on fire-box when door is closed.

The door casting has very large opening cut clear across above the center line, to admit of a large volume of air. This is regulated by a suitable slide.

When the door is closed the liner is automatically pushed to the angle shown in Fig 1, and the air passing in through the openings, being deflected upon the fire, is more perfectly mixed with the gases. When the door is opened the liner falls to the same position as in the old style, or common door, and as shown in Fig. 2.

I claim for this arrangement that it will save some little coal, will burn most all the smoke—in fact, has all the benefits found in using the English style of fire-door or deflector, without having any of its faults. J R ALEXANDER

Pittsburgh, Pa.

A General Manager's Idea of the Slip.

Editor The Locomotive Engineer:

From the number and credibility of the engineers who have witnessed the slipping of drivers, it must be conceded that they do slip, improbable as it may appear at first thought.

My explanation of the slipping is that the top of the wheel travels faster than the bottom, and when this extra velocity, combined with the weight of the driver, its counterbalance, rods and pins, overcomes the traction, that it must slip. Speed is all that is necessary to cause it, and they all agree that the slipping occurs only when running fast. Car and wagon wheels, running on the track or ground, are the same as a planet wheel, the bottom virtually being the center, around which the rest of the wheel revolves, the point farthest from the bottom traveling fastest, of course. This theory would slip every wheel in a train, if running fast enough, and it would make the top of a wheel travel 120 miles an hour when the engine was going 60.

ALLEN WOOD,
M. M. St. Augustine & South Beach Ry.
St. Augustine, Fla.

Only True Principle of Signaling.

Since the subject of signals, block or otherwise, has become a living topic among American railroad men, our inventors have gone to work to supply something for the demand.

Devices of all kinds are schemed up, many of them very ingenious ones, but the great majority of them are useless and some actually a source of danger instead of safety.

The great trouble with our signal inventors is that they do not fully realize what a system of signals should do, and mistake *time* for *motion*.

The most popular delusion is the automatic time signal—that class of signals that by clock-work, electricity or the flow of liquids, record the time that has elapsed since a train or engine has passed it—these signals do tell the engineer of the following train just how long it has been since the train ahead has passed the signal, but it fails to tell just what is most necessary to know—is it far enough away to allow the following train to run regardless of it?

The first train may break down and stop in the cut just around the curve, but the time signal may tell the engineer of the following train that it has been gone twenty-five minutes. It is not necessary or desirable to know how long a train has been gone, but it is necessary and desirable to know if the line is clear to the next signal.

No engineer can make extra fast time with comfort or safety when he is constantly expecting to find something in his way. If he knows that the next mile or two miles is clear, he will run at high speed with confidence.

Positive block signals are the only safe ones and the true principle; all others must give way for it in time—because it is the best. Block signals for double track roads are easy to design, construct and operate; a satisfactory and efficient block system for our great, single track lines is not so easy to design, construct or operate, and there is room for invention in that line; but don't go off on any half-way measures—every signal should say to the engineer either, "Line clear" or "Stop."

The positive block has always been a success—all other plans are, so far, in the nature of experiments—many of them disastrous ones.

Two Wabash Kinks.

On some sections of the Wabash road they are troubled with bad water, and all the engines are

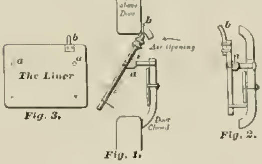


Fig. 3. Fig. 1. Fig. 2.

FIRE-DOOR DEFLECTOR.

rigged to blow out the boiler, if necessary, when running. The blow-off cock is a very large one, designed by Supt. of M P Barnes; it is located under the waist of the boiler between the guides, and opens toward the inside, so that the pressure tends to close it. There are no threads to stick, but the stem is forced in by a system of compound levers, operated by a handle on the running board. There are provisions for blowing out from either side of the engine, but this can only be done by taking off a cap on one pipe, and putting the blow-off pipe on there. This road also used a square, cast-iron whistle that is very efficient; is made in one piece, and has no machine work on it except to thread the stem and cut out two steam slots about four inches long and a thirty-second wide; cost about one-third of a brass whistle as usually made.

What has become of that big locomotive works that was going to be built at Cincinnati, the capacity of which was stated as being "750x500 feet, covering nine acres of ground, with a capacity of a locomotive every nine hours"? Now that the speculation on lots in the neighborhood of the proposed site has died out, we hear no more about the "works." By the way, there was just such a works to be built in Philadelphia last year.

Considerable interest has been manifest in the subject of sight-feed lubricator not delivering the oil to each cylinder in equal quantities, but so far most of those who write simply state that feeding "across" can or cannot occur. All the facts that can be gained from experience will be instructive—let's have them.

Repairing Injectors.

By J. B. RICH.

There may be fields in which the diabolical repairer gets in more effective ruination work than repairing injectors, but I doubt it, the natural tendency is to bore out some hole "so the thing can get a chance to work, these makers are afraid they'll do too much," and, as nature rules here, the tendency is followed.

The first instruction of a code of rules for repairing injectors would be—Don't; but why? is asked. Because the average repair man—*i. e.*, general repairs—though he may understand the working of an injector pretty well, doesn't know the necessary qualifications and proportions that must exist, to do the work properly. If, in connection with the repair shop, there is a brass shop with good facilities, it is not such a foolish undertaking as without, but it seems plain that a place where the parts are made in quantities can turn them out cheaper, and, what is more essential, exact in size and proportion, but many railroad shops are run for the sake of saying, "We do all our own work," apparently regardless of cost, and as these will persist in repairing things they know very little about, a few words may not come amiss. In the first place, note before you take an injector off how it was placed; if you can't remember, mark it. I see lots of men laugh at the idea of not knowing how an injector goes up, but I've seen more than one experienced engineer get them up wrong end to, and they were not drunk or crazy, either—forgot. If you feel it your duty to explore the internal regions of the animal, do it carefully; a crowbar and sledge aren't often needed, and remember how the tubes and parts came out (another smile of incredulity, perhaps), but again let me say I've seen them put in wrong, it will do no harm to note the relative positions of the parts, and may save a bad mistake.

Perhaps the tubes are worn large, as is often the case, some seem to think if they bore them out smooth—no matter how large it makes them—the steam and water will think it's all right, and slide in just the same as before—but they don't. You can rest assured the makers know somewhere near the right size for effective work, almost as well as the repairer, and it might be as well to follow some where near in the old lines as far as sizes go. The distance from tube to tube, also, has some effect, so don't bruise the ends poking them out, and then cut them off smooth, thinking the water won't mind the extra jump; sometimes it does. Remember these things, and if you must tinker—and some have to by company's orders—do it as nearly like the instrument originally was as possible. Sometimes the ball joint or seat of the union gets leaking, and it is necessary to re-seat it. We usually see a ball rose reamer filled with soap or similar substance to prevent "chatter" on the seat. All this is unnecessary, for with a "mill" tool properly cut there need be no chatter. Properly cut don't mean cut with precision in spacing the teeth, just opposite—cut hap-hazard, without regularity at all; pay no attention to spacing, but make the teeth as uneven as possible, and you'll have a smooth cutting tool, the principle is the same as in the file—what ailed the first machine-cut files was, they were too regular—spaced evenly, and they chattered badly; they've changed now. So it is with reamers and the like, more particularly "face reamers," as for ball joints in unions.

If some of the writers on locomotive valve motion, size of ports, back pressure caused by use of link, etc., would stop to think that while a well-designed link motion will give from 10 to 14 square inches of opening for the exhaust at the end of the stroke, the steam has to force itself through a nozzle of only five or six square inches area, it would ofttimes change the color of the alleged faults.

While most of the States have laws, more or less bad, governing the size of openings, etc., in smoke-stack and front end spark arresters, little if any attention has been paid to the fires caused from faulty construction or careless use of ash-pan slides and dampers. More fires are caused by the latter than by the former.

NEW YORK, AUGUST, 1890.

CONTENTS.

A Committee of Safety.

Grievance committees of labor organizations, especially railroad organizations, are formed as a sort of legislative committee to look after the interests of the whole body, especially in the matter of the dealings of the order with the company. The duties they are designed to perform are necessary, perhaps, and certainly time-saving and economical to the body; but the duties they often do not perform cause endless trouble and turmoil.

The protection of individual members from wrong and injustice is laudable and right, and cannot be carried too far where justice is given to others as well as demanded for the members.

There seems to be a great unworked field open to the orders in protecting the members and in providing for the widows and orphans of men who meet their deaths on the road. We refer to the power of the organizations to collect data concerning the condition of the road and its appliances on which they are employed, to be used as evidence where members are prosecuted for manslaughter, when accidents occur for the want of proper safeguards. How often it happens that when a man is killed the blame of the accident is laid at his door, and a cheap settlement is made with his family on the basis of his being to blame. Evidence to refute these charges, in the hands of a good committee, would prevent the cheating of widows and orphans, and lighten the load of sorrow on their minds in clearing the name of the victim of some open draw without a signal, or break-in-two, where no automatic brake was in use.

Suppose the grievance committee of every lodge of engineers and firemen in the land would prepare a certified statement of the condition of each division of every road on which its members ran, stating the present conditions of signals, switches, track, bridges, etc., the engines and cars, and state what modern appliances for safety were needed and wanting.

With it well known that this committee had such facts and figures at its finger ends, and would present them before any court, or in any press, to defend its members from wrong, there are few railroad officers who would dare to constitute themselves judge, jury and executioner, to condemn men as they do now.

If a bad system of train dispatching was practiced, how easy to collect evidence and demand a reform.

Is there a low bridge or a dangerous obstruction on the road? What would be the result if the superintendent were informed by an authorized committee of its existence and danger, and that the order or orders would hold the road responsible in case of accident to employes? The obstruction would be removed, or other means employed to avoid accident from the cause stated.

With such data in the hands of the men, railroad commissions could easily find dangerous practices and appliances, and demand reforms on lines in the right direction. Such data would not hurt honest managements who were really trying to furnish the best service possible, and it would prevent a lot of injustice and oppression now borne by employes.

Then, if the committee could go a little further, and report to the lodge, or the officials of the road, for punishment, all men who knowingly disobeyed rules of safety—these fellows who won't stop at grade crossings and drawbridges, who cut off and run for water, leaving the train to follow, the men who neglect to whistle for road crossings, forget to look at the bulletin board, don't examine their engines at the end of runs, and test the brake when they want to stop first, instead of before they leave terminals. We need men who look out for these things just as bad as we need signals, safety switches, brakes or protected draws, and just as bad as the trainmen need automatic couplers.

What would be the matter with a "committee of safety," who would hunt for every fault that threatened the safety of train and enginemen, and their passengers, and demanded a remedy for that fault, be it what it may, and counting the faults of the men just as dangerous and as badly in need of reform as the faults of the management? Would not such a plan be of equal benefit to the men, the company and the public?

The Commission Fever.

The arrest of ex-purchasing agent McKibben, of the Union Pacific, for doing too heavy a commission business, created only a nine days' wonder to the public, but his case has made many a railroad man wish that he "wasn't in it." Mr. McKibben, it seems, if the reports are true, was not fair with his company—it's a mighty mean purchasing agent who wants more than a 50 per cent. commission.

When a man, railroad employe or otherwise, puts himself to trouble and pains to introduce another's goods, it is but fair that he be paid for his services, but when a railroad puts the power to purchase supplies into the hands of a man because of his knowledge of prevailing prices, etc., and pays him a liberal salary, of, say, $10,000 per year, he ought certainly to do his best to buy goods as reasonably as possible, and not demand more personal profit than the original producer, and all the intermediate dealers combined.

It is not only the purchasing agents that have a finger in the pie; the commission itch is contagious, and has been known to affect all hands, up to the president. It has come to the point where dealers are plainly told that "*cheapness* is a secondary consideration; charge enough to pay about three commissions."

The "commission" fever is at its height just now—same as the Canadian fever among bank men—and will soon be declared epidemic by convening councils of stockholders—then there will be a quarantine and—reform (?)

The stockholders of American railroads pay about as much attention to the property they own as a sea turtle to her family; the turtle lays her eggs in the sand and goes off on her vacation, expecting to find a half grown family of turtles when she gets back—and is mad if she don't—the stockholders buy the stock, put the property in charge of a manager, and demand *dividends*. Let the motive power department keep the rolling stock up on as small a per cent. of the earnings as possible, or let it go down; the freight and passenger agent cut rates, the purchasing department collect toll for doing its work; put in stone ballast or cut wages and shorten hours—no matter, so long as a dividend is paid.

Maybe, sometime, railroad stockholders will keep an eye on the way their property is handled—just as they would if they bought a store or other private business.

Wanted, "Company Men."

We recently heard a young motive power officer express the wish that he belonged to a certain "gang,"—thought it would be worth considerable money to him.

He did not refer to any order or society, but to one of the organized bodies of supply dealers, who do business by processes now well known, but that are not always considered perfectly "straight." To all the young master mechanics who have an ambition to rise in their profession, and the older ones, too, for that matter, we want to say that the safest and best plan is not to belong to any "gang."

Be known at home and abroad as "a company man"—the railroad company's man. Put your best energies into your work, do the best you can for the company you serve, and let others do all the scheming, take all the bets, and drink all the wine. You will sleep well, eat regular, and stay as long as you want to, and go up higher when there is a chance. Keep on good terms with your men, and try to have among them the name of being just—remedy a wrong for them, just as quick as you do for the company. Don't be afraid of being called a "company man." If there is one thing above another that the railroads of America need in their motive power departments to-day, it is "company men."

The Regular Juggernaut.

A dispatch from Sycamore, Ill., dated July 23, says that a mail train ran into an open switch, collided with a freight train, killing a fireman, and adds, "The cause of the wreck and damage have not been ascertained." It looks to a man up a tree as if the cause was very easily explained; criminal carelessness and inadequate appliances had a good deal to do with it.

Every switch ought to operate a signal from the rails themselves, that would give the approaching engineer time to stop before reaching it if it was set wrong, this for single track lines. On double tracks no switch should have a facing point, then there would be no switches to run into. First-class roads are so protected. It would be a big improvement on some of those roads in the Middle States, if they would pay living wages to real, live trainmen. These two-for-ten-cent, make-believe brakemen don't know enough to shut a switch after a train has gone into it Ten enginemen have lost their lives since the first of July through this very class of accidents.

Promotions.

Judd Barnes, engineer, has been promoted to the position of traveling engineer of the Mountain divisions of the Denver & Rio Grande road, vice W. D. Lee, resigned to go into private business. Both these men were first-class engineers—as high a compliment as we can give any railroad man. The writer of this had the pleasure of doing considerable railroading "along of" both men in the early days of the Rio Grande's mountain climbing.

A E. Welby, formerly chief clerk to the General Supt of the Rio Grande Western road, has been promoted, and now fills the chair of his late chief.

Mr. William H. Owens, who has been for some years general foreman of the Richmond & Danville shops at Manchester, Va, has been appointed master mechanic of the Georgia Pacific, with headquarters at Birmingham. Mr Owens is one of the thinking young men who will make his mark.

Books Received.

THE OFFICIAL RAILWAY LIST FOR 1890 Being a tabulated list of all the operating officers of Railroads in North America Edited by Walter D Crossman. Published by the Railway Purchasing Agent Co. The Rookery, Chicago Price $1.00.

This list is the most complete, and in the most compact form of any published, and seems to have been carefully edited. It contains cuts of a number of the M C. B standards and other information of interest, together with a very large amount of advertising The chief value of the book is its official list, and is the best to buy, as it gives in condensed form, beside the names and addresses of officials, the length of road, gauge of track, number of locomotives and freight and passenger cars in service.

SPON'S ENGINEERS' AND CONTRACTORS' DIARY AND REFERENCE BOOK FOR 1890. Being a large blank diary book for use of contractors in machinery or on other engineering work, containing also numerous valuable tables, the recent reports of English engineering societies, and other information. E & F. N Spon, 125 Strand, London, Eng., and 12 Cortlandt st, New York. Price 50 cents

This is a large bound book of 200 pages, and would no doubt be of especial interest and value to contractors doing engineering work in the English colonies, and away from the home markets, as pretty nearly everything of an engineering nature is advertised in the book. It is much cheaper than any blank diary of the same size could be furnished.

PRACTICAL SANITARY AND ECONOMIC COOKING, ADAPTED TO PERSONS OF MODERATE AND SMALL MEANS By Mrs. Mary Hinman Abel. Published by the American Public Health Association. P. O. Drawer 289, Rochester. N. Y

This little work is one of the well-known "Lomb Prize Essays," and is issued by the American Public Health Association at actual cost, Mr Henry Lomb, of Rochester, N Y, giving the author a prize of $500. The inscription of the book is, "The Five Food Principles, illustrated by Practical Receipts"

The author starts out and explains, in an entertaining way, the principles of preparing food; assuming that the housewife has only the commonest utensils and moderate means, she "gets right into the flour," and really gives something practical, new and valuable. The author attacks and exposes some of the wrong impressions about food, and gives sensible and plain instructions in the economical and healthful handling of home kitchens. She shows how to make the most out of a little, and do it well, and her work has the advantage of having been critically examined and endorsed by a board of scientists that make a study of sanitary and hygienic systems and methods

There are numberless receipts, sample bills of fare for different seasons of the year, and a few sample menus for cold lunches that ought to be of interest to those who prepare and those who devour dinner-pail meals—and most of our readers know what that means.

The book is entirely new and clothed in new garments—it is nothing like your old cook book at home—it has nearly 200 pages, and is well worth the price asked, 40 cents bound, 35 in paper covers.

ASKED & ANSWERED.

(47) E. A. G., Philadelphia, asks:

An engine is square in the corner, but hooked up two or three notches is lame. Where is the trouble likely to be? *A*—In the position of the suspension pin or link saddle pin, and in the position of the tumbling shaft

(48) J J. C., So. Dorset, Vt, asks.

Where is the Monitor injector made, what is it like, and how does it work? *A*—This injector is sold from this city, and probably made here It is a simple, lifting injector with independent primer, working on the same principle as other instruments of its class

(49) E. G. R, Mt Savage, Md., asks:

Can you tell me a process by which scales, calipers, etc, can be silver-plated by their owners at home? *A*.—See answer to Question 54 in this paper; there is, however, no way so good or so cheap as having it done where they make a business of such work

(50) J. B F., West Millville, Pa., asks

1 Why will an engine that has large driving-wheels slip more easily than one with small driving-wheels? 2. Why is it that the balanced slide valve saves the wear of valve, valve gear, etc.? 3. What is the weight of heaviest locomotive in service, and where is it? *A*.—1. The large wheel will not slip the most, other things being equal. 2. Because it relieves the valve of part of the load on it, caused by the pressure of the steam in the chest 3. 152,000 pounds, U. P. Ry

(51) W T. B., Minneapolis, asks:

1 In what position should an engine set when setting up wedges? 2 When there are two keys in front end of side rod how should it be keyed? 3 Is it proper to key main rod when engine is on center? These questions all apply to a four wheel switch engine *A* 1 Put the pin on the top quarter and block the wheels on the opposite side, give the engine enough steam to bring a strain on the rods, then shut off and set up wedges; this pulls the box ahead and away from the wedge 2 The two keys in the front of side rod are to admit of changing its length; if there is but one key in the back end, key it first, and then key the front, letting the rod be free laterally, when engine is on the center 3. Yes.

(52) M C. G., Durham, N C., asks:

1. Please give simple rule for setting a slipped eccentric on the road 2 Who makes valve motion models, and what do they cost? *A*—If but one eccentric is slipped, set it by the other one, suppose it is the right back-up eccentric, put that side on either center, put the reverse lever in the forward notch—because the forward eccentric is all right, and the lever throws it into full gear—make a mark on the valve stem close up to the gland, then put the lever in the back notch—this throws the back-up eccentric into gear—now move the eccentric on the shaft *in the direction it is to run*, in this case back, until the mark on the stem comes to the gland again, then fasten; this may leave the engine slightly lame, but she will haul a full train 2 The estate of F. W. Richardson, Troy, N Y., build an adjustable model, worth about $250. Pedrick & Ayer, of Philadelphia, Pa., build one, not so adjustable, but a good one, price about $70. W H. Ermentrout, Reading, Pa, builds an adjustable model of wood that sells for $15.

(53) M R. B., Alexandria, Va., writes

1. I have a lever measuring 25 inches from the fulcrum to end of lever, 5 inches from the fulcrum to valve Valve is 3 inches in diameter, steam pressure 100 pounds per square inch. What weight would be requisite to hold this valve down until 100 pounds pressure is attained in the boiler? *A*—The pressure required to hold down a safety valve is found by multiplying the area of the valve in square inches by the pressure per square inch. In the problem given the valve is three inches in diameter, which gives practically seven square inches of area, it is desired to hold this valve down against a pressure of 100 pounds per square inch, and so the valve must be held down with a load equal to seven times the pressure, or 700 pounds; the valve, and all else that retards the free escape of steam, should be counted as weight If this was a common spring pop, the tension of the spring would be 700 pounds. To find the exact weight, the weight of valve, spindle and lever must be known, and the center of gravity of the lever found Ignoring these we find that, if we follow the well-known rule, and "multiply the pressure in pounds per square inch by the area of the valve in square inches, and this product again multiplied by the distance in inches from the center of the valve to the center of the fulcrum, and the last product divided by the length of the lever in inches, will give a quotient equal to the weight on end of lever" Thus

$$\frac{100 \times 7 \times 5}{25} = 140,$$

the weight required.

(54) D. D. C, Ft. Worth, Tex., asks:

1. Can copper or brass be silver plated without the use of a battery? 2 Will it stand any heat? 3 How can I construct a cheap and simple battery? *A*—1 Material such as mentioned can be plated without use of a battery by the following process Cut into small pieces a silver 25-cent piece, and put into an earthen vessel with a half ounce of nitric acid Put the vessel into warm water, keeping it uncovered, until the silver dissolves Add half gill of water and one tea-spoonful of fine salt, and let it settle. Drain off and repeat, adding water to the sediment until the acid taste is all out of the water Then add one pint of water and four scruples of cyanide of potassium to the sediment Put into this solution a strip of zinc two inches long, one inch wide, and an eighth of an inch thick. After thoroughly cleaning the article to be coated, immerse it in the solution for about half a minute, letting it rest on the zinc strip in the bottom, wipe off with a dry cloth and repeat; then polish with chamois or buck skin, the thickness of plating is increased by repeating the bath. 2. This, or any other than electroplating, will stand but little heat or wear. 3. You can construct a cheap battery by taking a gallon stone jar, and place in it a sheet zinc cylinder—like a piece of stovepipe—then inside the zinc place a porous earthen cup, a flower pot with the bottom hole corked up will do. Inside this porous cup place a sheet, or strip, of copper Use a solution of common salt next to the zinc, and a solution of sulphate of copper next to the copper in the porous cup. Keep the liquids in both vessels at a common level You can, however buy a battery of any dealer in electrical goods that will be much better and much cheaper than any you can make yourself.

A Car-heating Company's Plant.

The writer recently made a hurried call at the shops of the Martin Anti-fire Car-heating Co., Dunkirk, N Y. This company is, so far, the most successful one in its particular line of business, having its heaters in use on ten per cent. of all the passenger cars of the country

The shops are new, well arranged for a manufacturing business, and exceptionally well equipped with tools, many of them being special tools of their own design.

They have a number of pipe-cutting and threading machines that have been designed to do quick work where a great many pieces are made in duplicate.

For valve work they got up a special lathe, that is simply a small speed lathe, with a slide and a chasing bar. For small work it does all that a Fox lathe, costing twice as much, will do, and would be just the tool for railroad shops. These they build for the market Their regular line of work occupies a considerable part of the shops, but several outside contracts are being carried out, some brick machines, tannery pumps, and such work, occupying the lower floor. This company are building the De Kalb car window fixture. This style of window is destined to become popular, as it admits of ventilation without draughts. The sash does not raise, but is hinged by the fixtures to *each side*; a rod runs the length of the car above the windows, and is attached to the fixtures at each window by an arm; by setting this rod either one way or the other it locks one side of the sash and loosens the other; then the window can be shoved *out* on the loose side about four inches, or any part of this amount.

If the window is opened at the back from the way the car is running there is a good ventilation, and no draught or cinders are directed upon the occupant of the car. This is especially true for the occupant of the seat back of the open window.

By reversing the rod the front of the window can be swung out, or, by moving the rod to its central position, the whole sash can be moved straight out This is much better than the class of car windows that raise up about six inches.

Superintendent Barnes has a habit of getting up a special tool for almost everything, and some of them save lots of time. He also designed and built the special high-speed engine used by the company to drive their electric light plant. This engine has a very ingenious shaft governor that maintains a constant lead.

There is here a special design of core oven for small work that is very efficient; the unused fuel dumped from the cupola is enough to dry out all the work they have. The cores are placed on iron shelves, that are simply the flattened tops of the flue through which the heat escapes to the stack

More than twenty years ago Alexander Mitchell, M M of the L. V. road at Wilkesbarre, Pa., asked and obtained permission to build two iron tank frames. There was a great deal of argument against the idea, one of the greatest being that Mason had never built one, always using wood; but Mr. Mitchell built the frames thoroughly braced them, especially about the draught gear, and they are in service to-day, apparently as good as ever The tender frames made by the L. V are the heaviest and best we have seen

It is odd that with all the camel-back engines built and run for years that no one seems to have a good picture of one. We would like to get one.

Why Papers Miscarry.

We get a good many complaints from subscribers who fail to get THE LOCOMOTIVE ENGINEER regularly, and some of them think the publishers must be to blame. We are always glad to receive complaints, whenever occasion for complaint exists, and think nothing is too much trouble that will tend to lessen their number.

In a majority of such cases, however, investigation generally shows that the irregularity is due to want of definiteness in the address. A residence address, mentioning street and number, or a post-office box, is greatly to be desired in making papers carry straight to subscribers living in small towns even

A good many such complaints come from persons who change their address without giving us notice. No matter how often an address requires changing, it can readily be done, and will be done cheerfully. In giving this notice, mention both old and new addresses.

Another class of complaints come from subscribers whose papers are not even subjected to the tender mercies of the clerks employed in the general delivery department of the post-office. Such an one we have before us at this moment—it is a worse case than most—coming from a subscriber whose name we find correctly entered on our mailing list, but whose address is down simply as "R. & D. R. R., Greensboro, N. C." Now we think a street and number address or post-office box would remedy this trouble—not that we think our subscriber's diagnosis of the cause is necessarily correct, our idea being that a dishonest man seldom reads, and we try to make THE LOCOMOTIVE ENGINEER a paper which has charms for honest folks only—but because the address is very indefinite, and covers a large space in which papers can easily get lost without help from any individual. Here is the way our Greensboro subscriber puts it:

I like THE LOCOMOTIVE ENGINEER very much. I am sorry that I don't get it oftener than I do. I subscribed to it last December, and so far have got three copies—those for January, March and June. I am pretty well satisfied you mail them regularly, but I think somebody likes the paper as well as I do, and he gets the first grab at it. If he would just let me know who he is, I would send him a year's subscription, just as a sort of inducement to let mine alone. He certainly must be hard up.

Perhaps you may be able to do something by which I can get my paper Still, I don't know just what it will be. If the fellow who gets it could see this, perhaps his conscience—but I forget, people who steal have none.

A Light Locomotive.

Few railroad men realize how many light locomotives there are in service and to what uses they are put H. K. Porter & Co., of Pittsburgh, Pa., build more locomotives of this kind than any other maker, probably more than all the other makers. Their sizes range from those having cylinders 5 x 10 inches to 14 x 24 inches The styles are numerous, especially designed for certain work, there are little fellows without cabs or stacks, to go down in coal mines, open affairs for plantation use, and iron-clad ones for bloom mills and furnaces. There are truckless ones and some with single trucks in front and none behind, others with trucks behind and none in front, and several different kinds with trucks at both ends.

The drawings show the details of a popular style of street locomotive built by these works, and, as the sizes are nearly all given, there is little need of giving figures. Engines of this style are built with cylinders 7 x 12" up to 14 x 20", the one shown being 10 x 14.

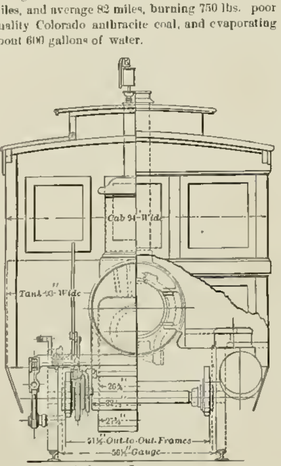
These engines are used in the streets of cities, have a noiseless exhaust, are fitted with steam, air or vacuum brakes, when so ordered, and have all modern improvements that big engines do. They are provided with Packer's easy motion rolling truck, that permits them to round curves as short as 40 feet radius.

All Porter engines are built with a view to renewing worn or broken pieces, and the works furnish parts for all their sizes, this is done because most of the machines sold go away from shops and are generally repaired by men of little experience. Driving tires go upon the wheel center on a taper, and are held on by bolts, by removing the latter the tire can be knocked off with a sledge without any heating at all.

