THE LOCOMOTIVE ENGINEER.
DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. I. NEW YORK, JANUARY, 1888. $1.00 per Year. or 10c. a copy.

From the Publishers' Standpoint.

That very many railway master mechanics and executive officers were once locomotive engineers and firemen is well known among railway men. Such officials, therefore, have a personal, as well as a professional concern in matters relating to the locomotive.

That many of the enginemen of to-day will step from the heroisms and responsibilities of the cab, to places of mechanical and executive control, is as certain as any future event can be. To such, also, the methods and appliances of the repair shop possess a double interest. Taking the locomotive as a complete machine at the hands of the designer and builder, it is evident, therefore, that there is, or should be, an intimate relation existing between the men who run it (many of whom have had more or less shop experience), and the roundhouse and repair shop employes, and master mechanics with whom they co-operate in the task of keeping it in condition to run. That this army of workers is known in railway circles to wield an influence in those circles, none the less potent because not fairly estimated outside, may be stated with entire confidence.

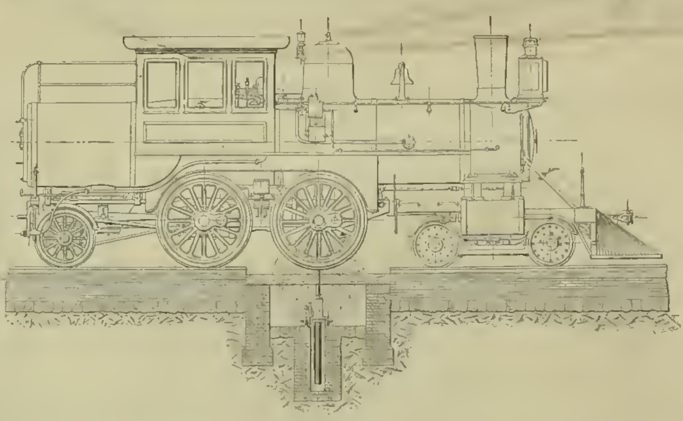
Unhampered by exclusive connection with either of the grand divisions of this army, the aim of this journal will be to indicate a common ground, upon which earnest workers in all can meet in the interest of progress, and to claim for all the meed of recognition which is their due. The editor, John A Hill, who has been for several years connected with the motive power department of the Denver and Rio Grande R. R. as fireman and engineer, with corresponding shop experience, introduces himself upon another page. We bespeak for him the good will and co-operation of all.

Naming Engines.

The old time practice of naming engines is coming into vogue again on some roads that long ago abandoned it as foolish. There is no doubt that the public like the idea, and a hundred people will talk about the feats of the "Quickstep" that would never remember the 194 for four days. For passenger service we believe it pays.

Vreeland's Transfer Jack for Removing and Replacing Locomotive Drivers and Trucks.

It is often desirable or necessary in railroad repair shops to remove a pair of drivers or a truck from under a heavy engine. The usual method is to raise the engine up by four hydraulic or screw jacks, placed under each corner, until the wheel can be rolled out. This required the lifting of the whole machine from fifteen to twenty-four inches. It not only makes the engine too high to work on without staging, but, as the jacks must be used elsewhere, the ponderous boiler is blocked up and left there—a dangerous and unhandy arrangement. Some very large shops have "drop tables" and "steam lifts" to do some of this work, but these are cumbersome, expensive, and occupy valuable floor space.

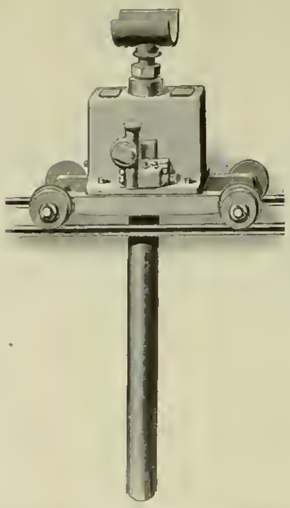


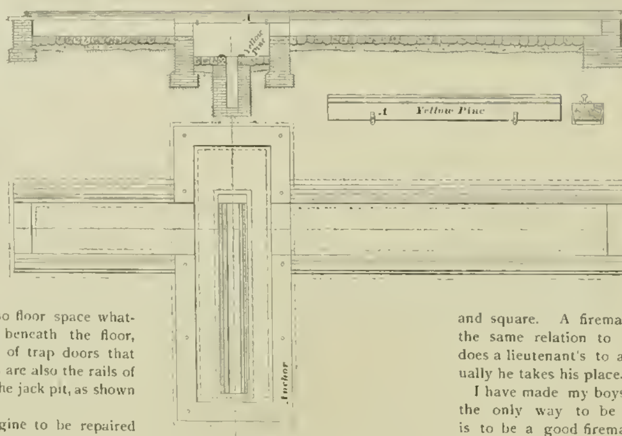
APPLICATION OF TRANSFER JACK.

Endless annoyance of this kind induced J. H Vreeland, master mechanic of the eastern division of the New York, Lake Erie and Western Railroad, to invent and build at his shops in Jersey City the jack here described and illustrated.

By reference to the cut of the tool itself on this page, it will be seen that it is merely a hydraulic jack, mounted on four small wheels, and having a very long ram. The pump is cast separate from the head or frame, and can be removed for repairs if necessary; it is operated by a removable lever, the same as used in the common hydraulic jack. The top of the ram has a curved head in which to rest the center of the driving axle; this is swiveled so that a pair of wheels can be turned around or placed on a track not in line with the track from where they were taken. The ram has a very long bearing at the top of the frame or head. The excellent engraving hardly needs an explanation.

By reference to the cut on the first page, it will be seen that the jack pit runs at right angles to and crosses the regular engine pits. This pit is wide enough to take in the largest engine truck complete, and is about twenty-four inches deeper than the engine pits. In the bottom of the jack pit is a slot about ten inches wide, and deep enough to clear the lower end of the long cylinder. On this page will also be found a ground plan of the pits.





The device occupies no floor space whatever, being entirely beneath the floor, which is in the shape of trap doors that are easily removed, as are also the rails of the engine pits, over the jack pit, as shown at *A* in ground plan.

In operation the engine to be repaired is run over the pit and pinched until the axle or truck-center is exactly over the head of the jack, the engine is left standing at its usual height, no raising being necessary; the jack is then pumped up until the weight of the pair of wheels is lifted, the removable rails are pulled out, and the wheels are dropped down far enough to clear everything, the jack rolled on its own track to an adjoining pit, raised up and the wheels rolled away to the lathe, the turn-table or the scrap heap.

All the shops of the N. Y., L. E. and W. are equipped with this jack, and it is a common occurrence to run an engine into the shop or roundhouse in the morning, after she has made her trip, drop a pair of drivers, refit one or more boxes, and send her out on the afternoon run; meanwhile the fire has not been disturbed or steam blown off. For cleaning out or fitting up main driving boxes, the wheels are often dropped a foot or so without disturbing the eccentric blades at all.

Four men are usually put on this work, two in the pit to do the pumping, and one at each side to steady the load, etc.

At the Jersey City shops four pairs of drivers have been replaced under a consolidation engine in thirty-eight minutes by a gang of four men. Watson & Stillman, of 210 East 43d St., New York, are the manufacturers and sole agents of the inventor.

Fighting Against Nature.

BY JOHN ALEXANDER.

I am a locomotive engineer, or runner, and have been a fireman; I fired for more than four years and have been running for more than eighteen; my oldest boy, Harry, is a fireman. So you can see that I can at least lay claim to a little experience.

When I learned you were going to start a journal solely for engineers, firemen and repair shop men, I was glad; I need it for my boys and I need it for myself. I am one of the few engineers that are perfectly willing that their boys should follow their own calling; my wife is now converted to my belief. I am proud of my occupation and the responsibilites I assume. I cannot think of anything I would care more to hear of one of my sons than for some man, who knew what he was talking about, to say: "That young man is a first-class locomotive engineer."

Enginemen of America, what does that remark mean? To a workingman it means a skilled mechanic, capable of earning from two to four times as much pay as a laborer. To the railway officials of the country, a man in whom they can safely trust the trains and property of the road, safe in his decisions, cool in emergencies and faithful to his trust. To the thinking public, a hero whom it will be perfectly safe to trust with the lives of the dearest ones on earth. To his family it means sobriety, thrift, manhood. To his friends, kindness, benevolence, honesty, honor and a good example. To society, a man and a gentleman, intelligent, grimy-handed and square. A fireman's position bears the same relation to an engineer's as does a lieutenant's to a captain's—eventually he takes his place.

I have made my boys understand that the only way to be a good engineer is to be a good fireman. I have three, and they are all as engine-crazy as I was myself. I made a rule that when they graduated from the city school they could go into the shop as helpers to machinists; then, after serving one year, they could make their choice of occupations. If they still wanted to go on the road, I would help and not discourage them. My father kept me off the road until I was of age just because *he* disliked the business. My second boy is in the shop and the third in school.

Engine running is hard work, calls for muscle as well as brains. So is plowing hard work, driving team, keeping books, clerking, or moulding gum-drops.

The sooner the young men of to-day, who are blessed with that great incentive to work up—poverty—settle this fact in their minds, that to advance hard work is necessary, the better for all.

Men who aspire to be good mechanics must go through several years of hard apprenticeship. There are too many young men who would make good blacksmiths that try to be bookkeepers. They dread the sweat, and their parents are foolish enough to think there is a disgrace in wearing a leather apron at $3 per day, that is not found in a pen behind the ear at $2.50.

If I had a boy that was a natural doctor, liked the study, would rather help cut my leg off than go over the road with me, how foolish I would be to force him to go on to the road as a fireman. Yet how many engineers do this very thing—upside down. A boy that wants to be an engineer will make ten times a better engineer than he will a doctor, and when we use every influence we can to make him what his nature says he is not and cannot be, we simply fight against nature. Nature always wins, or the boy is spoiled. I would rather my boys should be day laborers than botches at any business.

There is another thought that I want to air. Many a boy only thinks he wants to learn a certain trade or business. He may have an eye for machinery and think he must be an engineer; a few trips in the night and storms may show him that he was not intended for an engineer, lacks the nerve, caution or confidence, but he may turn his attention to the machine shop and find his forte. I always gave my boys a chance to look into the details of any business they took the least notice of or interest in, but they have come back to a locomotive just as a lost dog smells out his master.

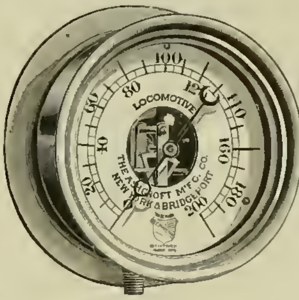
Workingmen, even skilled mechanics, can leave their children little more than sound bodies, a fair education and a good example—and this is enough. Josh Billings was sound when he said: "It would be better for the country if there were more kits of carpenter's tools and less legacies left to our young men."

Locomotive engine running is bound to be a noble, honorable and remunerative calling; it will grow in importance and dignity in the future more than it has in the past. It is bound to be filled by a class of intelligent men, who will be men in every sense of the word. I am proud of my calling and if my boys want to follow in it and excel their father, I am not going to fight against their natures as I know many an engineer is doing to-day.

Improved Steam Gauge.

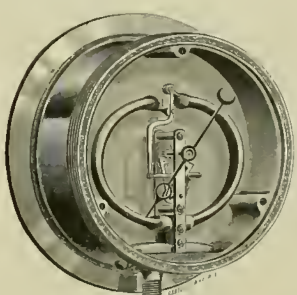
Every man who has watched a steam gauge for any length of time from either side of a locomotive cab knows something about its good and bad points. When an engine has been out for some time and the gauge has leaked, and been fixed; when the glass has been broken out, and the pointer knocked off and replaced by guess, and a few such slight accidents occurred to make him have some doubts as to the gauge's honesty, an engineer does not feel very safe to go and set the "pop" or safety valve by it. Such men know the value of large figures and in having the dial close enough to glass and rim far enough from figures so as not to shadow them at night. They also know what a nuisance it is to have steam from the outside get into gauge and cloud glass and sweat dial, and they know how much worse it is for them to leak internally and thus hide their own face in shame at not being able to tell the truth about the steam pressure.

In the gauge here illustrated no attempt has been made to get up anything particularly new, but to improve and perfect every detail of well-known gauges. In the first place, several thousand dollars were spent in trying to make seamless brass tubes of the proper thickness and shape. This has been accomplished, and avoids the dangerous leaking of these



IMPROVED STEAM GAUGE.

pipes inside the gauge—one great trouble with the brazed tubes. Then the gear and segment were so arranged that, when adjusted to the proper working pressure, all were perpendicular and in line, with no strain from weight of parts, etc. There is no connection to back of gauge at all to be affected by the heat, or twisting of parts if screwed to an uneven surface. All the



IMPROVED STEAM GAUGE.

gear and working parts are supported on the central connection of bent tube; the case merely surrounds it, and is no necessary part of it to insure true results. The gears are cut by watch-making machinery and have wide faces, to prevent wear. Around the gauge casing front is a deep groove holding a heavy ring of felt, on which the glass is pressed by the front or ring, which screws on, thus preventing jars and the breaking of glass by expansion. The dial is cut away in such a manner as to show the entire working parts, which are all finished. The gauge presents an inch larger dial than any other gauge of its size, at back, and the figures are large and very plain. It was especially designed for locomotives, and several hundred of them are already in use. They are manufactured by the Aschroft Manufacturing Co. of 111 Liberty street, this city.

One-Man Locomotives.

In a recent issue of a so-called mechanical paper was one of those little statements that amuse practical railroad men, and at the same time show them how little the writer knows of the actual facts in the case. In an article on the burning of oil as fuel on locomotives, the writer, as usual, went on to enumerate the advantages and the economy of the device, and among other things mentioned that it would reduce the expenses of the fireman's wages. as the engineer could easily control the fire from his seat by simply turning a valve.

There are many reasons why one man will never run a locomotive alone, and they are very plain to any man who "has been there." There are more duties for a fireman than merely shoveling coal. His duties are legion; he has supplies to draw, lamps to fill and clean, the interior of cab to keep clean, the whole engine above the running-board to care for, front end and stack to paint, water to take, bell to ring, etc. These duties cannot be performed by the engineer; his duties, both on and off the road, are as numerous as the fireman's: they cannot be entrusted to roundhouse men, because they cannot know just what is wanted, and it would take as long to explain to them as to do it.

Any engineer who has ever sent his fireman to flag on another train for a few miles and followed with the light engine, knows just how oppressive the lonesomeness gets. It is often necessary for some one to go out in front to relight or turn up a signal lamp or the headlight, put out a flag or dig down some sand. Can the engineer go, and leave the mighty locomotive, with its precious freight, flying along over crossings and bridges, through cuts and towns, with no brain to think, no eye to see, or no hand to stay its mad career in case of sudden emergency? Can the engineer set his engine at a tank, go back to take water, find spout too long or too short, and get down and "jim around" till he does get it right, take water, then oil, get up, ring bell as he wipes off oilcan, go over on fireman's side to see signal, then get back on his own side and pull out? The traveling public would kick, and kick vigorously. The delays would be demoralizing and the risk great. The only legitimate and proper school for engineers would be sealed forever, and, as more engineers would be killed, there would be no skilled men to take their places.

In cases of sudden sickness or death of engineer—suppose he fell off—who is there to stop the train? Who stopped the President's special train, a few months ago, when the engineer was killed by a broken side rod while running at a high rate of speed? The fireman, of course.

The economy of saving the fireman's wages in this case would be like saving the expense of the roof of a powder magazine. The day of one-man locomotives in road service is farther away now than it ever was.

The Roundhouse Foreman.

BY JOHN J. BINGLEY.

There is no position connected with the mechanical department of railroad operations that requires more tact, judgment and energy than that of roundhouse foreman on a large road, especially where the motive power is about half that required to move the freight and passsenger trains over the road, and more so if the rule is, first in first out. I have often seen engineers and firemen waiting from one to five hours with dinner pails in hand for the first engine to come in, and, as is often the case, when they begin to come, they come in a string. The first duty of the engineer is to make out his report of repairs needed; something like this: "Eng. No. 20; R., packing down; R. B. D., spring broke; R. F. E., truck, box runs hot; R., injector don't more than half work, etc." This the roundhouse foreman scans, while the foreman of engines stands at his elbow saying: "How soon can I have that engine? It is time she was down to the yard now. Train dispatcher is calling for engines." Now the roundhouse foreman is in a fix: he knows if the engine goes out, and she should break down on the road, the foreman of engines or the train dispatcher will not be held accountable, but the M. M. will call him to an account as to why the work reported was not done. His standard rule should be, not to let any engine go out that he would not be willing to go on and run himself.

Taking this as his rule, now the ball goes on. He orders Smith and Jones to put a new spring in, and hurry up; and "Brush, you get some oil and waste and pack that truck box, and be lively." Brush starts off muttering something about "it's always lively;" about this time comes the engineer with something he forgot to put on the report, and the foreman of engines wants to know how soon he can have that engine. By this time two or three more engines have come in, with reports made out, and there is pulling on all sides; and, what, with steam pipes blowing, eccentrics running hot, feed pipes leaking, and a hundred other things, our foreman is almost wild; goes round to Smith and Jones and finds the holes in spring are too small for the hanger to go through, and the air is getting blue with the blessings on the spring maker; then the hydraulic jack gets stubborn, and there's lots of (all but) fun.

I tell you the position of roundhouse foreman, if he is a conscientious man, is not a bed of roses, as was told to me some years ago when assuming that position on a trunk line, often having six or seven sections to one train, and going through the repairs on over 400 engines per month. The constant worry and responsibil'ty of a position like this is enough to turn a man's hair gray in a few years.

I desire to offer some few suggestions that may be of use to those in similar situations. In the first place, there must be a good gang of men, and the foreman has it in his power to make them good or bad. He must by his own push and "git," show them that he is the color bearer, and go-ahead, speak words of cheer and encouragement to the men, and give them credit or praise for a good job. Again, he must know his men, and let the same man, or pair, do the same work. For instance, let two men put all the springs in and do all smoke-box work; another gang do all work on passenger engines; another set out packing, file and line up brasses, crossheads, etc.; another do work on injectors, gauge cocks and oilers. By so doing, each set can have the tools suited to their work; the spring gang must keep the jacks in order, have chains, blocks, etc., in their care; the men that pack the oil cellars to have a half barrel of waste and oil soaked ready for use and securely locked up.

Tools are a very important item in roundhouse work, some of which I may describe later on.

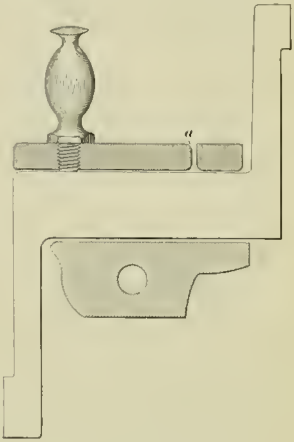
Bad Make-up of Trains.

We recently saw a long heavy freight train leaving an Eastern city, that one good look at would convince any railroad man that the yard men who made it up, the officers who allowed it to go out, or the crew that took it out, ought to be roundly censured. We do not know what was in front, only that the train was made up of all kinds of cars from many roads, the flat car next the caboose was piled high with telegraph poles; these had slid ahead and covered up the brake; the next four cars were loaded with long sections of an iron bridge, reaching over two cars; the brakes had been taken off, all but one, and this was connected to but one truck; the sixth car from rear was an empty gondola, or dump car, with a brake wheel at each end, one for each truck; the seventh, a tall refrigerator. What a man-trap! Suppose six, eight or ten cars should break off the rear of that train when running at any speed above ten miles per hour, and on any grade at all. The weight would make a terrible weapon, and it could scarcely help being shot somewhere. A man could get from way-car to train only by great care over the top-heavy load of poles, and when he got there, what could he do? No brakes to set that amounted to anything. If the train started back on a long grade, Heaven pity the poor fellows on the next train. If the cars broke off and followed the train on a down grade they would surely catch it, and with disastrous results. Here is a great argument for an automatic freight brake. But now, while we risk life, limb, and cash on the old hand brake, let the rear end of all trains be made up of cars with first-class brakes, and let such boomerangs as double loads of iron on brakeless cars be carefully distributed, with good brakes each side of them, and don't put a fortified car in front of caboose to keep men from getting out and over train quickly.

A double glass in your front windows will keep them from clouding or frosting over.

The Fountain Oil Cup.

This is not a new device; it is not patented; you have used it yourself, and you do not like it. The writer used to wonder how he oiled the outside of the rocker boxes, as well as the inside, or better. Take a look at the sketch and you will remember the one you have just like it. If you have a good feeder in the cup, it will let the oil down carefully and lubricated all right; but this cup is not moved like a rod cup and has no chance to get warm and every chance to get cold, so most engineers prefer to let the feeders be very loose, and when the cup is filled it runs down into the box, along the oil slot, and out of the drill hole that the cautious builder has put in the casting as an extra precaution. This extra hole catches dust, cinders, water, sand and several other things not of a lubricating nature. It would, in nine cases out of ten, be better never to have been bored; many engineers plug it up with cold tallow and find it pays.



Simple Glass Gauge Guard.

The breaking of sight feed lubricator glasses generally makes a nasty mess in a cab and the flying pieces of glass have hurt several men very severely. There are guards now made that protect the persons of the men who have to live pretty close to them. Some show the feed on a small mirror, but this is not always a convenient arrangement at night when the glasses are not handy to the gauge lamp, and not every company will buy improvements after once paying for the lubricator. The writer saw a little idea the other day on a N. Y., L. E. & W. engine that seems to fill the bill.

The device was simply a coil spring of brass wire just large enough to slide over the glass tube. This keeps a broken glass from turning into a bombshell; it costs nothing and can be pulled down or up out of the way while the glass is cleaned. Try it.

The Curtis Automatic Pipe Coupling.

Since railroads are putting in steam-heating devices on their trains, one of the stubborn little details has been a good hose coupling between cars, that would not leak, and a great many different kinds have been invented in less than a year. It was found necessary that each coupling should be complete in itself, and all alike; they must lock together firmly, without the use of tools, and unlock automatically should the cars be separated without unlocking them by hand; must be light, and so constructed as to be easily handled by hand when hot.

It would seem that the Curtis Regulator Company, of 59 Beverly street, Boston, have solved the problem in their "Automatic," which consists of the ordinary nipple for rubber hose, with a suitably packed joint, and three strong lugs or clamps to draw the faces together. The locking faces of the clamps are set at a slight angle with the face of the coupling, so that when turned in opposite directions by the levers, the packed surfaces are drawn firmly together, making a steam-tight joint.

Each coupling has a lever, or handle, and each handle has a fluted surface set at right angles to the axis of the coupling, and so adjusted in relation to the face of the coupling that when clamped together the fluted surfaces engage with one another, forming a locking device which holds the two couplings firmly engaged.

On each lever is an eye to which is connected a chain. The chain on each lever is fastened at the other side to the platform of its car, and being shorter than the connecting hose, draws the fluted surfaces past one another and disconnects the coupling before strain comes upon the hose.

It is obvious that these couplings can be handled with comfort, even when hot, by means of the projecting handles, while a sharp pull in opposite directions connects or disconnects them instantly.

The projecting clamps form a complete protection to the face of the coupling against abrasion from outside objects. The cuts need no explanation.

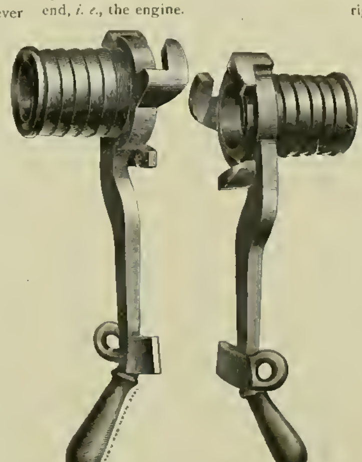
The Car Heating Problem.

The newspapers in the United States that have not published something under the above heading, or one similar to it in the past year are very few indeed. Each and every one of these criterions of the public mind prove one fact, and that is that the people all over the land demand that common stoves shall not be used in the cars. This brings the source of heat down to the locomotive, or a special car for heat only. Now we are not going to settle this matter here—we doubt if it will be settled for some years by anybody—but are going to offer a few suggestions to such inventors, or experimenters, as have had no practical experience on the road.

The greatest, and about the only objection that we have seen to the use of live steam, is the fact that most of our passenger locomotives have had about all they could do to keep up steam enough to pull their trains; the heavier and faster these

THE CURTIS AUTOMATIC PIPE COUPLING.

trains are made the worse this feature is, but this is not the only objection or danger. Statistics show that of all the accidents that railroad trains are heir to, more than 85 per cent. of them happen to the front end, *i. e.*, the engine.



THE CURTIS AUTOMATIC PIPE COUPLING.

Suppose now that an express train on one of our great plains, during a bitter cold night, plunges into a sand drift—they have those things out there—and the engine turns over, knocks off a steam connection and "dies;" it is three or four hours before another train is due, if the storm lets them in on time; if not, they may not come till the following day. Where are you going to get your steam? Suppose you heat by exhaust steam, where is your exhaust? If you heat by exhaust, how are you going to heat your train before you start unless you have a live steam connection? Using either system, how are you going to heat the car you pick up at the small station in the middle of the road? With the exhaust heater you must make provisions for such stops as ten minutes for changing engines, twenty minutes for refreshments, or two hours for a burned bridge.

The arrangement for heating by using very large pipes of salt water heated by steam, either live or exhaust, will keep the car warm for some time after the source of heat is removed, provided there are means used to keep the water from running out of the pipes in case of accident to one or more cars; but it takes longer to heat the car picked up away from home than by the live steam radiator system.

In any experiments you make there are more chances of success if you do not depend upon anything but on the car to be heated. Everything else being equal, this kind of a heater would be the most successful. Do not expect motion from the wheels to generate anything—they are not always in motion when you need heat Do not expect to always find steam in abundance on the locomotive—they are often cold in death. Do not expect that the exhaust of a locomotive is yours to use entirely: it is already choked down to a shrill whistle to force the draft; if you use it, they will have to use live steam to create a draft. Devices that work all right in the shop may be found wanting when put in motion, and some that are a success on time may become cold and dismal failures at a snow blockade.

Some State laws already forbid the use of stoves and prescribe certain kinds of heaters; this is very unjust; there should be no such strict law in any State. Has there been as yet a heating device gotten out that is known, by the severe test of actual use, to be a success? Railroads cannot respect State lines in passenger service without great annoyance and danger to the traveling public. Think of changing cars at every State line from here to San Francisco; through cars are now run from New York to Chicago, Chicago to Denver or Ogden, and from there to the Golden Gate; if each State had a certain heater of its own, no less than eleven changes would occur in that distance.

If laws are a necessity, let them be national ones.

It looks as if, with any system adopted, the stoves and a supply of fuel must be put in the cars to use in an emergency.

There is the iron car system that carries the fire and furnishes heat and light; the compressed gas system that furnishes the same from the baggage cars; the electric scheme, the soda scheme and a dozen other ideas, all having their advantages and their disadvantages, and all trying to solve the problem the best. Do not hamper these busy researches by wild and unreasonable laws, that will only have to be repealed, and we will venture the prophecy that out of the chaos of experimental contrivances will rise up a Phœnix of heat and light that will keep our feet warm in prosperity and not cook us to death in adversity.

The First Questioo.

Since the editor of this paper left the throttle of his engine to come to New York, he has received the following letter:

J. A. Hill: I like your idea of examination of engineers, if they have to be examined, but hope that you will not go too far. All the propositions you have made heretofore have been practical ones, and I believe your examination ideas are the same, but some of the men here seem to think you would give certificates to all who answered the questions; this would let in many men who have not had actual experience, but who were paper engineers. Of course they would fail on the train rights examination. Now I want to ask you one question: What is the first question you would ask a man after getting his name, etc.? I mean one you would stop on, if not properly answered. CHAS. E FLOYD,
St. Louis, Mo. Engineer.

The idea was not to propose a general examination, but if the examination was forced on us by law, to have a board of practical men appointed and practical questions asked. In answer to our correspondent's question, which was by private letter—and we take the liberty of making public—we would say, that in case of a man being examined for promotion, the first question asked, and we should require proof by a note from his M. M., would be: "Have you fired a locomotive on the road for three years or more?" If this could not be answered in the affirmative, the examination would stop, unless the applicant wished to see where he was deficient in the rest of the examination. We do not doubt that there are many men who have fired less than three years, who are better posted than others who have fired more, but there is a certain experience in practice that can be gained in no other way, and is necessary.

Such an examination would not force railroad companies to employ drunkards, or men in other ways not responsible enough to handle engines. The master mechanic could pick his men then as now, with the exception that he would have to pick from examined men, and hence experienced firemen.

Enough is Enough.

The man who invented the remark: "I know when I have got enough," was a benefactor to the human race, if they only knew it. But he should get out another: "I know when I have said enough." Railroad men should think of this; for instance, what is the use of superfluous remarks in an accident report? A few years ago, on a prairie road, the writer was riding on a freight train that passed a station where a red flag had been displayed and blown away by the wind. An extra was to meet the freight at this station, the orders being to hold the freight. A mile from the station we rounded a curve and saw the extra on a straight piece of track *two miles away*. We stopped, sent out a flagman and backed up. The poor operator was half crazed by the break, and the conductor put in his time abusing him. The extra passed without stopping, and after getting orders we went on. The conductor, in his report, said not a word of the blowing away of the flag, but added to the end of his remarks: "It was a very close call for us all, and this operator should be dismissed." The division superintendent was on that extra, and called on the operator the next day, got a frank explanation, was shown that the old depot was arranged with the telegraph office in the rear, and a freight room and waiting room in front of it, and between it and the main track. The operator could not see the flag, and it had blown out of a hole in a post provided for it. The result was, that the superintendent ordered that depot remodeled, and all others like it, and he suspended Mr. Conductor for thirty days "for misrepresentation and attending to duties delegated to officers," and no tears were shed. A plain, truthful statement of facts is what is wanted, without recommendation or comment.

Inspecting Watches.

The inspection of watches of railroad men is the latest official mania that is knocking the color-blind business cold, and is destined to do some real good. The idea is to appoint an inspector in the person of some well-known jeweler, and making it compulsory for all men running trains or engines to have their watches inspected once in three or six months; so far so good. *Fee for inspecting, 50 cents, to be paid by party for whom inspecting is done.* This is where the shoe pinches. Engineers and trainmen have to pay this fee, that amounts to a good round sum when all in. That there is a job in it has been proven in several instances, where reputable jewelers have offered to do the inspecting free for the good will and trade it would naturally bring to them, and have been refused. Engineers or trainmen who have invested from $100 to $200 in a fine watch, and, perhaps, $25 in a fine locomotive clock, feel as if paying fifty cents every few months for the privilege of informing the officers that his timepiece is all right is the last saw-log on the camel's back. If pay is necessary, let the company pay. If they cannot do so, from motives of economy, let them appoint men who would be glad to do the work without an admission fee.

The Oil Fiend.

The saying that a burnt child dreads the fire is no particular excuse for the child to grow up holding a piece of ice on the sore place. And because an engineer has had a world of trouble with hot pins or guides, or eccentrics, or driving boxes, is no particular reason why he should go through life trying to drown every engine he runs in oil. Do you know him? Do you fire for him? Haven't you heard the brakemen cod him about using a sprinkling pot or a pail and a dipper? Wasn't he over to borrow tallow of you last trip, and didn't you see him out on running board pouring it onto pins, guides, etc., and watching the flying parts slap it around and throw it from the stack to the second car in the train? Half of this is carelessness and the other half lack of judgment. Most of these heavy oilers are free-hearted souls, nothing stingy about them, they often break off the end of an oil can spout so it will throw a half inch stream and call it their "free-hearted can," or "general delivery," or "hurry up," and use it on all occasions. Now what is the use of all this? What good is the oil that runs off? It has come to such a pass now that men must figure to be decently economical in oil and more economical of time; every minute counts. Do your careful and heavy oiling before you start on your trip, and afterward only touch up places most likely to need it—the eccentrics, links, guides etc; do it quick and well. How often we see men who have a set rule about oiling, and taking in every hole, at one or two certain stations and oil a little extra at every stop. If they are delayed five miles from their regular oil town they oil there; but no amount of reasoning seems to allow them to pass the regular place without going over the whole machine again. Oiling a locomotive requires some sense and judgment. Young man, study on it a little, and don't be an "oil fiend."

Who Has the Switch Key?

Just what excuse any railroad management can give, if they were disposed to give any, for so carefully keeping firemen from carrying a switch key is more than has ever come to our hearing. Some roads are also too stingy to give the firemen a time card, yet they expect him to know a great many things that he can best learn from the card.

The fireman always has the switch throwing to do, if the engine goes over the road light, and if he loses the engineer's key they are in a fix. Suppose an engineer has a fireman who, in the hurry, puts the key into his pocket and forgets it, goes home and is sick next day so that an extra man takes his place; in the middle of a division a break-down occurs, the engine has to go to the shop "light" and on one side; they make a siding for the fast express, or mail, and find they are keyless. The engineer has his choice of breaking the lock and tying up the switch, or flagging the fast train and borrowing a key and then finding that he has got his old cripple on the dead center; for either offense he will be roundly censured by the very officials who ought to furnish the firemen with keys—as a safety element.

Men in repair shops who are obliged to do lots of work with ratchet drills, will find they feed and work much better if the pivot is placed in the center of a flat spring shaped like a Cupid's bow.

Correspondence

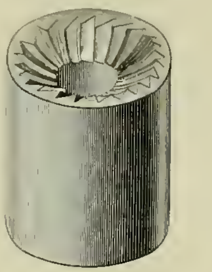
Of course, this being the first number, there is no correspondence to publish, but we expect that each succeeding issue will contain many letters of practical interest to practical men. Little bits of experience related here will interest and aid others. Send yours along.

Who is Best?

Governor Hill, of New York, has followed the example of the Governor of Massachusetts in appointing a locomotive engineer on the board of railroad commissioners. While we have no doubt that Mr. Rickard is a first-class engineer and a man of good judgment and common sense besides, it is to be borne in mind that in a board of only three members, it is impossible to have all the useful qualifications that might be wished for, and that therefore it is important to keep the membership as evenly balanced as possible. In Massachusetts, it is understood that one member must be a lawyer, one a "business man," and one skilled in the art of railroading. The latter expression allows considerable latitude, and Governor Butler, on the expiration of the term of an eminent civil engineer, appointed a locomotive engineer in his place, who has since been reappointed by another governor.

While the qualifications of Mr. Stevens of Massachusetts, or Mr. Rickard of New York, are not to be decided here, it must be observed that an eminent civil engineer is prima facie better qualified for a place of this kind than is an eminent locomotive engineer. It is not without precedent for a locomotive engineer, without previous technical education, to attain high position as a scientific authority, but it is uncommon, and has only been accomplished by means of severe study and intense body-killing application. It is rare indeed that a "self-made" man is not, to a greater or less extent, bigoted. The systematic training, broader cultivation and greater store of actual facts acquired by the civil engineer in his technical school course qualify him, other things being equal, for greater usefulness as a railroad commissioner. But other things never are equal. A member of the Brotherhood of Locomotive Engineers certainly should have sensible views on the relations between railroads and their employes.—*Railroad Gazette.*

In the above statement there are several corners sticking out that a railroad man can hardly help feeling. That railroad commissioners are often called upon to decide vital questions that require intimate knowledge of the real operations of railroading there can be no doubt. When no experienced man is on the board, the commission are obliged to take the statements of railroad officials, or men who there is every reason to believe may have been "fixed." In case of a wreck like Rio or Koutz, who could be better qualified to hear the statements of the engine and train men than an efficient engineer? Would these men dare make a false statement to him? Could any official of the interested railroad make him believe the fault was one place when his years of experience told him it was another? Can as much be said of a civil engineer? In case of a bridge breaking down, a civil engineer might get up a more elaborate report, showing strains, etc., but a locomotive engineer who keeps his eyes open is not easily fooled on bridges either. Railroad commissioners have a great duty to perform in deciding on rates, pools and the financial dealings between the railroads and the public, but they have a greater duty in acting as the public's guardians in matters of life and death, that not only require the learning of the lawyer and the business man, but the practical experience of an eminent man from the ranks of operative railroaders. The last line of the *Gazette's* article makes a very valuable concession. We honestly believe that a first-class locomotive engineer is of vastly more service to the public on the board of any State than any civil engineer, and rest assured that the governors of the two great States will never have cause to regret the appointment of Mr. Stevens or Mr. Rickard. As to the remark about self-made men being bigoted, we would advise the above paper to avoid that expression in illustrating prominent railway officials.



Milling Cutter for Ball Joints.

BY WILLIAM FOSTER.

Having had several years' experience in railroad repair shops, and knowing the wretched condition of the average shop of this kind in its lack of proper tools to do the work with, and the trials that the locomotive repair machinist must undergo from a lack of special or good tools to do his work, I have come to look upon the suggestion of a labor-saving and inexpensive tool or device for such shops and such men as an act of charity.

Some time ago I had a job putting fifty Mack injectors on our engines. I did all the work, bending the pipes as well as all the other work connected with the job. I made a tool for turning up the ball joints, after they were brazed onto the pipe. The old and usual way in most shops is to use a cast-iron socket, turned out on end to the proper shape of the joint to be ground. This is used with oil and sand, or emery, to true up the joint by forcing it onto the work, or the work into it. This is hard work, and takes time.

One day, when plodding along at this kind of toil, and in the absence of the foreman, I cut several creases into the face of this grinder to make it hold the sand and oil. The result surprised me; it cut much faster and a great deal easier. This set me to thinking. I showed it to the foreman, and asked him to let me make a miller, and turn the joints off instead of grinding. He saw the value of it and told me to go ahead and we would try it. I got a piece of good steel, turned it to the right shape, and, not having a milling machine, I spaced off the teeth with a pair of dividers, and chipped out the stock, finishing by scraping, and made a good job of it. This simple little device proved a great success for the work in hand. The old way required thirty minutes of hard work to each joint, and the miller did it easily in two minutes. In repairing locomotives time is often a big consideration. Since then I have made a set of these millers for all sizes of ball joints used on our locomotives, for pumps, injectors, heaters, oil pipes, etc., and no man thinks of grinding in a ball joint in this shop.

During the past seven years that these tools have been used we have had no trouble from leaky joints made by them. I send you blue print of the one we use for injectors; they are simple, cheap, and fill the bill. Shops having milling machines can make them very cheaply—perhaps two dollars each would cover all expense—and I am sure their use for a single year, in any repair shop, would save many times their cost.

The Locomotive Engineers' Monthly Journal is to be turnished free to every member of that order for 1888. This is a move in the right direction. The Journal will contain all lodge information, the death and assessment notices, etc., and should, of right, be a part of the order and placed in the hands of every member, without extra expense, for his proper information. The net proceeds of the Journal for last year created a fund of between nine and ten thousand dollars, which was all devoted to charity at the twenty-fourth annual convention recently held in Chicago. Any man or body of men cannot help but feel better, more independent and more secure, if they know they can help their friends and themselves, of their own bounty, regardless of outside influences; therefore there is a proud feeling among the engineers in particular, and workingmen in general, over the report of the grand officers of the B. of L. E., that in the past year that institution paid out to widows and orphans the handsome sum of two hundred and fifty-nine thousand five hundred dollars ($259,500), making a total of two million two hundred and forty four thousand six hundred and sixty-nine dollars and sixty-one cents ($2,244,669 61) that has been paid since the association was established in December, 1867.

This shows what men can do for themselves if they but try. This magnificent sum was all collected by small monthly assessments on members who were thus protecting themselves and families against want in case of disability or death. By furnishing the Journal to every member, and discontinuing the practice of issuing lodge circulars and notices, and publishing same in the Journal, every member can keep posted on every detail, whether he lives in a town where a division is located or not. We believe the new rule will materially lessen the list of expulsions for non-payment of dues and assessments, half the time caused by absence or forgetfulness.

The Work Book.

BY H. R. JONES.

Don't be anxious to put your name on the work book at the end of every trip.

It is not necessary, in order to be considered a good engineer, to display your knowledge of the various parts of your engine by covering a page with a long list of stuff about what is or is not the matter with your "right go-ahead eccentric strap bolt nut," or the "cap to the left back journal-box of the forward truck under tank." Of course it is your duty to report all the work that is *necessary*, but be sure that you know just what *is* necessary before reporting any exact thing to be done to any part of your engine. Don't report a valve as "blowing" and needing to be faced, when *perhaps* the trouble is in the packing. Such a report entails several hours of unnecessary work, besides the shop wear of taking the valve out and replacing it again. This shop wear is frequently the source of more expense than all the wear and tear on the road. Perhaps a nut or two has to be split, a stud is broken or thread stripped and a score of little hindrances that are quite likely to occur, as any machinist can testify.

Observe carefully the working of your engine, and report the repairs when you are certain they are needed. Leave a good deal to the judgment of the foreman or the machinist who is to do the work. Tell him the symptoms of the disorder rather than the exact disease.

Don't be too sure about the location of a pound. Nothing is harder to locate exactly.

Don't give yourself away by reporting the side-rod brasses pounding, so as to break the glass in the cab windows, on the first trip after she is out of the shop and has had a full set of new brasses all around.

Don't call the foreman out to watch the lost motion in the driving boxes and wedges, when he can't so much as see the grease wink while you thump her.

In short, remember that while it is true that "a stitch in time saves nine," it is frequently best to "let well enough alone."

There are two kinds of wear. One is that due to the natural friction of the parts as they work together; for instance, the brasses on their pins, cross-heads in their guides, piston rods, valves, packing, etc. The other is that due to a bolt or nut working loose, a frame working in a splice or joint, or brasses loose in their straps.

The first of these kinds of wear is expected and provided for in the design, and may go on for some time and to a considerable extent, without material injury to the working qualities of the engine.

The second is not expected or provided for, and when discovered should receive prompt attention.

Do not allow bolts, nuts, keys or set screws to run loose. Here is where a "stitch in time" comes in good play. Do it yourself, and so save a charge against your engine.

A loose brass in a strap is many times worse than an eighth of an inch wear on the pin of a side rod.

Oiling Wedges.