The hauling capacity of this size motor is placed at 575 tons of 2,000 and 1,000 tons for the larger size; they generally haul from 3 to 5 street cars at from 8 to 15 miles per hour. This engine is provided with a pilot at each end, but one was left off in the engraving, to admit of a larger sized picture.

The Muncie Street Railway, Muncie, Ind., has a number of this class of engines with 8x14 cylinder; the road is a standard gauge, 35 lb. rail, 4 miles road completed, 25 feet per mile grades, 50 feet radius curves—usual train 4 8-wheel cars 37 feet long, 9,500 lbs. weight of car, and 220 passengers in train, equal to 32 tons of train. Usually makes 64 miles per 8 hours, burning 650 lbs. coke, and evaporating about 400 to 500 gallons of water. They have run one motor 160 miles in 12 hours.

The Park Railway, Denver, Col., 7x12 cylinder motor, 42" gauge, 3½ miles, 40 feet radius curve, 90 feet per mile grade, 32 lb. rail—usual train 1 8-wheel coach—16,000 lbs., and 140 passengers, when crowded, equal to 15 tons train. Usual mileage 12 to 16, round trips, equal to 84 to 112 miles, and average 82 miles, burning 750 lbs. poor quality Colorado anthracite coal, and evaporating about 600 gallons of water.



A LIGHT LOCOMOTIVE.

Many years ago on the Great Western Railway of England, a spark from the locomotive set fire to a carriage, and a bad accident happened, because there was no means of communication between the guard and the engineer—that was before the days of electric signals, the bell cord or the air brake. After this accident an iron hood containing a seat was placed on the back of all tenders, and a porter was placed therein to watch the train, riding with his back to the engine, the iron hood protecting him from cinders. After several years, no similar accidents occurring, the watchmen were taken off but the seats remained, and on one of the once famous fast engines of the world, "Lord of the Isles," built in 1851, and now on exhibition at Edinburgh, this seat is to be seen.

General Manager Hallstead, of the Delaware, Lackawanna & Western, has notified all telegraph operators on that line that they must withdraw from the Order of Railway Telegraphers, or leave the service of the road. The following objectionable clause in the constitution of the order is said to be the cause for Mr. Hallstead's action: "No member shall teach the art of telegraphy without permission from the superintendent, chief operator or the grand chief telegrapher of the order; attested to by the grand secretary under the seal of the grand division."

Baldwins are building several more of the Mason-Fairlie locomotives, such as illustrated in the March issue, for the Central Mexicano.

Heat, Motion and Work, and their Units of Measurement.

BY F. F. HEMENWAY.

LAST PAPER.

Chimney draught is the result of the difference in temperature between the hot gases in the chimney and the cooler air outside. If the difference between the temperature outside and inside the chimney is slight, the draught will be sluggish; as this difference is increased—up to a certain point—the draught will be increased. But it costs coal to heat these gases to a high temperature, hence moderation is used in that respect. Right at the chimney is a material loss. We must get air through the fire, and to do this we must have chimney draught. The hot gases must also leave the heating surfaces of the boiler at a temperature higher than that of the steam, otherwise they will not impart heat to the water. Without entering deeply into the subject, which lack of time forbids, we shall not be far out of the way in concluding that 20 per cent. of the 14,000 heat units in the coal go up the chimney, and that they are usefully employed in maintaining draught. This will allow for a temperature in the chimney of about 400°. This should be the chief loss about a well-designed and well-arranged boiler; that is, it should exceed all other losses. A little loss will occur from coal falling through the grate, and a little from radiation from the boiler, but the sum of these two losses should not exceed 10 per cent. This would make the total loss of heat at the boiler 30 per cent., leaving 70 per cent. utilized in making steam. The loss may be less than this, but it seldom is less. A loss of 30 per cent. represents good practice.

Unfortunately the loss may largely exceed 30 per cent., and this is what you, as engineers, are interested in. You are interested in this because, when a boiler does not utilize 70 per cent. of the calorific effect of the coal, there is always a possibility of effecting a saving. Regarding loss from radiation five per cent. or a little more may seem a small allowance, but I believe it is ample, but for lack of care it may be greater. In boilers set in brickwork, if the setting is not properly done, the walls made of suitable thickness and joints well made, the loss from radiation may be much more than five per cent. So in boilers not set in brick, if they are not properly protected the radiation will be 15 or 20 per cent., instead of five or a little more. Here, then, is a chance for the engineer to exercise his judgment. The fewest possible metallic surfaces about a boiler should be in contact with the external atmosphere, and the brickwork should be kept tight, with no chance for leakage.

It has been seen that it is necessary to admit about twice as much air to the furnace as would be necessary under perfect conditions to produce combustion. The heating of this excess of air will require about half the heat that is lost at the chimney, even under favorable conditions. But if, instead of admitting only twice the quantity theoretically necessary, three or four times that quantity is admitted, it will be readily seen how the loss at the chimney may be doubled.

Air is for the most admitted to the furnace through openings in the grate bars. Now to get along with the least quantity of air it should be admitted as equally as possible through these openings, and the fire should be kept in as nearly uniform condition as possible. This permits the atoms of oxygen to more readily come in contact with the combustible atoms, and hence makes it possible to utilize more of the oxygen. If the air finds its way into the fire in a few places only, steam may be kept up if the furnace is large for the work, but the air will establish currents of considerable magnitude, which will hinder to a great extent the combination of oxygen and combustible atoms, and a greater surplus of oxygen will pass off through the chimney, carrying with it heat from the furnace. So if there are bad places in the fire air finds its way through, wasting heat. Whatever the size of the grate, it should be kept in equal use all over; if too large for this it should be made smaller, and all air spaces kept open.

But while there is loss from admitting too much air to the furnace, there may be even greater loss from admitting too little. Let us see how this is. The product of the combustion of carbon we have seen is carbonic acid, 2⅔ pounds of oxygen uniting with one pound of carbon to produce this. Carbonic acid when at a high temperature very readily dissolves carbon, and if the supply of oxygen is not sufficient it will so dissolve it, with danger of great loss of heat. When 2⅔ pounds of oxygen unite with one pound of carbon, the result is 3⅔ pounds of carbonic acid. Then if the conditions were entirely favorable for the purpose this 3⅔ pounds of carbonic acid would dissolve another pound of carbon, making 4⅔ pounds of carbonic oxide; not only would the pound of carbon that was dissolved by the carbonic acid be lost, so far as the producing of heat is concerned, but a large amount of heat would disappear in doing the work of dissolving the carbon. While one pound of carbon completely burned to carbonic acid will yield 14,500 heat units, if it is permitted to dissolve another pound of carbon the available heat of the two pounds will only be 8,800 heat units, the heat per pound of carbon being only 4,400 heat units instead of 14,500. While it would not be possible to perform in the furnace of a boiler so complete an operation as this in the way of making carbonic flames will break out, frequently with a weak explosive sound.

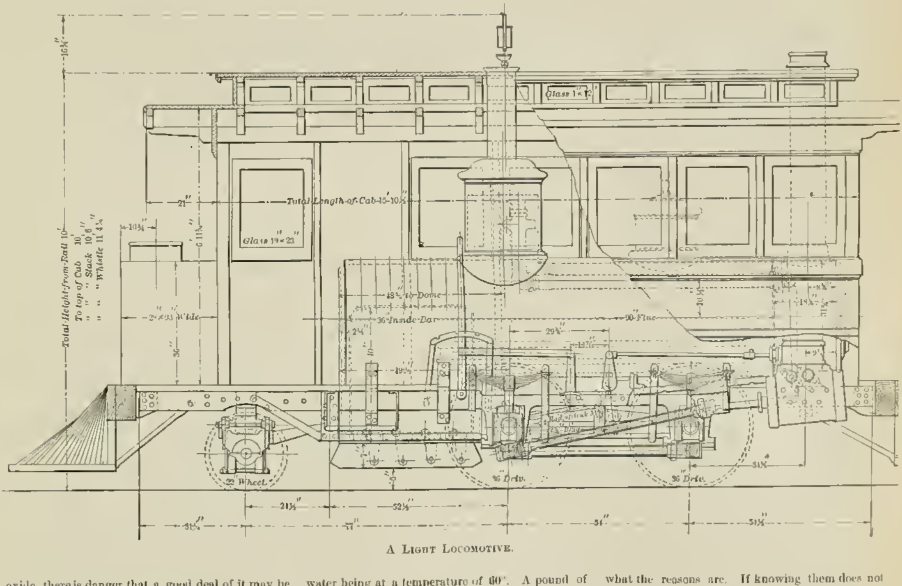
It requires all the skill of the skillful engineer to do so simple a thing as to burn coal without waste. The closest observation is necessary, and he should keep a record of his observations. By this means he will come to know the result of pursuing different plans, and learn to adopt the best, under whatever circumstances he may be working.

Under favorable conditions we have concluded that we can utilize 70 per cent. of the heat of coal in making steam, and as, under fairly good conditions, but eight per cent. is utilized in the steam engine, we must conclude that the loss is not chiefly in the boiler. I mention this particularly because not long since, in a technical journal, I read the astounding statement that more than 90 per cent. of the heat from the coal was lost in and about the boiler.

Let us see what this 70 per cent. of heat utilized in the boiler will do in the way of making steam. We put the heat value of one pound of coal at 14,000 heat units. Seventy per cent. of this is 9,800 heat units.

First let us see what heat will be required to vaporize a pound of water in an open vessel, the —heat of the steam. It is in no way hidden, but has disappeared in doing work. This heat, as heat, is not in the steam at all. This so-called latent heat of steam varies with the pressure, but at whatever pressure you make steam you always have to do with it.

But let us take a case that more nearly represents average practice. Say we are making steam in a boiler at 80 pounds gauge pressure, and that the water supplied to the boiler is heated by exhaust steam to 212°. By referring to steam tables, we find that a pound of steam of 80 pounds pressure contains 1,213 heat units, and subtracting the 212 heat units in the water leaves 1,001 heat units to be imparted. Dividing the 9,800 heat units which we find available in the pound of coal by this gives us 9.78 pounds of water that this pound of coal will evaporate under gauge pressure of 80 pounds, the feed water being heated to 212°. But to do this the conditions must all be excellent, and the coal of a good quality. In practice, if you do not find that you are evaporating from 8½ to 9 pounds of water, at ordinary pressure, for each pound of coal burned, you ought to look about for the reasons. They may or may not be such as you can control, but whether they are or are not you ought to know



A Light Locomotive.

oxide, there is danger that a good deal of it may be made, and pass away unconsumed. I say unconsumed, for if this carbonic oxide is, while hot, supplied with sufficient oxygen, it may be burned without loss. Hence the utility, where deep fires are burned, of admitting air above the fire.

Now the engineer is, so to speak, between two fires. If too much air is admitted then there is a loss; if too little there may be a greater loss. This is something in regard to which an engineer must in the main be his own guide. All of you who have had considerable experience in burning coal know with more or less certainty by the looks of your fire whether or not it is burning properly. You know you must not have air holes in it, and that it should have that peculiar live and even appearance that no description can cover. With any kind of coal, if there are dull places in the fire, it means waste. In regard to the great waste incident upon burning coal to carbonic oxide instead of carbonic acid, I never knew any means of judging by the appearance of the fire except this: If a considerable quantity of carbonic oxide is escaping, the surface of the coal will have a dead, uneven appearance; and upon partially opening the fire-door, thus admitting air above the fuel, irregular blue water being at a temperature of 60°. A pound of water at 60° contains, near enough for present purposes, 60 heat units. Water boils under the pressure of the atmosphere at 212°, and a pound of water contains at this temperature—let us say to avoid confusion, and because it is near enough correct for our purpose—212 heat units, reckoning as we are all the time from zero of the Fahrenheit thermometer. When we have applied 212 less 60 equals 152 heat units, the water is at a temperature of 212°, and begins to boil, and to pass off as steam. If we keep on until the pound of water is all converted into steam we shall find that we must apply, in round numbers, 966 more heat units, but the temperature of the water will not have been increased. It required the application of 152 heat units to increase the temperature of the water from 60° to 212°, and then 966 more heat units to do the work of vaporizing the water. These 966—or more exactly 965.7—heat units that have disappeared because they have not brought about any increase in temperature, constitute what is called the latent heat of steam at atmospheric pressure.

If scientists of the present day were to find a name for these 966 heat units that have disappeared, they would not call it the latent—that is hidden what the reasons are. If knowing them does not help you at the present, there is every probability that it will in the future.

The greatest proportion of the heat, then, has, we must conclude, passed out of the cylinder of the engine with the exhaust steam. This is something that, in the present state of the art, we cannot avoid, and while we cannot at this time follow the subject exhaustively, it is a subject to which, as engineers, you should give a good deal of attention. In a general way, then, we know that the steam, when the exhaust valve opens, contains a very large proportion of the heat that has been imparted to the water in the boiler. But although there is great loss of useful effect in the engine that cannot be avoided, we know that one engine may be, and is, much more economical than another, and that the management of an engine may be such as to vary, very materially, its economy. Here, then, is room for work.

Let us begin with the steam as it leaves the boiler. From that time on it will get no more heat. On the contrary, from that time on it will lose heat, which means that part of the steam will go back to the condition of water. If we were to fill the steam pipe with steam at boiler pressure, and close a stop valve at each end, we should find the pressure in the pipe gradually growing less. The steam would return to its condition of water, giving up its heat to the surrounding atmosphere, and, as the water would occupy only a small fraction of the space occupied by the steam, the pressure would fall as condensation went on. This condensation, and consequent loss, goes on when steam is passing from the boiler to the engine, but the lowering of pressure is prevented by the free communication with the boiler. Still the loss goes on, clear through the boiler to the source of heat, the coal pile. Now this loss will be in proportion to the extent of the exposed surface of the pipe, and it will be greater or less according as the pipe is protected from contact of the atmosphere. Here, then, is where saving may begin, outside the boiler. It is not only a loss of heat when we permit the steam to be condensed in the pipe, but water is introduced into the cylinder of the engine, which is something we want particularly to guard against. We would naturally, then, conclude at once that—first, our steam pipe should be as short and as direct as possible; and second, that it should be thoroughly protected from the atmosphere. It is a matter of astonishment in these days, when it is so easy to obtain covering for steam pipes, to see so many of them unprotected, giving out heat where heat is not wanted, and calling for the consumption of coal for a worse than useless purpose. This loss of heat is one that the engineer should understand, and use his best efforts to guard against.

Then the same argument that applies to the steam pipe will apply to the engine cylinder. It pays, most decidedly, to protect it from loss from radiation. I am inclined to believe that it pays to do this more than any figures will show, and I believe this from a little personal experience more than fifteen years old. I was called upon to make some quite material changes in a vertical engine driving a woolen mill. I made the alterations, and very carefully indicated the engine to see the result. The engine-room was not large, and an upward extension of the roof had been made for the cylinder, and there was a cover over this that could be raised to ventilate the room. Although the weather was quite cold, I found it uncomfortably warm up in this little extension, and after a time I raised the cover. I went on taking diagrams, and after a few minutes—perhaps fifteen—I found those diagrams taking on a form that, knowing all the conditions, I could not account for. I took my indicator down and carefully examined it, but it was in perfect condition. I thought several times of the open skylight and the large exposed cylinder head, but it did not seem possible that this could be the cause. It seemed that I must make a change in the valve gear to cover the loss shown by the diagram. Finally, more as a matter of curiosity than anything else, I closed the skylight, and in a few minutes the diagram was all that I could desire. I then tried the experiment of opening the skylight and covering the top of the cylinder with a lot of bagging collected around the mill, and the result was entirely satisfactory. Since then I have made other experiments in the same direction, and the results have been such as to satisfy me that there is a greater loss from unprotected cylinders than we are inclined to believe in.

Again, we know that economy in the use of steam in the steam engine is largely brought about by working steam expansively. To put it in a general way, we know that if we take steam in the cylinder at boiler pressure, and maintain that pressure to the end of the stroke, we can do a certain amount of work, using a cylinder full of steam to do it with. Then we know that if we fill the cylinder one-quarter full of steam, cut off the admission and let the imprisoned steam do work while expanding from a higher to a lower pressure, a good deal more than one-quarter of the work will be done. Now the engine that the stationary engineer has to do with is generally already made, and hence he cannot control the matter of working steam expansively, as he might like to do. But as most engines that are built at the present day are made to automatically cut off steam to control the speed, the engineer, by remembering that a little higher boiler pressure will bring about earlier cut-off, and hence, if the engine is fairly loaded, better economy, frequently has it in his power to effect a saving in this way.

The engineer may also bring about a saving by always bearing in mind the fact that friction is lost work, and that by using proper oil, and giving the required attention to lubrication, the coal-bill will figure in the result.

By way of recapitulation, we may safely say that while the least loss—as we use the term—in a steam plant is generally in and around the boiler, there is abundant opportunity for saving, all the way from the time the coal comes to hand till the exhaust steam gets beyond control. Next to safety, the economical use of fuel should be the engineer's study. A great deal can be learned through books and periodicals, but a large part of the engineer's knowledge must be gained by experience. Still the experience of a single individual can cover but little ground, and without a knowledge of the experience of others he is constantly working in unprofitable directions.

I am aware how little one can say in a talk like this. If I have touched upon a point or two in such a way as to lead you to further investigation, I am quite satisfied. It is certainly a pleasure to find so many earnest men seeking information as we find at the present day. It means progress for them and progress for the world. The typical soldier is the private, the man who carries the musket or mans the cannon; the man who digs the trenches and then defends them; who throws up fortifications and then fights behind them; the man who does the real work of the campaign. We exalt the general who plans, who issues the orders and takes the credit if there is any; but we turn to the soldiers who do the work and brave the danger, if we want to form an opinion of the character of the army. The general may direct never so wisely without meeting success unless the rank and file of his army is of the right material, properly equipped and instructed in their duties.

So it is in other affairs. We judge a nation not by the brilliancy of a few of its great lights, but by the standing of its masses; by the intelligence of those who produce common things. The millionaires of a nation do not make it rich, nor does the standing of a half-dozen thinkers constitute a valid claim for intelligence. The financial condition of the men who work establishes the condition of a nation as to wealth, and the mental condition of the people, as a whole, constitutes its intelligence.

A few years ago, as time goes, there was little call for steam engineers. To-day the stationary engineers alone constitute a great army, while there are upward of 30,000 on locomotives. There is placed in their hands a vast amount of wealth. To better fit themselves for their duties, engineers everywhere have entered upon an educational crusade. The demand for better engineers is sure to follow. Those engineers who do not join the ranks and push ahead are sure to fall behind in the race. It is hard work swimming against the current when that current is the current of progress. Engineers and all other workers in the great industries that make up about all there is of life, are fast finding this out.

Workingmen are apt to think that education, to be of much avail, must be had through some regular institution of learning. I have not a word to say against such institutions. They play an important part in the affairs of the world. But I have this to say. In this practical world in which we live no one cares how or where you get your knowledge. No institution in the world can make engineers of you. You must make engineers of yourselves, and you can do that though you never see even the outside of the great institutions of learning in the country.

The engineer who makes one pound of coal do that for which two pounds were required, is as much a public benefactor as is the man who makes two blades of grass grow where one only grew.

Some Little Comforts.

On some of the Flint & Pere Marquette engines they put a piece of 4-inch pipe about a foot long into the exhaust pipe from the air-pump, the regular sized pipe entering the bottom at one end, and going out near the top at the other, then a small drip pipe from this trap is provided that keeps all the water out of the pipe, and helps the boys keep their engines clean.

Here the blower pipe and exhaust from the pump do not enter the smoke arch, but go over it, outside, to the base casting of the stack.

The cinder slide is operated from the fireman's seat, and can be done when running, but is not, as cinders are dumped dry; the plan saves many steps for the men.

These engines have a fire-door that swings from the top and opens into the fire-box, becoming a deflector when open; this door is the same as that designed by Master Mechanic Hill, of the Camden & Amboy, some years ago, and similar to the English door of the same kind.

An apron made of an old belt, and ironed all around the edge on both sides, with strips an eighth of an inch thick and two inches wide, makes a quiet rig that lays down and stays down, requires no hinges, and prevents slipping in bad weather.

The engines rebuilt by this road have a very neat boiler, with dome ahead of sand-box, using a very short dry pipe.

Piston valves, designed by the general superintendent, who was formerly an engineer on the road, are being tried, the first set having now been in use seven months, and still tight.

The Pennsylvania Railroad Company buy all their oils, both lubricating and illuminating, by weight, and distribute them in the same manner. This practice has been found far superior to the old, half-guessing plan of measurement. The plan is in much favor now, though opposed at first—as all changes are. As it is necessary to weigh each can and its contents, exact weight of amount given is charged to engines or cars. When a fireman takes his can to the oil-house it is hung on a spring balance and filled there without the use of measures. It is claimed that the weighing plan takes just about half as long as measuring did, and is much more accurate.

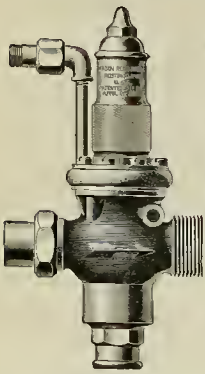
The railway mileage of the world at the beginning of 1889, according to the best authorities, aggregated a little over 357,000 miles, divided among the continents as follows: Europe, 133,900; America, 190,000; Asia, 17,800; Africa, 5,200, Australia, 10,500. Thus new America has already much more than half of the entire railway mileage of the globe, and is yearly gaining with great rapidity upon the older continents and nations. The United States have about 160,000, or nearly 45 per cent. of the grand total, and this country is every year building more than the entire railway mileage of many of the European nations.

Richard McDowell, of Lambertville, N. J., has patented a sand-box and drier for locomotives. He places an ordinary shaped sand-box around the stack in one form, and in another makes the box in the shape of a saddle tank on the smoke arch, while in still another form a box is located on each side of the extension. His idea is to use the smoke-box heat to dry the sand, doing away with driers. The plan may have some advantages, but it has the disadvantages of weight in the wrong place and excessively long sand pipes.

If there is any of our readers that wants to become a bright and shining example of modern railroad journalism, and has a cool thousand or two to invest west of the Missouri River, we can point out to him an opportunity the like of which has not laid out-door since H. Rider Haggard abandoned King Solomon's Mines.

In early days, when the Texas Central only reached from Houston to Bryan, the road killed a great many people and no end of cattle, and was nicknamed "The Angel Maker."

THE MASON AIR BRAKE REGULATOR.



For nearly two years this Regulator has been thoroughly tested on air brake pumps. During this time not one Regulator, out of 100 which are now in use on the Boston and Albany and Fitchburg Railroads, has been taken apart for repairs or cleaning. As the air chamber is entirely separate from the working parts, dirt from the train pipe cannot affect it. It can be applied without changing any of the present fittings, and we should be pleased to send one on trial to any railroad. Price $15, Net. Address

AIR BRAKE PRACTICE.

1st EDITION OF 2,000 COPIES ALL SOLD OUT.
2d EDITION NOW READY.

BY J. E. PHELAN.

A book of 107 pages which can be carried in the pocket, and which covers the practical work of operating Air Brakes intelligently, explaining how and why they do certain things under certain manipulations and not under others. Tells how to handle, inspect, repair and adjust all the different systems of air brakes in use. Explains both the Hodge and Stevens System of Levers. Contains full directions for applying Driving Brakes to old equipment, and gives road kinks that are alone worth the price of the book.

Two large Removable Plates show the latest form of Air Brakes, complete and in detail, in perspective and section, so plainly that no one can fail to understand.

SENT POSTPAID TO ANY ADDRESS FOR $1.25.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. III, NO. 9 | NEW YORK, SEPTEMBER, 1890. | $1.00 per Year or 10c. a copy.

A Model Passenger Locomotive.

The neatest design of an eight-wheeled passenger locomotive that we have ever seen is shown in our first-page illustration.

This is an anthracite coal burner just turned out of the Lehigh Valley shops at Wilkesbarre, Pa., by Alexander Mitchell, M. M. and Supt.—the designer of the first consolidation. This engine presents a very neat appearance, has nothing on her for show in the shape of brass or bright paint, but is as hand some a locomotive as is often seen—a finished machine.

The long, Belpaire fire-box sets on top of the frame and does not extend over it, as in many new engines now being built for hard coal. The cab is placed just over the drivers and ahead on the fire-box, this makes it easier to ride, keeps the cab free from dirt and smoke, and gives the engineer a better chance to see. The running boards, both in front and behind the cab, are wide, the ones at the rear protected by outside railings. In the cab special attention has been paid to getting things handy and comfortable for the men; the brake valve is on top of the boiler, but has a long, bent handle that comes down within easy reach.

Just under the throttle lever there is another lever, pivoted to the boiler, with which the runner can put on the left-hand injector, both right and left-hand injectors being operated by levers—they are Sellers', re-starting.

Good cushioned seats and arm-rests are provided, and all the cocks and levers placed so as to be easily reached from the seat.

The cut on page 162 shows the arrangement of braces in the Belpaire boiler, as well as a rear view of the engine.

On the back end of the boiler there is an iron shield for the fireman, and a steam gauge, to save him the trouble of going to the cab to note the pressure.

The fire-box drops some ten inches in front, and is provided with water grates 11 feet long.

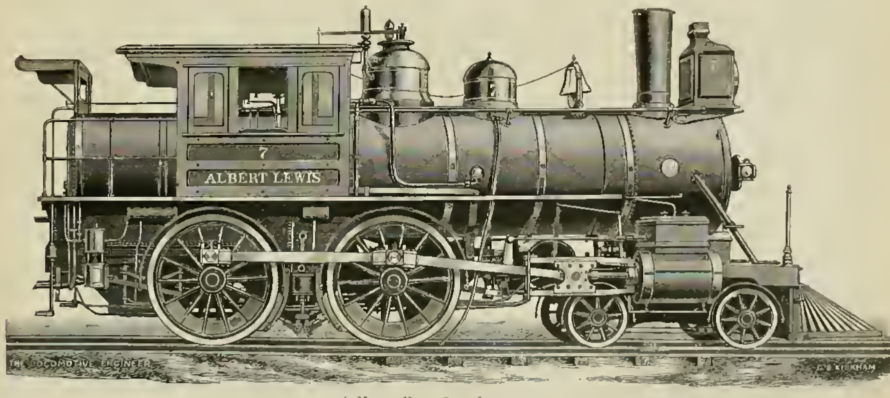
The extension is short and provided with one of the well-known L. V. cinder-boxes located under the front and between the frames.

With hard coal the fireman is employed in firing a very small part of his time while running, and can therefore spend a good deal of time in the cab, but with soft coal, requiring constant feeding, we doubt the desirability of separating the engineer and fireman; still the fireman is not of much use as a look-out when working with his fire; if the cab is set ahead on a soft coal engine the fireman should be provided with a comfortable cab of his own. That it is cooler, cleaner and easier riding in a cab placed near the center of the boiler, and that it is safer, and the view of track better for the engineer, we have never heard disputed.

This boiler has been very carefully designed and built, and at the top and sides of fire-box where it joins the barrel, as shown at *A* and *B*, page 162, there are heavy stiffening plates.

The principal dimensions of the engine are as follows:

Gauge of track	4 feet 8½ inches
Total wheel base	22 feet 11¼ inches
Rigid " "	7 feet 6 inches
Total weight	103,040 lbs.
Weight on drivers	75,488 lbs.
Weight on trucks	27,552 lbs.
Diameter of drivers	68 inches
Cylinders	19x24 inches
Delancey's balanced valves.	
Lap of valve outside, 1 inch, inside lap	3-32 inch
Travel	6 inches
Size of steam ports	1⅝x17 inches
Size of exhaust ports	3x17 inches
Boiler, steel	7-16 inch thick
Diameter of smallest boiler ring	58 inches
Grate surface	89 sq. feet
Heating surface in fire-box	185 sq. feet
" " " tubes	1,520 sq. feet
Tubes, 250, 2¼ inches diameter	11 feet 8 inches long
Outside throat sheet	⅝ inch thick
Fire-box sides	5-16 inch
Crown sheet	⅜ inch
Flue sheets	½ inch thick
Diameter driving axle	8 inches
Length of bearing	10 inches
Throw of eccentric	2½ inches
Width of eccentric	3 inches
Size of nozzle, double, each	3¼ inches
Capacity of tank 3,000 gals., weight loaded	60,000 lbs
Height from rail to top of stack	14 feet 1 inches
Service, passenger; grades, from	96 feet to 145 feet



A MODEL HARD COAL LOCOMOTIVE.

Complaint about common snap ring cylinder packing is invariably heard where it is put in wrong. Plain snap rings for cylinder packing are the cheapest and handiest packing, and will give good service, if given a show. After turning to within a quarter of an inch of size, and facing the sides, the ring should be cut, and a piece taken out, say one inch long for 18 inch rings, then spring the rings together, and turn the outside true; rings made in this way are round to start with, and have considerable spring or life, and will be tight. Springing rings into the cylinder that have not been trued up after cutting, is a poor plan; the rings never fit.