How many engineers have had trouble with the poor oiling arrangements on the top of wedges and shoes. They remind one of a hog trough with both ends out. There is generally a little corner chipped out of the top of driving box next to wedge and shoe, and this is often carried around the wings or projections on box, so that the oil is carefully ditched off and carried down to the ground *via* the frame, just as a farmer would scheme to drain a muck swamp of stagnant water. Why would it not be better to tap a good-sized hole through from oil pocket on top of box to the wedge and shoe? It would be under the waste, and not be full of cinders half the time, as the present endless trough is Wedges without oil soon cut and cause the engine to ride hard and prevent keeping the wedges properly set up. Our experience with sheet metal covers for driving boxes is that they catch and carry dust, sand and cinders away from the oil pocket, but onto the top of wedges and shoes. Waste above and covering tops of these exposed and important parts of the locomotive is better. It should be changed as soon as it gets dirty, without disturbing the lower layer of wool that feeds the journal itself.

Inventing New Devices For Locomotives.

When any man attempts to improve any existing kind of machinery he should first make himself thoroughly acquainted with the machines in use as well as with every detail of their use. How few men do this who attempt to improve the locomotive. The devices that engineers are asked to try, that are entirely impracticable, are legion. Many an engineer has seen where he could improve on some part of an engine, but something, perhaps modesty, kept him back. Not so with the genius who has got a new notion in his head about some change or other. He deliberately sets up posts and rods close to track to catch some hook he is going to put on engine that will turn some distant signal or ring a bell, or set the brake, regardless of how many heads it will take off besides. He puts a smoke-consuming device in the stack to eat smoke that eats most of the draft, some smoke, and sends the rest out of the ash pan to deaden the glare of the varnish on the cab. He puts a patent damper on engine that stands proudly up in the center of the deck and reminds the fireman that it is there at every turn. He puts a device on top of dome to save the steam wasted at the pop, and proposes to return its heat to boiler, and generally succeeds in getting everything else too hot to work—including the engineer. He gets out a new valve motion that does the work about as well as the link and perhaps a little better, but at the cost of twice as many parts, cost and wear. He gets up a self-closing glass gauge-cock that don't close. He invents a boiler compound that prevents scale from forming, and also soaks the form of steam so you can't drag it through the cylinders. He invents a 1,000-mile dope that will help the journals to melt in half that distance. He invents a side-shoot pilot that will throw a yearling bull over into a ten-acre field and not hurt him, but it throws a man into a wire fence. He invents a fire-box and stack that keeps cinders out of the car windows and don't let the water in boiler get hot enough to shave with. He puts a snow flanger under the pilot that comes off and ditches the engine. He invents a steam bell ringer that will keep you from ringing the bell all summer and freezes up and wont let you ring it in winter—or won't ring it for you. And thus the improvers keep nagging away; once in a great while they hit it, but the rest of the time they hit something or somebody else. Many of the parts and appliances of locomotives are crude and unhandy, but the principles are all right and only want the details carefully considered and improved to make them all that can be hoped for.

The "Do Not" Order.

On a great many single-track roads the use of the form of train order known to road men as the "do not," is being tabooed, as it deserves. This order has caused some very bad wrecks, and lost many a good engineer and conductor his position. The order is generally given not to pass a certain station, perhaps fifty or seventy-five miles away, because the dispatcher has a work train beyond there, or expects a special to leave the other end of the road sometime. Often this order is received, and then three to ten others are added to it before the station named is reached, and in the interim the "do not" is forgotten by all concerned, even the dispatcher. Any dispatcher who gives this order and does not order the signal for orders displayed, and kept displayed, at the station named in the order, should be dismissed; it should be used only in emergency, and with all the caution possible. Engineers have enough to worry over without the "do not."

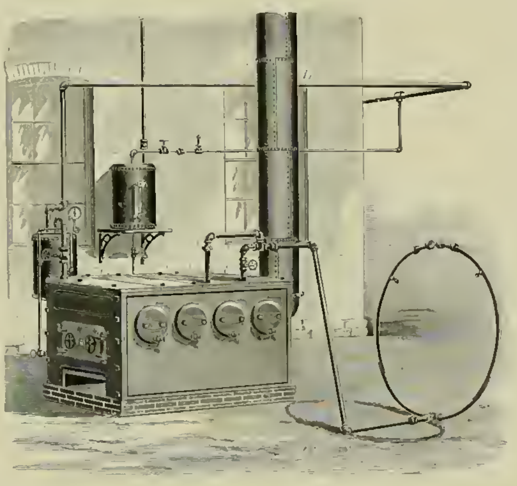
Headlight Wicks.

A young engineer was recently heard to remark: "I ran an engine over two years before I knew how to turn up the head light." Had this remark been ventured in any other than a railroad crowd, the speaker would doubtless have been considered a mighty poor excuse for an engineer, but the boys knew he was first-class and let him finish. "You see a wick is made of several wraps of Canton flannel, and it has to slide over one tube and inside another, and if one or both get a little rough, the wick sticks in being forced up and 'wrinkles;' when the engine gets to pounding over the road the wick works up and the headlight smokes without any seeming excuse. Now I just turn mine up too high, then down to where I want it, this straightens the cloth out and it works all right."

Apparatus for Heating, Setting and Removing Locomotive Tires.

A very complete arrangement for putting on new tires, or taking off old ones. It will do all the work connected with tire heating, setting, removing, shimming and replacing. In case of a loose tire, it is not necessary to take down the connections. In taking off or putting on new tires the connections are taken down. In all cases the engine is jacked up so that the wheels will clear the rails about two and one-half inches, to allow the burning hoop to be placed around the tire. This hoop is not a continuous ring of pipe; the ends are plugged up and are left a little space apart, so they can be placed on the wheels while the connections remain on them and small studs are placed in hoop to hold it off from the tire at a proper distance. The machine consists of a furnace or generator in which are four cast-iron retorts, three of them for making the gas, the other one for heating the air that is used with the gas; allowances are made in the construction of the furnace for contraction and expansion. In addition to this generator is an oil reservoir for holding common kerosene oil; an air reservoir, a gauge for registering the air pressure, a needle-pointed valve for regulating the flow of oil, and an injector arrangement for forming and mixing gas and air for burning in the hoop around the tire. The operation of it is very simple. After the oil reservoir is filled and the oil cocks shut off so that no oil will enter the retorts, build a fire in furnace with any fuel desired; in about half an hour the retorts will be hot enough to make gas; then place the burning hoop around the tire, connecting it to the connection containing the injector arrangement; start up the air pump until there is an air pressure of from 15 to 40 lbs.; open the needle pointed valve very little, until a very rich gas like smoke escapes through the holes of the burning hoop; then open the air cock to allow air to mingle with the gas and when a proper mixture is made, apply a torch, and an intensely hot and blue flame will strike the tire, penetrating it very quickly. As very little oil is required, a fine thread screw is made on needle valve, so that it is very sensitive. The device can all be mounted on a push car if desired, or arranged stationary. The gas is made only as fast as used, and as there is no accumulation there is no danger from explosion, and no waste. When the tire is hot enough, shut off the supply of oil with needle-point valve, the flame stops, also the generator. A 4½ ft. and a 5 ft. burning hoop are furnished with each machine. At the regular standard of shrinkage, tires can be taken off or put on in from four to ten minutes each. The cut shows the plant as erected at West Philadelphia shops of Pennsylvania Railroad Company. It is made by Pedrick & Ayer, 1025 Hamilton St., Philadelphia, Pa. We quote from their description.

Next month we shall give the result of some tests recently made at the Pennsylvania Railway shops with this device.



That Flat Driver Engine.

There is at present a locomotive at Boston, built for the Swinerton Locomotive Driving Company, who, to say the least, make some odd claims. The engine has but one pair of driving wheels, and the face of tire, instead of being round, has 105 flat surfaces or facets. The inventor, or the company that have the stock, claim that by having these flat places the tire has a "bite" of full two inches on the rail, and that by thus increasing the surface of the point of contact the engine will be able to do wonders, "will run up hill as fast as down," and, "having no *side bars* between wheels, can run around curves at full speed, where the present locomotives have to reduce speed to about fifteen miles per hour," and a thousand other extravagant claims, evidently written and conceived by men with no practical experience whatever. They say a round driver rests upon the rail only in a mathematical line; according to this reasoning their driver, in changing from one facet to another, will hardly rest on the rail at all. They say that many locomotives are now built with from four to ten drivers, in order to increase the surface of contact, and thus the tractive power; nothing could be farther from the truth. It is a well-known and proven law in mechanics that *weight* determines the amount of *adhesion*, and the adhesion the amount of *tractive* force the locomotive will be able to exert. Broadly speaking, if you put a weight of 1,000 pounds on a board four inches square, it will require as much force to move it as it would the same weight on a board forty inches square, and no more. All the weight of a locomotive would be placed on one pair of wheels if they could be made heavy enough to stand it and the track and bridges could be so used without great injury. Locomotives have more or less drivers to distribute their weight, over some length of track, not to increase the surface of contact. "One of the boys" who has ever rode an engine with one flat spot on her tire as big as a dollar, can easily think of many little inconveniences on an engine with 105 flat spots.

An Air Brake Suggestion.

While there are hundreds of engineers who are handling the Westinghouse automatic brake every day, and doing it successfully, there are few who can explain the action of the valves. They know how the brake works under all conditions, but not *why*. That it would be better for them to know no one can doubt. Men are but grown-up children, and object lessons the better way to teach them. It would pay every railroad using this brake, or the manufacturers, to keep on exhibition at all division headquarters a triple valve and an engineer's brake valve, with the cases so cut away that the action of every working part would be exposed. Engineers and firemen would study it, argue over it, and learn more of the brake than they could out of all the books that were ever written on the subject.

Some years ago the Westinghouse Company presented a lodge of locomotive firemen in Colorado a set of these sectional valves to use in their discussions in the lodge room. Those sections have done missionary work. An old-time engineer remarked to the writer, who was a member of the lodge, that he had handled that brake ever since it was invented, but really never did understand its action till he saw that model then he could not help himself.

The Grant Locomotive Works are just getting in shape again after their disastrous fire. They only built fifty-four new engines during 1887, and there are 1,752 of these splendid locomotives now running.

* * *

The Baldwin Locomotive Works built 650 engines during 1887, the largest number yet. This makes a total of 8,969 locomotives turned out by this concern. They are in every quarter of the globe where locomotives run, and carry the stars and stripes with honor in countries where our ships of war were never seen. This is the largest works of the kind in the world.

* * *

The Schenectady Locomotive Works built 247 engines during 1887, making a total of 2,474 produced by this company. The "McQueens" have one of the best passenger engine records on earth.

* * *

The Portland Locomotive Works built twenty-five engines during 1887. Their works build many engines for ocean-going steamers.

LOCOMOTIVE ENGINEER.
THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN LOCOMOTIVE MAINTENANCE AND REPAIRS

STANDING NOTICES.

☞ *We invite correspondence from Locomotive Engineers and Firemen, Roundhouse and Repair-Shop Employes, and Railway Master Mechanics, on practical subjects connected with Locomotive Operation, Maintenance and Repairs.*

☞ *Manufacturers of proprietary devices and appliances that are novel, and properly come within the scope of this paper, are also invited to correspond with us, with a view to showing their engravings of same in our reading columns. Such illustrations are published without charge and without reference to advertising considerations.*

☞ *Correspondents should give name and address in all cases, though not necessarily for publication.*

☞ *Mailing address of Subscribers can be changed at any time. Both old and new address should be stated. Prompt notice should be given whenever papers miscarry.*

NEW YORK, JANUARY, 1888.

CONTENTS

Salutatory.

THE LOCOMOTIVE ENGINEER will not be a social paper in any sense of the word. It is not the official organ of any association or organization, and does not expect or intend in any way to infringe on the rights or clash with the interests of the two excellent organs of the Brotherhoods—the finest examples of organized labor on earth.

We believe there is a field for, and a desire on the part of engineers, firemen and repair shop employes to see a journal devoted entirely to their interests in a mechanical way, and recognizing the fact that roundhouse men and firemen are silent partners in the great responsibility and honor of the successful handling of the millions of money and hundreds of thousands of lives that are daily entrusted to the ability, courage and honor of the locomotive engineers of the country.

It should show up and illustrate new shop kinks and new ideas and devices connected with and auxiliary to the locomotive, and keep track of the odds and ends of interest to operative railroad men. This place we shall try to fill.

Correspondence is solicited from engineers, firemen or shop employes, written in plain language that any one with a common-school education can understand—that is the way we intend to write ourselves.

This paper is not published in the interest of any particular manufacturer, machine or device. It will not publish any "catch" advertisements in its reading columns under any circumstances. It will advertise nothing but such articles as pertain to the various branches of locomotive service; no patent medicine or similar advertisements will be accepted. It will not accept passes from any railroad, or meal tickets from any eating-house; but is untrammeled, independent, and devoted to the interests of the enginemen of America.

When we say we shall try to represent the interests of the enginemen of America, we do not mean that we shall always champion the acts of these men, "right or wrong." We believe that in pointing out the fallacy, inconsistency or unsoundness of a belief or movement, we are serving the best interests of the men entertaining or inclining to such beliefs.

It is the purpose and intention to make this journal a practical paper for practical men in its special line. With this in view, the higher mathematics will be avoided the 'ologies and 'isms left to scientific journals, and practical locomotive maintenance and running discussed by practical men.

To "raise the grade" of this class of men will be the first great aim of this journal. Among its special aims it will advocate the following: Men of recognized intelligence for firemen first; opportunity and means of study and improvement next; then ample experience as firemen before promotion, as well as skilled men on locomotive repairs, and shop promotion on merit; locomotive running recognized as skilled labor of a high order, and paid as such; no examination for engineers on rules or time cards which superintendents cannot pass themselves, and no examinations as to the locomotive, for color blindness, etc., except practical ones actually made on the road.

We shall try to represent the interests of the class of readers we attempt to reach, and in demanding justice to them shall try to render justice to all others. We believe in organized labor—for *defense*, not *defiance*.

The editor selected for THE LOCOMOTIVE ENGINEER is not a graduate of any school of technology; he is not a mechanical engineer, a master mechanic or a machinist; he did not run the first locomotive in America and every kind made since—the first engine was probably worn out before he was born; he was a fireman for some years, and has been an engineer for several more; he did not run before the war or the day of lubricators and injectors, but left the throttle of a locomotive to accept his present position. He hopes and expects, as one of themselves, that the engineers, firemen and repair shop men of America will enter into the discussion of practical subjects in this paper with all the freedom they would enter into an argument in the roundhouse.

Reform Needed.

There is one railroad evil that, as far as has come to our notice, is as prevalent in one part of the country as another, and there seems to be a dislike on the part of railroad officials to remedy it, as well as of the men interested to ask a remedy. We refer to the terrible suspense and fear that the wives, mothers and daughters of engineers and firemen must stand after the report of a wreck on the road before they know positively whether their near and dear ones are injured or not. Reports of wrecks spread like fire in a railroad community, and they find delicate women in all ages and conditions of life. A report that the "morning passenger train was in the ditch" throws two, four or six families into a fever of suspense, as there are two or three passenger trains going out, and as many coming in before noon, and wreck reports do not, as a rule, get any smaller by being retold, and each wife or mother is half crazed by a terrible fear, always smouldering, that is thus suddenly fanned into flame by the near possibility or probability of fatal misfortune to some man always uppermost in their minds. There are several thousand women in this country that are called upon to undergo this trial from one to a dozen times a year. It is as cruel and unjust as it is unnecessary. There are plenty of easy remedies. One would be to send word at once to every family whose folks were out on the road that there had been a wreck, but the father, husband or brother was not in it; or make a rule that the family of the killed or injured alone should be informed, *at once, and all the truth told.* But this does not happen often enough to make it any burden for a company to send word to all the families, and say just who was hurt or killed, if any, so that kind friends could gather at the afflicted home and take some of the care off the less fortunate ones. Railroad men, as a rule, do not take as much notice of these facts as their families do, and we venture the assertion that the latter would welcome any set rule that would not keep them in suspense a moment longer than necessary.

The Coming Man.

There are a great many men in the world, ordinarily sharp business men too, who underestimate the influence of workmen in the shops and on the road. There are generals who underestimate the bravery, intelligence and soldierly qualities of many a man beneath his rank, who will, by the rule of the survival of the fittest, or better, the promotion of the worthy and deserving, wear the shoulder-straps of commands in future strifes, and all of us, we fear, forget in our pride that there are but a few years before the boys of to-day will be the young men who will excel us in all things to-morrow, and when they are our age, look back at our records and call us "old fogies."

Some of the greatest successes held up as models to the world were not built with the hope of pleasing the men of the day, but the youth. A few years and they are men and women; they remember these pleasures of their childhood, they are treasured in their homes and furnished to their children. How many men of their time bought and read Defoe's Robinson Crusoe, or Swift's Gulliver's Travels? How many wives and mothers bought and read Alice in Wonderland? Very few indeed. They were not written for men and women, but they are now known and loved, and bought by men and women for their children, because in youth they learned to like them and be interested in them.

The writers ignored the men and women of the day, and sought only the coming men and women. This generation of men and women came, and their children have come, and the children's books mentioned are as familiar to thousands of men with silvery hair as the ablest efforts of advanced thinkers addressed to men of mature age.

It is no new thing to say and prove that many men now in the ranks of the great railroad army will in time become its officers and directors. Engineers will be master mechanics and superintendents of machinery, foremen of shops and roundhouses and traveling engineers just as surely as your son must inherit your name.

This is not all; the engineers are the responsible parties of any railroad; it is the man at the throttle who takes your life in charge when you go away from home, not the man who takes up your ticket. Knowing this, officers, especially those who have come up from the ranks, take a great deal of advice from the engineers; oil that they condemn as no good is not purchased; coal that they say will not make steam is seldom paid for. The writer remembers, but a few years ago, when a large road changed the make of injectors, because the engineers wanted a certain kind that they understood and liked, yet both manufacturers claim that their instruments are "the best boiler feeders on earth." There is not a master mechanic, foreman or engineer who cannot recall a similar instance, or dozens of them.

The engineers will become officers as boys become men, only it is a matter of a few years instead of half a lifetime.

Manufacturers who are anxious to introduce new injectors, lubricators, headlights, oils, or even locomotives themselves, cannot do better than to bring their devices prominently before the working engineer. He is now approachable; when he is promoted he may not be. He will have a thousand cares, and will be more than likely to buy machinery and supplies of parties that he knows by reputation or personal contact. Make your tests with him, and bring your proofs to his notice. He will impress their good qualities on his officers, and don't forget that he is the "coming man!"

Our First Contributors.

On another page will be found a communication from the pen of H. R. Jones, a mechanic of recognized ability, who has come up by his own efforts. He was for seventeen years connected with the Northwestern Railway shops at Clinton, Iowa, serving in every capacity from apprentice boy up. On the establishment of the repair shops of the D. & R. G. Railway at Pueblo, Mr Jones became foreman, a position he held until a few months ago, when he was selected to take charge of the mechanical department of the great smelting works at Pueblo, Col. Few men have had more experience in locomotive repairs than he.

* * *

John J. Bingley, whose name will be found under a good article, was for many years master mechanic of the Hanover & Gettysburg Railroad, afterwards holding an important mechanical position on the Chesapeake & Ohio Railway, and is now head of a department for the Eames Vacuum Brake Co. Mr. Bingley has come up from the ranks, and was in active service before the birth of many prominent railroad men of the day.

* * *

John Alexander is a prominent engineer, pulling a fast mail train in and out of one of our Eastern cities. He has held several positions of trust, but always gave them up to go back to his locomotive. He is a modest man, and in reply to our note for a brief biography of himself, replied: "I am an engineer, and am glad of it; was forty-seven years old last Saturday; have a good constitution, a better wife and four fair to middling children. Let me be known only as a correspondent to your readers, and as plain old John Alexander to my personal friends. You shall hear from me again," which promise we feel sure he will keep.

William Foster is one of that small army of mechanics who have devoted themselves to the special business of locomotive repairs, and carefully studied every detail of it. He is now, as for many years past, in charge of the tool room and the making of tools at the shops of the Providence and Worcester Railway, at Valley Falls, R. I. This is acknowledged by mechanics who have seen it to be one of the most complete and efficient tool departments kept by any railroad in this country.

Why Machinery Advertisements are Read.

A man seeking for new points about machinery, can hardly do better than to read the advertisements of mechanical papers. This class of advertising is always up to date, fresh and complete, shows every improvement and presents every argument showing the superiority of this or that class of machines or tools. There is a fund of information that can be gleaned from advertising that can be obtained in no other way.

A Locomotive Engineer Becomes Railroad Commissioner.

Plenty of locomotive engineers have left the throttle to run the mechanical and executive departments of railroads. The Governor of New York, therefore, in making Michael Rickard, of the New York Central, a Railroad Commissioner, is only following a good line of precedents. Our gubernatorial namesake knows that the man who can handle a frisky locomotive successfully ought to be able to run a stateful of railroads, as a matter of course.

The *Firemen's Magazine* comes to us twelve years old and handsomely enlarged; it is the official organ of the Brotherhood of Locomotive Firemen, an organization of upwards of 18,000 men; is under the editorial management of Eugene V. Debs, one of the ablest young men of America; and withal a journal of such purity and manliness that any body of men might well feel proud of it. Long may it live to carry the grand motto of the grand organization it represents: "Benevolence, Sobriety and Industry."

ASKED & ANSWERED.