Where the Different Classes of Locomotives Got Their Names.

It is a little curious to note how different classes of locomotives got their names; most of them were named after the first or trial engine, but some were not

Geo. Stephenson's "Rocket" was a success, and upward of a hundred locomotives were built on its general plan, and called "of the Rocket class" or "like the Rocket" Following on the line of the Rocket, but an improvement on it, was the engine named "Planet," that raised after it a large family of "planets," of which many of the first successful locomotives built in America were members

The "Grasshopper" engines were so named because of the peculiar walking motion of the walking beams and connecting-rods, the first of the class was named the "York"

The "Crabs" were used, like the "Grasshoppers," on the B. & O., and had vertical boilers, but horizontal cylinders and an intermediate shaft, geared to the driving axles. They were named, it is said, because of their resemblance to a crab, in that they go when they look least as if they would.

Ross, Winans' "Mud-digger" was an 8-wheeled coupled engine, with the engine shaft geared to the drivers. They got their name from the fact that their weight and want of equalization pounded the old strap rails and ties on damp ground enough to throw lots of mud upon themselves and the trains.

The first engine Winans built, in which the pistons were coupled direct to the wheels, had a sloping fire-box, and in consequence, the cab was placed on top of the boiler, and this suggested the name "Camel," which was used for the first one, and the whole class of upward of 200 engines were called "Camels," and "Camel Backs."

The 8-wheeled engine became so popular in this country that it is known in all foreign countries as the "American locomotive."

The 10-wheeler followed the 8-wheeler; the first one was built by Norris, and named the "Chesapeake"

The first engine in this country to have six coupled wheels and a pony truck was named the "Mogul," and the name has followed the class, just as the name "Consolidation" followed the first 8-wheeled connected engine having a pony truck.

The first 8-wheeled coupled engine with double truck was named "Champion," but the class was named "Mastodons," and "12-wheelers," but very few were ever built when the first engines with ten coupled wheels and a pony truck were built they were named "Decapods"—meaning ten-legged—to distinguish them from the other 12-wheeled, or Mastodon engines.

The Forney engine, which has the engine frame lengthened to carry the tender, took its name from its inventor, M N Forney. This engine has no truck under the engine proper

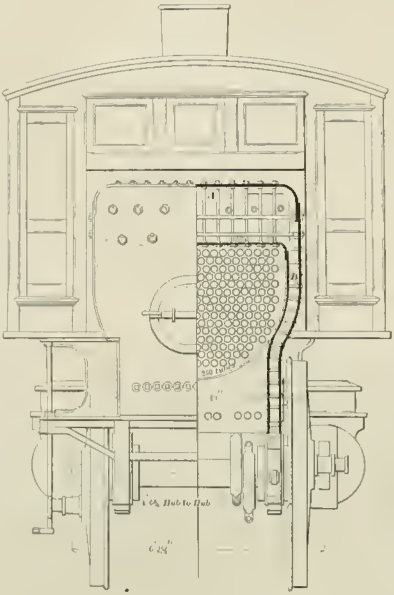
The Fairlie engine first designed in Europe, was introduced into this country by Wm Mason The peculiarity of this engine was the arrangement of the engine under the boiler, like a truck under a car, with a flexible steam pipe Mason added to this flexible engine Forney's extension of the frame to carry the tender, and the combination was called the "Mason-Fairlie," without regard to the number of drivers; there were 4-wheelers, Moguls and Consolidations of this class

It is a curious fact that no class of locomotives have ever been distinguished by any other peculiarities except the arrangement of the wheels. There are different classes known locally by some attachment or part that makes them peculiar, like the Wootten boiler, or the Belpaire fire-box, but the number and arrangement of wheels has been the distinguishing features of the classes

The death of Geo. W Tilton will probably put a dampener on the use of Swinerton, flat spotted driving wheels on the C & N W that was promised.

The Nautical Engineer.

"Speakin' of hook motions," said the old-timer, dropping his hat into the corner and crossing his legs as if he intended to stay, "speakin' of hook motions reminds me of a little circumstance as happened in '67, on the old M. & M Dick Shindler was running a 'nold gun-barreled Taunton and put her in the shop along in the fall rush. Dick was mised a sailor, some'rs down East, and went firin' sorter late in life, but, after all, makin' a more or less fairish engineer, but he stuck to all his old sailor talk. The gauge was a 'compass,' the cab 'quarters,' the caboose 'fo'cassle,' and the reverse lever the 'tiller' Well, as Dick's kittle was in, he got on the extra list, and finally one day he had to take the old twenty-five out on construction, this same twenty-five was a 'nold Dicky Norris hook, with independent cut-off, and what Dick didn't know about that kind of a 'nengin would fill a 'hole 'cyclopedi'a an' a pamphlet besides



A MODEL HARD COAL LOCOMOTIVE

"Things come his way, howmsoever, until about twenty miles out, when he had some switchin' to do; Dick got the handles mixed up and stuck acrost the frog. He tried every which way to move her, but the twenty-five was restin' to stay, and Dick finally concluded to disconnect her which he didn't exactly know how to do, being used to a link Well, after delayin' every one on the road two or three hours, one of the passenger trains flagged agin' him, expectin' to find him off the track The passenger engineer showed Dick how to handle her, and, to make a long story short, he finally got in, plumb disgusted.

"The sup'erinten'ent, as usual, jumped onto the master mechanic, and when Dick arrived the old man was waitin' for him, with his dander up.

"'What'en thunder's the matter with the twenty five and you, anyway?' sais he, 'don't yer know you bisniss?'

"Dick slid down from 'aloft' and sais, sorter respectful like, 'Cappen, that's the crankiest craft I ever sailed, dod blast her rotten bottom, she wouldn't luff nor she wouldn't stay'

"There was a twinkle in old Frosty's eye as he sais: 'I don't know as to your luffin', but it appears to me that you're both monstrous on the stay—you stayed pretty much all day;' then he went off laffin' to hisself"

New Feature in Railroading.

Our readers will be surprised to learn that all special trains leaving Denver on the various lines are numbered. This new feature has been introduced by the *Rocky Mountain* editor of the railroad *News* (exclusively). Some one told him that when verdant cloths fluttered from the front end of a U. P. cloud pusher, that that meant "special train." Looking through the lattice work of the great iron fence the other day, he saw an extra pulling out, and as he caught the figures on the wrecking car, he whipped out his note-book, and people "in railway circles" read in the *News* next morning that special train No. 015 left over the Union Pacific at half after 4 yesterday.

We railroad editors may go wrong on changes and promotions, but you can't fool us on green signals. Cuz we kin see 'em. See!—*Western Railway.*

The Federation of Railway Employes, representing the firemen, trainmen, conductors and switchmen, on August 25th declined to order a strike in aid of the Knights of Labor strike on the N. Y Central. Their supreme council express themselves as satisfied that the Central is waging a war of extermination on the Knights, and give them sympathy and moral support, but no sympathetic strike The council lived up to its laws strictly, and it did well in so doing—there are lots of easier ways of committing suicide than by a sympathetic strike. The cast-iron laws of the Federation make the way to a strike long and narrow—and there is no short cut to it.

The British steamer "Wellington," which arrived at San Francisco recently with coal from Departure Bay, went to Long Bridge on arrival to take on a locomotive which was to be shipped to the Esquimalt & Nanaimo Railroad, which operates a line from the Union Mine to Departure Bay, B. C. The steamer went up with her inward cargo on board so as to be low in the water and facilitate the placing of the locomotive. The locomotive had been hauled from the cars to a platform on the dock, and the steamer made fast alongside the wharf, port side to. A stout gangway was built from the dock over which the locomotive could be transferred to the ship, but while it was being lowered, the tackle snapped and the locomotive broke loose. It tore across the deck, crashed through the iron bulwarks on the starboard side and fell into the bay. The locomotive weighed sixty-five tons and sank so far in the mud, which is there about forty feet deep, that it could not be found when sounded for the next day.—*Ry. Topics.*

The railways of Peru are having a little life put into them again after a long period of idleness following the disastrous war with Chili. The Peruvian roads are built on the American plan, and equipped with American rolling stock, while the roads of the Argentine are principally equipped with English stock.

Another terrible warning against carelessness by railway employes, even in the smallest things, is given in the shocking accident on the Old Colony railway, by which at least nineteen lives were lost, while many others were injured. It appears that section men who were at work on the track failed to remove a track jack which they were using as the passenger train came thundering up, and that the engine was derailed by the obstruction and dashed against a stone wall, followed by several crowded cars, with most appalling results. Justice demands that carelessness which has such awful results should be followed by severe punishment.—*Ry. Age*

That is all right enough, but it should be remembered that the best and cheapest track jack is one that does not stand above the rails, and can be left in place while trains are passing. That the trackmen of this country get the thousands of clumsy jacks off the rails in time for the trains is a wonder.

Simple Lessons in Drawing for the Shop.

By Orville H. Reynolds.

ELEVENTH PAPER.

While the ability to make a correct representation of a machine, or any part of the same, by means of drawing instruments, is something to be proud of, to be able to neatly execute a free-hand mechanical drawing is also a creditable accomplishment, but one not possessed by all.

The end to be sought, however, is a sketch, whether well or poorly done. The importance of this is evident when we wish to convey an idea graphically, for then a few strokes of the pencil will do more than the most voluble tongue.

A free-hand drawing is a delineation of an object by means of the pencil, and with no aids other than the hand and eye, by which the several parts are shown, and the dimensions marked on for reference when making the finished drawing to scale.

A sketch may include a few vague marks in the sand, made by the toe of the artist's boot, or hieroglyphics scrawled with a piece of chalk on the first convenient place. It also may embrace a picture, made by the genius who has discovered that there is merit in the graphite, and who has given us the rough sketch, so-called, we may presume, because it *is* rough.

All the above may fill their little niche, but the ideal sketch is made by those who are familiar with projection, and who, guided by those rules, are able to intelligently place their drawing on paper, whether a copy of something already made or of their own design.

In making sketches, we will require, besides the pencil, a two-foot rule, with which to take our measurements, and a pair of outside calipers, to get the diameter of circular parts.

A little memorandum book, 5"x7", will be convenient to make sketches in, because the stiff board covers make it easy to hold in the hand, and it will be found better than separate slips of paper, as the sketches will always be found between the covers, and not lost or scattered when wanted.

The sketch being a preliminary to the completed drawing, it follows that the more nearly we make the sketch to look as the drawing should when completed, the plainer will it be to work up on drawing-board. If not to be used to draw from, but to be worked to in the shop in place of the drawing, as frequently happens when the drawing office is pressed for time, the sketch must then be made plain, the dimensions should all be put in their proper places, and square or circular parts shown or marked as such, the same as would be done on a finished drawing made to scale.

The hand, unaided by the T square, will, in free-hand practice, be likely to prove unruly at attempts to make a straight line, therefore the first thing of importance is to hold the pencil easily and surely between the thumb and third finger, with the first finger resting on top of pencil. The fingers should be nearly straight, and not too close to the pencil point. In this manner the pencil is firmly held and truly guided.

Straight lines should be practiced first, like short ones shown at *A*, Fig. 71, making their alignment as perfect as possible, then longer lines can be tried, having lengths equal to each other, as at *B*, Fig. 71, after which two parallel lines can be practiced, as in Fig 72.

A horizontal line, bisected by a perpendicular, is shown in Fig. 73. A perpendicular, crossing a horizontal line, is given in Fig. 74 This is a construction required so frequently to do duty as center lines, that it would be well to become proficient in the handling of it.

Fig. 75 shows six radial lines of equal length and equal angles, with ends of radial lines connected by straight lines, and having a circle inscribed within the hexagon. To sketch this figure, make a dot with the pencil point, around which make six other dots, which shall be at an equal distance from the central point, and also from each other, connect the dots by straight lines, passing through the center, after which connect the radial lines, and mark in the circle touching the sides.

To copy a bolt, as shown in Fig. 76, lay it down so as to present the side as shown; draw the center line, and near the top of same draw two parallel horizontal lines to represent the thickness of head, lay off four pencil dots, two at top and two at bottom, as nearly as possible equally each side of the center line, and draw through the dots, to represent the diameter of bolt; the length of bolt should be made to bear something like a reasonable proportion to the diameter.

For the width of head across flats, or the wrench fit, set off each side of center line a dot, as in case of the body, and draw to the horizontal lines The arcs to represent the chamfer can then be drawn

The next operation in this sketch is to show the thread, which, being a United States standard, it will be only a waste of time to delineate it as such, but instead we can adopt the shorter method of lines inclined to the axis of bolt, long and short ones alternating as shown. The short lines, representing the bottom of thread, should fall short of the bolt's diameter by the amount of depth of thread at each side; the longer lines, representing the top of thread, will, of course, be drawn the full diameter, which will answer all purposes for a sketch, and is thorough enough on a finished drawing of V threads, when the pitch or number of threads is given, as it should be in all cases, for the information of those who are not familiar with the standard

The standard referred to also decides the thickness of head and nut, as well as the distance between flats, for a given size of bolt.

In Sellers' "Treatise on Machine Tools" is found the following, bearing on this subject. "The distance between the parallel sides of a bolt head and nut, for a rough bolt, shall be equal to one and a half diameters of the bolt, plus one-eighth of an inch. The thickness of the heads for a rough bolt shall be equal to one-half the distance between its parallel sides. The thickness of the nut shall be equal to the diameter of bolt. The thickness of the head for a finished bolt shall be equal to the thickness of the nut. The distance between the parallel sides of a bolt head and nut, and the thickness of the nut, shall be one-sixteenth of an inch less for finished work than for rough."

When thread is left-handed, it will have an inclination in the opposite direction from that shown in Fig. 76, and should be noted on sketch as such The dimensions are next to be placed where they belong, in order that we may know what size to draw the bolt. First take the diameter of body with the calipers, and noting the size on the rule, mark it on the bolt in a space between two dotted lines, having darts or arrow heads indicating what points the size refers to, making two small dashes at the right and above the dimension to indicate inches (one dash in this connection would signify feet).

The distance over all on the bolt is understood to be from underside of head to point; we therefore measure this distance and place it as shown The length of body, which is from underside of head to inner end of thread, is likewise measured and its size also marked on; next the thickness of head and width between parallel sides of same, and we have complete working sketch of a one-inch bolt.

It will be observed that this sketch can be worked to just the same as though it were a finished drawing, the one view of head being sufficient when marked hexagon, as shown

An angle can be copied by taking any number of even inches, say 10, Fig 77, and laying off this distance from the vertex, on two sides, then measuring the opening or number of inches apart of the points on the sides as 5" on sketch, we have the measure of the angle in inches

Our dimensions will also be of use if we desire to find the angle in terms of degrees, since the length 10 would become radius, and the opening 5" the chord, from which, with a table of sines, we can determine the number of degrees, minutes and seconds contained between the two radii.

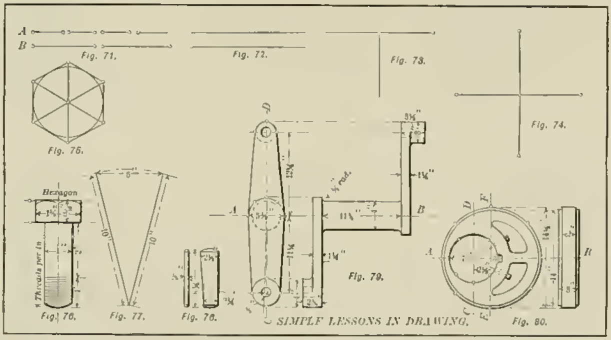


Fig. 71. Fig. 72. Fig. 73. Fig. 74. Fig. 75. Fig. 76. Fig. 77. Fig. 78. Fig. 79. Fig. 80.

SIMPLE LESSONS IN DRAWING.

To copy a piston rod key like Fig. 78, draw two lines, one vertical and the other slightly inclined, to represent the width, which is shown tapering; next draw the straight line at top and bottom, and connect the corners by arcs to represent the chamfers. Two parallel vertical lines are next drawn for the edge view, and the chamfers shown meeting lines projected at top and bottom from side view, same as would be done with T square, these lines make both views of same length. Measure the thickness of key and mark it as shown, find the width at top and bottom and place the figures near their respective ends, lastly, measure the length over all and mark it as shown.

The dimensions are placed as above for the purpose of having the sketch out plainly, which it does because all sizes are contained within the outlines, good practice when size of drawing will permit.

Let us next take a locomotive rocker, Fig 79, and laying it on a bench or some other convenient place, so that we can see it readily, make a sketch of it also. First draw a horizontal line *A B* and erect a perpendicular *C D*, crossing it near the left-hand end, these lines will be our center lines.

Lay off with the pencil point two dots on each side of line *A B* at as nearly equal distances as possible, and draw through them a straight horizontal line, which is the outline of the rocker shaft on side view.

Erect a perpendicular near *B* and draw another line parallel to it, this shows the thickness of upper arm.

Draw another and shorter vertical line at upper end of arm and connect this to the arm by a line at each of its ends; this shows the boss at end of upper arm. Produce the thickness of arm below bottom line of shaft, and draw a short horizontal line which will finish the upper arm. Draw lower arm in same order observed with one just drawn, mark the fillets or curves at the intersection of shaft with the arms, and we have outline of side view complete.

In order to have a good view of the end let us set the rocker on its end *B* and proceed to sketch end *A* We will begin by projecting to center line

C D all points from side view that will be of assistance, as the top of upper arm, after which comes the shoulder and boss on lower arm.

These projected points help immensely in making the two views proportional.

The curves at top and bottom of arms are best drawn by marking three points for the upper and four for the lower, drawing through the dots; this makes a semi-circle at top and a complete circle representing the boss at bottom. Three points likewise made for the curve of shoulder at top of lower arm, using intersection of center lines for an imaginary center, will, when drawn through, give the shape of arm at *A*. Lines now drawn tangent to these curves give outline of end view.

The holes in top and bottom arms are next drawn, when we can put on our dimensions.

Measuring the distance across the lower arm at its greatest width, we draw the dimension line and place the size $5\frac{1}{2}''$ within it as in other cases; taking the diameter of boss at lower end we mark that in also. Calipering the shaft we get the diameter and mark it on as shown.

The length between the arms is next taken and put on the sketch, also the thickness of arms and length of bosses, together with the size of holes at top and bottom. The radius of fillets is then measured and put on, when, after getting the length of arms from center to center, we have a thorough free-hand sketch of a rocker, one that can be worked to if necessary, and one that can be worked up into a drawing at any time because the sizes are all there. One more matter is to be looked into before leaving the rocker if we happen to be strangers to the build of the engine, and that is to determine whether or not the arms are in line as shown on end view.

To know this, lay the rocker on its side on a face plate and bring the centers in line with a surface gauge; if all the centers are in line, our sketch is correct; if not in line, note how much out of line, and mark amount of offset as shown at *E*.

An eccentric, Fig. 80, furnishes an opportunity to use in its construction the parallel lines of Fig. 72, the center lines of Fig. 74, and radial dots in Fig. 75. First, draw center lines *A B* and *C D*; around their intersection as a center make six or more dots, six will do, and draw circle through them to represent the hole for axle fit.

Parallel to *C D* draw *E F*, taking intersection of *E F* with *A B* as a center, make six points around and equi-distant from it (as was done for axle fit), and through them draw circle which will represent outside diameter or strap fit; within this circle, and concentric with it, draw another to represent bottom of tongue.

Spaces at *G* and *H* are usually made to lighten the casting, their outline, it will be observed, is on the outer side concentric with the strap fit, while on inner side the line is made from center of the axle, leaving a bar at center between the two spaces.

The outlines for edge view should be projected from side view, from which lines the thickness is shown, both of the tongue and over all by parallel lines drawn to projected lines.

If we measure the eccentric from which this sketch is made we find the hole for axle fit to be 7" diameter and mark it as on sketch.

The distance between center lines *C D* and *E F* we find to be $2\frac{1}{2}''$, this being one half the distance passed through in one revolution by the center *I* of eccentric. The throw would therefore, as commonly understood, be 5 inches.

To find this throw from the eccentric, measure from outside of widest part to the hole, also from the outside of narrowest part to the hole, and the difference is the throw.

Measuring over all we find the diameter to be $14\frac{1}{2}''$, and bottom of tongue to be 14", placing these dimensions between the views as shown, we find thickness of tongue 2", and width over all 3", and place sizes where they belong as in sketch.

The keyway and set screws are next measured and sizes noted, and we have all the information necessary to build the eccentric.

When sketching from the object it is of the greatest importance that all dimensions, the radius of all curves and measures of all angles, be accurately given.

All the figures in foregoing lessons will be first-class practice for free-hand work.

At the Ft. Wayne shops of the P., Ft. W. & C. they bore a set of tire for an 8 wheeler in 4 hours. This is quick work for wheels from five to six feet in diameter. Who does it in less time?

Jenkins Bros. have recently issued a new catalogue and price list of their valves, resuming their former prices and discounts; they say that dealers did not like the low list price and low discount, so they go back to the old and higher general list.

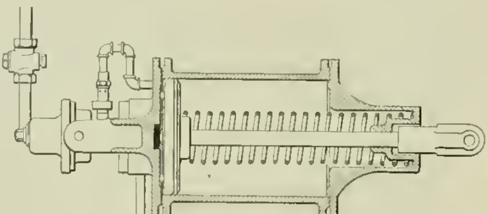

Fig. 1.

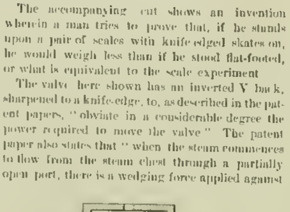
AIR-BRAKE QUICK RELEASE VALVE.

A Great (?) Invention.

The accompanying cut shows an invention wherein a man tries to prove that, if he stands upon a pair of scales with knife-edged skates on, he would weigh less than if he stood flat-footed, or what is equivalent to the scale experiment.

The valve here shown has an inverted V back, sharpened to a knife-edge, to, as described in the patent papers, "obviate in a considerable degree the power required to move the valve." The patent paper also states that "when the steam commences to flow from the steam chest through a partially open port, there is a wedging force applied against



sloping side of the V-shaped projection of the valve which tends to start it in its forward course." What the pressure on the other side of the valve would be doing at this time is not stated. It is not at all surprising that an inventor (?) can be found who would want to patent such a device—the woods are full of 'em—nor is it much more surprising that patent attorneys will push such claims through, as did Messrs. Brown Bros. in this case—there is something in it—but it is not only surprising, but deplorable, that such a ridiculous patent should issue from the office at Washington. Some years ago an English inventor corrugated the piston in a steam engine, claiming that he thereby increased the effective area of the piston and the power of the engine accordingly; but he made sharp ridges all over the piston, and according to the theory of Mr. De Groff, the inventor of this valve, he would have less pressure—as the steam would have no place to stand—as it were. Both of these inventors (?) tried to get something for nothing.

If this theory holds good, why not make a boiler of sharp seams or corrugations on the inside, then, if they were sharp enough, the steam could get no hold to push out, and, of course, the boiler could be made of lighter material—say tin.

Quick Release Valve for Automatic Air Brakes.

The Westinghouse Company have recently bought out the patent of Peter Grabler, of Allegheny, Pa., for a simple little device to hurry the release of automatic air-brakes.

His invention consists of a small valve screwed into the exhaust passage of the triple valve case, and connected at the other end, by a pipe, to the back end of the brake cylinder. Our engravings will make both its construction and location clear. Fig. 1 is a plan view of the cylinder, the triple valve case and the release valve, and its connections. Fig. 2 is a sectional view of the valve itself.

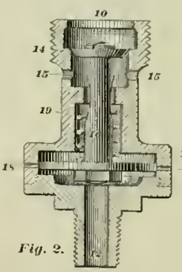


Fig. 2.

The automatic air-brake is quick in application, and the triple moves prompt and quick for release, but the air escapes through a comparatively small port in the valve, which, for obvious reasons, cannot well be enlarged, and the release is not so quick as is always desirable, although a slow release has its advantages for nice work.

With this release valve in use air is applied to the brakes as at present, and when the triple valve is moved to release the air entering, the exhaust port simply moves a piston in the release valve that opens a large passage directly from the brake cylinder to the atmosphere. In Fig. 2 there is a stem, 16, on one end of which there is a large valve, and upon the other end a small one. The large valve acts as a piston to move the small valve off its seat. The under side of the piston, 12, is connected to the exhaust passage of the triple valve; the top, 10, to a pipe direct to the brake cylinder. There are two rows of ports to the atmosphere, as shown at 18 and 15, but neither of these ports are open to the pressure in the brake until the large valve, 17, has unseated the small valve, 14.

When the brakes are applied the pressure in the cylinder tends to hold down valve 14, but when the triple moves to release, the pressure from the exhaust port flows under the piston 17, and, because of its greater area, forces it up, unseating valve 14 and opening the ports 15 direct to the brake cylinder, and ports 18 *via* the exhaust port, causing a very quick release; a light spring, 19, keeps the valves in their normal condition when the brake is released. This device can be applied to old equipment as well as new, and would, no doubt, be of use on fast suburban trains and local runs.

Roundhouse stoves look lots better in summer if whitewashed, and, when the job is a good one, do not look bad when in use. Salt used freely in the whitewash will prevent its rubbing off, and make it stand the heat better. Salt should be used in whitewash for shop walls.

The Strong engine, built some two years ago by the Schenectady Works for the A., T. & S. F. Railroad, has been lying idle at Topeka until very recently. She is now in express service.

Historical Locomotives.

THE "CAMELS."

Ross Winans' "Camel" engine marked a great advance in freight-moving power, and the reputation of these locomotives was, and still is, widespread; there is scarcely a fireman in the country who has not heard of the "camel-backs," as they are called by the rank and file. This name came from the expression, "riding on a camel's back," which, in the old days on the B. & O., meant running a "camel" engine.

Ross Winans was one of the most original and progressive of American locomotive builders, and to him is due the credit for many modern improvements, but his greatest service was in his fearlessness in putting heavy engines at work on comparatively light roads, and forcing thereby the freight-carrying trade away from the little toy engines, with which other builders and railroad officers were experimenting.

The first locomotive built in the U. S. with more than one pair of drivers was the grasshopper locomotive "York," built by Phineas Davis for the B. & O. in 1834; following this class was the "Coal Crab," like the grasshopper, except that it had horizontal cylinders.

These little engines did a great amount of work for their weight, and demonstrated the utility of coupled drivers.

Ross Winans proposed to build locomotives for the coal carrying trade, of a pattern different and heavier than any before attempted, and in 1844 turned out the first eight-wheeled connected locomotive. This engine had a horizontal tubular boiler, with a very large dome, the pistons were coupled to an intermediate shaft which was geared to the back axle, the 33" drivers being connected by side rods; this engine was named the "Buffalo," and was the first of six that became known as the "Mud Diggers"—because they pounded up mud and dust from the light superstructure.

About 1848 Baldwin commenced turning out six and eight wheeled coupled engines, in which the connections were direct to the drivers, and Winans saw the advantage of this form, and in June, 1848, turned out of his shop at Baltimore the engine "Camel," the first of that type, within the next ten years he built more than 200 of these engines, 119 for the B. & O. alone; they were used also on the P. R. R., P. & R., N. Y. & E., N. C., C. & P., and many other roads.

The breaking out of the war closed Winans' shops, and they were never permanently opened again.

The "Camel" shown in the cut was one of the last built by him, and was turned out in 1860; for this engraving we are indebted to the *Journal of the Franklin Institute* of October, 1878, and from which we quote as follows:

Among the features of novelty which distinguished the "Camel" engines from those of prior construction, may be enumerated the following:

The employment of eight driving wheels, set closely between horizontal cylinders, and a long overhung fire-box, the width of which is equal to, or greater than the width over the frames.

A fire box having a downwardly and rearwardly inclined top.

A dome and engineer's house, placed on top of the boiler, and close to the forward end.

An upper shute for feeding coal through the top of the fire box.

A fire box having no water space on its rear side, which was closed by doors so large as to expose the whole area when required.

The abandonment of crown bars, and the substitution of stay bolts connecting the crown sheet with the outer shell direct.

The half stroke cam as a means of affecting cut-off.

All these engines were of substantially the same pattern, except as to the fire-box, of which there were three classes, the short, medium and long, the latter, which is shown in the illustration, being 8 feet 6 inches in length by 4 feet wide. The grate surface of the medium class was 6x3½ feet, giving the enormous area of 21 square feet.

The boilers were of $\frac{5}{16}$ iron and 46 inches in diameter. The cylinders (except in a few early engines, which were 17") were 19"x22", and the diameter of the drivers in all cases was 48", with an extreme wheel base of only 11' 3".