Under this heading we hope to make an interesting column, and invite railroad men to ask questions and send answers. We desire, however, that this column be used to get practical information or give it, and not to propound questions that have no practical use, but only remotely bear on the locomotive. It will be of far more benefit to the fireman, for example, to ask questions about combustion, stack drafts, arrangements of the front end and draught pipes, compounds for cleaning, etc., than to dive into the mysteries of designing valve motion. Let the firemen and engineers, shop and roundhouse men ask us practical questions concerning the running, firing, repairing or rebuilding of locomotives, and we shall be glad to answer them. The editor of THE LOCOMOTIVE ENGINEER is not an encyclopedia of all this information, but New York is a very large village, and such questions as we cannot answer ourselves, we shall make it our duty to get answered by the best talent in that particular line. Asking questions is one of the best, if not the best way of getting information.

IN THE ROUNDHOUSE AND REPAIR SHOP.

Consolidation locomotives and others having the boiler extended through the cab, are now being built with the throttle gland in end of boiler same as an eight-wheeler, and connected by suitable levers over the end and on top to throttle lever, instead of piping the throttle stem to the dome.

***

The application of steam heating to cars goes on very rapidly. Many different kinds are being tried and adopted, many of which will have to go to the wall after a few years of trial, to give place to some standard that will come up out of the experience of all—much as the M. C. B. car axle and the promised coupler have come.

***

One of the handiest things we have seen lately is a block on wheels to put under engines being rebuilt or repaired; some of them have four wheels, others only two. It is very often desirable to move an engine ahead or back, after her wheels have been removed; this can be easily done when the blocking rests on a pair of small heavy wheels. For instance, to take out all the wheels and front truck with the excellent jack shown in this paper, these blocks are an excellent auxiliary, and are far ahead of the old timber blocks. With these blocks a locomotive can be run into the back shop, entirely stripped, and the boiler run out and into the boiler shop without lifting, loading or unloading.

***

It is a matter of some surprise that so many very old men, Chinamen, illiterate men and cripples are employed as wipers and machinists' helpers about railroad shops, especially roundhouses. That these jobs should be mainly held by young men who are being examined as to their proficiency to become firemen, and eventually engineers, there is no doubt. But roundhouse foremen get tired of being asked every few days for a chance to go out firing and the result is that they are glad to pick up these men who know there is no future in their jobs. Then when a fireman must be *made*, they get hold of some strong and ignorant young laborer about the yard. Often the one who generally has a cigar sticking out of his pocket when the foreman is near draws the prize. This thing is worse than it should be, and more of it is going on than many people think.

***

A look at many, we may say most, of the steps on locomotives and tenders throughout the country shows a poor lot of contrivances. These are handy enough in the shop, where they were made, but no good on the road, where they are used; in all shapes, of all materials, in all kinds of places, they are small, slippery and dangerous. The best plan for a tender step is a broad, long step of wood, closed up at the back and ends to prevent the foot from going through or off, and opening enough to let the water and dirt run through. Engine steps are not always necessary, but the hand-holds of the tank and cab should be large, smooth and strong, and not given to any gewgaw or dragon designs. Life and limb depend on their being handy and practical—more than can be said of many now in use.

On a cold, windy day, when a car door is opened there is a rush of cold air under the seats that sends a cold chill over everyone. This is especially aggravating since the trains are heated (?) by steam. Why would it not be a good idea to have a tight partition under each seat to prevent this?

***

The Rhode Island Locomotive Works, Providence, R. I., are very busy on a lot of heavy locomotives for Georgia and some for Minnesota, and are also building fifty-six engines of the Forney type for the Brooklyn elevated lines. These engines have every known improvement and comfort for the men handling them, and are provided with the American steam and Eames vacuum brakes. The works are putting in three large steam hammers, one each of 1500, 2500 and 4500 pounds; also, a cylinder shaping machine. At present, 1100 men are employed, and prospects are good for a busy year.

***

On many roads using the pony truck, on consolidation or mogul engines, the breaking of the large bolt or hanger that goes through the center pin and is attached to the front end of the long equalizer, is a great annoyance on the road. The engine has to be jacked up and blocked to keep this end from cutting into the truck axle. The Grant engines have the fulcrum casting under cylinders made with a hole about the size of a coupling pin, just ahead of the fulcrum pin; by jacking up until a car-pin can be inserted no other blocking is necessary. H. R. Jones, of Pueblo, Col., while foreman of the Rio Grande shops there, bored a large hole in the cast center pin and fixed the eye of the bolt so that an "extra" bolt could be put in on the road in a very few minutes, the engine needing no further repairs at the roundhouse.

***

The Taunton Locomotive Manufacturing Company are busy building a number of engines for the Lake Shore & Michigan Southern Railway. The plans being furnished by the road, the engines are peculiar as having the cylinders cast separate from the saddles, being bolted together, and having the steam pipe connected directly to the chest on the side toward arch. They are provided with Hudson's bell-ringer, a very simple device connected directly to the bell bracket. The engines have the flat front ends with the small door, not very handsome. The boilers are covered with asbestos cloth under ordinary wood lagging. These engines have a great many parts made to standard patterns of this road, and are all right at home, but the writer could not help thinking it would be best for the works to brand them "Made to Order," or something like it, to keep railroad men from saying: "Why, a Taunton engine has this or that; that is old-fashioned," when in reality, the company's own engines are models of beauty and convenience. This shop is being enlarged by a substantial two story brick building, to accommodate the rapidly increasing business of building the Huber printing press. There was in the shop for some changes a Forney engine of large size running on some short line about the city. This engine has two Sellers injectors on the right side of cab, both checks being also on the right side, and the air pump on the left. This shop has got ready for a rush in the past dull times, and new tools are to be seen on every hand. The entire works are provided with overhead tracks, lifts, etc, making the handling of heavy parts an easy matter.

One of the old style shops of the past generation can be seen at the repair shops, or shed, of the Fitchburg road at Troy, N. Y. The engines run through the main shed to get to turntable; on one side, in a sort of lean-to with open arches, are the lathes, planers, drills, etc., and on the other side the blacksmith shop and office. There is a side-track in main shed where cripples are repaired. The whole thing reminds one of the sheds of some of the poorer roads of England.

***

T. B Purvis, master mechanic of the Boston & Albany shops at East Albany, N. Y., has devised an extension cab for consolidation engines. This device is an extra section of cab roof, about six feet long, lying on top of the cab proper, and connected to it by three coil springs so arranged as to keep it in a certain position on straight track and allow it considerable freedom on curves. To the back of each side of this roof there is a heavy canvas curtain, fastened between the roof and the sides of tank, back of the oil and clothes boxes. There are also sliding side curtains for each gangway, making the fireman's house about as large as the engineer's. The scheme is very popular with the boys who ride the new consolidators, with nine foot fire boxes and cylinders 20x26.

***

The repair shops of the Delaware & Hudson Canal Co., at Salem, N. Y., have little to do now as compared to former years. The place is exceptionally clean and well kept, all machine tools are painted and striped, and everything seems to have a place and be there. The roundhouse is of the old-fashioned type, entirely enclosed, and as the pilots stick over the turntable pit, and the back draw heads are against outside of house, the only way to get around is to climb through the gangways. The table should be covered to a complete circle. We noticed a machinist turning the tire of a five-foot wheel on a common lathe of huge swing. There are very fine wood shops here, but they have been idle for some years. There was one engine in the shop, and those out look well and are nicely painted. Fred. Kegler has been master mechanic here for many years, and takes pride in the thorough and neat work turned out. This branch of the road still uses the old chair iron.

***

At the Mason Locomotive Works, at Taunton, Mass, they are building a series of engines for the South Atlantic & Ohio that are an improvement on the original Mason-Farlie that attracted so much attention some years ago. The original engine was a tank locomotive, using the Walschaert valve gear and the tumbling shaft on top of boiler, the engine being a truck in itself, independent of the boiler, and connected to it by a flexible steam pipe. The improved engine uses the Stephenson link and eccentrics; the reversing gear is obliged to be somewhat on the ball joint order to allow for the movement of engine under boiler, and is extra strong. There is a single truck in front of engine that is rigidly attached to engine frame; there is an arch turned over this truck axle its entire length, and carrying the brasses in each end, over its center an immense hook, solid with frame of engine, holds it down, and yet allows one wheel to raise above the other on uneven track, the object being to take the wear off the flanges of the forward driving wheels. The engines are also provided with a sight feed lubricator with a single glass, and feeding into the flexible steam pipe under the boiler. The engines show extra nice work.

A POPULAR PAPER FOR PRACTICAL RAILROAD MEN.

THE PRESENT ISSUE BEGINS THE PUBLICATION OF

THE LOCOMOTIVE ENGINEER.

A new monthly journal devoted to the interests of Locomotive Engineers and Firemen, and to Locomotive Maintenance and Repairs. Examination of its reading columns will show that its aim is to be practical, popular and original. It addresses itself directly and primarily to the great body of working enginemen and roundhouse and repair shop employes, who, from their intimate connection with the locomotive and the appliances and materials involved in its successful operation and maintenance, wield collectively and individually an enormous influence in their field of labor, standing, as they do, in the direct line of promotion to the places of mechanical and executive control.

HOW MANUFACTURERS REGARD THE NEW JOURNAL:

Like its reading columns, its advertising pages are genuine. The too-prevalent plan of filling up the advertising pages of a first issue, and sometimes of succeeding issues, with borrowed, unauthorized or bogus advertisements, intended only for purposes of deception, has not been resorted to, nor will it be in the future. A large part of the advertising orders already received are upon yearly contract, affording ample evidence that the manufacturers of railroad specialties value the good will and co-operation of American enginemen.

An order received by mail from a Philadelphia firm was accompanied by the following expression of opinion, being similar in terms to many others.

"A practical paper covering the field that THE LOCOMOTIVE ENGINEER proposes to, is certainly needed. We are glad that you make this move, and predict for you great success."

LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. II. NEW YORK, FEBRUARY, 1888. $1.00 per Year. or 10c. a copy.

A New Safety Improvement for Automatic Brakes.

The device here illustrated and described is intended as an improvement on the automatic air brake, and has been in use for some time on the extensive system of the Chicago, Milwaukee & St. Paul road.

It is so simple as to hardly need other description than the engravings. Lower cut on page 3 represents it as applied to the trucks of tenders, being practically the same as applied to four-wheeled trucks under all coaches. *G* represents a tumbling shaft running across the truck frame each side of the center piece; to this are fixed the short or trip arms *j*; these arms straddle the posts *E E*, and are tripped by the nuts *b*. The posts, *E E*, go through the lower part of truck frame or guides fastened to it, and are bolted to the buffer *H*. Through the levers *d* and connections a rod is attached to an air valve in the main brake pipe. The upper cut (page 3) shows the attachment as designed for six-wheeled trucks where the wheels *H* take the place of the buffer beam. The cut on first page represents the device as applied to the forward trucks of a locomotive.

The buffer beams *H*, or wheels *H*, are suspended directly over the track and near enough to it to be brought into contact therewith by the breaking of a wheel, journal or axle, or the derailment of a wheel, caused by a broken rail, the spreading of the track, a misplaced switch, or the encountering of any obstruction; and when this occurs, the beam or wheel and their posts are lifted, which action, through their described connections, instantly turns the valve lever of the air-brake pipe, letting out the air, and causing the setting of the brakes through every part of the train.

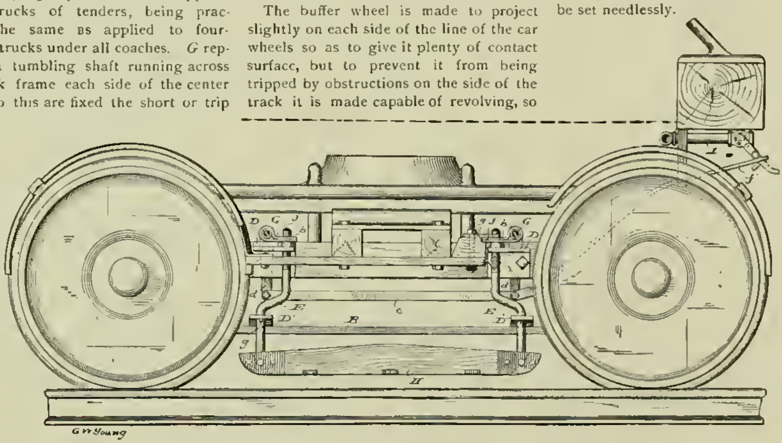
The buffer wheel is made to project slightly on each side of the line of the car wheels so as to give it plenty of contact surface, but to prevent it from being tripped by obstructions on the side of the track it is made capable of revolving, so that when it strikes such an obstruction it will turn, and its arms will wedge the obstruction aside and out of the way.

The valve can be opened only by direct upward pressure on the bottom of the foot or buffer wheel of between six and eight hundred pounds.

The only wear that the apparatus is subject to is that on the bolts which secure the beams *H* to the suspending posts, and these need be changed no oftener than once a year. No other attention is required.

The beams or wheels *H* hang from an inch and three-eighths to an inch and three-quarters above the top of the rails, and therefore a drop of two inches and a half from any of the causes named will apply the brakes before the wheels have time to strike the ground or before a broken axle can do any material damage.

As the beam with its straps across it follows immediately after the tread and flange of the wheel, and does not project beyond on either side, it cannot be struck by any object except one in the line of the track, and as the posts are made to yield to slight obstructions, the brakes cannot be set needlessly.



AUTOMATIC BRAKE ATTACHMENT TO ENGINE TRUCK.

The brake is known as the Wescott, Bristol & Hinsey Automatic Safety Brake, and Mr. J. A. Hinsey, the president, Milwaukee, Wis., will give any other desired information.

The Jack-of-all-Trades.

He used to be the mechanical oracle of every community, great and small. He could patch up a machine that the machinist swore wasn't worth the rivets required in the patch. He could make a condemned boiler carry more steam than ever without a simmer. He could repair a watch, grind skates, put rivets into bladeless knives, make humming tops and botch up good work with a caution. He was attached to the machine shop and roundhouse about the same as a liveried fool was to the court of foolish kings. His work is over and his days numbered. This is not the stone age, or the iron age, or the age of steel, nor yet the age of progress—it is the age of specialties. A few years ago and a printer must be a writer, proof-reader, pressman and compositor, and know all the details of the business from blank paper to gilt-edged book—even to living on store orders. A machinist must be everything, from a watchmaker to a foundryman. A locomotive engineer must know how to build his engine, repair it, clean it, wash boiler, teach firemen, know the rules of the road and laws of the State concerning the same and we had mighty poor engineers until locomotive engine running was recognized as an exclusive mechanical specialty, and men trained for that specialty. A few years ago, if a breakdown occurred in the shop, all hands sat down and waited for the Jack-of all trades to come to the rescue Now they have men specially trained to look out for the breakdowns. At the Providence Locomotive Works they have a man who has charge of the belting, and if a belt needs lacing he does it in his own room—for he keeps a duplicate of every belt in the place in reserve. If the main belt breaks there is not a hundred men idle while half a dozen repair the belt, the "extra" takes its place and the other is repaired and itself goes on relief duty.

The writer was in a railroad repair shop recently when the division superintendent brought in a typewriter to be fixed—said it was out of kilter. The foreman looked at it, struck a key or two, and remarked: "I don't know much about these things." "Why," exclaimed the superintendent, "you have the reputation of being the best mechanic on the road; I thought you were just the man." The foreman turned to the speaker and said: "I am a locomotive repair machinist, and have carefully studied it for fifteen years; if you will bring me any job on a locomotive that I cannot do that any other mechanic can, I will resign; life is too short for a man to spread himself out so thin as to attempt to be familiar with all classes of machinery. There are men who make a specialty of typewriters, as I do of locomotives. They can repair that machine in half the time, for half the money, and twice as well as I can. I would be as foolish to attempt to put new letters on that machine as they would be to put a new tire on a locomotive."

Let every mechanic have a specialty and stick to it.

Improving the Details.

It is remarkable that men who are employed in a thinking business, like running engines, will not think. We do not refer to the work in general, but to the many little details that make up the whole. Men get used to doing things a certain way, and, being satisfied that is about the only way, never think of such a thing as doing it different or better; all men are not this way, but there is a large majority who are. We remember a few years ago there was a road built over a mountain pass; the grade was extra heavy and the speed of trains, of necessity, was very slow. There was a water tank half way up on each side, and the first man up tried to oil the valves there, after shutting off, but the train was standing still before he got half ready. It was tried a few times, and decided that in order to get any oil on valves in that fifteen miles they must have some in the oil pipe to blow down, or else have self feeding cups in chests. The regular mountain engines were soon provided with the latter.

A short time after, a young runner from one of the valley divisions was obliged to go over the mountain to help the regular "climber." Before starting, the old mountain engineer came over and told the valley man that he could not oil valves at the tank stop; it was so steep the train would stop in a couple of car lengths. The young man tried to get oil down at the tank and got it on roof of cab. Then he commenced to think it over. Before starting back on the other side of the mountain, the young man went over to the mountaineer and told him he wanted to run by the tank ten or fifteen cars, and then let the train drop back to tank, holding it with the air brakes. The old 'un wanted to know what for, and was told to "watch me." At the tank they ran by ten or fifteen cars' lengths, shut off, and the train soon stood still; then it started to drift back; the new engineer pulled his reverse lever back, held the train with the air brake, and the fireman oiled the valves. When they stopped the old man came back and said: "That is a pretty smooth trick; wonder I never thought of that, but don't you know us old cusses don't think of new kinks enough; simple—simple as fallin' off a log. My old father used to say: 'Of all fools, darn a foolish fool.' He must have known me pretty well." Simple as this little story may seem, it is an actual fact, and we doubt if there is an engineman in the country who cannot recall a similar incident. But this is not a wonder; it is the way all railroad improvements, great or small, have been discovered and developed.

Better Signals Wanted.

There is a growing demand in the United States for a uniform system in all departments of railroading. The Master Car Builders' efforts to establish a standard car coupler is a move in the right direction and should be followed at once by the adoption of a uniform system of signals; not particularly station, switch and crossing lamps and signals, any more than the signals or signs given by trainmen. There is such a great difference in this respect that a brakesman from one road may get a job on another road and do considerable damage by giving a "sign" to go ahead when he meant to back up. We believe the Association of Train Dispatchers are attempting to have adopted a uniform system of train orders that, if in use, would be of service and an element of safety to the public. If there was a national rule about engine whistles, the public would soon learn what is meant. Now, every road has its own rule, and these are modified to suit the tastes of different engineers—some of whom never whistle and others are all whistle.

The High Water Mark.

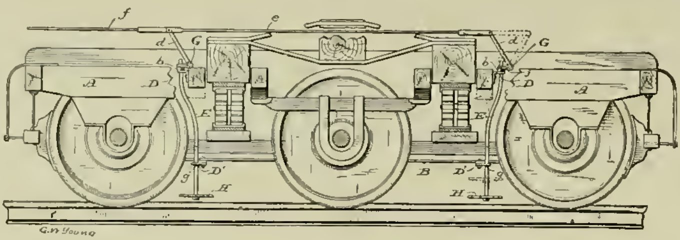
That there are many men who carry water altogether too high for cleanliness, dispatch or safety, all enginemen well know. Often this is because they have been badly scared sometime by some boiler suddenly dropping her water out of sight, and resolved then and there to have enough, anyhow. Others go on the principle that "you can burn 'em, but can't drown 'em," but the great majority of runners seem to think that if there are three gauge cocks they are to keep water in, and they set their pump or injector to "just supply," but there are a hundred things that change the conditions, and, all unknown to the engineer, the boiler gets full. Now why would it not be a good idea to put in one more gauge cock about two inches above the top one, and brand it "steam only." Some will say, "What is the matter with the glass gauge?" Nothing, only that a very small percentage of roads use them, and some master mechanics do not believe in them at all, and hence do not furnish them. We believe the extra gauge cock could be used to great advantage as a safety element.

Relief Valves.

How many men are there now running engines who have not, in their time, blown off a steam chest cover, broken a chest, cylinder head, or broken the bolts in steam pipe joints, or remember some other runner who has? This was generally done by reversing the engine when running at a pretty fair rate of speed; the cylinders becoming air pumps thereby and forcing a pressure into the chests and steam pipes more than their strength would stand. In case of accident, or a desire to avoid it, men will often reverse an engine without opening the cylinder cocks or throttle, the only means of relief. However, there are now many locomotives in service, as well as most of the new ones being built, that have a relief valve, a plain safety valve, placed in the steam chest. This valve is set to carry from ten to twenty pounds more than the boiler pressure, so that a dangerous overpressure cannot be obtained. The device is doubtless a good thing.

Dangerous Train Signals.

We often see outsiders about stations giving signals to trainmen ; and at a wreck each employe of the company has a burning desire to give the engineer signals. The section boss will want you to slack ahead about an inch, and give a signal to go, that, if obeyed, would let you go to the next station. The roadmaster and division superintendent are worse yet. We remember once of being at a wreck where the division superintendent was flying around like a chicken with its head off, and keeping the engine jerking and pulling at derailed cars that could not be put on the track until properly blocked. The engineer was a cool, sensible, experienced man, and he got tired of it, and finally refused to move the engine. The high and lofty official came over to know why his orders were disregarded, and was quietly told that the wreck would have been cleared before had he not arrived on the scene. The engineer calmly said that they had already pulled the trucks out from under a couple of cars and turned one over, by not properly blocking up under them before pulling at them ; said he would take signals from his own train crew only, and Mr. S could do with them as he liked. The youthful official was pretty mad, but he did have sense enough to see that the man was more than half right, and he went down to the depot to get warm. The engineer went back and helped to get the cars yet standing up properly blocked and set, before pulling at them, and on the arrival of the superintendent most of the cars were on the track. There is not only danger to property, but to life and limb by other than train crews giving signals, and all railroad men should discountenance it ; engineers cannot always see who gives the signals from a distance There is more than one brakeman who has lost a few fingers because some boy around the train gave a signal he had no business to. If you have not the right to give signals and see a chance to give one where you think it will help some one out, all we can say is, "Don't."

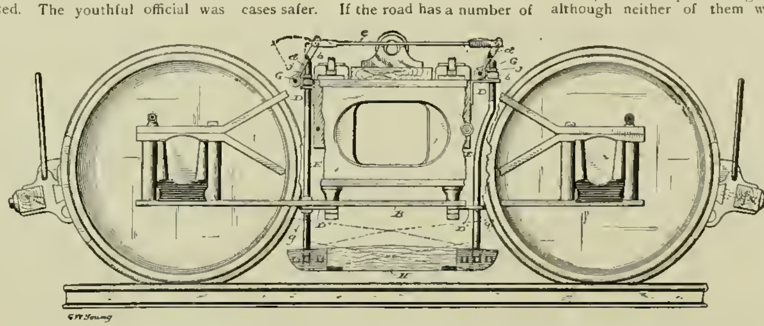


AUTOMATIC BRAKE ATTACHMENT ON SIX-WHEEL TRUCK. SEE PAGE I.

A Point About Automatic Brakes.

Every little while there happens a railroad wreck that could have been avoided if freight trains were provided with automatic brakes, and where the costs of the wreck would go a very long way toward equipping the road with brakes of this description. An affair like the great wreck at Koutz, Ind., last fall, would have been averted had the freight cars been provided with an automatic brake and the passenger train properly flagged. It has been proven that very quick stops can be made with automatic brakes on very long and heavy trains. To hold a train down a heavy mountain grade for many miles, there is no doubt that straight air, or non-automatic, brakes are easier and in many cases safer. If the road has a number of sags or "let ups," so that the auxiliary cylinders can be recharged, the automatic is all right ; but on a grade that to release the brakes for a moment means a runaway, the men are afraid to risk the automatic.

On all ordinary grades, up hill, etc., the automatic is the best ; in case of breaking in two, if the conductor wants to stop for some trouble at the rear of a long train, or any like cause, it is superior to any non-automatic brake, but its great advantage is that it cannot be neglected. In hard times, hose that leaks, pipes that leak, etc., must be kept in repair, or the brakes will set ; to be used at all, to allow the trains to move, the brake must be in repair ; on a non-automatic brake, it can run down until it becomes entirely useless.



AUTOMATIC BRAKE ATTACHMENT ON TANK TRUCK. SEE PAGE I.

The Fool-Killer Wanted.

"An old engineer told me the other day that locomotives were habitual cranks. 'Why,' he said, 'only a year ago two engines came from the same shop, were made from the same castings, were put together by the same workmen, but one of the two engines wouldn't budge an inch faster than fifteen miles an hour, while her companion could easily roll off sixty miles an hour under half the steam it took to send the other engine fifteen miles an hour. We crowded every pound of steam upon the fifteen miler, but no! she wouldn't move an inch faster, although she would draw four more heavily loaded freight cars than the engine that rolled up sixty miles an hour to her credit. Suddenly the fifteen miler came to a dead stop between stations, and there she stuck and couldn't be made to move again. Almost at the same time the sixty miler, on another portion of the road, came to a dead stop also, and she couldn't be made to move. Both engines were drawn back to the shop, were taken apart, examined, put together again, but no! they could not be made to move even under 150 pounds of steam. Stop running they would, and stop running they did, although neither of them were a year old. Finally they were broken up and sold for old junk.'"—*Albany Argus.*

What blatherdash. If any engineer ever told this little lie to the alleged reporter he was engineer on some horse-boat—not a locomotive. That engines have peculiarities no engineman will dispute, but the day of mysteries about machinery is dead and rotten. The management that would sell for old junk $16,000 to $20,000 worth of year-old locomotives because they were "cranky" does not exist up around Albany. If this reporter, or any of his acquaintances, will show us a locomotive that won't go "and can't be made to go," we will eat it, tank and all.

What Is Nerve?

From a railroad standpoint, it is often questioned whether a man has nerve or the lack of it that makes him face any emergency as cool as if he were only sitting down to his dinner.

Is it the absence of nerves or the control of them? We are inclined to think it is the latter. Many a man who has acted the cool hero in a fatal catastrophe has found himself prostrated by nervous exhaustion the next day. This kind of men have the first physical requisite for successful engineers, and to this nervy control of themselves many a train load of passengers owe their lives or limbs.

Not long since a brother engineer pointed out a man on the street, and said: "There is the nerviest man in this State. Why, he could cut your heart out and hold it in his teeth and sew up the hole, if he thought it was best for you or the community, but he would be sick next day. Two years ago he was running the snow-plow engine and struck a lot of ice at a tank siding on the A—— branch, turned over and had a narrow escape. After steam blew off, he found the fireman was under the tank and had his leg badly crushed, and was pinned down by the tank flange. Most men would have been crazy and gone for help; not he. It seems he took in the whole situation at a glance. He crawled under, and found the fireman was stunned by the shock and had a very bad leg. Instead of trying to bring him to to thrash around in his frenzy to get out, he just made sure he was alive and crawled out. Then he made sure nothing could take fire, and then went and threw the switch at each end of the siding, so that no train could run into the wreck. On returning, he built a fire; there was no house for over three miles, and no train due for nearly four hours. Then he went under that tank and got his fireman roused up, and then did something I never would have thought of, and could not have done if I had. He took his knife and stripped the pants off the fireman's crippled leg, took a piece of the bell cord and tied around the limb above the knee and twisted a stick into it. Then he cut off his leg where the tank had it crushed onto the frozen ground. Well, he worked a long time, and finally got him loose, wrapped up the bloody stump in his own shirt and carried him out to the fire. He dare not leave the man, as it was bitter cold, so he made him as comfortable as he could on the cushions and clothes, and built a wind-break around and over him with a lot of new ties and kept the fire up. Never got scared a bit, and even talked that fireman into believing he wasn't so terribly hurt anyhow, and kept his spirits up till a train came. It was my train that got there first, and what did I find? The fireman's arms around Jim's neck, and Jim in a dead faint; yet he was standing by the fire when I struck the lower switch, and he was the sickest man of the two for the next month. Why, he tells me it makes him kind of sick just to see blood. Now that is what I call nerve. Oh, the fireman, he got along all right and is running the stationary over at the shop. And what did the company do for Jim? Oh, handsome, handsome; after puffing the road till spring over Jim's bravery, they allowed him full pay for the time he was off—after a committee of us fellows went to the office the second time and insisted on it.

"Well, stranger, I must get my old girl out, as I leave at .38. Come up to the division to-morrow night and I will introduce you to Jim. Cigar? Well, yes; don't care if I do. Well, be good to yourself," and he was gone. Since then we have become very well acquainted with "Jim," and find him a kind and gentle husband and father, a man who loves his calling and studies it; cool, level-headed, temperate, plain Jim, with a woman's heart and an engineer's nerve. May his sons and his grandsons be like him!

Little Things.

Did you ever think how the world is made up of little things? Did you ever think that the great Polar whales subsist entirely on minute little insects, and wonder how many million a day it took to keep a monster of over a hundred feet in length? The writer has been impressed with the importance of small things by the breakage of some small part of a locomotive, that caused great damage; but the value of little things, when there were lots of them, was forced onto our notice a short time since by seeing a large machine in the shops of the Elevated road, for destroying tickets. An L ticket is a very small affair, but they must be counted and destroyed. When General Foreman Campbell showed us this machine with its hopper and two cylinders of revolving knives, and told us its use, we asked at once why not burn them, and was told that their sale as waste paper amounted to a considerable item. The elevated roads carry half a million people every day, and 500,000 pieces of pasteboard make quite a pile.

Unhandy Tanks.

The common locomotive tender has some very mean and unhandy parts. In the first place, there is a flange all around tank to keep in coal, cinders and water. The water hole is placed on top of a sort of deck, and to fill the tank full of water and not run it over, and do it quickly, is about as easy as to drink out of a glass balanced on top of a lead pencil. The water run over makes mud and dope of coal-dust and cinders, rusts out top of tank, and makes firemen a world of work to keep the back of tender as tidy as most roads expect. A flange around coal pit only, and the coal-pit made larger at top, would be an improvement. Some arrangement should also be made to send the overflow of water to the ground by some other route than the coal pit. In winter, this would be found a big saving in the way engines steam.

Remembering Orders.

The writer was riding on a locomotive some time since when the engineer got an important and complicated order. He read it over a couple of times to himself and said to the fireman: "Don't let me forget my orders." The fireman said nothing, and we steamed out. Ten minutes later the engineer whistled for the next station. "Don't forget those orders," said the fireman. "All right," said the engineer. At the next station this was repeated, and so it was at the third and fourth; at the fifth the engineer showed some signs of annoyance, and finally said: "Got a do-not for the Springs." The Springs was several stations away yet, and the fireman was mute till we got there.

Now how much better it would have been had that engineer have given the fireman the order to read, or read it to him; by so doing he would have made him an interested partner in his own responsibility; he would have acknowledged him as an intelligent workman, as an apprentice; he would have lessened his own danger and had the help of an ever alert lieutenant. Engineers cannot do a better thing than to reform the close-communion train order system. Put up a hook and hang every order on it and tell the fireman to read them as soon after they are received as possible. You will feel better as an engineer, the fireman will be proud of your confidence, the company receive more perfect and intelligent service, and the public more safety, and there will be fewer forgotten orders.

The Oil Box.

One of the first things that strike an English engineer or fireman as odd, on stepping upon an American locomotive, is the oil box, with its six or seven kinds of lubricating juice. There is the bucket of tallow, the five gallon can of black or engine oil, the two-gallon one of sperm, the one-gallon can of headlight, and its half-gallon cousin of signal, and an old beer-bottle of boiled oil to paint the stack, and perhaps, a little can of a secret mixture or "oil cocktail," that this particular engineer believes is good for his wheezy old air pump. In England there are few roads that furnish more than one kind of oil—a clear, amber-colored fluid that is a good lubricator, and burns well in the signal lamps.

Blindfolding Locomotives.

Men who care for good headlights, and have to run on roads where they double head, know how soon the cinders peck up and frost over the glass in headlight of the second engine. On some roads, the boys have the light fastened to bracket board with one central bolt and thumb-screw nut, and, by loosening this they easily turn the whole headlight around and let the cinders peck up the back. Others have a curtain made of oil-cloth and "blindfold the old girl," as they call it. Either scheme saves the glass.

More About the Roundhouse Foreman.

BY JOHN J. BINGLEY.

It is a very important part of a roundhouse foreman's duty to see that his men are supplied with a sufficient quantity of labor-saving tools, and the next important thing is to have a place to keep them when not in use.

The writer at one time, on taking charge of a roundhouse, made out an order for about thirty-five wrenches at one time. I had two boards ten by eight feet put up on the wall, and a sufficient number of pegs and hooks placed in rows on which the wrenches, spanners, chains, jack levers,

Fig. 1

etc., were to hang. A large R. H. was cut with a half round chisel on every piece, and an order was posted above them, stating that any person using these tools and not returning them would be subject to suspension, and any of the wrenches marked R. H. found on any engine would be reported to the M. M.

By this means a good set of tools was secured, and after a week or two the men soon learned to put them in place. They soon learned to call certain wrenches by name, as check wrench, feed pipe wrench, pedestal bolt wrench, injector wrench, etc., so that as soon as they got the order one would say to the other, you bring such and such tools, and profanity and bad tempers soon vanished.

A bar of iron (Fig. 1) 3x½ in the center and tapered at the ends, four feet long, was used to lift off steam chest covers, the oil cup was taken out, and the casing taken off, the nuts taken off, and the cup was put through the hole in this bar and screwed into the steam chest cover, and a man at each end could lift it off very easy and lay it on the floor, and no fingers burnt. A stud puller was often needed; this was a round bar with an eye and set

Fig. 2

screw (Fig. 4) at one end. After they were started with this, a pipe tongs or alligator wrench would take them out.

In putting in springs small jacks, 1½" to 4" high, were very useful to raise the equalizer so as to couple or uncouple the spring hangers. A small hydraulic jack, like Fig. 2, was very useful; it was made of soft steel 2" square; a ⅞" hole was bored in both ends; a nut with a thread in was screwed on one end; in this was a ⅞ fine thread screw with a leather cup on the end; on the other end was a plug fitting the hole, with a leather cup on its inner end; the screw was run back to the outer end, the plug taken out and the jack filled with oil and the plug pressed down; by forcing in the screw the plug was forced up, and did good service in raising equalizers.

Chains with grab hooks made of square iron, and close enough to grab the link on the outside, were often used with a pinch bar to pull down the end of the spring to make the last hanger.

Fig. 3

Flat bars (Fig. 3) 2x1" with ¾ holes drilled at about 1¼ center to center, and a hook bent on each end to hook on the top guide; a pin or bolt put in these holes formed a fulcrum by which the crosshead could be pinched from one end to the other when the packing was to be examined or the brasses filed.

Many were the devices employed to get the piston out of the crossheads; a small screw-jack with spanner nut was used sometimes. Often a drift and a nut or two was put in between the wrist pin and the end of piston, and a sharp blow would start it out. But a better plan was to make a steel drift to go in the crosshead keyhole; it was narrow enough to admit of a half round piece of steel about ⅞ thick, to slip in and bear on the end of piston rod, and two pieces, one above and one below, resting against the crosshead end of the keyhole, and the key drop down between them until tight; then by driving the key the rod was forced out; with this rig it was not necessary to take down main rod.

Blocks to block the crosshead should always be used when the main rods are taken down, if steam is in the boiler; for if the throttle leaks, or some one not knowing the rod is down may try to move the engine, out will go the cylinder head I have seen more than one go out this way.

It is very important that a supply of bolts and nuts of the different sizes be at hand, ready for use, for if they are not prepared beforehand, they can never be found when wanted; wedge-bolts of the different kinds, oil cellar bolts, gum washers for unions or feed pipes, and flat keys, and split cotters. I effected quite an item of saving in flat split keys on one road by a little device like this: in the spare time, when the trains had all gone, I had the men get the old hoop iron 1" wide that came around the bales of waste, and with a pair of bench shears one man would split it in two ½" wide; another man would take these strips, say 24" long, and with a block with two pins, one ½", the other ¼", set close enough together to place the hoop iron between (Fig. 5); the flat

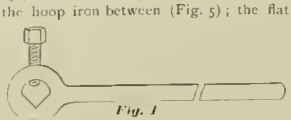


Fig. 4

keys could be made very fast; they would make 300 at a time, and for a long time these were the only keys used, and were as good or better than the commercial ones, as we could make them any width, and did not have to run to the storeroom every time we wanted a few. The short end was put between the pins and bent back slightly, and the long end brought around and given the "set" over the small pin, as in Fig. 6; one was made on each end and then cut off by the shears.

A Proving Test.

A number of tests have lately been made with the tire-heating device that was illustrated in our last issue, that are very flattering both as to the economy and efficiency of the apparatus. At the shops of the Pennsylvania R R. Co. at West Philadelphia several 48" tires were removed in from six to seven minutes, and

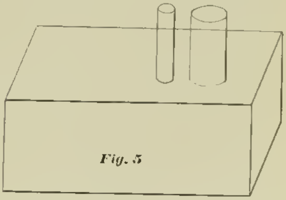

Fig. 5

several new ones of same diameter put on in from twelve to eighteen minutes each. The Lehigh Valley road furnished a hard subject in a pair of 54" tires that they had tried to remove in several ways, without success. The tires were rusted to wheel centers, and both wheels cracked through the hub.

As the tire expanded the cracked center also expanded; this center was cooled with hose, when the tire came off easily; the second, although cracked worse than the first, came off in forty minutes. The tires taken off these broken centers were measured while hot, and again after they were cool the day following. They had expanded a full ¼"; the tire was not round; the largest way was ½" larger than when cold, and the small-

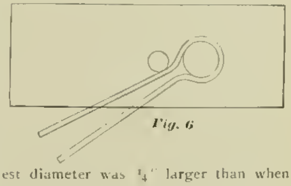

Fig. 6

est diameter was ¼" larger than when cold.

Tests were made in the presence of Master Mechanics Kinsey, Mitchell, Clark, Hofecker and Campbell, of the Lehigh Valley R. R. Co., and Mr. Garrett, Master Mechanic of the Pennsylvania R. R. Co. The quantity of oil used averaged from half a gallon to three-quarters to a tire, a gallon of oil being used up in about thirteen minutes.

H. K. Porter & Co., Pittsburgh, Pa., built 104 locomotives during 1887. They make a specialty of light locomotives for all purposes.

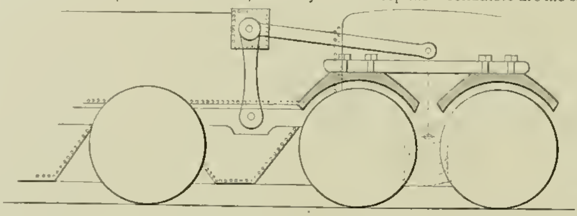
The P. & Ft. W. Road built 35 new engines at the Ft. Wayne shops last year.

About Driving Brakes.

Driver brakes are now being applied to a great many locomotives, and a few minutes' study of them presents several thoughts. In the first place, it depends a great deal on the make and kind of locomotives they are to be applied to, and the country and climate in which they are to run. Every engineer will look at the different kinds and different ways of applying them and then judge of their merits or demerits from his own footboard and his own country.

The first and general mode of application was to place both shoes between the drivers and force them apart by a toggle joint movement. This is hard on the machinery as well as the brake; the drivers are forced apart, and all the strain brought to bear on the driving boxes; it affects the side rods, and one wheel is trying to tear the shoe up and off, and the other driver is trying to shove its shoe down under its tread, where it seems to think it belongs.

The later style of placing the shoes on each side of the drivers, and bringing them together, takes a great strain off the boxes and is much better, but has a disadvantage in that it multiplies parts, and, on consolidation engines with small wheels, it is in the way, and especially so in a country where there is much snow. The writer was employed for some years on a mountain road in the far West using heavy consolidation engines with but 36 inch driving wheels. The grades being 217 feet per mile, it was necessary that engines should be well provided with means of controlling themselves light. As one would take as many cars down a mountain as several could get up, a large per cent. of the mileage was made by lone engines. The entire equipment was provided with the straight air brakes, and the engines had tender brakes, water brakes and most of them had driving brakes. Owing to the crowded condition of the heavy machinery, these driver brakes were obliged to be placed between the forward and main driver, and the air cylinder was in front of link, making it hard to oil these parts. From the size of wheel, the brake shoes had to hang very low. These brakes were only to use in an emergency, and a great nuisance they were. If you ran through snow, and that was more than half the time, they were a solid mass of ice, and carried it up and over the working parts of the engine. If you used sand, they carefully sifted it over the links, eccentrics and driving boxes. If you got off the track, they would break the casting or catch on the rail and shove up. If they broke off, you were glad of it, if they did not, you had to disconnect and take them off before you could get a frog under the wheels or block up to get them over the rail. If you used them while running, two to one they would tear off and put your mill on the ground, and, taken altogether, they were an element of safety and danger that a man had been learned to think well of, but which his experience said was a first-class nuisance. A few cases where, at the dread hour of midnight, the writer was obliged to take off an icy driving brake from each side of his pet, while the fireman was half a mile down the track flagging the express, that was stuck fast four miles away, and the mercury capering around the bulb of the thermometer, rather got us down on this class of driver brakes; but, like a boy who has no faith in his father's religion, we disliked to say much about it, but kept up a lively thinking; the driving brakes were there before we were and were our superior by right of seniority. A man cannot think of anything very long or very carefully without thinking out something new, good or bad, and finally we had in our note book a sketch something like the one below, and we reasoned thus: Now, if we could put those shoes on top of the wheels, they would never get in the way. If they were on the two center pairs of drivers they could have shoes the full width, as these drivers have no flange; the braking force would wear on a part of the tire now only used to turn off, and they would keep the



grease off the face of wheel. By being on top they will catch no sand or snow, won't have to come off to get engine on track or won't break off when she strikes the ties. By placing the cylinder in the center of frame and in front of fire box and connecting to a cross-beam, the strain will be equal on all the shoes and do away with one cylinder and four toggles. The breaking force will simply be a matter of lifting the weight of engine from the journals to the periphery of wheel—the true principle. By stiffly bracing the connecting bar to the expansion brace lug on fire box, we prevent the shoes from being forced ahead or back. It can't stick. It is cheaper than those in use. It is not in the way when oiling. It can be repaired without getting under the engine. All of this and a few similar points we learned by heart, and finally decided to go three hundred miles to headquarters, show our great invention (?) to the kindly superintendent of machinery, get it adopted and take our place among the inventors of America and benefactors of civilization. We recall how grand we felt; like the first spasm of true love, it was too pure to talk about. We took the night express and struck the big shops about 7 A. M., got an excuse for breakfast and went over to the roundhouse to await the arrival of the highest official. The first engineer that came in was an old passenger runner who had a new engine. He was twenty minutes late. "Well, can't you make it?" tartly asked the foreman. "No," said the runner, "nor anyone else with that engine till she is fixed; she is logy, slow and won't start to move for a minute after you open the throttle, and don't swing 'em when she does go. You have got to put some life in her—give her more lead." "More lead!" echoed the foreman; "now let me give you a little advice—don't you say 'more lead' to the old man; he will tell you mighty quick that if that engine needed more lead she would have got it in the shop where she was built; they know what they are doing." "I will trade back for the old engine and give boot; she is little, but she can make that time better than the big one, till she is doctored," remarked the engineer, as he went home disgusted. The next man came in with coal-dust and a tired look about his eyes, sat down his lunch pail, threw his coat on it and pulled the register towards him with a look as if he would have liked to own a rubber stamp to save the exertion of writing his name. "Say," to the foreman, "you will have to fix that seat. All these new consolidators are the same; you can't sit on it and look out of the window; it is too low and too far back; can't reach the throttle either, and it is so narrow that a man can't half sit on it—wish you would change it." The foreman looked at him in a lofty manner and said: "Young man, if you want to take the responsibility of boring them new cabs full of holes, all right, I won't. I ain't going to have the old man jumping onto me. He was East when them engines was built, and that seat is there for some use, or they wouldn't put it there. I know what I am doing; just go and strike the old man and see how soon he'll tell you what is what." The engineer swore he was not fit to go out the next trip, laid off and went home. We commenced to think of the changes we were about to propose, and forgot half our piece. The foreman talked on, half to himself and half to three or four of us who stood around. "Nothing makes the old man as mad as some of these engineers coming around and wanting to change something; nothing is good enough for them. How are we going to ever get the engines down to standard, I'd like to know?" We went over and waited for the terrible "old man." We had never spoken a dozen words to him in our life, and the longer we waited the less we felt like opening our heart to him. About 9 A. M. he came, recognized us, asked how the snow plow was, and what we were doing there, and what he could do for us, and led us into his office. After two or three gasps we managed to tell him we had a little business there, and if he would give us a pass home, we would go up on the noon train. And thus was lost one of the great inventions of the day, and this is the first time it has ever seen daylight since. We believe it would be the best thing yet in the place it was intended for, and we also believe that foreman was a lazy liar, and we were foolish to pay any attention to him, and that the superintendent of machinery would have tried the scheme if we had showed it to him.