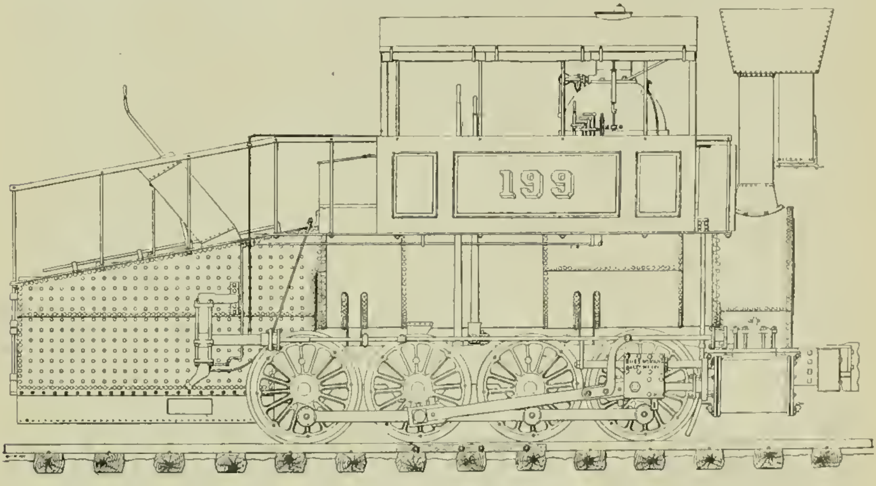
The pump was located back of the drivers, and driven from the crosshead or the main rod—as in this case—the long plunger rod running through several guides on the frame.

Double plate frames were used; these plates were something like half an inch thick, and far enough apart to have the equalizers and springs hung between the plates and out of sight. No wedges were used except on the main box, and this was in front, instead of behind.

The stack had an extension instead of the front, and such cinders as would not go through the netting found their way into the trap and could be dumped out.

The side rods had no knuckle joints, but were in three short, solid-ended pieces.

The whole back of the fire box was doors, and the front of the tender had a "pit," the deck of which was on a level with the ash-pan, and the fuel deck was almost breast high, there was a second deck on the tank just above its top and over the fireman's pit; from this deck the head brakeman was required to fill the shute shown on top of the fire-box (there were two of these in some engines); these shutes held several bushels of coal, and had a trap door at the bottom that could be opened by the lever shown at the top or the one shown on the fire-box, within reach of the fireman in the pit, so when he wanted coal ahead in that 8-foot box he pulled the lever, dumped the coal and then spread it with his fire irons.



The front and rear wheels only were flanged, and end play left in the boxes to admit of the passage of the engine around curves. Chilled cast-iron tires, were used, fastened on by hook-headed bolts passing between the center and the tire; in some of the earlier engines chilled wheels, without separate tires, were used. The weight of these engines varied from 25 to 29 tons (2,000 pounds). The valve motion was the old "drop hook" pattern, and the valves could be operated either by an eccentric or a half-stroke cam for cutting off, as desired.

In regular service these engines hauled eight loaded cars, 20 tons each, up grades of 116 feet per mile, with frequent curves of 600 feet radius, but they did, for a period of two months, perform the remarkable and probably unparalleled duty of hauling a tender and one loaded car up a grade of 1 in 10, or 528 feet to the mile, having curves of 300 feet radius, at a speed of 13 miles per hour. This was done on a temporary track laid over the Kingwood tunnel on the B. & O. road.

The "Camels" have now nearly disappeared, but there are still quite a number of them at work and doing well; as an engineer handling one in the Cumberland, Md., yard remarked: "You can't hurt one of them much, they're tough."

These engines never had any lagging or jacket on their boilers, steam chests or cylinders. The throttle lever, shown on the back of the dome, hung down and moved to and from the runner; it was dubbed the "grindstone crank," for its resemblance to that well-known handle.

In some of these engines, built years afterwards by the B. & O. road, the draw bar went through the ash-pan, but in the original ones the draught irons were secured to the frame ahead of the fire box, ran under the ash-pan, and were firmly braced to the back of the fire-box, having a short bar coupled from there to the tank.

There was a short combustion chamber ahead of the grates, the latter were cast-iron bars running lengthwise, and so hung that by putting a lever on the back end each one could be rocked sideways.

The "Camel" engines did remarkable service in their time, but were so heavy and long on such a short wheel base that they were prone to bob around at high speed, and often hunted the ditch. We may easily see that Mr. Mitchell's "Consolidation" engine of 1866 was simply the improvement and development of the "Camel", he put a pony truck ahead to steady the engine, keep it from "nosing," and swinging, and help to guide it, spread the drivers, placing one pair under the fire box, thus getting the weight distributed better, and so developing an engine that has become the recognized standard for freight service at home, as well as in several foreign countries.

Correspondence

Knowledge is Power.

Editor The Locomotive Engineer

Not long since I saw a man struck by lightning—"Jersey lightning"—and the experience was certainly interesting and amusing.

It happened at night. I was riding upon a locomotive that was hauling a fast express train, and from the beginning of the run noticed that the fireman acted in a peculiar manner and was remarkably communicative. I soon discovered that he had been imbibing the "Jersey fluid," and was feeling its effects. We had gone perhaps ten miles, when an employe left the baggage car, climbed over the tank, entered the cab, pulled a bottle from his inside pocket, and offered it to the engineer, who declined, then turning to the fireman, he said, "Try it, Jack," and Jack tried it, and put himself outside of about four fingers of the contents, and reluctantly returned the bottle to its owner, who took a long pull at it, held it before the gauge lamp to see how much remained, handed it again to the fireman and told him to finish it, which he did in a twinkling. The employe then returned to the car, and the fireman began telling me how much he knew, and how well he could handle a locomotive.

Said he, "I'm different from other people, I can take a drink, and it don't make a fool of me. I always know twice as much when I get a drink in me and I can make the 'old gal' steam red-hot all the way over the road. Say, I know twice as much now since I had that drink, just watch the pointer of that gauge waltz around towards Boston, you'll hear the old scald pot pop in a minute; there she goes," and he opened the furnace door, and dropped in a few scoops of coal. "Say, the old man's pulling her for all she's worth, but he can't make her sour on me to-night. I know too much, I know three times as much about a locomotive when I get a nip or two. It don't make a fool of me like it does of some people. We've struck the hill now, and the old man is dropping her down; he can pound her to-night, but she'll have the fog all the same, let me get outside of a snifter of old rye, and I can keep the putty on the worst old iron heap the company owns; there, she's poppin' again. Crack it at her, old man, we're over the hill now, and she's doing her mile. Say, do you know a drink of whiskey makes a fool of some people. Yes, sir, makes the biggest kind of a fool of 'em, but it don't affect me that way."

His tongue wagged incessantly during the whole trip and the last thing I heard as I left the engine was, "Say, I know twice," and I was out of hearing. BAX

Elizabeth, N. J.

[The writer of the above, who is an engineer with a record for veracity, assures us he has reported the case *verbatim*, and that the fireman who knows how to be twice as smart has since been promoted.]

A Plea for Automatic Steam Valves.

Editor The Locomotive Engineer:

On the 19th inst. an Old Colony R. R. passenger train, known as the "limited," from Woods Holl, was derailed near Quincy, Mass. Twenty-one persons were killed, and some forty others injured. The Boston *Herald* of Aug. 20th credits General Manager Kendrick, of the Old Colony, with the following statement: "It was here," wrecked car No. 263, "that all the fatalities occurred, as I am informed—either from the shock itself, or from the escaping steam, which arose from the broken pipes of the engine."

This last brings forcibly to mind the advisability of using a flap valve inside the boiler in connection with the check valve, so that should the latter be broken in an accident, the flap valve will be closed by the pressure within the boiler, and thereby prevent the escape of steam and scalding water through the broken check valve.

I do not wish to be understood as blaming the mechanical officers of the Old Colony R. R. for not using this valve on their locomotives, for it is possible that the wrecked engine was so equipped, but I wish to call the attention of your readers to a simple and cheap device, which may be the means of averting a severe scalding accident.

Narragansett Pier, R. I. EDW. L. FOSTER.

Cure for an Engine that Slipped Shut Off.

Editor The Locomotive Engineer:

In reply to Mr. Arnold, would say that the side rods on engine 121 are solid rods, and are lighter than her old strap rods by 25 lbs. each.

E. A. G. wants to know what we mean by, or rather how the word slipping should be construed. What I meant by engine 121 slipping was this, when running along, say, 25 miles per hour, her driving wheels would slip ahead as fast as if she was running 50 miles per hour without slipping.

This engine came out of the shop about two months ago, with new driving axles in the same wheels she always had. She don't slip any more. We have had several engines on the N. Y. Central that acted the same as the 121, and in each case the axles were twisted, and by putting in new axles the slipping was cured. I wonder if the cramping or springing of side rods, while passing the center, would have a tendency to cause slipping?—Hardly.

Syracuse, N. Y. W. F. RELYEN.

Flat Spots on the Tire—Why Always in One Place?

Editor The Locomotive Engineer:

I am firing on a road that runs along the Mississippi River. We have fifteen sixty-five ton ten-wheel engines of the Rhode Island make, also thirty eight-wheeled standards of the same make, twelve of which have a larger wheel for passenger service. The road is level, but very crooked. Engines pull from thirty-five to fifty loads. Those engines, with very few exceptions, pound out a flat spot in their left forward driving wheel tires just as she passes her forward center. As soon as the flat spot begins to appear they change it half way around, and after a time another flat spot appears in the same place. Can you tell us why those engines pound out a flat spot on her left forward drive wheel and on no other wheel? Passenger engines being the same. C. B. NORTH.

Galena, Ill.

[This is the second letter we have had from the same source and on the same subject. If the reports are true we cannot account for the flattening action. Some engines slip slightly when working hard, when both main pins are below the axle, but this wears the tires alike. It often happens that when the center of an engine truck is out it will throw more weight upon one side than the other, and in case of excessive slip the wheel bearing the heaviest load would wear the most—but not in spots. If this trouble is the same with a large number of locomotives of one build it seems strange that no complaints have been filed with the builders. Give us all the particulars—what do the motive power officials of the road say about it?]

How to Make Lubricators Work—Tallow vs. Cylinder Oil.

Editor The Locomotive Engineer:

I have been a subscriber of your paper for some time, and am frank to state that I consider it one of the very best of its kind.

I have just finished reading the August number, and wish to say a few words about "Old Mossback," and his faith in the "good old tallow and old-fashioned tallow pipes."

I presume he would not object to the still older arrangement—the cup on the steam chest—but I fear the fire boys would kick at this day if they were required to climb out to put a little tallow in the cylinder, as of old.

As to sight-feed lubricators cross-feeding, I believe the Detroit cup has been often charged with this fault. However, I have run an engine with the Detroit cup for about one year, and in that time I never detected it cross feeding, but have heard other men on the road say they have.

I am at the present time running an 18x24 Baldwin engine on fast passenger with a Nathan cup. We use nothing but cylinder oil, and I make 212 miles with a cup of oil, over a level road, and do local work. The valves on our engines are not, as a general rule, even scratched when they go into the shops after making from 40,000 to 60,000 miles.

Some twelve years ago on another road the M. M. introduced cylinder oil, and told the boys it must take the place of the "good old tallow." They kicked, and said they would not be responsible for their engines. The M. M. told us that cylinder oil had to have a fair show. There were no valves nor cylinders cut, and we heard nothing further about it. It is in use to-day on that same road, giving the best of satisfaction.

When cylinder oil was introduced on the road I am on at present, a howl went up from the boys, but my advice to them was to give it a fair show, as I had been there before.

I consider cylinder oil just as good as tallow as a lubricator, and it will not eat out steam chests and cylinders like the "good old-fashioned tallow."

If "Old Mossback" will give the sight-feed cups and cylinder oil a fair show, and decide on their use by their record in service, he will soon have to bury his prejudice and become a convert to all these "new-fangled rigs." J. L. ANDERSON,

Florence, S. C. Engr. Atlantic Coast Line.

About Big Engines.

Editor The Locomotive Engineer:

Old Timer is after me about the big engines, and I am surprised that he waited over a month—been sort of expecting him. All I have to say is that, where big engines have been introduced slowly, and the service cheapened to the company, the freight agents have cut the rates, and in consequence secured more tonnage, and therefore needed more engines and more men to move it. I don't believe there is a road in the country that does not now employ as many engineers as it ever did, yet 80 per cent. of them have adopted big freight engines within the past ten years. Whenever you do the same work for less outlay, or more work for the same outlay, there will be a cheapening of service to the public, and an increase in the volume of business. This is proven in the history of every industry in the country, except where the cost to the public has not been reduced, because of some false guard—such as a high tariff. That big engines temporarily cut down the number of enginemen, if introduced in large numbers, I do not dispute, because so much work is done before rates can equalize, and an increase of traffic occur.

We have a case of that on our road now, probably the biggest case of the kind on record. The N. Y. C. & H. R. R. have always stuck to the 8-wheeler for freight service—and not very heavy ones at that—the officers, as well as the men, declaring that they would pull as much, and run on less expense than Moguls, Consolidations, or any other class of large locomotives doing service elsewhere. About two years ago they made a trial of a 6-wheeled connected engine, and found that they could haul more cars, and consequently make more money with them. Then, instead of replacing old engines with larger ones, and letting them work in gradually, as other roads have done, they bought them of several works in batches of fifty or so, and put them to work as fast as received. The result was that it cut down the number of trainmen and enginemen, and there was a row at once. Trace the strike this month on our road to its origin, and you will find it right here.

We ought to have had heavy engines ten years ago, and long before this the road would be handling as many trains as now, and using as many of the big engines as they are now using of the small. Suppose, however, that big engines do retire enginemen, what are we going to do about it? Can we ask the roads to keep the small engines in service at a loss, to employ more men? Why not ask them to adopt engines of the "Rocket" pattern, that could probably pull four cars? That would increase the number of enginemen ten to one.

Brothers, these things will equalize, if given a little time, the number of enginemen in service in America is steadily on the increase, and—let me prophesy a little—will continue to increase in numbers during the next decade, as they have in the past, and the size of the engines they run will not affect their numbers in the end, at least, that is the opinion of an engineer "what ain't afraid," who signs his name W. E. ANDROS.

Albany, N. Y.

John Alexander's Advice to Young Runners—None Genuine without the Signature—Shake Well Before Taking.

Editor The Locomotive Engineer:

My boy Fred has been promoted—real, live, made-a-purpose engineer, now.

I am glad of it, and as proud of him as David was of Absalom, and yet there is a sort of lingering, sneaking regret about it somehow, just as there is when you suddenly realize that your children are no longer children, but men and women; just as there is when a parent sees a loved daughter marry the man of her choice, and the one she wants—we feel as if the new responsibilities might call for qualifications not in stock—a dread.

Fred has fired long enough to know his business, and I think he does know it, but, like all the rest of us, he will realize now what responsibility is; that firing is principally physical exertion—with a little figuring, and thought, and care around the edge, and that running is principally care and thought and figuring, just seasoned with enough labor to make it interesting. A man that don't realize what grave responsibilities he assumes when he takes charge of a locomotive had ought to be employed on a sheep ranch—not a railroad.

Fred has been asking me for a little advice—curious thing for a young runner to do, too, but Fred always was odd. I was just thinking that of all the young men who read the L. E., and who are striving for promotion, Fred is, perhaps, the only one who can go to a father for advice, and have that father the greatest living engineer on earth—I would have told you this a long while ago, except for my natural modesty.

I've been telling Fred a few things, and pointing to a few shoals, and if any of your readers want to get the benefit of the lecture let 'em crawl under the tent and listen.

Sais I to Fred, sais I:

Don't treat because you have been promoted—wait to see if you can hold the job down.

Look over the engine you are going to take out, but don't touch a bolt or a key until you have run her, and are sure you know what she needs and will stand.

Be careful to see that she has all tools and supplies.

If she has a regular fireman tell him that it is your first trip, and that you want him to give you all the pointers he can about the engine and the run, don't assume that you are made of different material, or know more about all railroad and locomotive work than he does—very likely you don't—enlist and interest him in your success.

Say to the conductor "Charlie, this is my first trip, and I may be paying more attention to this old mill than to the time-card; don't let me make any breaks." He will help keep you straight, and will give you credit among the other men for not knowing too much—a fatal railroad fault.

Look out carefully for the time-card, sacrifice almost anything but safety to keep on time and make your meeting points—this is really the essential qualification, and will give you a reputation for efficiency in the trainmasters' office, and the dispatchers will rise up and call you blessed, and cut down your layouts to the minimum.

Remember that the first law of railroading is "protection"—keep out of everything on wheels, and keep everything on wheels out of you.

Make a cast-iron rule that you will never drink on duty, and mighty seldom off, and that no man, yourself included, shall sleep on your engine while in motion.

Do your work cheerfully, if the trainmaster asks you to haul twenty cars more than a full train, spit on your hands and pull at 'em with a smile—tell him you can't do it *after* you have tried rather than before.

Always give your orders to the fireman to read—he may help you.

Now, about the engine. The ideal locomotive engineer is the man that has his engine in such condition that he can run her without looking at her or thinking about her, but can look at the road and think about the time card and the orders.

Let the builders *make* locomotives, and the shop men *repair* 'em—you *use* them.

Keep every stuffing-box neatly packed, and the headlight clean—that is your work.

Don't change the eccentrics or tile rod brasses—that is not your work—it is a mighty good man that does his own work.

When you get an engine regular fix all her oil-boxes and cups so that she will keep cool with as little waste of oil as possible, and try to run a long distance between oilings; don't have towns where you oil anyway, and others where you don't—oil the engine, not the town. Fix your front end so that the engine steams well, and then keep out of it—you don't keep on taking medicine after you are well.

Wedges should be set up about right, and securely fastened, then left alone for at least six months.

Key your side rods solid, brass and brass, and so that they are free on the pins, and then let them alone until you change your wedges—never key them up snug when the rest of the engine can come and go through wear—that kind of care is what sends them through the cab.

Keep both ends of your main rod keyed up fairly well, and have the crosshead lined up when you can put a piece of tin between it and the guides near the *ends* of the guides—not the middle.

When wedges are set right, rods keyed and securely fastened, eccentrics keyed, and all the bolts in the motion work fast, and the nuts keyed on, don't touch anything but the handles in the cab—it is the man that *works* on his engine that has the hot pins and cut brasses.

I could preach you a whole sermon, my son, on this little text alone. Work till you get them in pretty good shape, then consider that they have suddenly become sacred—and don't touch them. Don't try to get them just perfect—you can't.

Report work carefully, and not until you know it ought to be done; study your engine, and don't have jobs done a few months before she goes to the back shop that could be made to do until she did go there.

It is not the sign of a good engineer to book work every trip; the best ones have the least work to do.

If you want to make a record for economy in fuel look to all the little causes of waste; remember that the pop is throwing away coal instead of steam, that you can save a lot by careful pumping, and careful firing—don't get after the nozzles, the valve gear, or the valves, until you have looked up every motion of the fireman and yourself from the time the coal is piled upon the tender until it leaves the stack.

Engineers are the brains and nerves of the locomotives, and the locomotives pull cars over the road, thus earning every cent a railroad takes in, so you see that on your judgment, and reason, and ability depends the success of the road—try to be the best engineer on the line.

The best engineer is the man who pulls the most freight the nearest on time, with the least expenditure of fuel, oil, or for repairs, and the least damage to his train.

Keep away from the offices, do your work with the least fuss and smoke, have few kicks coming, and few favors to ask, and you will be more successful when you do kick or ask a favor.

Do not kick at every change that is made on the road, or on the engines—reforms can only come through a change—give every plan and every device a fair trial, and your verdict on its merits alone. Locomotives are far handier, safer and better than they were when first I tackled one, yet the engineers have kicked against every improvement that has been introduced in the past thirty years—I say it to their shame.

When the air-brake was first introduced the old-timers howled and squirmed, and I am ashamed to say that I once refused to run an engine because she had solid-ended rods—I wouldn't have any other kind now, if I could help it.

Defend your rights, but don't forget that every one has just as many as you have.

Keep your life insured and your board paid—you can never tell when something will get on the right of way, and put the 211 in the ditch and the great extinguisher upon your light—be ready for it.

Study your business, be a thinker—lead, don't follow. Save a little money as you go along, and, maybe, when you are old, like me, you won't have to run a mail train that leaves at 11.10 P. M., but can keep a cigar stand or own a sponge foundry of your own.

If you don't meet anything on the main line I may tell you something more next trip.

Boston, Mass. JOHN ALEXANDER.

Explanations are in Order—A Reverse Lever Question.

Editor The Locomotive Engineer:

We use in freight service here 20x24 consolidation engines with 48" wheel. There is something about these engines I don't quite understand, and I would like to have the opinion of your many intelligent correspondents in regard to it. When these engines are rolling down hill without steam, say twenty-five or thirty miles an hour, and the reverse lever is let down anywhere in the neighborhood of the corner, or even two-thirds of the way down, the reverse lever and running gear jar terribly and kick up such a racket that one would think everything was being torn to pieces. And it takes a full-grown man to pull the lever back towards the center again. The consequence is that a majority of our men don't let the reverse lever down when rolling down hill without steam, and, of course, this is detrimental to valve seats, as it wears them only in one place. Now I would like to find out the cause of this jarring. The engines are all new and in first-rate order, and use Allen-Richardson balanced valves, and large relief valves on steam chests.

They are Baldwin and Schenectady, first-class builders. I have thought about this matter a good deal and have not come to any satisfactory conclusion. I have also asked a good many experienced men about it, and have never received any very definite answer. The faster these engines run without steam the greater the jarring is. Hope I will get some information about this. "TAR HEEL."

Greensboro, N. C.

[We have heard this complaint from several sources, mostly from 10-wheelers having an intermediate connecting bar from the link to the rocker, in order to avoid the front axle. The writer has had experience of the same kind from engines of this class. We wish all who have had experience with engines affected in this way, and especially if they have found the cause or a remedy, would let us know about it. The trouble is so serious in some cases as to make it impossible to get the lever out of the corner at high speed.]

The Haberkorn Triple Valve in Service Stops.

Editor The Locomotive Engineer:

I was interested in reading the article in August number on the Haberkorn brake, but would like an explanation of one point in the operation of the triple valve. When a slight reduction of pressure is made to set the brake lightly, the triple valve piston, 2, will move down until exhaust valve, 3, seats, and will then stop. The pressure from drum will then pass around graduating stem to brake cylinder and set the brake, and will continue to set harder until the pressure in brake cylinder is equal to that in drum, and brake is fully applied, or the flow is stopped by releasing brakes.

It seems evident that the triple valve piston will never stop between the position where valve 3 seats and the full emergency position shown in cut. If my reasoning is correct, this brake when once set would continue to go on tighter until it was applied with full force or released, and would work just as the brakes do that are sometimes met with, which, owing to leaks in trains, set themselves continuously harder as soon as the air is applied at all. We all know how vexatious this is, especially in holding a train down a long hill. Perhaps I have overlooked some point in the operation, but this seems to me a serious defect. WM. BOHANNAN.

Argentine, Kan.

[The graduating stem, or plug, between the shoulders 1 and 2, is supposed to close the passage when the end of the stem touches lever 4 to exhaust valve. If it does this the valve will hold the brake on all right in service stops, if it leaks the brake will creep on.]

The Vacuum Automatic Brake as Used in England.

Editor The Locomotive Engineer:

I have been much interested in the articles published from time to time in your journal on the subject of automatic brakes, and have wished that we had here in England a similar paper devoted to teaching drivers, stokers and fitters how to repair and handle brakes and other locomotive devices.

The Westinghouse atmospheric brake has pretty much of a monopoly in your country, if I understand it, and the only trouble is to get the men to understand it, but here it is different; we have no less than four different systems of automatic brakes, good and bad, and the rolling stock being exchanged, it is often that we find two and three kinds of brakes in a train, and, of course, can use very little if any of it. All accidents in this country are investigated by the Board of Trade, a government committee, and they have laid down five rules, called the "Board of Trade conditions," that a brake must fulfill to be deemed a safe and proper brake; but I am sorry to say that the chairmen of many of our lines pay no attention to them at all.

These "conditions" are as follows:

1. The brakes to be efficient in stopping trains, instantaneous in their action, and capable of being applied without difficulty by engine drivers or guards.

2. In case of accident to be instantaneously self-acting.

3. The brakes to be put on and taken off (with facility) on the engine and every vehicle of a train.

4. Brakes to be regularly used in daily working.

5. The materials employed to be of durable character, so as to be easily maintained and kept in order.

England is indebted to the United States for the invention of the automatic air-brake and the simple vacuum brake, but our own inventors have given us two or three kinds of automatic vacuums that are, I am told, unknown in your great country.

Here it makes all the difference in the world whether you say "vacuum automatic," or "automatic vacuum." This last brake is known as the "leak-off," because, after being applied, it automatically leaks off in about two minutes, and is a very dangerous brake, as you can well see. The "vacuum automatic" does all that the automatic air brake does, it is in very extended use here, and I will try to explain it to you—faults and all.

I guess all American enginemen know that the simple vacuum brake, as invented by Mr. Smith, is worked by the pressure of the air on diaphragms or cylinders, from which the air has been drawn out by a jet of steam.

Mr. Smith brought his brake to England in 1874 and it took at once; it was cheap, quick, had no moving parts on the engine, required no oil, and very little attention; but it was non-automatic, and therefore dangerous; our inventors made it automatic. I have traced some cuts of the principal parts from a book recently published here on the subject of "Safe Railway Working," and think by their aid I can make the brake plain to your readers.

In the first place, they still use the large annular jet of steam to produce a vacuum in the train pipe, but this holds the brake *off* instead of *on*, as in the Smith vacuum, then, after producing the vacuum, they shut off the big ejector and use a little one to keep the vacuum up against leaks. Fig. 1 is the engineer's valve; it is placed on the side of the boiler just as shown, and the handle works up and down instead of to and from you, as in the Westinghouse.

When the driver puts the handle at "off" the big ejector quickly produces a vacuum and releases the brake, then he moves it to "running position," and the big ejector is shut off, and the little one, shown in the center of the big one, is put to work, the gauge telling how much vacuum is maintained; when it is desired to apply the brakes the handle is moved to "on," and air is admitted through the many perforations shown in the body of the valve, and the brake is applied.

Now let us see how it does this. Fig. 2 shows the brake cylinder and auxiliary drum, or what takes their places; the outside shell is large and hung under the car vertically on the two trunnions shown, so as not to cramp the piston rod, which is

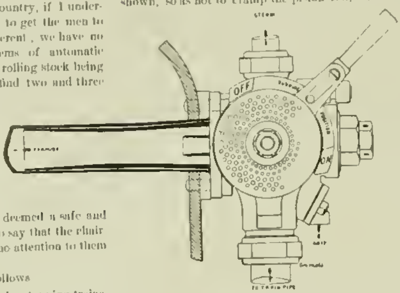


Fig. 1.

attached by levers to the brake gear, the train pipe is connected by a short piece of hose. Inside of this drum there is a cylinder, open at the upper end, and in this cylinder a piston with a shell head, as shown, around this piston head there is a round rubber ring—like a bicycle tire—that rolls between the piston head and the cylinder, forming a tight joint with very little friction; in the cut it is shown at the top. At the bottom of the drum there is a valve case with an opening from above and below the piston, and in this valve case lays loosely a rubber ball; this ball valve is shown in detail in Fig. 3. Now, when a vacuum is created in the train pipe the air is taken out from under the piston and from above it, the ball valve having

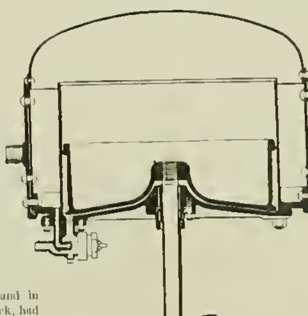

Fig 2.

no tendency to move in any way, and so, when running, the brake piston lays at the bottom from its own weight, but let air be admitted to the train line and it pushes the light rubber ball ahead of it, and against the seat where it is shown; this prevents the air from going above the piston and admits it freely below it, raising it at once and applying the brakes, which can be taken off only by restoring the vacuum.

Fig. 3 shows the ball valve; this ball is enclosed in a brass cage, the cage being movable in the case, and prevented from leaking by the diaphragm shown by black lines; this case is connected to a rod outside, and by pulling the cage out the ball is pulled away from its seat and air is admitted above the piston, releasing the brake; this answers the same purpose as the means for "bleeding off" the airbrakes.

Fig. 4 shows the guard's valve; this is located in the guard's van and answers two purposes, affording the guard opportunity to apply the brake and aiding the driver in making an emergency stop. Just above the valve there is an enlarged chamber to which the guard's vacuum gauge is attached; this chamber is connected to the train pipe by a small hole drilled through the valve spindle as shown, the top being kept from the air by a disk nearly as large as the valve; the valve seats down on edge of case, and around the case, above it, are numerous holes; now when a vacuum is produced in the pipe the air holds the valve down, and the chamber above the valve contains the same vacuum as the pipe, but should air be admitted suddenly to the train pipe it destroys the equilibrium between the top and bottom of the valve, and it is lifted from its seat, admitting air direct to the train line through the perforations. If the guard wishes to set the brake he does so by lifting the valve by means of the lever shown.