How a Superintendent Flagged.

Some years ago, not very many, however, there happened on one of our Western roads one of those little incidents that are interesting, amusing and instructive, but where the laughable part is not really enjoyed until some time after, things being serious just at the time.

The reason that we don't say just when and where this all happened is because the engineer is alive and well yet, and the superintendent is now vice-president and general manager of a great system, and will appreciate this joke on himself all the better for not being given entirely away; but for the tale:

It was snowing everywhere from the Mississippi to the Rocky Mountains, and what trains were not stalled in drifts stack high, or abandoned to avoid stalling, were not on time by many hours. The mails must be kept moving, however, and the mail car and one coach were about the size of most trains, and passengers hardy enough to venture were few.

One old engineer succeeded in getting over his division nearly on time, and found at the end of the run that there was not another engine to go over the next division as "pilot engine," to run ahead of the train to clear the track of snow, cattle and other obstructions, and he was asked o go by the superintendent himself. The old man shook his head, remarked that it was "pretty rocky," but finally said he would go if they would wait till he got ready. As there was nothing else to do, they waited.

Our hero was cool, he looked out over the prairies into the storm, and told the hostler to take the engine to the house, have the ice knocked off the running gear, a full tank of coal and water put on, and the oil cans all refilled and fire cleaned, while he and the fireman got outside of a hot supper and had their lunch pails filled for a siege. In half an hour all was ready, the light engine stood in front of the train, and both in front of the office. The superintendent was nervous and concluded to go himself on the light engine, so that there might be no mistake. After oiling around carefully, looking to the headlight and pounding the sand pipes open, our engineer got up on the engine. The fireman had the pointer at 140, and all in readiness for a hard run. The superintendent was perched up on the fireman's seat, hid in an ulster and a pair of No. 13 overshoes, and inwardly chafing because the engineer was so slow As the old man wiped off the oil can, he said to the fireman: "Light me a lantern and put a couple of torpedoes on the guards." The official had to get up for Mike to find the booms in his seat-box, and asked the engineer: "What in thunder he wanted another lamp for, the fireman had one lit." But the old man put the light in front of his box, got his legs in front of the reverse lever, and remarked as he pulled out: "That is for me." The storm was raging in all its fury, and at every cut or bank the engine dove out of sight for a moment, and then emerged covered with a shroud of purity. Through every crack and opening in the cab there was a thin knife of sharp wind and snow pointed at the three men, who were straining every nerve to see before them; when out onto a high fill this was possible, but any other time it was not. Half a mile back they could catch occasional glimpses of the headlight of the oncoming train.

After passing a certain bridge, the engineer turned to the fireman and said. "Mike, fill her up to the crown sheet." The fireman obeyed, but wondered what had struck "the old man." When Mike had a couple of tons of coal in the firebox, he dropped the curtain and the old man said: "Now, don't pay any more attention to the fire, but look out for stock; these cuts will be full—half snow, half bulls." "Got one here," said the fireman, as they emerged from a cut. "Look out, now," said the engineer, but they made a mile or two at a good speed without seeing any stock; but the old man kept up his lookout and cautions. The next deep cut had a herd of stock in it, huddled up to keep out of the fierce wind; into this cut the old Roger plunged, covered herself with snow—and cows—reeled a little, and stopped.

Experience had taught the fireman that that reeling meant off the track, and he had lit head first in a snow drift at the first lurch. The engineer coolly threw the reverse lever ahead again, and said, "Mike, flag the train." But Mike was gone. "I'll flag," said the half-frozen official, as he got the fireman's lantern; "but why don't you go? you're out of the cut, and they may run into you" "The trucks are on the ground; you fly!" was the command; he did fly.

Our superintendent was one of those men who can get a poor engineer or conductor up into his office and scare him into the blind staggers by deep questions on operating railways, but when he came to the trials of the operation he was as bad as a green boy off a farm. He had the lantern and he was off the engine in a minute, around the tank in another, and before the third minute was up he stumbled over a dead steer rolling down the bank, and his lantern went out at the first stumble.

Our engineer quietly, but quickly, turned up "his" lamp, and started to go back himself, but met the bold Mike at the gangway, and that hearty seized the signal lamp and went back on a double quick. In a few minutes the express stopped a few feet behind the disabled engine. The hatless, snow-packed officer now showed up, and never ventured a remark while the train men coupled the second engine into the first and pulled her onto the track, gave her a shove through the next snow cut, and came back for the train. He took a seat by a red hot stove and tried to dry out.

A few days later he met the engineer and said: "I learned a little real, live railroading the other night. If you were as green at it as I am there would have been blood spilled over there." "And," said the engineer, "if all the engineers in the country were as poor practical railroad men as yourself, what then?" The young but honest official shoved his hands deep into his trousers pockets while he hunted his brain garret over for a fit comparison, and finally remarked: "We'd better have the cholera." "Remember one thing, old man," said the knight of the throttle, "and that is to always protect yourself, running or standing still; look out that you keep out of the other fellows and keep the other fellows out of you. I am going out with a very leaky old scrap heap to-night, come along, and I will give you a practical answer to your oft-wired question, 'What is the cause of this delay?'"

A Chance for a Novelty.

There is a good investment, on a small scale, for some builder of novelties to put on the market a cheap but fairly accurate model of a locomotive valve motion. It need not be all made of metal, but the larger parts can be made of wood; it is not necessary that any of it should be polished, but all measurements should be correct. It should be adjustable to different strokes of piston and different travel of valve; the eccentrics should be arranged on shaft so that they could be set at any point and slotted to change the throw; it is not necessary, for the purpose proposed, that different radius of link should be used Ordinarily strong and simple, all parts named and sizes given. A device of this kind may be sold in large numbers if it is not too expensive. If it costs $25, a good many lodges of engineers and firemen would buy them, but if the expense could be brought down to, say $10 or $15, not only most of the lodges, but hundreds of individuals would gladly buy one for their own instruction and reference. No invention is necessary; drawings of good valve gear models are to be had in many places, notably at locomotive works.

Who will supply the want?

John J. Bingley and H. R. Jones, contributors to No. 1, come out again with instructive letters in this issue.

J. E. Phelan gives enginemen some sensible advice that will be read by all in the motive power departments from heads down, the more so as Mr. Phelan is well known as having charge of more than 3,000 miles of road, as general road foreman of engines under the general master mechanic of the Northern Pacific.

James Heron writes from the shop, and his showing up of some of the practices in boiler shops cannot fail to attract wide attention.

Correspondence

Criminal Boiler Work.

I received a copy of your paper and was much pleased with it; it has occupied a field much in need of such a monitor, and I am sure you will do good. When I was a young man reliable mechanical papers were not to be had, and a mechanic could not learn different systems of doing work, and keep track of the improvements in new machinery in his special line without working in many different shops. I traveled a good deal in my time, but if I was to learn boiler-making over again I should not weigh anchor so often, as a man can see cuts and read well-written descriptions of all new machines and get hold of all new kinks in a paper like yours, and at his own fireside. I have worked in the boiler department of many shops, and have always found that in shops where there was system, good management and intelligent work, you would find reading mechanics, and in rule-of-thumb, strong-and-ignorant shops, men who do not read. I recently resigned my position of foreman boiler maker in a large shop, to work as a journeyman in another shop, a railway repair shop, for a short time, to get the run of the shop and the men before taking hold as foreman. I found that of over forty men in the boiler department, not one took a mechanical paper, and the machine shop was no better. These men had been employed in this shop from ten to twenty-five years, and all they knew was learned there. They were behind a Chinese wall of ignorance of good boiler practice and did not know how to get out, and did not want to get out. Foreman or men were never allowed a day to visit other shops. Their system was the cut-and-try kind, and their work crude as the boiler work of 25 or 30 years ago. These men had lived for a decade amidst the greatest improvements in steam boilers and knew nothing of them. Right in the same neighborhood another road does the best of work; the shop is run on a system, the apprentices are obliged to attend drawing-school, mechanical papers are furnished and read, and improved machinery or tools discussed and studied, and graduates from this shop find positions of responsibility and trust open to them from far and near.

While I was at the old-time shop, there was an engine brought in for general repairs and the boiler sent to our shop for a new fire box. Here the flange turner is also the fitter up. He goes to the saw mill and gets six pieces of pine about an inch square and six feet long; he uses these to get dimensions Out comes his knife, and a nick or notch is cut for a size where his thumb comes. When he gets the sticks cut up enough off he goes, and comes to a halt about ten yards away and comes back—he has forgot what the top stick in his left hand stands for—and he repeats, sometimes more than once. He got out in this case a fire box that would fit almost any boiler better than the one it was made for. He used the old crown sheet and brought it up level, and made space over fire door 2½ inches instead of 4 inches as before; this brought the crown sheet back 1½ inches, and, as the crown bar rivet holes in crown sheet were there and the crow-feet on shell of boiler riveted fast, with the new order of

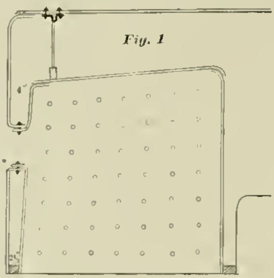


Fig. 1

things, "nothing fit anything else." In Fig. 1 you see fire box as it came to shop. Note sloping crown sheet, the space over door, and stay to shell. In Fig. 2 you see the new fire box, closing space over door and throwing stay out of plumb; see position of holes for stay bolts in shell and large space left near back end not stayed; also note that the flue sheet is not square with flues, being 1½ inches out of plumb. I pointed out to him his mistake and was told that he had put up more fire boxes than I ever saw, and that he had worked there for twenty five years. When I called his attention to the matter, he had not drilled holes in side sheet of fire box, and by loosening up a few clamps he could have placed the box in proper position, but he had an idea and hung to it. I thought that as the M. M. had asked me to take charge in a short time I would go to him, as I considered the job a dangerous one. At noon I made a sketch of parts as here shown, and took it to him.

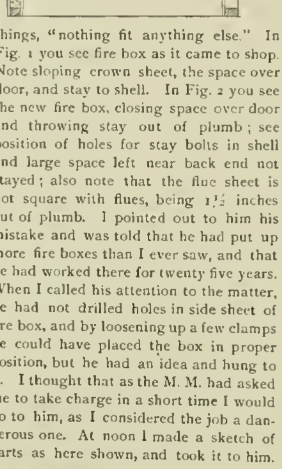

Fig. 2

He did not show up in boiler shop, and the job went on. They had to cut away most of the flange of fire door to get box in shape, and the rivet holes came close to edge and in the flange. They wanted me to finish it, but I refused, showed foreman how stay bolts came opposite rivets, etc., and he finally let another man finish the work, asking me to rivet and calk. When the box was in shell and ready, the crown bar stays were all out of shape; No. 1 brace came nearer fitting No. 2 bar than its own; they were going to bend the jaws of the braces, but finally decided to change the crow-feet on shell; these they took off, and instead of making new ones, plugged holes and welded on a piece, setting the lug to one side, thus:

Now what will a thing like that hold? All the strain comes on the short side, the long one will stretch; and think of a weld in old iron through a plugged hole. After the new crow-feet were in we had to bend the lug to one side to get jaw of stay on. In some places we put in 1½ inch stays where the original size was ⅞. They did not put the expansion plates back inside of shell; the M. M. said they were a humbug. Think of this kind of work in a locomotive boiler carrying 140 pounds of steam. This kind of work is little short of manslaughter, and might furnish the clue to some of those mysterious (?) boiler explosions. I now called on the M. M. and resigned, and told him if I took charge of his shop I must make some changes in the method of doing work. He said that to make any change would lose some of his oldest hands, and he did not like that. Finally I asked him how he would like it if I would guarantee to put in a fire box in three days where it now took seven, and he said he would have nothing of the kind: he now understood his methods and his men, and wanted nothing new, good or bad. I am still alive and foreman of a first-class boiler shop where they don't do patchwork on the rule-of-thumb.

JAMES HERON.

Facts and Fixtures About Locomotives.

THE LOCOMOTIVE ENGINEER enters a field for usefulness bounded only by the desire of enginemen for information concerning their calling and the vast territory through which the ramifications of railroad lines run; and will stand out as an Engineman's Bureau, singly and singularly independent and unique in its character for missionary work among the votaries of locomotive machinery.

We want it to condense the mass of phrases and technical points of mechanical learning and feed to this busy world of employes in small doses with plain directions.

All enginemen who are given to reading will profit by its instruction. All enginemen who do not form habits for reading and study may be reached by the force of example and average conduct and performance of those who do.

Education being the steam generating power and valve motion of good government, so must it be the fundamental principle on which must rest the future weal or woe of efficient and economical service for railroads. Where this education commences and where it will end only thoughtful minds can imagine.

The prime object of a railroad is to satisfy the demands of commerce and give a profitable return on original investments. The prime object in the necessity for locomotives and enginemen is the transportation of commerce over railroads and for earning and increasing the proportion of capital invested. If no necessity for profit existed there would be no object in improvement; no object in having skillful engineers and firemen to manage locomotives. Hence, it is as plain as a fire-box door that if the profitable management of a railroad requires skillful enginemen, it is to their profit and advancement for enginemen to become skillful.

For economical work firemen must commence with the management of the scoop-shovel and dampers, and the control of their fire and steam pressure. One of the living wants of the present time is for some one to write a book that may gradually allow the fact to dawn on the minds of many firemen, that all engines have dampers, and that they were originally intended for use. In conjunction with this is a profitable field for some patent-crank who will fix up an automatic arrangement with a "stuffed club" to stand over the "seven-up" firemen to remind them of this and other facts. The automatic arrangement should also take in the right hand side, for "seven-up" firemen usually have the same kind of engineers.

If a fireman cannot count on what a given quantity of coal put into a fire-box at a certain time or under certain conditions is going to accomplish, he don't properly understand the principle of his business, or else there is something dead wrong with the engine or the engineer, or both. An ordinary scoop of coal will average about twenty pounds, and it don't take long to scoop into consumption a ton of this product.

A fireman who will use coal or other fuel only to generate steam that must pass through the cylinders, and hence go into profit of conducting transportation, is the coming man. The engineer who keeps his engine in good repair, free from wasteful blow or demoralizing pound; who uses an injector to supply only sufficient water to make steam demanded for work in sight; who uses steam only in sufficient quantity to supply the actual demands of speed and force required to propel the train under required conditions, while paying proper attention to train orders, signals, and the numerous other duties required, is the first class engineer, and it don't want to be imagined for a moment that such an article can be made out of bass-wood.

To have such enginemen on engines intelligently designed, free from lost motion, pound or blow, is the proper condition of locomotive equipment desired. On the other hand, there is much to be remedied, and we can but hint here at one or two shining marks for the reformer's aim. Who can blame a fireman for developing into an indifferent engineer, when he has never fired an engine known or suspected of being in good condition in any respect; or who has never received intelligent instruction concerning his business from any source? When one finds an engineer possessing a disposition to learn and improve by example or instruction, future skill is assured by a little perseverance. In this busy age we can learn a little every day, but we occasionally stumble over an individual whose head is swelled, and in his own mind has emptied the store room of knowledge, locked it up, and thrown away the key. The sooner such a fellow gets a tie-pass out of the country, the better for all concerned. In his travels he may find some one knowing less than himself and take a pointer.

On many roads we find engines designed with gun barrels for boilers and with cylinders equal in diameter to shell of boiler. Every revolution of the drivers empties a whole boiler of steam into the cylinders. The fireman sweats and cusses or despairs in trying to keep up steam; the mechanical journal comes along with long discussions on the best mode of draft appliances for free steaming, but concerning these engines the natural born fact remains that the only way to keep steam pressure is to choke up the exhaust nozzle, not only to sharpen the draft and add to the vicious consumption of fuel, but also to keep steam from escaping from the cylinders rapidly enough to empty the boiler. Hence, the nozzles become speed regulators and train tonnage regulators also, and the retarded motion of the engine comes down to a bed-rock basis of supply and demand, where the supply regulates the demand. For such boilers dynamite would be a good fuel, but prudence demands that they pass out of existence in the usual way. The class of engineers who take matters easy, and, understanding the expansive principle of steam, diligently apply it, are very valuable employes for such machinery. The principle should exist among enginemen, of making the best possible use of engines and material at hand for doing work. Where such a spirit exists everything runs smoothly.

It is to be hoped that men who have designed such engines may die off in time, if they are not dead now or have not learned better methods.

The discussions of mechanics' conventions and the various railway clubs picture the dawn of a better day. The progress of master mechanics is self-evident. Finely proportioned engines appear as a result, with boilers fully adequate to size of cylinders and diameter of wheels. If the locomotive engineers and firemen will only keep pace with the master mechanics, the successful and economical management of engines for the future is assured.

Enginemen should work and study for the purpose of knowing and doing right. Such virtue is its own reward; but those who think correct methods are not known and appreciated by superiors, don't size it up right.

In any event, patience will be rewarded, for the most patient and persevering men usually die when their time comes.

J. E. PHELAN.

The Man Who Does Not Read.

He is very likely to be a little conceited and think that he knows just how to do things without help from any outside source.

He is inclined to think disparagingly of a "book" engineer or machinist, as he sees fit to call the man who reads and tries to keep posted and up with the times.

He is generally the first to condemn any new appliance that comes out. When the air-brake was first introduced, I heard such an engineer denounce it as a "nuisance, and too much trouble; the engineer had enough to see to, without being brakeman."

Not long since, one of our Western roads applied a few sight-feed lubricators to some of their locomotives. The man whose duty it was to explain to the engineers how to operate them had not carefully read the directions sent with the cups, and so was totally ignorant of one very important valve, the intelligent use of which was essential to the successful working of the lubricator. The manufacturer had to send out an expert to save the reputation of one of the best appliances ever added to a locomotive.

A man who reads was placed in charge of one of our modern automatic stationary engines. The valve, and what was inside of the steam chest and cylinder, he had never seen, and of course knew nothing of its construction. He sent to the builder and procured a "descriptive catalogue," and in one evening, by its perusal, he had a good idea of what was going on inside of that engine.

The man who does not read wonders what is inside, but does not find out until it is torn apart, and even then he does not get the builder's idea, and know why it is so made. It takes him weeks, months, or years to find out what a few hours of study would enable him to ascertain.

How many inventors spend long sleepless nights in "getting up" something, and then find out that the thing won't work, because it is not constructed in accordance with the laws of mechanics.

I know a man holding a high official position on one of the largest railroads of the West, who built, at a great expense to the company, a hydraulic pile-driver, which, with two men, was to do the work of a ten horse-power engine. He had seen the tremendous force exerted by a a hydrostatic wheel press, and concluded that this was just the power to lift a pile-driver ram, and as the pump was so small, two men could easily work it. It is needless to add that the result was failure, and an addition to the scrap heap.

This is a fast age, and the man who expects to keep pace with the times must not expect to find out everything by the slow coach of experience, but take advantage of the delving of others, as it may be condensed in their writings. It saves time, hard work, and many mistakes.

H. R. JONES.

The new engines of the Boston & Albany carry 175 pounds of steam.

CONTENTS.

The Seed of Accidents.

The last year has been a very busy one for railroads, and also for the coroner. It is always so. That there should be more accidents where there are more trains is perfectly natural. But the increased number of trains is not the greatest cause of accidents. When business crowds the roads all the motive power available is kept in motion, and the increased traffic makes the officials more than ever careful how they send out new engineers. They urge the engineers to make extra trips and thus make a little extra money during the "rush." In most cases this is blood-money. Blood-money for the already over-worked engineer, and blood-money for the public. In the United States during 1887 there were, not many, but many thousand of trips run by engineers who had been on duty from eighteen to forty-eight hours, and many cases of even more.