The vacuum automatic is a good brake, very quick, both as to application and release, thoroughly automatic, has few moving parts, is easy to keep up, and is cheap, but it has one fault—the little ball valve sometimes freezes to its cage through moisture being admitted to the pipes in the air, the worst of this is that the driver and guard can have no notice of it; the vacuum gauges showing all right; you admit air to the pipe to apply brakes, and it goes over as well as under the piston, and you overrun your station and perhaps hit another train. But I have had air pipes on the air-brake freeze up on me as well. If this explanation of our vacuum automatic proves of interest to my American brothers of the foot-plate I shall be repaid. I have a great respect for your American engineers, having made many good friends among them during two years of engine driving on the Grand Trunk of Canada some years ago.

Swindon, Eng. BENJ. HOWARTH.

The Vacuum Brake.

Editor The Locomotive Engineer:

Briefly replying to one query of "Old Timer" in your August number, as to "How the automatic vacuum brake works," would say that two ejectors are used on locomotive, called the large and small ejector respectively. The large one is of about the same size as that used with the non-automatic brake, while the small one discharges a $^5/_8$ steam jet and maintains vacuum through train while running. The car equipment consists of the usual diaphragm and connections, and when brakes are off a vacuum is maintained on both sides of diaphragm. Additional vacuum space is furnished by a reservoir similar to the "Auxiliary" of the Westinghouse system. This reservoir is piped to one side of diaphragm, viz., that side toward which diaphragm moves in applying brakes. The connection between *that* side of diaphragm and the *train line* contains a check valve, while from the opposite side of diaphragm a free pipe is run to train line.

The action is as follows: When a vacuum is produced in train pipe, air is drawn from both sides of diaphragm and a vacuum of course maintained on both sides. If air be admitted to train pipe, either through engineer's valve, or by bursting of hose, it passes to one side of diaphragm, but is prevented from reaching the other side by check valve above referred to. The brakes are thus applied and are held on until a vacuum is again produced by the ejectors, train line being intact. The engineer's valve has four positions: The "Release" by which the large ejector is opened and connected to train pipe; the "Running," in which the small ejector is to put train line and maintains vacuum therein, and on both sides of diaphragms, as described, blowing continuously, a "lap" next beyond the "running" position, and lastly, the "application" port, by which air is admitted to train line to apply brakes.

Without going into details of construction, this is a brief description of the automatic vacuum brake as manufactured by the Eames Co.

New York. C. H. W.

Some Practical Points on Valve Setting

Editor The Locomotive Engineer:

The following remarks on valve setting are not intended to teach experts any new kinks (nor any one n ten-minute rule), but to teach beginners a short and quick method as can be practiced with any degree of satisfaction. We will suppose our engine's upper and lower rocker arms are the same length, and that you, or our beginners, know how to get an engine on the dead center.

To beginners it is better to have steam-chest lids off than to depend on the tram on the valve stem alone. Put engine on front center, with reverse lever in full forward gear, and with a pencil make a note of how your valve is. If it covers the forward steam port, find how much, and make your memorandum this way: "Forward gear, front end, $\frac{1}{4}$" blind," or, if the port is open a $\frac{1}{4}$" say, "Forward gear, front end, $\frac{1}{4}$" lead." Now put your reverse lever in back gear, pull, with all your strength, the valve stem toward front of engine (which will take up the lost motion occasioned by moving reverse lever), then make a memorandum of position of valve now, but say, "Back gear, front end, blind so much, or so much lead."

Now turn engine to back dead center, note position of valve, and you have the back gear ready for adjustment. Put reverse lever ahead, pull the valve stem backwards this time (to take up lost motion). Note position of valve again, this time for forward gear, back end. You are now ready to look at your paper and tell just what alterations to make in either the forward or the back gear of this side of the engine.

Say you find forward gear, front end, $\frac{1}{4}$" blind, and forward gear, back end, $\frac{3}{8}$" lead. Now, as you want her to have $\frac{1}{16}$" lead, at both ends of the cylinder, it takes $\frac{1}{8}$" total lead to give her proper lead. You see you must subtract the distance she is blind from the lead, and must have $\frac{1}{8}$" left, which you have, exactly, in this case, and it follows that your eccentric is exactly right, but the rod is wrong. Now you ask, Which way wrong? Think a minute, and you will see that it is $\frac{1}{4}$" short. Make it a $\frac{1}{4}$" longer and your forward gear is exactly right.

But suppose the back gear memorandum shows $\frac{1}{8}$" lead front end, and $\frac{1}{4}$" lead at back end cylinder, you have a total lead of $\frac{3}{8}$", which is $\frac{1}{4}$" more than you want, and you know your eccentric has slipped at once, and the blade, or rod, is not the right length, either, as she did not have the same lead at both ends. The first thing to do is to lengthen the back motion eccentric rod $\frac{1}{16}$", and then roll your eccentric backwards enough to reduce the lead at either end to $\frac{1}{16}$" and the back gear is finished. But suppose you find that on the other side forward gear shows $\frac{1}{4}$" blind for both front and back ends cylinder (which is the most common derangement). You know, by both being the same, that your rod is the right length, and that nothing needs doing but to set the eccentric, which you must move or roll forward enough to slide the valve $\frac{5}{16}$", which will give you the $\frac{1}{16}$" lead equal at each end. If the back motion shows just the reverse, or has equal lead but more than is needed, you know you only have to roll your eccentric back to reduce the lead to $\frac{1}{16}$.

The four examples cited above are the only ways that the eccentric or eccentric rod can affect the exhaust of an engine, and if, after setting her valves according to the above, she does not exhaust right, you may know that the rocker arms, or shaft, are sprung, or the link hangers are not the right length, or improperly hung. I will have something to say about the effect such derangements would have some time in the future. S. PARKER, M. M.

Plymouth, N. C.

[The foregoing article teaches a valuable lesson in showing the beginner where to look for derangement of the link motion, and what causes the different derangements. Many men who ought to know better will tinker with eccentric blades to increase or reduce lead, which can only be effected by the eccentric; and again, they will attempt to manipulate the eccentric to make the valve travel equally each side of the center of the seat, while this can be done only by adjusting the length of the eccentric blade or rod.]

Some Good Cleaning Receipts.

Editor The Locomotive Engineer.

Regarding the cleaning and scouring of a locomotive, I agree with "Petaconsett" in July number of THE LOCOMOTIVE ENGINEER; namely, that "the easiest way is the best." But with thirteen years of diverse experience as a fireman and machinist on different roads and all classes of engines, I differ with him in the art of cleaning. A dozen years ago engines were emblazoned with brass and copper fixtures, etc. All this brass work was supposed to be kept polished, for the engine was built for a thing of beauty, an ornament, as well as for usefulness. The master mechanic generally would pride himself then on the beauty of his engines. This cleaning and scouring was all done by the man who had handled tons of coal, or "heaved" cords of wood

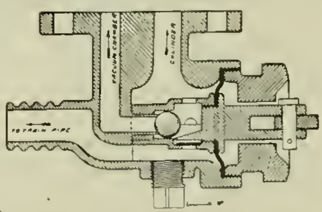

Fig. 3.

for his day's labor, and without pay for it. To-day, however, the locomotive is not built for an ornament; master mechanics and superintendents of motive power have done away with brass work and ornamentality. A new idea has established itself in our mechanical world, and that is, that it does not require an engine bronzed and polished to perform its work, and that this ornamentality is not only useless, but a detriment to true economy as well; mileage, power and economy are what engines are built for at present, our officials have a more liberal view regarding the work of firemen. They look more to the economy of fuel and material in general, and at the same time a moderate degree

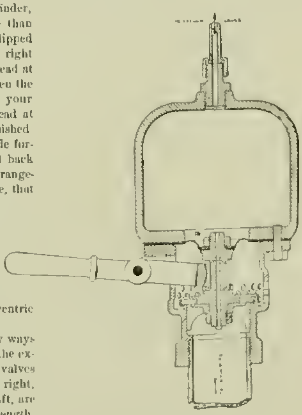

Fig. 4.

of cleanliness. I find the easiest, quickest and best way of keeping a neat engine, as follows.

The brass work is left alone in its original color, this can be easily accomplished by first removing all oil and dirt stains, and then giving it a light coat of colorless varnish, then, by wiping it with a piece of cotton waste at the beginning of each trip, the brass, hot and cold, will retain a comely and cleanly color for months without polishing; acids such as are used will eventually harden brass, and not only that, it will form a corrosive matter in "joints" and threads, thus weakening, more or less, the metal.

Boiled oil, Japan, drop black and black varnish, are used throughout the land, but the labor of keeping a "front end" or smoke-arch in good condition with these ingredients is unceasing; through gumming, scaling, etc. Smooth the front end down with emery paper, and then give it a coat of plumbago or stove polish; this will make a smooth and lasting polish and a neat and pretty background for the painted number plate and headlight.

On all paint work, inside of cab and out, I use a solution of turpentine and boiled oil, equal parts. This will take away all dirt and maintain the gloss on the paint, while the lye and acids of soap aid in deadening it. For jacket, I use a thin dope of tripoli and kerosene. This will give the iron a sky-blue color, and if the jacket is blackened and gummed through former neglect, a bucket of water with concentrated lye dissolved in it will remove the dirt, then followed with the dope. I do not think the use of cold water on a hot boiler head, to remove scale, practical, for obvious reasons. Tallow is not a cleanly article to use, as it gums and creates a bad odor in the cab. Using a sharp scraper or chisel, and then smoothing it with emery paper, is the best way to remove the dirt; to polish it use common beeswax; this will give the boiler head a pretty color without unpleasant odor. With these inexpensive articles of cleaning you need never be ashamed of having your traveling engineer or master mechanic ride with you. MANITAU.

Creston, Iowa.

Will Go to See One.

Editor The Locomotive Engineer:

I have been reading so many articles in your paper on the cause of locomotive engines slipping their wheels while steam is shut off, and there have been many reasons given for it up to date, but it appears to me that it would be quite a good idea for some one who has *that kind* of an engine to notify some "skeptic" like the writer and let him go and see the *thing done*, and by so doing one might be able to see "the why" of it. It is useless to look for a remedy for any *cause* that does not exist. The writer would put himself to considerable trouble to be allowed to ride on one of the above engines, as it is now, it makes one feel as though he had fooled away the most of his life without seeing anything of much account.

Who and where is the man that has that kind of an engine? Now, don't too many speak at once, for it would be apt to get one "rattled." It appears to me that if this thing can be worked out in the right shape, it will make Mr Keeley, with his world-wide famed motor, "hustle." Awaiting the many replies, I am,

Germantown, Pa. HOGBACKER.

Lubricators Connected Direct to Steam Pipe.

Editor The Locomotive Engineer:

I am overhauling a locomotive, and I propose to put a single pipe through the steam dome into the dry pipe to lubricate valves and pistons, instead of running a pipe to each steam chest under the jacket, and to this single pipe attach a sight-feed lubricator. Will it lubricate the valves as well as the two pipes attached to top of steam chests, as is in common use? If not, why not? Would like your opinion or the experience of any engineer that has tried it.

ALLEN WOOD, M. M.

St. Augustine, Fla.

[Lubricators connected direct to the steam pipe of a locomotive work as well, if not better than those connected to the chests when the engine is working steam; the trouble has been to get them to oil the valves properly when running down hill shut off.]

Our correspondent W. E. Andros gives a clue to the possible cause of dissatisfaction that led to the strike on the N. Y. Central. He ought to know what he is talking about—he was on the ground.

Again we must notify correspondents that we cannot use anonymous communications; don't send them without your name.

Reason in All Things.

The news of a strike on the New York Central Railroad was a surprise to most people, not only on account of the suddenness with which it took place, but because it has been thought that the relations existing between this road and its employes were exceptionally pleasant, and, indeed, such as to make a strike almost an impossibility.

And it will seem to most people who calmly view the situation that this is a strike which it would have been easy to avoid, and which would probably have been avoided if those in authority had been mindful of their obligation to the public, and had exercised a little tact, and been a little more disposed to consider the fact that there are usually two sides to a question.

In the old times when communication between different towns and different parts of the country was by vehicles drawn by horses upon roads which all could use upon equal terms, no falling out which could possibly occur between an employer and his men could prove very serious to the general public, both for the reason that the public in those days depended much less upon travel and carrying traffic than we, and the means for using the highways were in the possession of the people generally, so that almost any one could make full and efficient use of them.

In these times, with our much more highly developed social organism, this has all been changed. The principal highways upon which we now depend for getting about from place to place, and for the transportation of food, etc., are not the simple affairs of former years, but complicated systems of railways which only those can use who have by experience and training acquired the necessary skill. And even if the skill, and all else required for the operation of these roads, were in the possession of the people, no one except the owners of them would have the right to operate them, so that when these owners fail to keep them in operation the public must get along without the highway as best it may.

And when such a system as the New York Central road becomes suddenly paralyzed, even for a short time, it is a very serious matter. The people having given to a corporation the exclusive right to occupy and use a continuous strip of land for the purposes of a highway, have a right to demand, it seems to us, that that highway shall be kept open, and in an efficient condition for service, so long as by any practicable means it can be so kept open. And it seems to us that just here the management of this road has failed entirely in its duty to the people. The immediate cause of this strike seems to have been, and most likely was, the refusal of third Vice-President Webb to receive and talk over the matters in dispute with a man who was the accredited representative of employes, who, whether rightly so or not, evidently believed that they had a grievance which should be adjusted. It was the plain duty of Webb to the company he represented, to the men, and, above all, to the public, to receive this man, talk matters over with him, and adjust the difficulties if possible. It made no difference that this man was not an employe of the road, nor that he was an officer in an organization not approved of by Mr. Webb; he was the accredited representative of the dissatisfied employes, and should have been received as such, and the questions in dispute settled solely upon their merits, if possible.

Some of the demands said to have been made by the men we do not consider to be fair. For instance, what is called the seniority rule, by which promotions are made in the service solely upon the ground of the length of time an employe has been in the service. We think this is demoralizing and unfair to men who are willing to take pains to study and improve in their business. It is simply putting a premium upon inefficiency, and is, so far as we can see, wholly wrong. Then the demand said to have been made, that when men were to be laid off it should be always the men last employed, we also think is wrong. If this rule were strictly enforced, what chance would a railroad company have to improve its service, or to choose the men best adapted to the work? When an employer has to let employes go, he will naturally want to dispense with the services of those least profitable to him, and it is not only right that he should do this, but in the end it is manifestly better for the men themselves, for it is only by some such process of natural selection that each man who works can be in the position where he can work most efficiently, and with the best returns to himself.

In this case, however, the main difficulty seems to have been that the men claimed that some of their number had been discharged solely because they were members of the Knights of Labor. This charge the railroad officials denied, and claimed they had made no discrimination, but Mr. Webb refused to meet the men's representative who called to talk with him about these matters, and ordered him to leave his office—a line of behavior which, human nature being as it is, he should have known would almost certainly have resulted in trouble for his road, and for the public depending upon it for transportation. For this the almost universal public sentiment seems to be against him. No harm can ever come from a candid and courteous discussion of differences, while much harm has repeatedly resulted from a refusal of one or both parties to do this or to listen to reason.

Studying to Improve System of Doing Running Repairs.

The minor details on a locomotive represent a large investment of money, and the repairs of small parts constitute a large percentage of the outlay represented in running repairs. Half the time put in by machinists on locomotives in roundhouses is done in grinding in some of the numerous valves, or repairing or tinkering at injectors or brakes. Where a road is short of power a larger force of men are required to keep up these repairs, as they have to be done hurriedly in order to keep the engines in service.

It has got so now, especially where they double or treble crew engines, that no attempt is made to repair an air-pump or an injector in place—they are taken off to be repaired at leisure and replaced by others known to be in working order.

This plan can and ought to be carried just as far as possible in all running repairs—replace, instead of repair parts.

On a few roads it is customary to take out globe or angle valves and put in new ones when in a hurry; but it is not necessary to break so many steam joints. For the same money as now paid for plain valves, a class of valves requiring no grinding of the seat can be had; these valves have a round seat and a loose button-valve with a disk of Jenkins packing or prepared asbestos to form the joint, these disks are removable from the stem and can be replaced in one minute, extra buttons or valves costing but a few cents—this saves time, does not require extra skilled labor, and is a better job when done than the old, ground valve.

Every steam valve in a locomotive cab—except the gauge cocks and glass—ought to be tapped into a fountain, or duck's nest, and so arranged that one large valve would shut off the whole from the boiler, then any valve can be made as good as new in less than ten minutes with a full head of steam on.

Some day driving-box wedges will be arranged just as solid-ended rods are—so that there will be no adjusting them—then side rods will be repaired and boxes adjusted together, there will be fewer cut wedges, shoes and boxes, and no stuck ones. Systematic repairs, or rather renewals, will then be made on a mileage basis and side rods will be interchangeable.

There is a chance to save considerable expense in running repairs, and we are of the opinion that it can be done easiest by scheming to replace instead of repair worn parts, and every mechanic in the line should study to get his work into such shape that by simply taking off something and hanging a duplicate on he can let the engine go out.

The idea of letting an engine lay in for a couple of boiler makers to stand on her finished work all day to put in a new cone or stack netting, is old fogy; give her a new stack and let the men repair the old one at their own benches, where they do not have to carry tools and material to and from the work.

Repairs that are made in the shop, when there is no hurry, and time given for a good job to be done and tested, will last a great deal longer than the "good enough for this trip" excuses with which so many American locomotives run from day to day.

We recently saw a passenger engine laid in because she had a broken air-pump, and they had sent a freight engine—without air—out on her run. When we asked the foreman if he didn't have an extra air-pump he said, "Oh, yes, but this one is not broke so as we can't repair it all right." It seems never to have occurred to him to put the extra pump on and keep the engines on their own runs.

This was on one of those roads where every piece, great and small, is branded with the number of the engine, and it is not to be supposed that water would go through check valve number 186 and into boiler number 219 and know what it was doing.

A little intelligent exercise of gray matter in this line will save time, confusion and—dollars.

For M. C. B. Standards.

John W Cloud, secretary of the Master Car Builders Association, has issued a pamphlet stating clearly the questions, and calling for letter ballots on the adoption of a standard journal box lid for 60,000 pound cars, 40,000 pound cars; racks for loading bark and logs on cars; draw-bar and safety chains for passenger equipment cars; brake beam levers and train pipe for steam heating.

The votes will be yes or no on the following questions.

a Are you in favor of the adoption, as a standard of the association, of the journal box bearing (with wedge) and malleable lid for 60,000 pound cars, as shown by drawings on plate "A," when modified as above explained as to lid?

b. Are you in favor of the adoption, as a standard of the association, of the same form and size of malleable lid for the journal box for 40,000 pound cars?

c. Are you in favor of the adoption of the plans shown on plate "C" for loading logs and poles on cars, as standard?

d. Are you in favor of the adoption of the plan for racking cars for loading bark, as shown on plate "D," as standard?

e. Are you in favor of the adoption as the standard height for draw-bars on passenger equipment cars, of 35 inches from top of rail to center of draw-bar, when car is light?

f. Are you in favor of the adoption as standard, of the size, location and arrangement of safety chains for passenger equipment cars, as shown on plate "E," with all links made of $\frac{3}{4}$ inch iron, and $1\frac{3}{4}$ inches wide inside?

g. Are you in favor of the adoption, as standard, of 40 degrees as the lateral angle which the brake beam lever makes with the vertical?

h. Are you in favor of the adoption, as a standard of the association, of a fitting on the ends of train pipe for steam heating, consisting of a 2-inch female pipe fitting with standard pipe thread?

The Wrong Remedy.

We take the following item from the *Master Mechanic:*

Some recent engines of the American type are credited with a weight of 80,000 pounds on the drivers, or 20,000 pounds per wheel. It seems to us that such great weights as these very nearly, if not quite, reach the limit beyond which it is unsafe to go if cast-iron is to be retained as the material for wheel centers. The calculation of the magnitude of the stresses in a driving wheel in revolution on the road is so exceedingly complicated as to be useless for any practical purpose, even supposing its results to be approximately correct, which is doubtful. We have, therefore, to rely entirely on the teachings of experience, and that kind of sense that is generally, but erroneously, called common. But although failures of driving wheels are fortunately rare, and convey scant information when they do happen, we certainly think it is high time that more serious attention was being paid in this country to other materials, notably wrought-iron and steel, for this purpose, if we are to continue to enjoy the immunity from fractured drivers that we have in time gone by.

This seems a strange proposition from a mechanical paper. If it were necessary, there is not a locomotive builder in the country that would not put double the load mentioned on a cast-iron wheel center. It is the driving box that can't stand the load, and must be enlarged and improved as the load upon it becomes heavier.

Train wrecking has become so safe that its prevalance everywhere is not to be wondered at, unless it is to be wondered at that human beings can bring themselves to murder innocent workmen for petty spite at their employers or for purposes of robbery. In almost every case of train wrecking the engineer and fireman lose their lives, it is seldom a passenger is hurt. Every week some poor fellow is brutally butchered in this way, and we hear only the old excuse, "No clue to the perpetrators of the crime." Placing obstructions on a railroad track should be a capital crime, and counties or districts where such murders take place should be made to find and punish the criminals or pay for the lives and property destroyed.

Promotions.

L. C. Hitchcock roundhouse foreman on the M., St. P. & S. S., M Ry. at Minneapolis, who is well known to our readers through his clear and concise contributions on running repairs, has lately reaped some of the benefits to be derived from efforts to be somebody. He has just been appointed general foreman of the main shops of the "Soo" road. Hitchcock is not through yet, he has but just started.

Mr. William Buckley, an engineer of the Louisville, Evansville & St. Louis road, has been made assistant master mechanic of that road.

A. W. Gibbs, Division M M., of the Richmond & Danville, at Alexandria, Va., has been appointed Supt. of M P. of the Georgia Central road Mr. Gibbs is one of the brightest young master mechanics in the country.

George W. Tilton, for many years past Supt. of M P of the Chicago & Northwestern road, died on the 17th inst from injuries received in a derailment. Mr. Tilton learned the machinist trade at the Manchester Locomotive Works, and went from there to the C. & N. W at its inception. William Smith, Asst. Supt. of M P, will succeed him.

Books Received.

POOR'S MANUAL OF RAILROADS FOR 1890 Twenty third annual number H V & H W Poor, 70 Wall street, New York. Price, $6.

This well-known work on railroads has been issued for 1890 and the present number maintains the standard of excellence that has kept up for years its well earned reputation The book contains upward of 1 500 pages, and is recognized both at home and abroad as a reliable record of railway progress and upon the financial standing of railroad property

The special new feature this year is the addition of fifty-one new maps of systems of roads that are correct, and show not only the location of the road, but the topographical features of the territory as well. It takes a well-informed railroad man to follow all the ramifications of his own road, if it is a large one, and few, if any, of the average railroad investors, could point out on a general map the line of any road These maps will be of especial value, and will, no doubt, be added to from year to year until all the large lines are so shown.

The general exhibit for the fiscal year ending December 31, 1889, makes very interesting reading, and from it we cull a few points as follows Length of tracks in United States, 161,896 64, increase for the year, 6,268,43; total liabilities of companies owning this mileage, $9,931,153,116, total assets of same, $10,205,493,020 During the year passenger trains ran 279,620,145 miles; freight trains, 430,719,737 miles, and mixed trains, 18,432,291 miles, or a total of 728,772,142 miles. There were 495,124 767 passengers carried, which equaled one passenger being carried 11,905,720,015 miles There were 619,137,237 tons of freight moved, that equaled 68,601,012,894 tons being moved one mile. For this work the roads received $992,856,856, and paid out for operating expenses the sum of $674,731,517, which left a balance of net earnings of $318,125,339; and they received from other sources, such as rentals, etc., enough to make the net earnings $406,929,187 From this amount there was paid in interest, etc., the sum of $376,102,967, leaving an excess of available revenues over actual payments for the year of $30,220,520.

"Poor's Manual of Railroads" stands alone in its particular field, and is as valuable to the railroad official, the investor and the bankers, as a pen to the copyist

REPORT ON THE SUBSTITUTION OF METAL FOR WOOD IN RAILROAD TIES By E E Russell Tratman, C. E Government Printing Office, Washington

This report is a very elaborate review of the tie question, and contains a vast amount of information on what has been done with metal ties in every part of the world. Accompanying the report are plates showing the forms of all known metal ties. Any one interested can, we presume, secure a copy free through the Congressman from his district.

THE LAW OF WAGES, THE RATE AND THE AMOUNT By John Richards. Industrial Publishing Co., San Francisco, Cal. Price, 25 cents.

This little work is a series of short chapters on the labor problem, from the pen of the venerable editor of *Industry*, a Pacific coast mechanical paper The author lays great stress on the difference between the *rate* and the *amount* paid to labor.

The work is interesting and valuable, inasmuch as it points out the inequalities and wrongs in wages as now paid to labor, but it offers no particular remedy except in increasing the efficiency of labor and thus the reward The book is worth far more than its price to any one interested in the subject of labor

ASKED & ANSWERED.

(55) C. B. N, Galena, Ill., asks

Why does an engine's driver brakes hold better when the piston has less travel? *A.*—Other things being equal the length of stroke will make no difference with the retarding power of the brakes.

(56) A L. D., Port Royal, B. C., asks

What is the weight and size of the Denver and Rio Grande heavy, narrow gauge consolidation locomotives? *A* —Weight, 72 000 pounds, 62,000 on drivers, cylinders, 16"x22"; driving wheel, 36"; smallest ring in boiler, 52", gauge of track, 36".

(57) Reader, Cherokee, Iowa, asks

Which gives the most strength in putting patch on cylinder part of boiler in front, where it connects to front flue sheet in a half round shape, to let back of patch rest on inside of boiler, or lap it on outside, of course using the same number and same size rivets in each case (see sketch) *A.*—Either form will be strong enough, and it should be located where it is the easiest to work on to do a good job.

(58) J P. D., Aspen, Col., asks

How do you find the radius of a curve when the degree is given? Any railroad man can form some idea of the size if you tell the radius all he has to do is to imagine part of a circle so many feet to the center, but I for one can't get any idea of the size when they talk about degrees *A* —You can find the radius of any curve when the degree is given by dividing 5,730—the radius of a one degree curve—by the degree Dividing this figure by 28 gives $204\frac{9}{14}$ feet the radius of a 28 degree curve

(59) Green Fireman, Dexterville, Wis., asks

Should you break off both hose connections what would you do? *A* —First close both tank valves to save water then repair break if possible, whether you can do so or not depends on where the rupture takes place; sometimes a goose neck is broken on one side and the hose on the other, then, by putting the good hose on the good goose-neck, water can be got into the boiler No two accidents of this kind are likely to be the same, and no rule can be formulated; the ability to meet and overcome obstacles of this kind distinguish the real locomotive engineer from the helpless stopper and starter

(60) J. E. Waterville, Me, asks

Why, in the case of mogul and consolidated engines parallel rods could not be made in one forging instead of using two or three rods with knuckle joints as is commonly done I understand about the difference it makes in handling them in taking down and putting up, and suppose that a thing like a low joint would be bad for one continuous rod Now I want to know if there are other reasons against it *A* —On an uneven track the right rod would be bent or broken, or would break the pins, even on an absolutely level track there would be enough movement of the driving boxes to cause the pins to heat and cut

The report recently published about the discovery in Germany of a worm that eats steel rails and beams, reminds us of the excuse of an engineer in the far West, who scorched the rafter bolts of his crown sheet. When asked how it happened, he facetiously said it was on account of the fireman, who had taken water with worms in it, and they had eaten off the crown stays.

Pedrick & Ayer, of Philadelphia, have issued a pocket price list of their special railroad tools that is very handy and neat. It contains cuts, a brief description, and the price of all the machines and tools built by them.

Frank Johnson sends us a dollar bill for a year's subscription, but does not tell where he is, and his letter was mailed on the cars If Frank will name his town and State the paper will reach him.

Some Early Valve Motions.

SYSTEM OF TWO LOOSE ECCENTRICS

Probably the device used by Jackson in England was the best known of the "loose eccentric" breed of valve gears, and while it is probably fifty years since one of them has been built for locomotives, practically the same thing is still in use on some classes of small steamers.

Jackson's early engines, like Stephenson's, had but four coupled wheels, without trucks, and were of short wheel base; he placed the eccentrics on the back axle, extending the rods, or hooks, through to the front of the engine, and there engaging the rocker shafts that moved the valve stems, the latter entering the *front* of the chests.

Our illustration shows a plan of the motion, looking at the bottom of the engine. The rocker shafts were in front of the cylinders, and the arms of these shafts entered a hole in the end of the valve stems and moved them, sliding up and down in the slot in so doing.

A set of levers extended back to the cab for hand use, and the engine could be worked by hand in either direction when the eccentrics were out of gear. The two eccentrics were made in one piece, or fastened together, and had on each side a steel plate with holes in them These holes engaged with pins fixed in collars each side of the eccentric. When moved in either direction these holes were caught by the pin in the fixed collar, and moved the motion with the axle. When the eccentric block was midway between the collars, the axle revolved in it, and no motion was transmitted to the valves

A forked lever, such as used in clutches, was placed in the recess in the center of the eccentric blocks, and so arranged that, by pressing a treadle on the footboard, the eccentric block could be engaged with the pin in either collar, or held central between the two without revolving. It is needless to say that the pin in one collar when engaged with the eccentric block was so set as to run the engine in one direction, while the other pin would cause it to move in the opposite direction.

The eccentrics were placed at right angles to each other, and when the engine was moving, and it was desired to reverse, the shaft would make a partial revolution after the eccentric was disengaged from one collar before it could be engaged with the other.

If the engine was standing, and in, say, forward gear, and the runner desired to back up, he would place his foot on the pedal and disengage the eccentric from one collar, and hold it against the other, and move the engine until it hooked onto the opposite collar If the engine would not so move; he would unhook the eccentric rods by use of the levers then move the engine by use of the hand gear until the eccentric caught.

This form of gear was trappy, very liable to derangement, and was, of course, a full stroke gear, like the single fixed eccentric

---

Under the heading of "Death and Doggerel," the editor of the *Locomotive Fireman's Magazine* puts his foot down and declines to publish any more mongrel poetry dedicated to the poor fellows who lose their lives on the road, or in any other way. Those who have laid down their lives are helpless against the poetry (?) fiends and should be left alone. The *Magazine* is progressive.

Our correspondent, W. H. Ermentrout, after several years of service in the P. & R. shops at Reading, Pa., has established himself in business. He will manufacture a new device for lining up locomotive guides, a new plumb bob, valve motion models, and any other small tools or devices that seem to have merit.

A Midsummer Night's Trip, and What Came of It. A Frontier Fable.

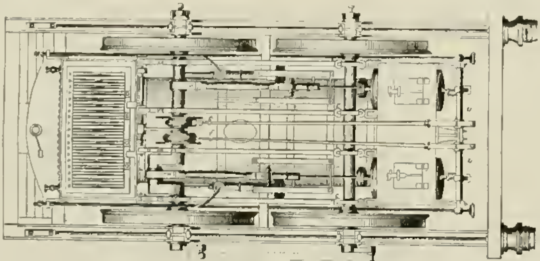
BY JOHN ALEXANDER.

It's more than ten years ago now, since the little incident happened that I am going to tell you about It don't amount to very much, and railroading has mighty little to do with it, but I just thought that, perhaps, it might interest the boys, and go to show how it is that men in the transportation department push themselves ahead of us conservative fossils in the motive power and get things that we want, and, perhaps, ought to have. After the strike of '77, you will remember, I went into exile in the wild and woolly West, mostly in "bleeding Kansas," but often in Colorado, New Mexico, and Arizona—the Santa Fe gets almost everywhere in the Southwest.

One night in August, I was dropping an old Baldwin consolidator down a long New Mexican grade, after having "helped" a stock train over the division by "double-heading." It was close and hot on this sage-brush waste, something not usual at night in high altitudes, and the heat and the sheet lightning around the horizon warned me that there was to be one of those short, fierce storms that come but once or twice a year in these latitudes, and which are known as cloud bursts.

The alkali plains, or deserts, as they are often erroneously called, are great stretches of adobe soil, known as "dobie" by the natives. This soil is a yellowish brown, or perhaps more of a gray color, and as fine as flour.

Water plays sad havoc in it, if its shape is such



Connecting rod to couple the wheels when the engine conveys goods

LOOSE ECCENTRIC VALVE GEAR.

as to oppose the flow, and it moves like dust before a slight stream On the flat, hard baked plains, it makes no impression, but on the railroad grade, be it ever so slight, the tendency is to dig pitfalls. I have seen a little stream of water, just enough to fill the ditches on each side of the track, take out all the dirt, and keep the ties and track afloat until the water was gone, then drop them into a hole eight or ten feet deep, or if the wash-out was short, leave them suspended, looking safe and sound, to lure some poor engineer and his mate to death.

Another peculiarity of these storms is that they come quickly, rage furiously for a few minutes and are gone, and their lines are sharply defined, it is not uncommon to find a lot of water, or a wash out, within a mile of dry dirt that looks as if it never saw a drop of water

All this land is fertile, if it can be brought under irrigating ditches and watered, but here it lays out almost like a desert. It is sparsely inhabited along the little streams, by a straggling offshoot of the Mexican race; yet once in a while a fine place is to be seen, like an oasis in the Sahara, the home of some old Spanish Don with thousands of cattle or sheep ranging on the plains, or perhaps the headquarters of some enterprising cattle company. But these places were few and far between, at the time of which I write; the stations were mere passing places, lone side tracks, with perhaps a stock yard and section house, once in a while, but generally without buildings, or even switchlights.

Noting the approach of the storm, I let the heavy engine drop the faster, hoping to reach a certain side track, over twenty miles away, where there was a telegraph operator, and learn from him the condition of the road. But the storm was faster than any consolidator that Baldwin's ever built, and as the lightning suddenly ceased, and the air seemed to become heavy, hot and absolutely motionless, I realized that we would have a furious storm upon us in a few moments.

I had nothing to meet for more than 30 miles, and there was nothing behind me, so I stopped, turned the headlight up, and hung my white signal lamps down below the buffer beams, each side of the pilot—this to enable me to see the ends of the ties and the ditch.

Billy Howell, my fireman, and a good one, hastily went over the boiler jacket with signal oil to prevent rust; we donned our gum coats, I dropped a little oil on the Mary Ann's gudgeons, and we proceeded on our way without a word. On those big consolidations you can't see well ahead, past the big boiler, from the cab, and I always ran with my head out of the side window. Both of us took this position, standing up ready for anything, but we bowled safely along one mile, two miles, through the awful hush, when as sudden as a flash of light, "boom!" went a peal of thunder as sharp and clear as a signal gun; there was a flash of light along the rails, the surface of the desert seemed to break out here and there with little fitful jets of greenish-blue flame, and from every side came the answering report from the batteries of heaven, like sister gun-boats answering a salute. The rain fell in torrents, yes, in sheets. I never before or since saw such a grand and fantastic display of fireworks, nor heard such rivalry of cannonade I stopped my engine, and looked with awe and interest at this angry fit of nature, watched the balls of fire play along the ground, and realized, for the first time, what a sight was an electric storm.

As the storm commenced at the signal of a mighty peal of thunder, so it ended as suddenly at the same signal; the rain changed, in an instant, from a torrent to a gentle shower, the lightning went out, the batteries ceased their firing, the breeze commenced to blow gently, the air was purified. Again we heard the signal peal of thunder, but it seemed a great way off, as if the piece was hurrying away to a more urgent quarter, the gentle shower ceased, the black clouds were torn asunder overhead, invisible hands seemed to snatch a gray veil of fleecy clouds from the face of the harvest moon, and she shone out as clear and as serene as before the storm. The ditches each side of the track were half full of water, ties were floating along in them, but the track seemed safe and sound, and I proceeded cautiously on our way. Within two miles the road turned to the west, and I found the water in the ditches running through dry soil, carrying dead grass and twigs of sage upon its surface, and then suddenly passed the front of the flood, tumbling along through the dry ditches as dirty as it well could be, and fast soaking into the soil—we had passed beyond the line of the storm.

Billy put up his seat and filled his pipe, and I sat down and absorbed a sandwich, as I urged my steed ahead to make up for lost time; we took up our routine of work just where we had left it, and —life was the same old song.

It was past midnight now, and as I never did a great deal of talking on an engine, I settled down to watching the rails ahead, and wondering if the knuckle joints would pound the rods off the pins before we got to the end of the division.

Billy was smoking his second pipe of weed, and humming a tune, with his eyes on the track ahead, and the Mary Ann was making about forty miles an hour, but doing more rolling and pitching, and jumping up and down, than an eight-wheeler would at sixty. All at once I discerned something on the track away down where the rails seemed to meet; the moon had gone behind a cloud, and the head light gave a better view, and penetrated farther, Billy saw it too, for he took his pipe out of his mouth, and, with his eyes still upon it, said laconically, as was his wont

"Cow"

"Yes," said I, closing the throttle, and dropping the lever ahead.

"Man," said Billy, as the shape seemed to assume a perpendicular position.

"Yes," said I, reaching for the three-way cock, and applying the tender brake, without thinking what I did

"Woman," said Billy, as the shape was seen to wear skirts, or at least drapery.

"Mexican," said I, as I noticed the mantilla over the head. We were fast nearing the object.

"No," said Billy, "too well built."

I don't know what he judged by, we could not see the face, it was turned away from us, but the form was plainly that of a handsome woman; the light clothing fitted the form like a glove. She stood between the rails, with her arms stretched out like a cross, her white clothes fitting her form tightly, and a black, shawl-like mantilla over the head partly concealed the face; her right foot was upon the left-hand rail—she stood stock still.

We were within fifty feet of her, and our speed reduced by half, when Billy said sharply:

"Hold her, John—for God's sake."

But I had the Mary Ann in the back motion before the words left his mouth, and was choking her on sand.

Billy sprang upon the boiler-head, and pulled the whistle cord, but the white figure stood still.

I shut my eyes as we passed the spot where she had stood, and as we stopped a rod or two away, I took the white light in the tank and sprang to the ground. Billy lit the torch, and followed me with alacrity.

The form stood upon the track, just where we had seen it, but it faced us, and the arms were folded.

I confess to hurrying slowly, until Billy caught up with the torch, which he held over his head.

"Good evening, Señors," said the apparition in very sweet English, just tinged with the Castilian accent, but she spoke as if nearly exhausted.

"Good gracious," said I, "whatever brought you away out here, and hadn't you just as lief shoot a man, as scare him to death?"

She laughed very musically, and then said:

"The washout brought me just here, and I fancy it is lucky for you—both of you."

"Washout!" said I, "where?"

"At the dry bridge beyond"

Well, to make a long story short, we took her on the engine, she was wet through, and went to the dry bridge, a little wooden structure in a sag, about a mile away, and found that the storm we had seen some distance back, and out of whose track we had run in a loop and had now returned to, had reached this spot, and played sad havoc at each end of the bridge. We did not cross that night, but after placing signals well behind us, and ahead of the washout, we waited till morning, and all three of us sat in the cab of the Mary Ann, chatting as if we were all old acquaintances.

This young girl, whose fortunes had been so strangely cast with ours, was the daughter of Señor Don Juan Arboles, a rich old Spanish Don, who owned a fine place, and immense herds of sheep, over on the Rio Pecos, some ten miles west of the road.

She was being educated in this city of Trinidad at some Catholic school or convent, and had, the evening before, alighted at the Big Corrals, a few miles below, where she was met by one of her father's Mexican rancheros, who led her saddle broncho. They had started on their fifteen-mile ride in the cool of the evening, and following the road back for a few miles were just striking off toward the distant hedge of cottonwoods that lined the little stream by her home when the storm came up.

There was a lone pinon tree about half a mile from the track, and riding to this, Miss Josephine (pronounced Hosepheta in Spanish) had dismounted to seek its scant protection, while the herder tried to hold the frightened horses, as peal on peal of thunder resounded, and the electric lights of nature played tag over the plain, the horses became more and more unmanageable, and at last stampeded, with old Paz muttering Mexican curses, and chasing after them wildly.

After the storm broke, Miss Josephine waited a lonely hour for Paz and the bronchos, and then debated whether or no she would walk home, or back to the Corrals.

Adobe soil is very tenacious when wet, and the wayfarer needs great strength to carry the load it imposes upon the feet; then again, she thought of the half mile of timber along the river, and the fact that timber wolves invariably found all the stray sheep left outside the corral; then she knew the ford would be a torrent and impassible, and as she stood there thinking what was best to do, and of the long miles between her and other human beings, a sound came to her ears from the direction of the timber and from home; she recognized it in an instant, and without waiting to think further, or to again strain her eyes for a sight of Paz, she turned and ran with all her strength, not toward home, but—away from it.

Across the wastes of stunted sage she sped, the cool breeze upon her face, her strong, young muscles bent to carry her away, and her heart brave and fearless, for she was raised amid the dangers of the frontier.

Nearer and nearer came the sound, deeper and deeper sounded the regular bay of the dreaded timber wolf. These animals are large and fierce, they do not go in packs like the smaller and more cowardly breeds of wolves, but in pairs, or, at most, six together, a pair of them will attack a man even when he is mounted, and lucky is he, if well armed and cool enough to dispatch one before it fastens its fierce fangs in his horse's neck or his own thigh.

As this brave girl ran, she figured upon her chances of life, and what she would do, and before she had gone a hundred yards had mapped out a plan for her own safety, that under ordinary conditions would have been successful, but "the best laid plans o' mice and men gang aft agley."

Her plan was to run to the track and climb a telegraph pole, which, owing to her free life at the ranch, she knew perfectly well how to do, by resting upon the cross-tree she could laugh at her tormentors, because they cannot climb, and she would be sure to be seen and rescued by the first train that came along after day-break

As she approached the track she ran upon dry ground, and found that the telegraph poles were upon the other side of it; she sprang nimbly into the ditch, and as she did so, saw something moving rapidly toward her—it was the front of the flood. On the opposite side it had passed and barred her from the line of poles—her plan was foiled. Instantly she decided to run up the track between the walls of water, this would put a ten-foot stream between her and her pursuers, and change her course enough, she hoped, to throw them off the scent. In this surmise she was partly right, for the regular bay showed that they were going direct to the track, as she had gone, instead of cutting across toward her; in this way she gained considerable. She reached the little aroya spanned by the dry bridge; it was like a mill pond, but the track was afloat, and across it she scarcely slackened speed, although the ties rocked and moved on the spike heads holding them to the rails.

She hoped the hungry brutes would not dare pass this place, even if they gained the track, and as she sped along, her heart sank as she noted pole after pole down and afloat in the ditch—there was no lessening of the flood—and heard the hideous voices of her tormentors directly in the rear

So close came the bay that she glanced over her shoulder to see if they were in sight, but she saw only the nodding heads of sage But a strange, metallic sound greeted her strained ears, what was it? Where was it? She ran on tip toe a few paces in order to hear it better; it was in the rails, the vibration of a train in motion. She glanced up, a star shone directly between the rails, no, it was a light, a train, a headlight, but it was so far away, so very far, and that awful baying so close. But the Mary Ann was fleeter of foot than the beasts upon her track, the light grew big and bright, and the sound of working machinery came to her on the breeze.

Would they stop for her, could she make them see her? Then she thought of the bridge; it was death for them as well as her—they *must* see her. She resolved to stay on the track until they whistled her off, but now the light seemed to come so slow. A splash at her side caused her to turn her head, and there, a dozen feet away, were her pursuers, their tongues out, their eyes shining like balls of fire, and just entering the water to come across to her. They fascinated her by their very fierceness, and forgetting where she was, for the moment, she looked dumbly at her enemies, until called to life and action by a scream from the Mary Ann's whistle, that echoed across the desert wastes like the wail of a lost soul.

She sprang from the track just in the nick of time, and actually laughed as she saw two grayish-white wolf tails bob here and there among the sage brush as they made themselves scarce. This was the story she told us as she dried her clinging garments before the furnace-door of the Mary Ann, and I confess to holding this cool, self reliant girl in high esteem—she never once thought of swooning—but along toward morning did say that she was scared then, just thinking of it.

Early in the morning a party of herders, with Josephine's father ahead, rode into sight, they were hunting for her. Josephine got up on the tender and attracted their attention, and soon she was in her father's arms. Her frightened pony had gone home as fast as his legs would carry him, and a relief party swam their horses at the ford, and rode forward at once.

The old Don was profuse in his thanks, and would not leave us until Billy and I had agreed to visit his ranch and enjoy a hunt with him, and actually set a date when we would meet him at the Big Corral.

I wanted a rest anyway, and it was perfectly plain that Billy was beyond his depth in love with the girl at first sight, so we were not hard to persuade when she added her voice to her father's.

Early in September Billy and I dropped off of No. 1 with our guns and "plunder," as baggage is called there, and a couple of the old Don's men met us with saddle and pack animals

I never spent a pleasanter two weeks in my life, the quiet, almost gloomy old Don and I became fast friends, and the hunting was good. The Don was a Spaniard, but Josephine's mother had been a Mexican woman, once noted for her beauty, those Mexican girls are plump and fully developed maidens at 15, matrons at 20, and hags at 30 or 35, Josephine's mother had been dead some years, at the time of our visit.

Billy devoted most of his time to the girl, and they were a fine looking young couple, he being strong and broad shouldered, with laughing blue eyes and light curly hair, she slender and perfect in outline, a typical Southern complexion, black eyes, and such eyes they were, long hair and eyebrows like a raven's wing—a perfect type of Spanish beauty.

A few days before we were billed to resume our duties on the deck of the Mary Ann, Miss Josephine took my arm and walked me down the yard, and pumped me quietly about Mr. Howell, as she called Billy, she went into detail a little, and I answered all questions as best I could, and they were all in the young man's favor—I could not do otherwise, he deserved it She seemed satisfied and pleased

When we got back to headquarters, I was given the care of a cold-water Hinkley, with a row of varnished cars behind her, and Billy fell heir to the rudder of the Mary Ann. We still roomed together, and Bill put in most of his lay-over time writing long letters to somebody, and every Thursday as regular as a clock one came for him, with a censor's mark upon it. Often after reading one Billy would say

"That girl has more horse sense than the rest of the whole female race—she don't slop over worth a cent"

Billy invariably spoke of her as "my Mexican girl," and often asked my opinion about white men intermarrying with that mongrel race.

Sometimes he would say that his mother would go crazy if he married a Mexican, his father would disown him, and his brother Henry—well, Billy didn't like to think just what revenge Henry would take.

Billy's father was manager of an eastern road, and his brother assistant to the first vice-president, and Billy looked up to him as to a great man and a sage. Billy was West for practical experience in the machinery department, and to get rid of a slight tendency to asthma—he could go East any time, and "be somebody" on the road under his father.

Finally Billy missed a week in writing—there was a cog gone from the answering wheel from the other side to match. Billy shortened his letters—the answers were shortened. Then he quit writing, and his Thursday letter ceased to come.

Billy had thought the matter all over, and decided, no doubt, that he was doing what was best, both for himself and the girl, and his family's high-strung ideas of *caste* would not be outraged by a Mexican marriage—Billy had put a piece of flesh-colored court plaster over his wound, not healed it.

Early in the winter, the old Don wrote, urging us to come down and hunt antelope, but Billy declined to go; said the road needed him, and that Josephine might come home from school, and that would make them both uncomfortable. But Henry, his older brother, was visiting him, and I could take him, he would enjoy the hunt, and help him drown his sorrow over the loss of his aristocratic young wife, who had died a year or so before. So Henry went with me, and we hunted antelope till we tired of the slaughter. Then the old Don planned a deer hunting trip in the mountains, but I had to go back to work, and the young railroad officer and the grave old Don took their trip together. While they were gone Josephine came home, and Henry Howell's stay lengthened out to a month, but I did not know that he had met the young lady till long after.

Billy was pretty quiet all winter, worked hard, and went but little—he was thinking about something. One day I came home and found him writing a letter. "What now, Billy?" I asked.

"Writing to my Mexican girl," said he.

"I thought you got over that a long time ago."

"So did I, but I didn't; I've been trying to please somebody else beside myself in this matter, and I'm done. I'm going to work for Bill now."

"Take an old man's advice, Billy, and don't write that girl a line—go and see her."

"Oh, I can fix it all right by letter, and then will run down there."

"Don't do it."

"I'll risk it."

A week later Billy and I sat on the veranda of the company's hash foundry, figuring up our time and smoking our cob meerschaums, when one of the boys who had been to the office, placed two letters in Billy's hands. One of them was directed in the handwriting that used to be on the old Thursday letters. Billy tore it open eagerly, and—his own letter to her dropped into his hand.

Billy looked at the ground steadily for five minutes, and I pretended not to have seen; finally he said, half to himself:

"You was right, I ought to have gone myself, but I'll go now, go to-morrow," then he opened the other letter.

Billy read its single page with interest, and when his eyes reached the last line, they went straight on and looked at the ground again for fully five minutes. Without looking up, he said:

"John, I want you to do me two favors."

"All right," said I.

Keeping his eyes where they were, he said slowly, as if measuring everything well:

"I'm going up and draw my time, and will leave for Old Mexico on No. 4 to-night. I want you to write to both these parties, and tell them that I have gone there, and that you forwarded the letters; don't tell 'em I went after reading 'em."

"And the other favor, Billy?"

"Read this letter, and see me off to-night."

The letter read:

Phila., May 1, 1879.

DEAR BRO. WILL—I want you and Mr. A to go down to Don Juan Arboles by the first of June. I will be there then. You must be my best man, as I stand up to marry the sweetest, dearest wild flower of a woman that ever bloomed in a land of beauty. Don't fail me. Josephine will like you for my sake, and you will love her for your brother. HENRY.

Most engineers' lives are busy ones, and full of incident and accident, and having my full share of both, I had almost forgot all these points about Billy Howell and his Mexican girl, when they were all recalled by a letter from Billy himself a few days ago. With his letter was a photo. of a family group, a bewhiskered man of 35, a good-looking woman of 20, but undoubtedly a Mexican, and a curly-headed baby, perhaps a year old. The letter read:

City of Mexico, July 21, 1890.

DEAR OLD JOHN—I had lost you, and thought perhaps you had gone over to the majority, until I saw your name, and recognized your quill in THE LOCOMOTIVE ENGINEER. Write to me; am doing well. I send you a photo. of all there are of the Howell outfit. *No half breeds for your uncle this time.* WM. HOWELL.

New Valve Gear for L. P. Cylinder of the Webb Compound.

Mr F W Webb, chief mechanical engineer of the London & Northwestern road, has recently turned out some compound locomotives, of his well-known three cylinder design, in which he has very much simplified the valve gear for the large cylinder. Instead of using the Joy gear for this cylinder, handled from the cab by an extra reverse lever, like the one on the P. R R., he uses a single eccentric; this eccentric is loose on the shaft and has two stops on the crank throw that prevent its turning. The gear is entirely out of the hands of the engineer; if a stop is made, and it is desired to reverse, he reverses the high-pressure engines, and as soon as they move the engine the stop on the crank throw leaves the loose eccentric against which it has rested, and when part of a turn of the axle has occurred the second stop moves the eccentric so as to admit steam right for the reverse motion.

The new engines also have a "bye-pass" valve in the exhaust pipes of the high-pressure cylinders, to admit of their exhausting directly into the stack, leaving the low-pressure engine temporarily out of business.

The Mahoney Foot Guard.

Every year there are a lot of switchmen and brakemen who lose their lives by being caught in frogs or guard rails and run down. In some States there are laws requiring frog and guard rail openings to be filled with wood or other material, but, as a usual thing, this is worse than useless, as it must be as low as the deepest flange, and makes it harder, if anything, to get the foot out once it is caught. The best device we have heard of for this work is one invented by yard-master Mahoney of the St. Louis & San Francisco road, at St. Louis. His guard consists of strips of sheet steel cut at one end to fill the tapering openings at frog points and the ends of guard rails, the other end is bent down, and riveted or bolted to the bottom plate or base of rail. This spring stands flush with the ball of rail, will hold 300 pounds, and so keep the feet of workmen out of the traps; the flanges of wheels simply depress the guard until they have passed it, when it springs back to place.

The railroad commissioners of Missouri endorse and recommend this device, and it has met with the approval of many prominent railroad men. It has been in use for some time in the yards of the above road, and at the M P. yard at the Union depot in St Louis.

Trouble with a Very Old Style of Switch Engine.

Last week we announced the death of Henry Baxter, a subscriber to the *Railway Herald*, and a driver of a horse employed in shunting at Toton. The unfortunate man was kicked by the horse and thrown under some wagons, which ran over and killed him. At the inquest the coroner strongly advised the company to remove the horse from the railway. The jury returned a verdict that the deceased was killed by being run over by a wagon, and they were agreed that the horse was not a fit one to be used for shunting purposes.

It was well known to the officials at Toton that the horse in question was vicious and liable to kick, and those in command should have removed such a brute from the line. Their neglect, in the opinion of an authority, gives the widow and three children of our late subscriber a right to claim three years' wages as compensation under the Employers' Liability Act, and we are glad to learn that the necessary notice, as required by the act, has been duly served upon the company, together with the claim for the full amount allowed by law. The case is in very good hands, and will no doubt be successfully concluded.

If railway companies are made to pay damages in these cases we shall soon see "kicking horses"—of which unfortunately there are far too many—removed from our shunting yards. During the year 1889 we find no less than two men killed and 111 injured on railways by being trampled on or kicked by horses.—*Ry. Herald* (England).

Horses used for switching purposes seem more dangerous than locomotives, but some cities insist that no switch engine shall be employed within its limits, on account of the noise. There is no doubt, however, that horses are much more dangerous than locomotives, both to employes and the public.

What Grease Costs.

From the annual report of the C. & N W. Ry the *Railway Age* culls the following:

"Lubricating material forms no inconsiderable item of cost in the operating of any railroad. We find from the report of the Chicago & North-Western railway that the cost of oil, waste and tallow for the year was as follows: Used on locomotives, \$92,064.54; on passenger cars, \$22,498.81; on freight cars, \$69,109.90; on tools and machinery, \$6,960.70; making a total of \$190,634 paid in a single year by one company for these three apparently insignificant items. For the same period this company paid for stationery and printing \$181,104, for salaries of general officers, \$178,097, for renewal of rails, \$172,141; for passenger conductors' wages, \$167,903; for advertising, \$104,911; each of these amounts being much less than the expenditure for 'oil, waste and tallow,' while all the advertising done by this great system cost only little more than half as much as those three inconspicuous items."

At the coming convention of the Brotherhood of Locomotive Engineers there will be, no doubt, some attempt made to lessen the number of delegates to forthcoming conventions. Four hundred men, most of them new to parliamentary proceedings, cannot be easily handled, much less be held down to the routine work. There have been two plans proposed: representation by States or districts or by systems of railroads. The first plan has the disadvantage of giving a very uneven representation, and admits of the clashing of interests and jealousy in electing a representative. The system plan will allow one delegate from each system of road, and will be nearer fair and assemble a more truly representative body; it will also cut down the number of delegates to considerably less than a hundred, and, as these men would in all probability be the most experienced, more work and better work could be done in less time.

Strong brine will kill grass and weeds, root, branch and seed, if you doubt it try it on your lawn. Every year our railroads spend a great deal of money in cleaning the tracks and grade of vegetation. Elaborate machines have been devised for the work, and many men employed, and yet it is seldom thoroughly done. Salt is the cheapest chemical in existence—it sells as low as 50 cents a barrel for the refined article—it costs more to load crude rock salt at Salt Lake, Utah, than the salt itself is worth at the quarry. What is the matter with thoroughly wetting down the line with brine? The plan ought to be efficient and cheap.

On the Suburban Rapid Transit Elevated road in this city they use Forney engines, and to aid them in rounding curves when running with drivers ahead—which they do half the time—they have a device for oiling the flange. This is a short piece of pipe with a wick and a spring in it that rubs the wick slightly against the tire and prevents cutting when rounding curves. Mr. Wetmore, Supt. and M M, we believe, gives THE LOCOMOTIVE ENGINEER the credit for suggesting the plan but he has carried it out so simply and ingeniously we would not have recognized the scheme. It is in use on all their engines.

At an early date we hope to show complete drawings of the valve gear of the "Camel" engines. Their gear was very ingenious and efficient.

A New Track Sander

Henry L. Leach, Jr., who is Assistant Supt. of M. P. of the Fitchburg road, in charge of the Fitchburg shops, has recently patented a track sanding device used by him.

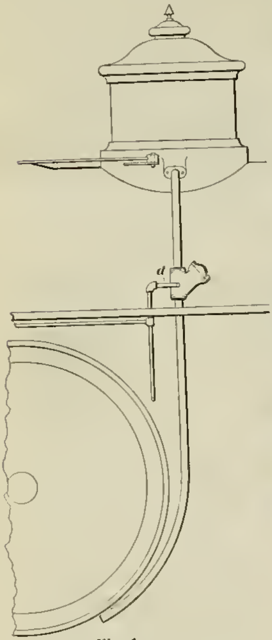


Fig. 1.

His invention consists of a sand trap, in the ordinary pipe as now used, and a jet of air to carry the sand in small quantity to the rails.