It is a rule on some roads to require the men to "double the division." This may be 100 or 150 miles; a freight train gets over it in from 10 to 14 hours, and the engine crew doubles back; before reaching the terminus the engineer has been on duty more than 24 hours, and that they endure it and keep awake and attentive to duty is one of the wonders of the day.

The trouble is a serious one; no man will dispute that a locomotive engineer on duty has responsibilities as grave and great as any other human being—more lives depending on the proper exercise of his good judgment and his nerve, the matter of property in his hands we leave out of the question—no human being will dispute that passenger engineers have grave responsibilities; no human being who has ever thought the matter over seriously for five minutes will dispute that freight engineers, especially on single track roads, have many times the responsibilities of the passenger engineer.

Let the engineer of the passenger train be ever so good, always alert and watchful, always in full control of every nerve, and pull his train along at lightning pace, knowing that he is on time, and has the full right of way, does not make the butchery any the less if some over-worked, careless or incompetent freight man meets him between stations. The freight runner must know his own rights and the rights of all other trains on the road and clear the time of all superior class trains.

Few passengers think, as they pass train after train, safely out of their way in a side track, of the care and worry and work for brain and nerve it took from those dirty-faced freight engineers in their blue over-clothes, to thus protect themselves and the public.

Locomotive engine running must be recognized as skilled labor, treated as such and paid as such.

Skill is paid for its quality—labor for its quantity.

Paying engineers by the hour or mile at pay little above that of laborers is requiring quantity regardless of quality. The quality is good and efficient when not over-taxed, and is worthy of pay in proportion.

No first-class concern tries to work its draftsmen over six hours; knowing that longer hours mean less accurate and less reliable work. An over-taxed draftsman may spoil a machine that can be replaced; an over-taxed engineer may cause great loss of life that cannot be replaced.

Eight hours per day is long enough for any man to run any locomotive in any service, and if the greedy companies will not throw this safeguard around their patrons the general government should throw it around the public.

Instead of making laws to license engineers, would it not be better to make a law preventing companies from using half-dead men to run their engines?

Locomotive Enginemen and Railway Purchasing Agents.

A mistaken impression exists in some quarters regarding the relations which should exist between these two classes of railway employes. No doubt there are cases from which one might conclude that the average purchasing agent considers the views and experience of enginemen as unworthy of notice. But we believe these cases are only the exceptions that prove the rule.

The official who does the buying for a railroad, whether president or purchasing agent, if he has the true interests of his road at heart, knows that the practical men employed in the various branches of locomotive service, from the very nature of their duties, gain information regarding the working and wearing qualities of locomotives, their auxiliary appliances and materials, which is of value to him in determining what to buy and what to pay for it. In the very nature of things, no buyer can sit at a desk year in and year out, and, by any kind of instinct or business shrewdness, act intelligently and wisely on everything coming before him, without "expert evidence" derived from locomotive service men, using those words in their broadest sense, and including all positions, from superintendent of motive power down.

No such official can afford to close up the avenues of information on which, in a great degree, his highest usefulness depends. Least of all can he afford to do so with a view to being "independent," as that word is sometimes used. The true way to be independent is to be at all times well-informed.

It may be thought, with respect to appliances and materials that have been long in use, the buyer needs no further information. But what he knows of their quality is only knowledge gained as to the results given by them in actual service. Qualities often deteriorate, while new things come up from time to time, in competition, concerning which special comparisons and experience may be of the greatest value.

Even in the case of the master mechanic, whose duties bring him into near contact with the practical work of locomotive and car service, the eyes with which he can see quickest and surest are usually the eyes of the working enginemen on the road and in the shops, who are under his orders. If this be true with him, how much more true it is with those officials whose daily duties do not bring them into this kind of contact.

If one make of signal lamps, for instance, is less effective in actual service than another, the difference being any night liable to be emphasized by accident, danger and loss, why should a slight difference in price insure their extended use, when the truth can be readily ascertained? If a certain kind of copper is wanted in the shops, for a special use requiring copper of that particular quality, where is the economy in sending an inferior kind for that purpose, even at a little less cost per pound? Isn't it better economy to use the kind that is adapted to the work? Illustrations equally pertinent could be multiplied, running through the whole range of locomotive service.

It can be safely set down as a fact, that the railroad company whose officials put themselves out of relation with the men who are in position to tell them the frozen truth in practical matters, squanders a good deal of money in the course of the year.

Accidents on the Elevated.

Accidents on the elevated roads are getting rather too numerous for the peace of mind of many people who ride on them, and also many others who are obliged to travel beneath them. The engineers on the elevated roads should not be allowed to work over eight hours nor go on duty unless they had just had at least six hours of rest. The impression has gone out in the country that because these roads run so many trains a day a man has to be a pretty fine engineer to make a success on the aerial line. Such is not the case; an engineer who has never run an engine except on these roads, could not run on any single track surface road in the country with a single degree of safety to himself or anybody else. All the lines of the elevated are double-tracked ones—except, perhaps, a few little connecting branches of a few blocks in length—and one train follows another; none meet, all in plain sight of one another except at a few curves, and these are all guarded by distance signals and watchmen. The engineer of the L needs to be sober, cool, attentive to duty and exercise good judgment about handling his brakes. He has no "flyers" to let by, and no superior class trains to meet.

As usual, the most of the late accidents have been attributed to the engineer. Would it not be a good idea to find out how long these men work per day and how much rest they get? As good wages means good men, find out what wages are paid. Half a million people are carried by these roads every day, and as many more risk their necks by doing business under them. The engineers in this service should be noted for sobriety, good judgment, good pay and short hours.

Sand or Water?

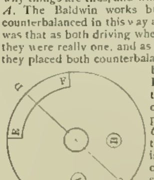
They have re-invented the water jet in England to take the place of sand on rails. This has been used about coal mines in this country for many years, and is in many cases better than sand; it does not make the train pull harder, as sand does. There is another invention which injects small quantities of sand, by steam, directly under the driving wheels. All of these are good in their way, but we believe the sand the best yet. In case of impending accident, sand under the train is very much to be desired, and in some kinds of weather is almost a necessity to even a fair stop. If all road locomotives were provided with good wire brushes behind the drivers, that could be raised and lowered from the cab, the engineer could wipe up sand used for traction and send back that needed for stops at will. The following item taken from the claims of the inventor of the jet system, and published in *Invention*, an English mechanical paper, shows some little difference between the practice of "sanding" in England and in Yankeedom: "It has been customary to drop sand upon the rails in front of the driving wheels, and numerous valuable lives have been lost from men falling off while sitting in an exposed and unprotected position upon the front part of the engine to sand the rails."

Headlight manufacturers for the past two years have been indulging in a general skirmish in the way of cutting prices. And, of course, railroad buyers take advantage of this state of things. As a rule, there are two sides to the profit and loss account in such fights. Quality is apt to become a secondary matter where the chief competition centers in the slashing of prices. By and by some manufacturer will take steps to get the verdict of practical enginemen on his wares, and then the fight may turn upon quality, not price. Quality in a case of this kind means safety or danger; and competition, where price is the pivot, is always on the side of danger

ASKED & ANSWERED.

(1) Northwestern, Chicago, writes:

I am firing a Baldwin locomotive that has a heavy counterbalance in each wheel, but it is not opposite the crank pin; now I have always thought this weight was to balance the weight of pin-boss, pin and connection rod, but my engineer says it is to lift the rod and pin up and past the center, and it is placed there so as to be ahead of the weight it lifts, and thus have more purchase. I think he don't know much more than I do; the roundhouse foreman can't explain it; and when I saw your paper I made up my mind to ask you why things are thus, and what advantage it has, if any? *A*. The Baldwin works built a lot of locomotives counterbalanced in this way a few years ago. The idea was that as both driving wheels were fast on one shaft they were really one, and as the pins are "quartered" they placed both counterbalances on a symmetrical line



between the two pins. Look at the sketch, *A* is the crank pin on one side of the engine and *B* the pin on the opposite side. *C D* is a center line between the two pins. *E F* is the counterbalance placed opposite the two pins, the same on both sides. We believe the idea had more disadvantages than advantages, as the works abandoned them. No doubt a pair of wheels so counterbalanced would be in perfect balance on a knife edge or a still balance, but in rapid motion would cause the engines to ride very hard, and axle boxes to heat. Take, for instance, a very wide pulley and have a weight at one edge; if you put a counterbalance opposite, but on the other side of the pulley, the pulley will be in perfect still balance; but put it in rapid motion and it will give a jerking and twisting motion to the shaft, one weight pulling one way, while the other is pulling in the opposite direction and heating the boxes; change the weight to a point exactly opposite and one balances the other in its path, producing no effect on the shaft.

(2.) Fireman, Tyler, Texas, writes:

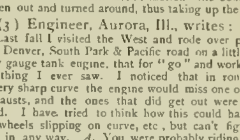
My engineer has been at the roundhouse foreman for a month to get him to "turn his driving boxes around;" for what reason I have been at a loss to find out, and I made up my mind not to show my ignorance by asking. It looks to me as if THE LOCOMOTIVE ENGINEER was the place for us firemen to go and find out for sure Can you help me out? *A*. Most shops make driving boxes $\frac{1}{16}$ or $\frac{1}{8}$ thicker on one side than the other, and when the outside of box and inside of hub of wheel get considerably worn—so that the engine has too much lateral motion—the boxes are taken out and turned around, thus taking up the wear.

(3) Engineer, Aurora, Ill., writes:

Last fall I visited the West and rode over part of the Denver, South Park & Pacific road on a little narrow gauge tank engine, that for "go" and work beat anything I ever saw. I noticed that in rounding a very sharp curve the engine would miss one or two exhausts, and the ones that did get out were extra loud. I have tried to think how this could happen, by wheels slipping on curve, etc, but can't figure it out in any way. *A*. You were probably riding on a Mason-Farlie engine, where the engine is pivoted under boiler, same as a truck under a car, and the tank frame and boiler strongly framed together; this class of locomotives use the Walschaert valve gear, the link being on outside and acting as a rocker arm, the reversing being done by moving the link block in link instead of the link itself, as in ordinary locomotives. These link blocks are worked by a tumbling shaft over top of boiler. You will readily see in rounding a sharp curve the elevation of the outside rail would cause the long boiler and tank frame to tip toward the inside of curve; this pulls the link block on outside of engine up to near center of link, often cutting steam entirely off, while the inside block drops down in link and gives more port opening It is the same as if you had a reverse lever for each side of the locomotive and pulled one of them back to the center or "out" and let the other down a notch or two. You are not the first man who has been stuck on a "Jim-Crow," as the boys out there call this class of engine

(4.) Beginner, Altoona, Pa., writes:

In setting up wedges on a locomotive when under steam, does it make any difference in what position the engine stands, and if there is a right way, what is it, and why? *A*. In setting up wedges always put your engine on or near the top quarter; for the



"why," see sketch. *A* is the front end of main rod, *B* the crank pin, *C* the axle, and *D* the point of contact with rail. *E F* is a line drawn through the point of contact, the axle and the pin. This line can be called a lever, *D* is the fulcrum, *C* the load, and *B* the power applied; if you pull the main rod ahead, the top of the lever is forced ahead and the axle at *C* is pressed against the front of box, and the box against shoe; this relieves the wedge, and, if there is lost motion, it can be set up easily. If you should reverse your engine and apply steam, the lever would bind the wedge and relieve the shoe, hence it is best to set tender brake and take up slack in forward motion.

(5) Construction, Kansas, writes:

I run a construction engine at the front and do all my own work. I grind in all brass cocks with coarse emery and oil, the only stuff furnished. I find that they cut the seats and themselves, and need grinding in very often. I think the emery imbedded in the brass does the mischief. Is there anything as good or better? *A*. Grindstone grit, used with oil or water, cuts about as well as emery, and washes off completely, not being sharp enough to imbed itself in the metal.

(6.) H. L. H, Harrison, N. J., writes:

I am a young fireman and notice that the drivers slip when the rail is a little wet, but stick when it is real wet. Can you tell me the reason? *A*. When the rails are but slightly wet they retain the moisture and are greasy, the moisture remaining upon face of rail with rust, oil and dirt. In a heavy rainfall the rail is washed clean by the force and larger quantity of water. It has been noticed by enginemen that rails wet from fog or mist cause the drivers to slip much more than rails wet from a direct rainfall Some roads use a strong jet of water instead of sand on grades in damp places like tunnels and coal mines.

In the Roundhouse and Repair Shop.

The Pittsburgh Locomotive and Car Works built 117 locomotives last year. These works have made many important improvements during the year.

* * *

The commissioners report that there are in the United Kingdom of Great Britain 15,400 locomotives and 528,090 "vans, wagons and vehicles" of all descriptions.

* * *

The gross earnings of the Manhattan Elevated roads for the year ending September 30, 1887, was $8,010,887. How is this for 5 cent fares and not a pound of freight?

* * *

The Brooks Locomotive Works turned out 144 engines during 1887, making a total of 1,315. Many improvements have been made in the works, that will increase the output. 16 were built in December.

* * *

THE LOCOMOTIVE ENGINEER acknowledges the receipt of a handsomely-bound and illustrated catalogue of the American Brake Company, St. Louis, Mo. The catalogue will doubtless be of service to us in answering questions about details of this brake.

* * *

Engineers, firemen, or repair shop employes who have got up any new tool, device or machine used on locomotives or in railroad shops, patented or not, should write us, giving description and sketch of same. Let your light shine; the exchange of kinks will be beneficial to all.

* * *

At the Taunton Locomotive Works they are building tanks with entire iron frames and having a deep flange around the coal pit only, the top of tank being clean and corners rounded off. It saves all shoveling down of coal and the rusting out of tank, is clean, and keeps dirt from flying in backing up.

* * *

What railroad man ever saw a brakeman stumbling along in front of a locomotive trying to keep the pilot off his heels and hold up a 150-pound draw bar to couple onto a car, without a shudder? A step of three-inch stuff, a foot or two long on each side of the pilot, would decrease this danger 1,000 per cent.

* * *

There will be no correspondence in THE LOCOMOTIVE ENGINEER of a personal nature, or lauding the paper any more than the law allows. The mechanical points will be carefully sifted out and used. It is our aim to make every article and item of this paper show up a point, or convey information valuable to locomotive enginemen.

* * *

The writer recently went over four different lines of road that were heated by steam. It was not a cold day by any means, but raw and disagreeable. The cars were poorly heated, and we noticed that at every stop the blower of the locomotive was singing its doleful song. Can it be possible that those big boilers can feel the drain of a little one-inch pipe of steam?

* * *

The *Engineer*, of London, England, has in its advertising columns a cut of quite an extensive apparatus, called a centrifugal water separator, and its use to "wring the water out of steam." How would one of these machines do on the smoke-stacks of some of our locomotives whose engineers believe in the water cure? If it wrings the water out of steam, it ought to do as much for smoke.

* * *

The Mason Regulator Company, of Boston, report that they are very much behind their orders on reducing valves for steam car heating. Among the large orders received recently are those from the following railroads: Pennsylvania, Boston & Albany, Connecticut River, Lehigh Valley, New York, Susquehanna & Western. Also from the Martin, Sewall, and Graydon car heating companies.

* * *

A good many engineers and firemen do not like the extended front and open stack for the reason that it throws out a shower of dirty water when the engine is first moved, unless handled very carefully. Some roads have a one-inch pipe tapped into the lowest point of the exhaust passage, and fitted with a taper plug cock connected with the cylinder cock rigging to open and close; this drains off most of the water and is a good idea.

* * *

Pedrick & Ayer, of Philadelphia, have printed a small slip which they enclose in their letters and shipments, in which they ask repair shop employes and engineers who have invented any new tools or appliances peculiar to railway repair shop work, or who know of anybody who has, to communicate with them, with the view to manufacturing on royalty or other satisfactory arrangement. They have lately bought ground on which they will build new and greatly enlarged shops.

* * *

The snow-plows and flangers are abroad in the land, but not as thick as usual at this time of year. While a fall of eight or ten inches in England often blockades its roads, as many feet of the beautiful on some of our Northwestern roads do not discourage the management or keep the trains from getting through in fair season. The devices for handling snow are now so perfect as to discourage travel but little in the most rigorous seasons and snow-mantled districts.

* * *

We recently went through the shops of the B. & A., at East Albany, and found everything about the place clean and neat, shops newly whitewashed and windows clean, all tools wiped up. There were twelve engines in the shop for general repairs, and were of all classes, some old Hinkleys with out domes, and pumps under cab run by a crank on the main pin; others of the latest designs. The 45-stall round-house was full of engines, and as soon as one went out another took her place. We shall have occasion to mention many labor-saving devices we saw there at another time.

* * *

This paper is in no way connected with any order or insurance scheme, but we want to say right here that it is our advice to every engineer and fireman to insure their lives at once. You are young and can get in better now than when old age creeps on. Married or single, it is a good thing. The insurance systems of the two great Brotherhoods are fine examples of what men can do for themselves and their families. If you do not belong now, and can do not put it off. We wish the round-house and repair shop men had half as good a system; they ought to try and organize.

* * *

Engineers running locomotives with open cabs, common eight wheelers, know what a nuisance the opening of the fire door is. The light blinds a man so that it is almost impossible to see ahead. The writer saw a nice little device on a Boston and Albany passenger engine, that made him wonder why he never thought of it himself, and that was a shield of sheet metal about one foot square, soldered onto the gauge cock dripper in such a way as to keep the glare from the open furnace from the engineer's eyes. It costs nothing, is not in the way, and must be a great relief at night.

* * *

At the Rhode Island Locomotive Works, a number of new engines are being built that are lagged all over boiler and dome with an asbestos mortar that is easily applied and makes the job all one piece. The preparation is put on while the boiler is under steam, and a couple of days are needed to apply it properly. It is claimed that it is not necessary to remove it when the engine goes into the shop, as the least leak is shown through it, and a piece can be cut out, the leak repaired and replastered. It cannot fail to be a better job than wood, and is fire-proof.

* * *

On a recent visit to a railroad blacksmith shop, the foreman pointed out two steam hammers at work and said: "Now there are two hammers, by two different makers, just the same size, yet this one on the right will do a great deal the most work, not because it is faster, but just on account of the design of that anvil base; you see, the other one is very large, and has a big hoop close up to the anvil proper. We have no end of trouble to do anything on it that is very crooked, or has legs or arms to it. Now the other one has as much surface on the ground, but is long and narrow at the anvil; we can stick the pedestals of a big frame over that one and get the anvil in the corner for a top blow." This is a point that makers might well look into when tools are to be used in a repair shop.

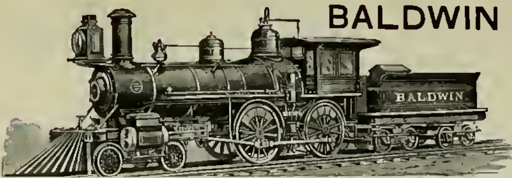
* * *

There has been a number of slight accidents and runaways in cold parts of this country by air pipes about the engine freezing up; this is especially true of such locomotives as carry the air drum at rear or on top of tank. Drip cocks are provided, but are not always in the right place. The drum and pipes should be carefully blown out every trip, and greater care used in keeping air pump properly packed in winter than summer.

Steam and water coming from packing gland on steam cylinder is sucked in at air gland. A ring or "necktie" of three or four strands of wicking tied closely around the piston rod will catch a great deal of this water and send it outside of the gland instead of down around piston. Do not use too much oil in air cylinder; use a thin well oil, and not very often.

* * *

Employes of locomotive repair shops do not need to be told to what an extent bushings are used in repairing locomotives, especially the link gear. There are about as many different ways of making bushings as there are shops making them. Some use steel and temper them; some bronze, a few cast iron, but most of them use wrought iron and case-harden them. This is the cheapest, as a rule, and the hardening is easily drawn to rebore, etc. The different processes of making and finishing bushings are expensive and slow. Bushings for locomotive work seems a small thing to make a specialty of, but John S. Leng, of this city, has put upon the market a series of these bushings of seamless, cold drawn, steel tubes, made to such nicety as to size, that no turning is required on the outside, and the inside merely needs grinding out same as any bushing. These bushings will take a slight temper and can be case-hardened.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

ANNUAL CAPACITY 650

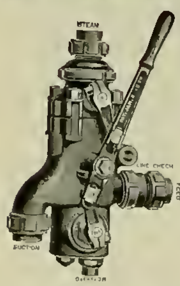
LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable.

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, Etc.

Illustrated Catalogues furnished on application of customers.

BURNHAM, PARRY, WILLIAMS & CO., Proprietors, PHILADELPHIA, Pa.



OVER 100,000 INSPIRATORS SOLD.

THE "NEW IMPROVED"

Hancock Locomotive Inspirator.

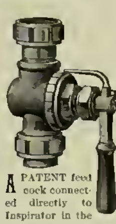
Awarded the FIRST PRIZE, A GOLD MEDAL, at New Orleans Exposition, 1885.

The Most Perfect Locomotive Boiler Feed.

Most Durable.

Most Economical.

Most Convenient.



A PATENT feed cock connected directly to Inspirator in the cab.

Send for descriptive circulars to

VOL. I. NO. III. NEW YORK, MARCH, 1888. $1.00 per Year. or 10c. a copy.