Fig. 1 plainly shows his method of applying the trap, and Fig. 2 is a section, on an enlarged scale, of the trap itself. When the sand lever is used a large quantity of sand is allowed to escape from the box, usually much more than can be used for increasing the adhesion of the drivers to the rail, and which is

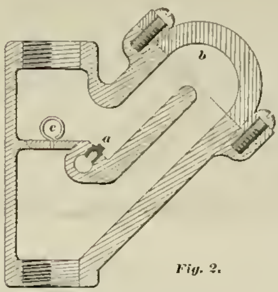

Fig. 2.

taken up and carried by the wheels, causing the train to pull harder and increasing the wear.

With Mr Leach's device the surplus sand stops at the trap, and air pressure from the main drum being turned on through the small pipe *d*, in Fig. 1, entering through the side of trap into an opening in the partition, as shown in Fig. 2, escapes in a small jet directed over the partition, carrying with it some sand.

There is a plug *c* that can be taken out if it is found desirable to use, direct from the box, sand in large quantities.

The cap *b*, of course, will wear fast under the sand blast, and provision is made for renewing it cheaply. Mr. Leach uses an air nozzle about $\frac{1}{16}$ of an inch in diameter.

This device ought to be economical in the use of sand, and distribute it evenly, but it is often desirable to use sand in large quantities, as, for instance, to increase the holding power of brakes, to avoid accident, and to drop under an engine the last length or two, where she takes a siding very hard to back out of. We should suggest in this device that the plug *c* be hinged, and operated at will from the cab.

The new "downward draught" locomotive is being tried, and, as usual with new devices, ridiculous claims made for her

Logging railroads are built under almost as much difficulty as lines are constructed in the African jungles. All the iron and the equipment for the new road now being built by the St. Anthony Lumber Company is to be hauled by team from thirteen to twenty miles, after first having been shipped by rail and boat nearly three hundred miles more. But difficulties of this kind do not intimidate the average lumberman.—*Lumberman*, Minneapolis.

One of the oldest general shop foremen in the country will soon commence a series of short articles on "Running Repairs" in the L. E. Each subject will form a paper by itself, and there will be no "continued in our next" business. Every reader who has a shorter, better or cheaper way of doing work than that shown by our correspondent is expected to explain it in these columns for the benefit of his brother workers.

Engineer Bowels, of the Illinois Central, recently went insane on duty from overwork. It is a wonder that more enginemen do not go insane, there are lots of them running twenty-four and thirty-six hours without rest.

The *Railroad Gazette's* record of train accidents in July includes 84 collisions, 59 derailments and 6 other accidents, a total of 149 accidents, in which 70 persons were killed and 249 injured.

Two Pinkerton men who were assisting in making up a train in the Albany yard, during the recent strike, were run over and killed.

The switchmen of the world seem to have the strike fever. They are "out" from Wales to Missouri.

Between 2,000 and 2,500 men went out on the Central—most of them are still out.

On some of the roads in the Andes Mountains coal is worth $25 per ton.

Locomotives for Japan.

The Imperial Empire of Japan is fast waking up to the introduction of Western ideas, and is many years in advance of her larger, but less progressive neighbor, China.

There are in Japan several roads of moderate size, and their success has been so marked that a great many miles of new road are projected.

The service is rather light, and tank engines have, so far, been generally employed. Japan is disposed to test the merits of both English and American locomotives, and Baldwins are furnishing several from this side of the world, while the Vulcan Foundry Co. (Limited), of Newton-le-Willows, Lancashire, England, furnish the English machines.

We show on this page the two types of engines. The Baldwin is a mogul, with a six-wheeled tender, and differs little from American practice in the same class, the double buffers and six-wheeled tender being the most noticeable changes. As will be seen, the tank flange is straight, and there is no projecting of the platform under the tank.

The principal dimensions of the Baldwin engines are as follows:

Gauge, 3' 6", standard of the Imperial railways.
Cylinders, 18x22, link motion.
Drivers, 48" diameter, truck wheels, 30".
Total wheel base, 19' 8".
Driving wheel base, 12'.
Total weight, about 85,000 lbs.
Weight on drivers, about 72,000 lbs.
Diameter of boiler, 56".
Number of tubes, 200.
Diameter of tubes, 2".
Length of tubes, 10' 9".
Length of fire-box, inclined grate, 89¼".
Width of fire-box, 29".
Tender capacity, 2,600 gallons.

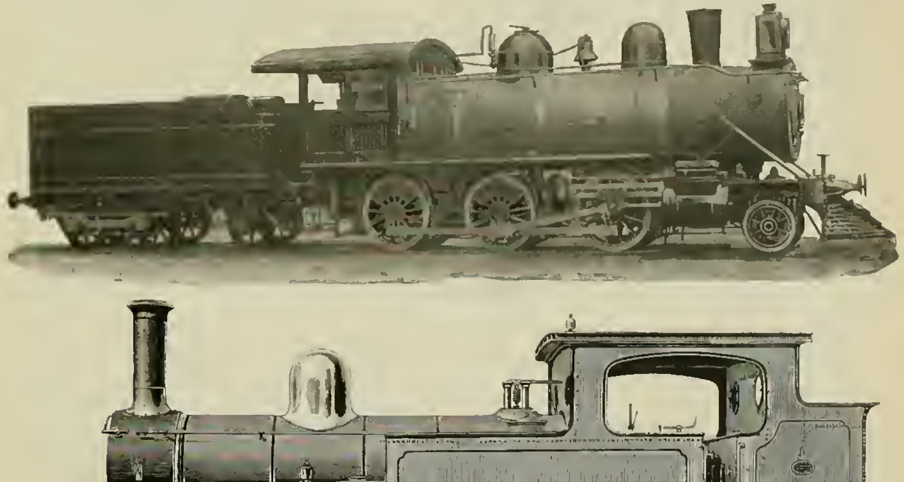
Our second illustration shows the Vulcan Co.'s machine, built for the Sanyo road. The principal dimensions are as follows:

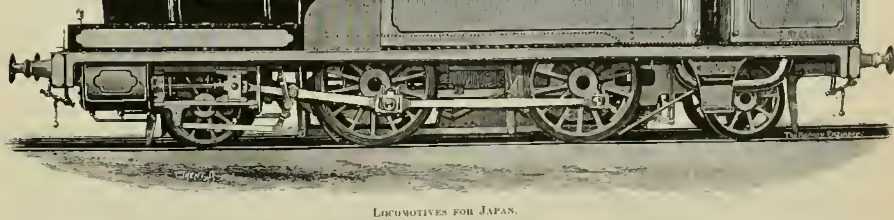
Gauge of road, 3' 6". Cylinders, 14×20, Joy valve gear. Drivers, 4' 4" diameter; both forward and back truck wheels, 3' 1".

The fire-box has 70 square feet of heating surface, and the tubes 654 square feet, making a total of 724 square feet.

Grate area, 12 square feet.

Water is carried in two side and one rear tank with a total capacity of 1,000 gallons, and a coal bunker of 45 cubic feet. For the engraving of this machine we are indebted to the *Railway Engineer*, London, Eng.





Locomotives for Japan.

Committees of the M. M. Association for 1890-1.

The following committees have been appointed to prepare papers on the subjects given, for discussion at the 24th annual meeting held next June.

EXHAUST PIPES, NOZZLES AND STEAM PASSAGES.

Investigate best form and size in proportion to cylinders.

C. F. Thomas, A. W. Gibbs, L. C. Noble, F. C. Smith, John Y. Smith.

TESTING LABORATORIES, CHEMICAL AND MECHANICAL.

George Gibbs, Philip Wallis, G. W. West, L. S. Randolph, D. L. Barnes.

ADVANTAGES AND DISADVANTAGES OF PLACING THE FIRE-BOX ABOVE THE FRAMES.

Fred. B. Griffiths, James Macbeth, W. A. Foster, A. G. Leonard, Louis F. Lyne.

RELATIVE VALUE OF STEEL AND IRON AXLES.

John Mackenzie, J. S. Graham, John S. Cook, E. B. Wall, Thomas Shaw.

PURIFICATION OR SOFTENING OF FEED WATER.

W. T. Small, Harvey Middleton, A. W. Quackenbush, J. B. Barnes, John W. Hill.

THE PRESENT STATUS OF THE CAR COUPLER QUESTION.

Investigate whether this association can endorse the action of the Master Car Builders' Association from a mechanical standpoint in recommending the vertical plane type as a standard.

John Hickey, G. W. Rhodes, Sanford Keeler, R. H. Blackall, M. N. Forney.

EXAMINATION OF LOCOMOTIVE ENGINEERS AND FIREMEN.

On their duties relating to the use of fuel, care of the locomotive, and ability to deal with disorder or disability of machinery; to what extent practiced, and best plan for conducting the examination.

W. H. Thomas, John Player, F. D. Casanave, J. W. Luttrell, L. R. Pomeroy.

OPERATING LOCOMOTIVES WITH DIFFERENT CREWS.

Investigate the comparative advantages of operating locomotives with different crews on the "first in and first out" plan, and that of confining men to certain engines, the latter not running a greater number of miles than can be rendered by their regular crews, discuss any improvement in the method of running engines.

Ross Kells, W. W. Reynolds, W. F. Turreff, C. G. Turner, John A. Hill.

LOCOMOTIVE FOR HEAVY PASSENGER AND FAST FREIGHT TRAIN SERVICE.

Investigate the types best suited for this service, and the relative economy and safety of eight-wheel, ten-wheel and mogul locomotives for the service in question.

Pulaski Leeds, James Meehan, E. M. Roberts, C. E. Smart, W. A. Smith.

ELECTRICAL APPLIANCES FOR RAILROAD USE.

Report on the progress of electricity into motive power, car lighting, signaling, welding and kindred uses.

T. W. Gentry, G. B. Hazelhurst, Albert Griggs, John Ortton, F. W. Dean.

STANDARDS OF THE ASSOCIATION.

Wm. Swanston, Wm. Garstang, C. H. Cory, J. S. McCrum, Thomas Shaw.

These subjects are interesting, and are attracting the attention of some of the best railroad men in the country. Post up on these things, and let your officers see that you take an interest. Discuss the questions offered, and make suggestions—practical pointers often change opinions. Don't be so afraid of making a mistake—everybody makes mistakes. Don't be so afraid you will expose your ignorance—nobody knows everything.

Charles Bockwell has just died at New Haven. Over forty years ago he was employed by the N. Y. & N. H. road to write the tickets used on the line.

Sensible Overflow Nozzle.

Every man who has or does use a lifting injector on a locomotive knows what an intolerable nuisance the shower-bath attachment to the overflow is. This can be remedied by making a union coupling there, but then you have to look outside for the water. This you cannot do when overflow pipe is introduced into the ash pan. The Rue Manufacturing Company, of Philadelphia, who make the Little Giant injector, now send out an overflow cup for the pipe that won't let the shower-bath work. It is a short cup, slightly smaller than the overflow pipe, and has no taper. The pipe used is the same size as the water supply, and will carry off all that comes out of the nozzle. The old plan of delivering the overflow water to the waste pipe under pressure, and expecting a ⅜ pipe to carry off all the water from a ⅜ nozzle, was rather inconsistent.

The citizens of New York kicked so vigorously against the squeaking noise made by the chilled-face Lappan brake shoes on the elevated roads, that the management went back to soft cast-iron. The Lappan shoe lasts longer than two common shoes, but it will squeak. This would not be noticed on a surface road, but over the heads of thousands of people 3,600 trains a day were stopping every five blocks, and the thousands of people kicked.

An English Variable Nozzle.

The accompanying cut, for which we are indebted to our English contemporary, *Engineering*, shows a new form of variable exhaust nozzle now in use on the Great Eastern Road. This nozzle is the invention of Mr. George Macallan, manager of the road's general shops at Stratford, and Mr. Charles Adams, of London.

As will be seen, there are two hinged nozzles or tips, that can be thrown down upon the nozzle stand; when one is down the other is up out of the way, and there is provision for throwing them both up and leaving the large nozzle free to exhaust into the stack.

This plan gives a variable nozzle in three fixed sizes, and of such shape that they can be easily cleaned—clogging up has been the fault of all former attempts in this line.

The segmental gearing that provides for a partial movement of the hinged nozzles, and the holding of one out of position, without further movement, while the other is being operated, is very ingenious and is plainly shown in the engraving.

We are not aware how the blast and the coal used in England affects the exposed parts, but in this country the cinders, acting like a sand blast, would cut off the hinged nozzles and all the other exposed parts. This trouble could, in a measure, be helped by casting heavy projections below the hinges, and placing the operating gear outside the arch.

A saving is claimed for this nozzle when light trains are hauled, as the runner can increase the size of nozzle to prevent excessive steam making, instead of opening the fire-door or manipulating the dampers. The design is simple, and there seems little chance of its becoming inoperative from getting foul.

A Noted Bridge to Come Down.

Kinzua viaduct, on the Erie road, has long been a noted piece of engineering; it was built by the firm of Clarke, Reeves & Co., and was the highest bridge in this country, and, with one exception, in the world.

The structure is too light to carry the heavy traffic now being done on that division of the Erie, and it is to be replaced with a detour. Kinzua viaduct, which spans the gorge of Kinzua Creek, is 2,400 feet long and is 305 feet above the water. It was built for a single track at a cost of $237,000, and consists of twenty towers, each 10 feet by 38½ inches at the top, and of varying width at the bottom.

It carries a branch of the New York, Lake Erie & Western Railroad from the petroleum fields of Bradford County to the coal fields of Elk County, and was completed August 29, 1882.

[The above item has appeared in about two hundred papers, railroad and otherwise, within the past month. It is interesting and all right except in one particular—it is not true. The bridge is all right and will not come down.]

A Curse.

In no country but this could private individuals and firms hire a small army of toughs to protect themselves against interference by their employes, the public, or the civil authorities. Even Russia has no such curse as the Pinkertons. John Burns' speech before the Manchester workingmen, in which he declared that such an armed force in England would be torn limb from limb, their force met by force, and their bludgeons met by other bludgeons, has met with the approval of all England. The press generally declare that such a blight upon English civilization would not be tolerated. Whatever else is done about strikes on our railroads, the Pinkerton toughs have got to be dispensed with; they are trouble breeders, use their firearms upon a crowd, whether strikers or not, and the civil authorities of any city or any State that tolerate them for one day should be held responsible. The people have a right to resist the sword by the sword, and if no other relief shall come, workingmen have a right to arm themselves and meet the Pinkerton army in a war of extermination.

The Reason Why.

The cause of boiler explosions is an ever fruitful source of speculation. We thought we had heard everything mentioned to which they could possibly be ascribed, but here is a new one from the Pacific coast: "An investigation into the causes of the explosion resulted in the acceptance of the theory that it was caused by a leakage of steam from the hand-hole under the boiler. The air rushing in caused the explosion. There was only sixty pounds of steam on at the time of the accident."—*Power*.

Several large railroads, including the Baltimore & Ohio, Allegheny Valley, Western New York, and Pennsylvania, Pittsburgh & Western, Cleveland, Lorain & Wheeling, and Pittsburgh & Lake Erie regularly purchase and furnish to firemen Winterton's metal polish. This polish has a good reputation among enginemen who buy it largely to save themselves work, but it is far better, and will be used more, where the company pay the bill.

Erastus Winan has proposed to build a tunnel from Staten Island to Long Island, under New York harbor, and a company has been formed for that purpose.

James Nasmyth, the inventor of the steam hammer, left an estate valued at a million and a quarter.

A great tunnel is proposed between the north of Ireland and Scotland.

Keeping Data.

One of the most interesting things for a railroad man is an old note or memorandum book kept by some railroader with a natural bent for figures and sizes

The sizes of different parts of locomotives have been greatly changed in the past decade, sometimes being an improvement and sometimes not. It is only by comparison that we can keep track of improvements and the progress made.

Sometimes two roads, or the same road, put in service engines alike, except in one particular; this may be slight and of any nature, from an inch difference in wheel centers to two feet difference in grate; it may be only half an inch more length to the driving-box, two inches difference in port, in one or the other, or any such difference, and it is interesting and highly instructive to watch, for a number of years, the difference in service rendered or cost of repairs.

Changes are often advisable for one cause or another, and where a lot of sizes and designs of other roads are at hand, possible changes are suggested that have the advantage of having passed the experimental stage.

Draftsmen and foremen of shops can, and generally do, have blue prints on a small scale, giving most of the data concerning each class of locomotive in the service, but this usually covers but the home road.

What is wanted is some form of data that can be used by engineers, firemen or shop men to keep up data in a uniform style and in shape to be easily referred to.

About the best plan we have run across is the one used by Lewis R. Pomeroy, of the firm of Coolbaugh, McMunn & Pomeroy, of this city. Mr. Pomeroy has got up a set of tracings for prints with the outlines of an engine of each class and blanks to fill out; this, in book form, is easily carried in the pocket, and, when visiting a road or shop, dimensions are easily picked up; perhaps but a few of those given on the blank are secured, but all are useful.

By copying general dimensions of engines given from time to time from railroad papers, data is kept together in such shape as to be easily referred to, and the cost is slight.

His outline sketch of an 8-wheeler, shown here full size, has dimension lines on the drawing itself for the principal sizes, and it will be seen that the full lines show a short, deep fire-box, placed between the frames, while a long fire-box on top of the frame is shown in dotted lines. If dimensions are for the latter he simply draws in full lines over the dotted ones, and thus makes one outline for both kinds of 8-wheelers.

In the same way the mogul can be changed more or less, it being understood that pencil lines over the drawing are to be taken for the true outline.

Mr. Pomeroy has a composite outline for 10-wheelers and consolidations, which we will publish at another time.

Many mechanics and enginemen have kept a great deal of data of this class heretofore, but it is very hard to find in an ordinary diary, while this plan furnishes a great deal of information with the least possible amount of writing.

Down on Attorneys.

The Western Railway comes out strong in favor of railroad officials refusing to meet any but employes of the road. It makes no difference whether the representative of the men is an employe or not, so long as he is the accredited representative of the men—the railroads employ attorneys to represent them. We don't like the "walking delegate" plan, or the committee of trouble soothers, but they have a right to exist and be heard just so long as they are sent by the men. Professional grievance hunters are dangerous; when things are wrong a special committee representing the men is fresh, comes from headquarters, and are not, as a rule, as offensive as professionals. Standing grievance committees in times of peace are a constant menace to peace. If everybody followed Bro. Warman's advice it would kill off all the lawyers—or set 'em to sawing wood.

Big Engines for the St. Clair Tunnel.

The Baldwin Locomotive Works, Philadelphia, have the contract for building four decapod tank locomotives for service in the St. Clair tunnel. These engines are to have cylinders 22x28 inches, five pairs of driving wheels 49 inches in diameter outside of tires, and will weigh, in working order, including 1,800 gallons of water in the tank, about 180,000 pounds. They will have boilers 74 inches in diameter, carrying 160 pounds steam pressure. The fire-box is 11 feet long by 3½ feet wide. There will be about 280 tubes, 2¼ inches in diameter and 13 feet 6 inches long. The cab is placed centrally over the boiler, with foot-plate and coal-box at the rear of the boiler. The wheel-base is 18 feet 8 inches. As the track through the tunnel is straight, the engines are not required to pass curves on the main line, and are only required to enter ordinary sidings. Additional play will be given the tires of the extreme driving wheels. The second and fourth pairs of driving wheels will be flanged with the usual play, and the distance between their centers is 8 feet 9 inches. The tires are to be secured by Mansell retaining rings, and each engine will be fitted with two sand-boxes and two headlights, a Cooke steam bell ringer, and the Westinghouse automatic brake, with equalized driver brake fixtures acting on all the wheels. The fuel will be anthracite coal or coke. The load which these engines are intended to haul is about 760 tons, and the grades are 105.6 per mile. They are to be delivered in January.—*Railroad Gazette*.

These locomotives will have the largest boilers carried on wheels—6 feet 2 inches in diameter.

Steel rails are worth $31 per ton in New York. Old rails have sold this month as high as $26.

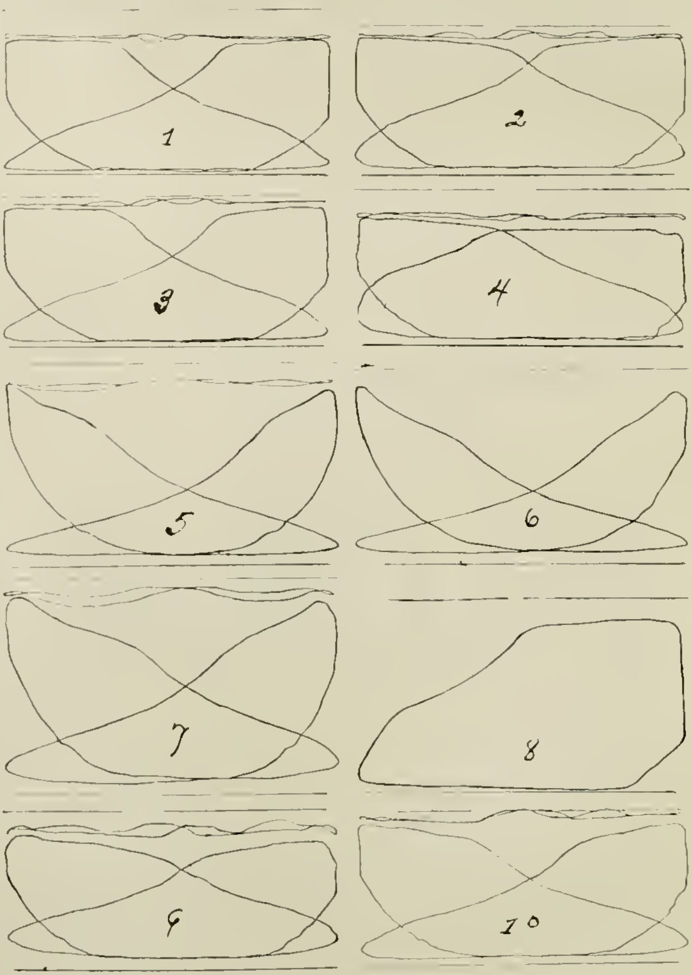
Some Every-day Indicator Diagrams.

As a usual thing, when indicator cards are given out for publication they are about as nice ones as can be had, and considerable allowance has to be made when you come to figure on the general practice of the whole road It is, therefore, considerable satisfaction to get a look at cards not intended for outsiders, and taken at random from an engine; not to test her valve gear, but to hunt for leaks in another direction.

The accompanying cards were taken from consolidation engine No. 583, on the Richmond & Danville road, by Mr. A. W. Gibbs, M. M., at Alexandria, Va. They were taken to see if the Smith triple expansion exhaust pipe had a tendency, as had been charged, to increase the back pressure, and to cause an excessive "hump" in the card, when starting, due to the pressure in the exhaust nozzle of steam from the opposite cylinder—a common fault with single nozzles.

Some thirty cards, from which these were selected, were sent to Mr. Smith by Mr. Gibbs, and in a note under date of June 16th he says:

"I send you herewith some cards taken from engine 583, but I do not consider them as good as should be; we can do much better. I am not particularly anxious to advertise these cards as the performance of R & D engines, owing to a light train necessitating a light throttle. This engine has cylinders, 20"x24"; drivers, 50" diameter; steam ports, $16''\times1\frac{5}{8}''$; exhaust ports, 16"x3"; travel of valve, 5"."



Mr. Smith sent us these cards to show us how ungrounded were the claims of excessive back pressure, and we publish them without asking leave or consulting anybody.

However, Mr. Gibbs has nothing to be ashamed of in these cards All of them were taken from the left cylinder, the engine being on a local freight train of 22 loads. The cards are exact size of originals.

No. 1 was taken with the boiler pressure at 142 pounds by the gauge; revolutions per minute, 60, scale of the spring, 100; and shows a mean effective pressure of 68.9, and an indicated horse-power of 314 59.

No. 2. Boiler pressure, 137; revolutions, 80; scale, 100; M. E. P., 79 4, I H. P., 483.9

No. 3. Boiler pressure, 137; revolutions, 48, scale, 100; M. E. P., 71.4, I H. P., 258.

No. 4 Boiler pressure, 142, revolutions, 78, scale, 100; M. E P., 77 9, I H. P., 455.3.

No. 5. Boiler pressure, 147; revolutions, 130; scale, 80; M E. P., 47 6; I. H. P., 470.9, throttle quarter open, lever in 15th notch.

No. 6. Boiler pressure, 142; revolutions, 200; scale, 80, M E. P., 42.2; I H P, 642.28

No. 7. Boiler pressure, 157, revolutions, 179; scale, 80; M E. P., 62; I H P., 827.2

No. 8 Boiler pressure, 150; revolutions, 40; scale, 80; lever in corner, throttle half open—a splendid starting card. The way the card approaches the atmospheric line just before the exhaust port closes and compression begins, shows there is no tendency of the exhaust from the other cylinder to put back pressure upon this by temporarily choking the exhaust tip; this card must have been very gratifying to Mr. Smith.

No. 9 Boiler pressure, 147; revolutions, 114; scale, 100; M. E. P., 67.5; I H. P., 585.5.

No. 10. Boiler pressure, 142, revolutions, 113; scale, 100, M. E. P., 66.5; I. H. P., 571 8.

For cards taken from a heavy freight engine, being chain ganged early and late, we doubt if these do not show a condition of motive power considerably above the average.

Metal vs Wooden Ties.

Metal ties have not yet been designed that are as good as oak: they are too rigid, noisy, and act as anvils under the rail when the ground is frozen. Those philanthropists who are worried lest the railroads of the United States shall use up our forests for ties, might turn their attention to the northern half of North America, where there is standing hundreds of square miles of available timber—enough, surely, to last this continent until a second growth shows up—what is the matter with using this? As it is, there is a high duty on timber, and Canadian choppers are imported to cut down our own forests The latter can be saved, ties cheapened, and American workingmen not disturbed by removing the import duty. Facts are stubborn, and will finally be seen—this is a fact.

The average car axle-box, wreathed in a cloud of smoke and a smell of decayed mule, rattling along over the country, without a cover, and with a great gob of greasy waste soaked full of dust hanging out of the box—without touching the axle—is about as unmechanical, dirty, careless, trampy-looking a thing as our railroads have, and ought to be ashamed of.

The Pittsburgh Locomotive Works are building some 19x26 ten-wheelers for the K. C., Ft. S. & M They will have Dean guides.

The nominal capital of the railroads of this country, represented by stocks and bonds, amounts to the enormous sum of $8,518,718,677.

The Valve Gear of the Ross Winans "Camel" Engines.

Last month we illustrated one of the "camel-back" engines built by Ross Winans, of Baltimore, more than thirty years ago. These engines were original in almost every particular, the valve motion being no exception. The cut-off mechanism was peculiar in that it worked steam expansively while all the time operating the valve its full stroke, and it is claimed by many engineers that it was the nearest approach to an ideal cut-off ever made on locomotives, using as it did but one valve, and being particularly simple. The valve motion of the day was the drop hook, and this Winans adopted, and added the cut off. Across between the frames of his "camel," just in the center of the wheel-base, was a shaft on which were the two rockers—one for each side. These rockers, shown in Fig. 1, had a curved arm that extended over the wheels and terminated in a bearing for the back end of the valve stem, as shown at *P*; on top of this curved arm was cast a socket, shown at *S*, for inserting the starting bar when necessary. The shaft went through the body of the rocker, as shown by the dotted lines; below the shaft there were four arms carrying at the bottom a steel pin or bolt that extended through them all, forming three bearings as shown at *D*, *D*, *D'*, Fig. 2. Now there were two eccentrics on a side—one set for the forward and one for the backward motion—these eccentrics operated drop hooks, each having its own place in the lower end of rocker. Then, beside the eccentrics, there was a cam, as shown in Fig. 2, operating another hook This cam worked in a square frame or yoke *Y*, as shown, the frame being suspended from the boiler by the hanger *L*, and it operated a hook *H* exactly like the drop hooks of the eccentrics.

The reverse lever merely tumbled the shaft *T*, and this shaft carried six cams like *C*, three for a side, each cam being under a hook When the lever was in the center, or "out" notch, all the cams were turned enough to lift the hooks clear of the pins in the lower arms of the rocker, and the valves would not operate while the hooks worked back and forth, sliding on the cams. If the lever was put into the back-up notch the cams under the back up hooks presented their low sides at the top and the back-up hooks would fall down and engage the pin *D'*, and operate the back-up gear.

If the lever was put in the forward notch the back-up hooks were lifted, and the forward motion hooks dropped into gear.

Ahead of the forward motion notch there was another, for the cut-off, and when the reverse lever was dropped into that, both forward and back motion hooks were lifted out of gear, and the hook of the cut-off cam dropped in.

There was a guide, or yoke, under each hook, to prevent the top from striking the rocker, and to provide a rest for the hook to slide on when out of gear. These hooks had nothing to hold them in gear but their own weight, and the friction, in forward motion, and once in a while in backing up, if the eccentrics got dry, they would unhook. If the engine was standing still and out of gear, or it was desired to change from forward to back or *vice versa*, the hook that was out could not be engaged with the pin *D*, so a starting bar was dropped into the socket *S* on the rocker, and the rocker moved until the hook engaged the pin, then the bar was taken out and set into a stationary socket provided for it.

The "four motion cam," as it was called, was so shaped that it filled the frame *Y* in every position, so that there was no knock. It caused the valve to travel five inches, just as the eccentrics did, but the valve stood still twice during each revolution. When the pin, which is shown at *B*, was at the dead center, the valve was opening very fast, and opened wide almost instantly, and closed with a quick motion when the pin reached the quarter, here the valve rested, allowing the steam to work expansively, while at the same time holding the exhaust open for the other side, until the piston had traveled nine-tenths of the stroke.

The exhaust, of course, was just as sudden as the admission, and produced a very sharp and intermittent blast on the fire, which was generally believed to be the cause of the camel engines being so hard on fuel—no great difference being noted in the amount burned between the cut-off at quarter stroke and the hook at full stroke.

These engines with very small ports and short valve travel did exceptionally good work with low-pressure steam. With this valve gear an engine could break her forward eccentrics or her cut-off cams, and yet go along with her train; and we are told of one man who broke the cut-off and forward motion eccentrics, but got his camel turned around and took his full train to its destination, backing up.

The sketch of this cut-off motion was made by Henry F. Colvin, general manager of the Rue Manf'g Co. of Philadelphia, who used to haul coal with a "camel," away back in "the merry old times that were."

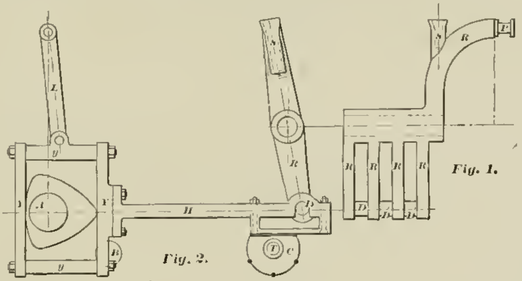


Fig. 1. Fig. 2.

Valve Motion of the Camel-Backs.

The Big 4 road has issued an order against the draping of engines or cabooses when men are killed in train service. This is the rule on several roads now.

In England the Board of Trade regulations call for the printing of the price on all railroad tickets.

Four Signal Plans.

An exchange describes a "permissive" block system adopted on the Erie, between Geauga Lake and Mantua, as follows:

There will be two "blocks," one extending from Geauga lake to Aurora, the other from Aurora to Mantua. The system adopted is "permissive." When a passenger train is on a block no other train can enter that block except in case the wires are not working, when a second train may follow fifteen minutes after the first. A freight train may follow a previous freight after a 10-minute interval under a caution signal

If this description is right, the "permissive" block system would appear to be almost as good as no system at all. The plan of following a train after the lapse of a certain number of minutes is the usual plan, and no signal system is of any use that uses it—you don't want to know how long the preceding train has been gone, but where it is.

The Central of N J have put up an electric search light on the signal bridge at the tower in the Jersey City yard. It gives a very bright and penetrating light, and may be a nice thing for the men in the tower to turn into the station, or on the yard, to note the condition of things, but after an engineer has looked at that he won't be able to see a signal, or even the station, for ten minutes.

The Dickson Locomotive Works, at Scranton, have delivered thirty heavy locomotives for use on the new line of the N. Y., Ontario & Western, known as the Ontario, Carbondale & Scranton.

Santa Fe Notes.

John Player is quietly rattling up the dry bones on the Santa Fe. He is a progressive man and a man of resources; he has hold of a collection of grotesque mechanical standards and the motive power plant of the longest road on earth. His first move has been to indicate the engines as fast as they come out of the shop, with the result that many went back and had their exhaust ports widened and the passages straightened out, with a very perceptible benefit. Some of the engines indicated, when cutting off at eight or ten inches showed excessive compression—before the piston had completed its stroke by two or three inches—above that in the steam chest, although the valves were line and line. On most of these a remedy was had by simply making the exhaust closure later, and in others a marked increase of power was obtained by increasing the clearance. The general shop at Topeka is being fitted up with a complete grinding department, grinding is an art that our American railroads have neglected. One man in a well-fitted grinding room will do as much finishing as half a dozen with old methods; keys, straps, nuts, bolts, guides, etc., can be finished quickly and neatly in this way—the Pennsylvania Company brighten their pipes for hand rail and like work on grindstones at a very slight expense

A compressed air plant will be put in, and with small engines on tracks such work as cylinder boring, valve facing, drilling, etc., will be done cheaply and with expedition, it is also the intention to provide all heavy machine tools with cranes operated by air

The Santa Fe is almost too big for one man to handle, the power is scattered over 8,000 miles of single tracks, and shops are located more than 2,000 miles apart; he who succeeds with it will be an organizer—not one of those who personally see to everything, like a peanut vender, but one who gets things in something the shape of an 8 day clock—just needs the touch of the key occasionally. Mr Player has a good reputation for push, and he has a great big chance to exercise that propensity where he is now.

The Santa Fe road have some bad water, and are at present experimenting with a view to separating the solids by a live-steam heater. This arrangement is located between the injector and the check. Where the trouble is principally from lime, there is little doubt that a live-steam heater does the best, but whether this should be carried upon every locomotive or located at each water tank is a question. We are inclined to think where the trouble is great that the latter plan will be the best and most effective, although there is not, at the present writing, a device on the market that just fills the bill.

The accident on the Reading last month, in which twenty-one lives were lost, was caused by a pile up of coal cars from a train breaking in two. This wreck covered all the tracks, and had barely taken place when a passenger train dashed into it—on another track—with the terrible result stated The flagman of the coal train is blamed. The wreck occurred on a curve; we fail to see how a flagman is to know that all tracks are blocked when the train stops suddenly. This road haul as high as a hundred coal cars in a train, coupled with hook and chains with more than a foot of slack to each car. A collision at the head end has something the same effect on the caboose that would occur if the engineer pulled the engine over. Were all the coal cars equipped with automatic air-brakes there could be no pile ups from breaking in two

---

Where the rails are used to operate electric signals or crossing bells, it is necessary to insulate the wheels of hand and push cars so that they will not operate the signals. This is done by using a wooden wheel center

Some Early Valve Motions.

PLAN WITHOUT ECCENTRICS.

Early builders of locomotives were afraid of eccentrics, claimed they were, at best, weak, and it was hard to get movement enough with them, and several builders in foreign countries tried to devise valve motions that would do away with them.

One of the earliest of these was the plan of Hawthorn, a builder of some note

He took his motion from a pin on the main rod, something after the plan now used in the Joy gear. See illustration.

Supported on a stationary link at the bottom, and the long arm of the bell crank *D* at the top, was a slotted frame *C, H*, and in this slot the pin on the main rod worked, having a roller upon it to prevent excessive wear The movement of the main rod, up and down, caused this frame to vibrate the bell crank at the top; this crank had an extension above its fulcrum at *E*, and a bearing pin there for the hook to engage, it is perfectly plain that when this top pin moved in one direction the lower pin *F* would move in the opposite direction, and the engine was reversed by lifting the hook out of engagement with one pin, and upon the other, by the system of levers shown

The movement of the rod is not alike at each end of the stroke, but the inequality was corrected by adjusting the length of the lower link, and the short lever *L* and by getting these right the lead could be equalized.

This gear could only be used on slow-motion machines cut off only at one point of the stroke, and its disadvantages are obvious; it was, therefore, short lived.

A New Crosshead Jack.

Stebbins A Teal, of Missouri Valley, Iowa, has recently been granted a patent on a screw crosshead jack, of which the accompanying cut gives a good idea.

As will be seen, the body of the jack carries a short plunger or ram *G*, that is moved out by a wedge behind it The back of this plunger is rounded off where the wedge comes in contact with it so as not to bind, and is prevented from turning by a dowel pin that extends into the slot shown below the letter *G*; the wedge is a round pin *D*, flattened off tapering; it is prevented from turning by the dowel *F*, and is lifted up by being connected to the main screw *B* by a swivel nut *E*. The body of the jack has a slight depression at *A*, to enable it to rest securely on the crosshead pin, against which it rests when at work forcing out the plunger *G*.

This jack is small, easily made and kept in repair, and can be used in cramped space

The largest grain elevator in the world is at Minneapolis Junction, Minn It is 366 feet long, 92 wide and 175 high, with a capacity of 2,000,000 bushels. It can handle 200,000 bushels per day, and has loaded 250 cars of wheat in ten hours.

The D., L. & W road had a boiler explosion a few days ago; the barrel of the boiler was stripped off the flues from the wagon-top to the front course. The engine, the 25, was an old wagon-top with flat sides on the fire-box and the taper sheet—a weak point. Three men were in the cab, and though the engine was derailed, no one was seriously injured.

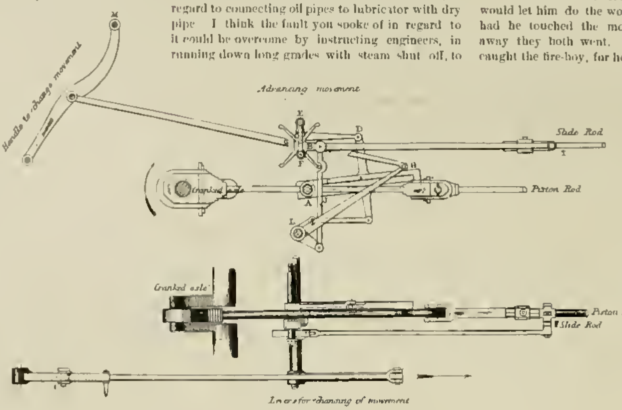
Correspondence

Another Argument Against Connecting Lubricator to Dry Pipe.

Editor The Locomotive Engineer

I see an article in September number of THE LOCOMOTIVE ENGINEER from Allen Wood, M M., in regard to connecting oil pipes to lubricator with dry pipe I think the fault you spoke of in regard to it could be overcome by instructing engineers, in running down long grades with steam shut off, to open throttle valve every few miles, and give a little steam—enough to drive oil from dry pipe into cylinders I think there is another objection to connecting oil pipes in the way mentioned. If it was necessary to put engine in back motion in order to stop, and she ran long enough to pump up more than boiler pressure, the oil would be forced from dry pipe into boiler and cause engine to foam.

Altoona, Wis IRA F. WALLACE.



EARLY VALVE MOTION.

Electricity on a Locomotive.

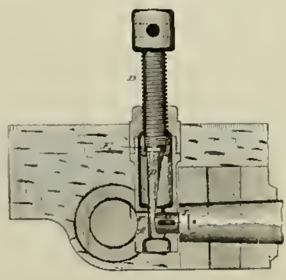
Editor The Locomotive Engineer:

I see an article in the August number of THE LOCOMOTIVE ENGINEER from Old Timer, Baltimore, Md, asking if any one ever experienced any electricity when engine was blowing off steam. Seeing no one made a reply in September number, I will give a little of my experience in regard to it I think it was five years ago this coming winter my engine came out of shop. I started out one cold, still night, on a freight train. I noticed she did not carry standard pressure of steam.

We ran about thirty miles, when we had to take siding for a passenger train, and while waiting thought I would go and try my hand at setting the pop. I took monkey wrench and started on hurricane deck to do the job. The engine was blowing off steam at the time. I gauged the wrench to other pop and then applied to one blowing off steam, or tried to; for no sooner had I touched the metal with wrench when away went Mr. Wrench and Mr. Engineer. Mr. Wrench went out in snow, and your humble servant on his back on top of cab. For an instant I did not know whether I was blown up or struck by lightning. After I regained my horse sense I shouted to fire-boy to fish the monkey wrench out of snow somewhere around engine. He found it, and I told him to come up and help me. This time I held the torch and told him to screw her down. (Thought I would let him do the work this time.) No sooner had he touched the monkey wrench to pop then away they both went. I dropped the torch and caught the fire-boy, for he was going to follow the monkey wrench this time. I could not keep from laughing if it had killed him. After he regained his speech he says to me, "You think you're d—— smart, don't you?" and he looked cross-eyed at me all the rest of the trip.

After she stopped blowing off I got up courage to try it again, and succeeded in setting pop all right; felt no more electricity, but our arms were lame for two weeks after it. I thought of speaking to some expert electrician about it, and get an explanation as to cause, but neglected to do so, and am in ignorance yet in regard to cause of it. Who can explain?

Altoona, Wis IRA. F. WALLACE, Eng'r C. St. P., M. & O. R'y.



CROSSHEAD JACK.

Side Rods.

Editor The Locomotive Engineer:

Have been reading an article in the *Car Builder* for September about "Side Rods and Crank Pins" The subject is well handled from a mechanical standpoint, and will be of service to many. The writer fully agrees with its many good points which are shown up, but it appears to some that the entire cause for breaking is not poor workmanship in shop, neither is it all due to wheels being ⅛" larger or smaller than should be. If side rods only broke from duty that should be required of them there would not be *one* broken where there are now *fifty*, and my object in calling your attention to this matter is, it is quite possible for it to be brought to the notice of many who do not see the *Car Builder*, and also to get another class, who are more interested in this subject than any one else, *i. e.*, the engineers, who can do much to assist the mechanic in doing away with this evil. It ought to be thoroughly understood by everybody interested that the duty of a side rod is to convey the surplus power from the main wheel to rear wheel (am now speaking of a standard American type of eight-wheel engines), which only occurs when front wheel fails to give the amount of adhesion required for work done, and in no case can this surplus power be more than one-half of cylinder power of engine, which shows it is not excessive, for it is very common practice now to find engines with very small main rods, which seldom give any trouble. Why side rods break, straps give out, and crank pins drop off, in nearly all cases is the *undue strain* brought upon them by not being the *proper length* or not having a sufficient amount of *lost motion* to adjust themselves to the varied conditions under which they are compelled to perform their work. These varied conditions are brought about by the several different parts of the engine, which come directly in connection with this matter, *i. e.*, the driving-boxes, wedges, axles and crank pins. When an engine is new, or just out of the shop, there is not any trouble to know how to have side rods put up that will not give trouble, either in running or breaking. A good way to put them up and know they are correct is to have the engine standing on a level track, with both driving-boxes in same position in pedestal, *i. e.*, same height from frame; then fit rod on to each pin so it is a good running fit. After this is done the rod should be taken off, and one pair of wheels raised up until the driving-boxes come to the frame, and the other boxes come down to truss braces at the bottom of pedestal; then the rod should be put up against the pins and see how much short it is; when this is found the brass should be filed out to allow the rod to go on in as free a manner as if that was to be the position that they were expected to run (and this last measurement should be taken when engine had steam on, so that all expansion could be had). This will make the brass in back end of rod elongated to whatever extent the two measurements differ in length, which will be enough to set many a good man to thinking how it was possible that he had never broken more side rods when put up as they are many times. When making this back brass elongated, do not make it any wider than diameter of pin, and there will not be any rattling of the rods, such as one often hears where the solid end is used, and which is very annoying to some, while it is fine music to others, who have thought it best to go back in the tank on occasions when side rods had broken. And now this is all that need be said on this subject, if the engines did not wear while in service; but they do, and this wear must be compensated in some way; the driving axles will get smaller, and the brasses in driving-boxes get larger, wedges get slack, wear more in one spot than another; and pins do not always wear to keep true with their centers.

Each one of the above aggravates the trouble, and a good way to do is to allow whatever wear there comes to the side rod alone until the wheels, boxes, pins, wedges, etc., are all put right again when in shop. There are engines of recent build running, that have their side rods so constructed that whenever a key is driven it changes the length of the rod, which in nearly every case will shorten it when it ought to be longer. Go around any engine house and find the man that does the fast running, his engine is getting towards a point where it will go to shop in a short time; its boxes are bad, wheels need turning, axles want truing up; in fact, "all to pieces." He feels like doing something to keep going as long as possible, so he will "line up side rods" and have them right, even if the rest is bad, it being the only thing he can do, and he feels as though, if the engine does give out with him before going in shop it will not be his fault, for he has done whatever it was possible for him to do, and he is strictly honest in so doing. But if one will hunt up the breaking of side rods he will find that very many of them are broken at about the time these things occur, *i. e.*, when the engine is about ready to go in shop with some one who is doing his level best to get a little more out of it. There is one thing that all engineers, more particularly those running fast trains, should always keep uppermost in their minds in regard to side rods, and it is this: There never was a side rod broken on account of running with "too much lost motion" in them. It is the want of the proper amount that produces the undue strain upon them that metal can only stand for a time. There is not any doubt but the solid end rod, made with I section, is the best one in use, but it is not as much due to the section as it is to the solid end, which does away with much of the "monkeying" that is too often the case with other types of rods.

If this will be the cause of a few of the many who see it to *think*, the writer will be fully compensated. R. W. CAMEL.

Big Engines and Longer Hours

Editor The Locomotive Engineer.

I see in THE LOCOMOTIVE ENGINEER of September that Brother Andros comes down some, and admits that big engines have a tendency to do up engineers in some cases. I never kicked against them on account of reducing the number of men. What gets me is that I must haul twice the number of cars, use twice the amount of sand, and put twelve hours to make a trip instead of eight as I used to do.

This is what I call being done up. I never thought of asking the company to buy me a toy engine to run. Neither did I think of telling them that a sixty-ton engine is better than a forty-ton engine for all concerned. When I make up my mind to write for the interest of the public instead of the engineer, who does more work for the same money, then I will sign my own name.

Baltimore, Md. OLD TIMER

[When a locomotive engineer puts twelve hours in where he formerly put but eight, his pay should be increased accordingly. Engine men are already on duty much too long for safety.]

The First Locomotive in America.

Editor The Locomotive Engineer:

Some time since you told us that the first locomotive in America was the "Stourbridge Lion," and that she ran on the D. & H. C. Co.'s road at Honesdale, Pa. The school history of the U. S. states that the first locomotive was put to work upon the South Carolina road, and now Mr. Hemenway says Hero, of Alexandria, constructed the first steam engine 2,000 years ago.

Now which is which? A. F. COOK.

Lilly Pond, Ga.

[All are right. Hero made the first steam engine (not locomotive); it was a mere toy. The "Stourbridge Lion" was imported from England and was the first locomotive to turn a wheel in America, while the "Best Friend" was the first locomotive *built* in America, and she first ran upon the South Carolina road. There were a number of locomotives in use in England before the "Stourbridge Lion" was steamed up.]

Slipping.

Editor The Locomotive Engineer:

I have read all the articles on the cause of locomotives slipping when running down hill with steam shut off, and the many theories advanced to account for it. In my experience of six years on the footboard I never knew of one slipping in that way, or heard of it, until I read of it in your paper.

W. F. Relyea, on page 166, says the axles of Engine 121 were twisted, and that she does not slip ahead since getting new axles. Now I would like to ask Mr. Relyea how he accounts for both the main and back axle being twisted alike. Does he claim that the pins and side rods are stiff or strong enough to stand the strain to twist the back axle, even if there was power in the cylinders to twist the main one?

I am like "Hogbacker"; I would like to ride on an engine once that turns her wheels fifty miles per hour, when running twenty-five with steam shut off. FRANK PHELPS.

Use of Copper Fire-boxes in America.

CARELS BROS. LOCOMOTIVES AND STEAM MACHINES.

Editor The Locomotive Engineer:

We beg to ask for answer as soon as possible in one of the next issues:

What is the metal generally used in America for locomotive fire boxes—copper or steel?

Do you know such companies of railroads who have employed steel fire-boxes for locomotives, and leave them out after, and the causes of this?

Apologizing for the trouble and thanking you beforehand. CARELS BROS.

Gand, Belgium.

[There are probably a few copper fire-boxes still in existence in this country, but very few, if any, have been built in the past fifteen or twenty years. Steel is the metal generally used, and is probably put into nine-tenths of all locomotives built for use in this country now. No builders or roads here ever went from steel back to copper, but some did go from steel back to iron, but this was before steel plates were brought to their present perfection. First class fire-box iron is now more expensive than steel. Steel fire-boxes are a success in every way, as long years of service have abundantly proven.]

Pull of Reverse Lever.

Editor The Locomotive Engineer:

The cause of reverse lever jerking, and my understanding of it, as I have had the same trouble, I think it is caused by the link wanting to slip up on the link block, from the fact that, in running at a high speed shut-off, and with small drivers, the vibrating motion of the link is so quick that it does not overcome the inertia of the valve and other moving parts of the valve gear, which gives it a tendency to climb up on the block, and, of course, it transmits motion to the reverse lever through the hanger and tumbling shaft.

Having a balanced valve would make no difference when not using steam, as the load would have to be moved under all circumstances. With the short eccentric rods of most ten-wheeled engines the case would be more aggravated. Think one cause of the lever being hard to get out of the corner is the friction of the four eccentrics trying to keep the link down. We all know that the reverse lever wants to lean the way the engine is running, and it offers strong objections to a contrary position. I offer this as a theory, not as a fact.

In regard to the driving wheel slipping ahead, let us accept the theory of the counterbalance as one of the causes; but is it possible that there may be one small wheel in the lot, and the rail acting as a driver, the small wheel as the driven, and that the counterbalance has the wheels on the point of slipping, the quick motion of the smaller wheel will furnish the shortage, and start them all to revolving faster than the engine runs. Now, if this theory is correct the engine would slip easier with the main rods down than with them connected. Have fell down a hill pretty fast at times, but never noticed this peculiarity about my engine, as I was giving my attention to good jumping ground.

Corry, Pa. W. DE SANNO.

Improving the Service—A Little Experience.

Editor The Locomotive Engineer:

I have always taken an interest in your paper, because in it I recognize the means of picking up information—the experience of other men in the same calling. Thousands of engineers and firemen, shop men and officials now read the paper, and generally seem to want to extend its circulation, but I don't think they are as free to ask questions or advance arguments as they should be—only the *exchange* of information is fair. I have been thinking for some time that the railroads are pretty fair with engineers, and pay us promptly and fairly well, so we should give as good service as we know how. It is almost entirely in the hands of the engines' crews whether economical performance shall be rendered or not. I came to the conclusion that it was *drops* of oil that filled the big can, and *lumps* of coal that filled the tender, then I commenced to be careful of the *drops* of oil and the *lumps* of coal. I oiled as carefully as I could, taking pains to get little or nothing on the *outside* of the bearing, and watching the wastes; if I got up on the engine and found a lump of coal in the gangway, instead of kicking it off on the ground I threw it back on the tank.

Don't try to save *tank* loads of coal or *gallons* of oil—just *lumps* and *drops*—and you will be surprised to see the difference on the performance sheet. Just try it.

I also think that the right thing for an engineer to do when he has a very light pulling train is to say so, and offer to take a heavier one, if there are cars to go, and not kick and roar when the conductor pulls the pin to pick up an empty. I know this will not be seconded by many—they have been raised the other way—but why is it not the right thing for engineers to do just as they would for themselves? If we got our pay *per ton per mile*, as the company does, we wouldn't go over the road light.

A man that is known as one who wants to do all he can will not protest in vain that his train pulls too heavy to take on more cars, while the one known as a general kicker can't get his judgment accepted, right or wrong.

St. Paul, Minn. J. J. LEIGHTON.

About Engineers, Their Duties and Their Pay.

Editor The Locomotive Engineer:

Our friend J. J. Clair seems to be somewhat offended about my racket on valve motion, but he is off the track bad.

I am an old fireman runner, and there is no class of men I respect more than the locomotive engineers, but he knows as well as I do that we have men among us that imagine they can improve on any kind of work that may be done on their engines at the shops.

As to lost motion, I do not approve of it any more than he does, but I do assert that I can set a valve, and with lots of lost motion still make her beat square.

As regards the pay of my engineers, we pay the same on this road as standard gauge, and if you wish to know my sentiments on this, I do not think it enough. Engineers are worth more money than any class of railroad men, but they should fully fill the duties of engineers, and when they do this they always make money for the companies.

Furthermore, I am one of those that think the more money paid my men the more I will get for superintending the work. I allow my engineers thirty cents for every hour delayed, even if only one hour.

I hope this will convince you that I am not a "Cheap John."

Now, Mr. Clair, you must not forget that you are not the only man that takes this paper. Mill men, coal roads, and a good many private individuals own locomotives, and as they will want their engines to beat square I tell them how to do it without taking eccentric blades down.

I did not tell this expecting engineers to try it.

Houston, Tex. E. A. CAMPBELL.

A Splendid Specimen that Should Have Been Preserved.

Editor The Locomotive Engineer:

Few men would care to live their erratic lives over again, but if it were possible, the writer hereof would like to make amend for one bad job. Away back about 1854, while a cub at the machine shop of P. F. Geisse, Wellsville, Ohio, I had the very questionable honor to be appointed, together with another boy, to wreck a locomotive. The old man bought a fine "Grasshopper" engine at Cleveland, and had her towed into the shop, and set us boys to cut her up, which we did, with many regrets on my part. She was a good specimen, and apparently in good working condition. I remember the superior workmanship and fine proportion of the connecting rods, which were hollow and very light, made with forked ends to fit the polished brass walking-beams. The beams were hinged to the top of the vertical boiler, and the engines coupled on at about two-thirds the length from the fulcrums, while the rods were coupled to the ends. She had a hook valve motion, but I can't describe it now. The boiler contained about 400 small tubes, and had a fan to create draught. The engines were connected to a countershaft, and thence to the driving axle by gears. The drivers were small—probably three feet. She was built by Winans, of Baltimore, and was probably of the same design in detail as the one illustrated in your paper a few months since.

I never felt quite right about that bit of vandalism, but congratulate myself that I was not the instigator of it. I got nothing to speak of for the job, being only an executioner *ad interim*—a poor excuse is better than none.

The Stephenson locomotive erected at Darlington, England, as a monument, suggests the idea of disposing of all our old veterans in a similar way, and I regret now that this one was not spared for such a purpose.

Brazil, Ind. C. W. CRAWFORD.

Injectors.

Editor The Locomotive Engineer:

In a recent issue of your paper you make some reference to "Alexander's Ready Reference." Will you please give me your opinion of a statement taken from the above book? On page 12, of his "Reasons Why," explaining the principle of the injector, he says: "Steam confined in a boiler may be considered a body at rest; the instant it is released from the boiler it becomes a body in motion, and thus, in passing through the pipes and injector, it sends water into the boiler at a force much greater than that at which it left the same boiler only an instant before."

Where does the *extra* pressure come from? S. A. A. explains by an illustration. True, if we take a pound weight and let it fall one foot we obtain one foot-pound; if two feet, two foot-pounds, and so on, which is, as I understand it, a force generated by the *falling* of the weight (by attraction of gravity); but, are the same conditions present in a boiler? I have always believed that the "self-feeding" feature of steam boilers, by means of injectors, inspirators, etc., was owing to the *reduction* in area at point of admission of feed water to the boiler, from that at which the boiler is tapped for steam. JOHN BRUCE.

Pittsburgh, Pa.

[The pressure in the boiler may be considered static force—a body at rest—while the feed water is dynamic force, or a body in motion. The injector works because of the difference in velocity between the flow of steam and water at the same pressure. Steam flows about twenty times as fast as water, and the steam flowing through an injector gives up part of its heat and velocity in order to pick up water and gain weight. The extra velocity imparted to the water causes it to lift the check and enter the boiler. The more steam you can use on a given amount of water, the greater pressure you can force the feed against. Testing injectors are made that take steam from a boiler at 100 pounds pressure, and force it into another against 300 pounds pressure. They are so constructed as to throw a small quantity of water at high velocity. The steam nozzle of an injector is always larger than the combining or delivery tube, and this may be considered as the large steam cylinder of a pump with a small water cylinder, except that in the jet instrument the movement of the piston is continuous, and that there must always be enough water to condense the steam used.]

Criticism of the Lehigh Valley Engine.

Editor The Locomotive Engineer:

Speaking of the engine on first page last month you say that "it is cooler, cleaner, and easier riding in a cab placed near the center of the boiler," and that "it is safer, and the view of track better for the engineer." Now, if you will look again, I think you will see a mistake here. In case of a side rod breaking, the cab is in just the place for it to come up through the running board and paralyze the engineer or fireman. Again, in case of a head-end collision, it is easier to get off if the cab is on the back end of the boiler. It is just as cool, and easier to clean the jacket if it is all in front of the cab, and I never heard an engineer complain about seeing ahead out of a cab placed on the end of the running boards, and it certainly looks more natural than stuck up so far in front, and if placed on the back end it does not separate the engineer and fireman, which should not be done. It is a fine engine in many respects, and will, no doubt, do good service and make a good showing. The short front end is very neat. If the check of the feed pipe was placed up within 6" of the front flue sheet it would improve her looks and steaming qualities by giving her a better water circulation. Another improvement would be to take that spring balance off, and set the whistle in the top of the dome.

Now, Mr. Editor, you may think that I have lots of "gall" writing this way, but it is my nature. Some time I will tell the boys about my first lesson on pumping and running an engine so as to make her steam, do her work, and not kill the fireman.

In conclusion I will say that I wish THE LOCOMOTIVE ENGINEER was a weekly instead of a monthly paper. "COWBOY."