The Silvey Electric Headlight.

We illustrate herewith the lamp and reflector of a new electric headlight recently perfected and put on the market by the Silvey Electric Co., of Lima, O. The difficulty with former attempts to u e electricity for headlights has been that the constant jar of the locomotive disarranged the feeding mechanism of the carbons, made a flickering light, and one that could not be relied upon; many of the earlier kinds were also too complicated for care of engineers. In the headlight here shown the common reflector is used; behind this is an iron upright, on which slides the two carbon holders; these are fed toward each other by the right and left hand screw, shown immediately back of upright; this screw is worked by the ratchet wheel and dog shown at base, and is regulated entirely by the current—no hand manipulation being necessary after the carbons are once adjusted. The current is furnished by a small combined engine and dynamo on one base and under one cover, the complete machine occupying a space of three feet by fourteen inches and eighteen inches high; it is placed in any convenient place on the locomotive; preferably on left running board, in front of cab. The light has had a very severe trial for some months on a switch engine, and has given satisfaction. The feed being a solid screw, and positive, the lamp will burn as well on its side, or upside down as in any position.

Fancy Penmanship on Train Orders.

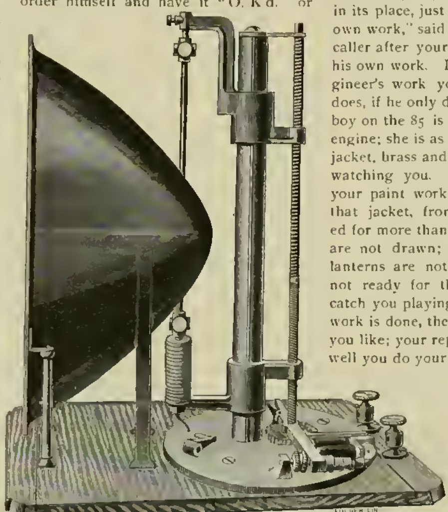
Just about once in so often the "press" of the country record a fatal calamity resulting from a misunderstanding of train orders.

Train orders, as a rule, are not carefully enough read. Train orders are not carefully enough written. A fatal collision recently occurred where the conductor read Somersett for Summit. This may have been caused by poor or fancy penmanship, or poorer attention in reading. Many operators try to see how many flourishes and how much fringe they can work on to a train order, and the idea should be sat down on by train men.

The writer was one of the star performers in a little circus of high and lofty tumblers caused by an operator giving an order where "*2nd* section number 29" was made to look like "*and* number 29." First 29 was the ringmaster that made all hands hunt for plowed ground.

Too much care in writing and reading train orders cannot be used.

The writer has often thought that some system of orders where the conductor or engineer had to write the body of the order himself and have it "O. K'd." or



NEW ELECTRIC HEADLIGHT.

"Corrected" by the operator would prevent mistakes in reading and understanding orders. Its greatest disadvantage would be that it is a slower process than that now in use.

There are now in successful operation several systems of receiving and sending telegrams on moving trains, and in this case the order received could be written by the conductor if necessary.

Mistakes and blunders in this line are calling for many victims per year, and means should at once be taken to cut down the death-roll.

A Fireman's Lesson.

On a recent trip through a roundhouse with the master mechanic in charge, we came to a man busy cleaning the headlight.

"Where is your engineer?" asked the M. M.

"He said he wouldn't be down to-day," answered the fireman.

"Well, you put that reflector right back in its place, just as it is, and go at your own work," said the M. M. "I'll send the caller after your engineer, and let him do his own work. I don't care how much engineer's work you or any other fireman does, if he only does his own first. That boy on the 85 is packing, but look at his engine; she is as bright as a dollar, paint, jacket, brass and front end. I have been watching you. You have not cleaned your paint work for a month. Look at that jacket, front end, stack not painted for more than a week. Your supplies are not drawn; your signal lamps and lanterns are not filled; in short, you are not ready for the road. Don't let me catch you playing engineer till your own work is done, then do as much of his as you like; your reputation depends on how well you do your own work, not the engineer's." Don't wait for your M. M. to say this to you before you tumble.

Boiler washers can save lots of trouble on the road by a little care in washing out. Where there is lots of scale, and especially where fire boxes are above frame, deposits of mud and scale in driving boxes and eccentrics are an element of danger. A little care—a piece of sheet iron or an old piece of gunny sack under a wash-out hole, would be a great improvement over the rough-and-ready methods so commonly used.

If your fireman wants to clean the paint, jacket or bell, or paint the stack, while running down grades, do not allow it unless something out of the general run is going on. It is a dangerous practice in more ways than one.

Buying Polishing Material.

We find that there are hundreds of firemen on many roads throughout the country that are buying and paying for, out of their own pockets, certain kinds of polishing material that will do better work with less hard labor than the crude cleaning materials usually furnished.

Railroads can buy the best of cleaning compounds, in bulk, very cheaply, and if they have firemen that are willing to keep their engines clean by paying more for it at retail, they would doubtless keep them cleaner if furnished with more dope at no cost to them but their labor. It would be just as fair to expect the company to buy the fireman's clothes, as for the fireman to purchase needed supplies for the company.

Purchasing agents would serve the interests of their companies to find out what cleaning compounds are so badly wanted by firemen and supply them.

How Shall They Die?

Firemen who take great pride in keeping the brass, paint and windows in the interior of their cabs clean, are just now deeply interested in the discussions going on as to the best mode of executing criminals, in the hope that roundhouse men who fire up locomotives and keep the door half open to smoke up everything, will soon come under the head of those in immediate danger. So far as heard from, the boys seem to prefer something slow and lingering.

Comfort Wanted.

Consolidation engines, as a rule, have very poor seats for engineers and firemen. They are hung on side of cab like a table leaf, and cannot be cushioned too heavily without being in the way while down. Consolidators usually have small wheels, and do not ride any too easy. Some men put a coil spring on the foot rod that holds seat up, this helps; others put a small leaf spring on side of cab also—this hurts. A man naturally leans out of the window when sitting down, and when the seat tries to absorb some of the "lift" it jumps up and down and tries to tear a man in two at the third rib, as his shoulder is firmly braced on the arm rest. A simple spring seat that carries the arm rest with it would let a man "teter" a little and not break his back.

The Half-Notch.

Many engines are now being built with the May style of double-latch reverse lever; this admits of very close regulation. The old idea of arranging a quadrant to cut off at a certain number of inches was generally superseded by quadrants cut as full of notches as possible; then thinking engineers began to put the handle of a set screw wrench in the notch and let the reverse lever rest against it; then they got to making a regular little piece to put in the notch, and then came the double latch that makes it possible to work *between* the close-cut notches. The best results in stationary engine practice are obtained by automatic engines whose governors control the point of cut off instead of throttling the steam. In a locomotive the engineer is the governor, and that he should get better results by handling the reverse lever than the throttle is but natural.

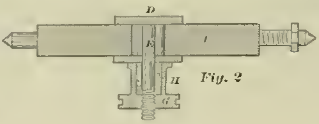


Fig. 2

Driving-Box Center.

By Hiram R. Jones.

This device is very convenient for getting the center of a driving box. The steel points A and B, Fig. 3, are firmly set against one side of the bore of the box by screwing the set screw C against the opposite side. This gives a bearing at three points, and holds the body of the tool very firmly in its place.

A fine center D is made on the flat head of the steel bolt E. The hole through the body F is one-half an inch larger than the stem of the flat-headed bolt, so as to allow a lateral adjustment of the same. It is held fast by the milled thumb-nut G. By loosening the grip of this nut a very little, the tension of the spring H will maintain sufficient friction on the head of bolt so that it will not slip of itself, but will allow the center mark to be adjusted by a slight touch of the finger. When the adjustment is complete the nut is screwed tight.

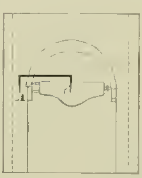

Fig. 1

In connection with this, I have found that a rigid tram made of ¼ inch round steel and six inches between points, to be very handy to transfer the center to face of box as at A, Fig. 1.

This tram has the advantage of being a known distance; is always the same; does not have to be set, and will not change as will a pair of dividers. When the point A is established, it may be used thereafter and measurements taken from it when center is removed from the box.

Fig. 3

A Handy Injector Kink.

Many roads have adopted some means whereby the engineer could use both injectors from his own side of the cab. Some use a non-lifting instrument on the left side, and put the throttle and lazy cock on the right; others put two non-lifters on the right side; and still another scheme is to use two lifting injectors, one in front of engineer (where boiler comes through cab), and the other across boiler head. Any of these arrangements prevents the fireman from operating the instrument, and would call for an entire remodeling of pipe fittings where it is desired to make the change on engines already in service. On the Lehigh Valley road they have the best arrangement we have yet seen. There they use only injectors or inspirators that are operated by one lever, and one is placed on the left side of cab, as usual; to the handle is attached a short rod, the other end being jointed to a lever which is fulcrumed to top of boiler and terminates in a handle convenient to engineer. By pushing this lever ahead, the left injector is started from the right side, and the fireman can use it from his side just as well. It is cheap, handy and efficient.

Headlight Dope.

An old engineer told the writer the other day that he had used for years a headlight dope of his own. He has a bottle of alcohol and lampblack mixed about as thick as paint. He wipes the reflector out with a coating of this and the alcohol instantly dries, leaving the lampblack in splendid shape to polish with. He does this with the reflector in lamp, and does not take it out to clean more than once in three months. It is worth trying.

The Spring Automatic.

Another railroader has been educating the public (?) by telling a Chicago paper how the automatic air brake works—the air holds the brake *off*, and when the pressure is deduced the springs slap it *on*. Young mechanics and railroad men who do not actually have to use or repair this brake, believe this, without further thought.

As a matter of fact, no springs are used, except a light one to hold the brake off; the automatic principle being to store air on each car in a small drum, connected to the brake cylinder by a pipe connected through a triple valve; this valve has a piston valve that is forced *up* when air is admitted to train pipes, and is held there, allowing the air to *pass* it and fill the drum through a small opening, and the pressure on one side balances the other, by suddenly reducing the pressure below this piston; the air above forces it down and opens communication from the drum to brake cylinder. The air does the work, not the springs.

If engines without air, or those with it, that break down on the road, should get hold of a train of spring brakes, the boys would have some fun prying the shoes away from wheels and blocking them so.

The Canadian Locomotive and Engine Co., of Kingston, Ont., built 18 locomotives during 1887, making a total of 332 manufactured by this concern.

Many Uses for Compressed Air About Railroad Shops.

Since the adoption of the air brake on most of our principal roads a small air plant has, in many cases, sprung up about each shop, for one purpose and another, generally using one or more air pumps as compressors. N. W. Sample, superintendent of motive power, of the D & R. G road at Denver, Colo., uses it more extensively and successfully than in any place we have visited.

It is customary in these shops to use three or four pumps—generally ones just repaired are tested in this way. They are located on an iron frame in the machine shop and are run by direct connection to boilers. There are one or two air drums, same as used on the locomotives, in different places in the shop and a line of pipe is hung overhead, the entire length of shop, with pipes coming down at convenient points and provided with a globe valve and hose connections.

They have at this shop three small, plain, slide valve engines mounted on a little, truck, having four 8-inch wheels and provided with a handle to facilitate moving from place to place; these engines have a number of different sized pulleys, easily changed; and are used for many purposes; they are connected to air system by hose and exhaust into the open air. They are rigged to do all the drilling about boilers, frames, etc., and for a thousand purposes where a small, independent power is needed. Pipes and brakes are tested, dirt is blown out of planer slots and drill holes, cylinder boring machines are run, etc., and, when an engine has been rebuilt, her boiler is filled with sixty pounds of compressed air, and with this she is run out of shop and to yard without fire, smoke or dirt; at the end of the shop a hose is connected to a T in the blower pipe and the draft kept up enough to prevent smoking up cab while fire is being built

This line of pipe extends through both the roundhouses, and a pipe comes down at every post, the air being always used when firing up dead engines; it saves time and is conducive of cleanliness.

Underground pipes conduct air through the coach yard and shop and to pits in freight car repair yard using the common hose coupling; when an air brake or any of its parts are repaired, or reported out of repair, the hose is coupled and the brake tested.

The boiler shop and blacksmith shop are also amply provided with air pipes. One of the main features of the boiler shop being the drilling of holes in firebox, etc., by the air-operated engines and flexible shaft.

At another shop on the same line, a pump just repaired is connected to boiler and tried, but instead of bolting the pump to frame by bolts, the same as on a locomotive, the bolt lugs of the pump are merely hooked into properly made hooks on the frame, saving time and being amply secure for testing purposes.

At the N. Y., L. E. & W shops at Jersey City, they put up the pumps to test, but bolt to a frame. They have an engineers' brake valve, auxiliary air drum, and a brake cylinder connected. Here the road men can go and practice handling the brake, and, having the entire equipment under the eye, can see just what results are obtained by a certain manipulation of the engineers' valve.

Such plants are very inexpensive, and of inestimable value to a shop.

High Locomotives.

We have received several letters from enginemen, on both sides of the cab, asking for an explanation of the advantages, disadvantages, safety or dangerous features of locomotives with high centers of gravity.

Locomotives with extremely high centers of gravity are of recent design and are fast coming into use.

Their principal advantage is that they ride much better than engines with low centers of gravity; they are much easier on the track, their boxes and flanges. The boiler being well up off the frame gives the designer more chance to set the proper springs, etc.; is consequently easier to oil, inspect and clean. All the disadvantages we ever heard urged against them is that "they don't look natural"—a harmless form of prejudice.

It is well known by engineers that locomotives that will "roll" generally ride better than those that will not. Engines with boilers set well up are noted for their ease in riding. When on a curve, an engine like this would "roll;" the boiler and frame, being the greatest weight, would resist the pull of the wheel flanges and try to keep on in a straight line, but the wheels, held down by the weight and turned by their flanges against the curve of the rail, pulls the monster above it to one side; this causes the boiler to roll or lurch toward the outside of curve, and this roll, in a high engine, is transmitted by way of the springs in a more nearly *downward* motion on to the boxes of the wheels. The shock is on the springs and on the box in such a way that they can move up and down in the jaws of the frame. Now in a locomotive with a low center of gravity, and under the same circumstances, the shock from contact of flanges with rail at a curve would be received more on the *side* of the driving box, the weight of the boiler, being low, acting as an immense hammer on the box and flange. Heavy engines with low centers of gravity often break axles from this cause alone. It is easy to see that when a blow is absorbed by a system of springs it must be much easier on boxes, flanges, track and men than one that strikes from the shoulder.

Not You.

There are over 6,000,000 people in the United States who can neither read nor write; over a quarter of a million of them in the State of New York. We believe there are very few men on locomotives who cannot read, and hope the few, if there are any, will be all gone before another issue of this paper makes its appearance. Men cannot run locomotives in road service who do not read, and we hope that if there is a fireman in this broad land who cannot read, that he will speedily learn. Any man who will try can learn to read ordinary newspaper print and to write his own name in two to four weeks by devoting an hour or so a day to it. There is no possible excuse for a young man to not be able to read. False pride may prevent, but real pride ought to overcome the false. There is no confession more humbling than that of illiteracy. Go to any one you know, old or young, rich or poor, male or female, make your confession and state your determination to get out of the dark and ask for a start—you will not be refused once in five thousand times. If you were pitched into the sea you would try to swim; you are in a sea of darkness—swim.

A Better Way.

On a recent visit to a railway repair shop we saw a large mogul engine jacked up, and several mechanics were at work fitting up driving boxes, shoes and wedges. When a wedge or shoe was fitted and found all right, it was held in place by a common cast iron clamp around the frame, and when a driving box was fitted, it was tied up to frame by a piece of rope. A better way to hold driving boxes is to bend a piece of ¾ round iron in the shape of a staple and let one leg rest on top of frame and the other support the box by hooking under the brass. They are not in the way of the centers and are easily put in or removed. A very neat device to hold shoes or wedges is made by making a T-headed bolt, threaded on the long shank, and with the cross-head wide enough to cross the shoe and have a slight projection on each end to prevent it from turning; run a common nut loosely on the long shank and slip the bolt into a short piece of gas pipe. A few turns on the nut against the pipe holds both shoe and wedge, with no projections in the way of other work.

A Coal Hopper.

A chute, about as high as the bottom of fire door, and about as wide, extending from boiler head back about three feet, is a new idea on coal burning engines. The bottom of chute is sloping enough to allow all pieces of coal that are dropped to slide into the furnace. The door is placed as low as possible. We understand the idea was gotten up to prevent the necessity of raising the door where wood burners were changed to coal burners. We fear, if obliged to fire one of these mills for the first time, we should be apt to aim high for fear of our knuckles.

Baldwin Locomotive Works have recently built engines with as much as 44,000 pounds on the front trucks — almost enough traction wasted here to employ another pair of cylinders.

Not a Safety Valve.

Not long since the writer was waiting for a train at an Eastern city, and naturally drifted out into the yard, where there were a number of locomotives standing.

It was quiet and three or four engine crews were gathered around a U.P. car provided with the automatic air freight brake. This brake is provided with a ten pound pressure valve, set on top of a ½ inch pipe and fastened to the end of car about four inches from the roof. There was no one in the crowd who knew what its exact use was; the firemen crawled under the car and examined it and climbed up the ladder and looked at the little brass valve, turned the cock a few times and talked about it. The engineers said nothing and looked wise. Finally one of the firemen exclaimed, "Here comes Uncle Tom, he'll know!" Uncle Tom climbed down off a passenger engine and came over to the crowd and was at once asked about the "pesky little cock on the end of that long pipe?" Uncle Tom took a look, changed the quid of weed to his other cheek, and remarked, "Why that is a safety valve to keep some of these young, reckless bucks from skidding wheels with the automatic!" The other young engineers looked at the firemen with an "I told you so" gaze, when they had not said a word about it, and all hands seemed perfectly satisfied with the explanation.

Uncle Tom was off his base. Now we want to kill two birds with one stone, etc. In the first place there are too many Uncle Toms whose word is accepted on all such subjects. Second, it is harder to un-learn a thing learned wrong than it is to learn right in the first place.

Uncle Tom has had experience and is talkative, but has been busy and getting old, and the business of railroading being young, in comparison, has got ahead of him.

The great developments and improvements in railroading have not all been made on one road, at one time, or in one place. Uncle Tom has not traveled enough to "keep up," nor could he if he tried. He would be spread out too thin. Good papers devoted to special branches of railroading have a corps of men, each keeping up a certain department, and if they should answer such a question as Uncle Tom did, in the way he did, they would be held up to the world and laughed at by a hundred other papers; hence they are careful. Refer such questions to good papers in your line, then discuss their answers and you will soon be well posted and posted right.

Now that ten pound pressure valve will not keep you from "skidding" wheels at all; it is merely a valve having a weight on top and attached to the exhaust passage of the triple valve under the car. It is used on long, heavy, mountain grades. It is well known that to re-charge the auxiliary cylinders under the cars it is necessary to release the brake; on such grades the train often gets beyond control on this account. To prevent this the valve mentioned is used. Ordinarily this valve is "cut out" and the brake releases into the air, but on a grade the brakemen run along over the train and "cut in" a few of these valves and the valve keeps a pressure of ten pounds in the brake cylinder, and the auxiliary is then re-charged easily. Of course on ordinary grades this is not used, and at a station, etc., would prevent the train from being moved. It is a safety valve coming down, but not a safety valve going up.

Handy Crane for Locomotive Repair Shops.

At the Worthington Hydraulic Works, Brooklyn, we noticed several handy, cheaply-made lifts that struck us as being the very thing for roundhouse and railroad repair shops. The device was simply a piece of common brass pipe four to six inches in diameter and as long as lift required; they have a head screwed on top with a ring in it to suspend them by, and drilled to admit air; the bottom head is provided with a packing gland through which works the piston rod; this has a leather packed piston head on one end and a simple hook on the other; it is operated in some cases by water and in others by compressed air. When suspended over a lathe on a track allowing for movement across and in the direction of the length of the lathe they are a very handy crane. It makes no difference where the load is, as the piston cannot be cramped out of line with the cylinder.

At Worthington's they handle the flasks in the foundry by one of these cranes on a traveling frame; it is worked by air, and is very quick and accurately handled; the hose supplying it runs over pulleys, and has a loop that takes up slack hose by a weighted pulley.

There is scarcely a railroad shop in the country where they do not have air or water pressure, and one of these simple contrivances can be easily made by any mechanic, and would be just the thing around a roundhouse to remove locomotive stacks, cabs, etc. They can be used in any position, vertical, horizontal or at any angle, and a man can shoulder one and carry it any place. They were designed by Mr. Flynn, general foreman of the Worthington works.

Brained, Yet Alive.

Do you see that big fat engineer over there? Does he look like he had his brains knocked out? Hardly. Well, you ought to hear him tell about it, but he won't do it if you ask him, so I will give you the story as he told it to me. It was a long time ago, when he was firing on a new road in one of the Middle States. One night as they pitched over a long hill he took the big tallow pot and went out on the running board to oil the valves—that was before the time of inside oilers. I suppose he was a little sleepy, and, being used to the work, a little careless, and the result was that he walked off the end of the footboard and went headlong into a sandy cut. The engineer missed him in a few minutes, as he did not come around to oil the right valve, and stopped. As the train was running very fast they had no idea but that the poor fireman was dead as a clam. When our fat friend struck *terra firma* he woke up, rolled over a few times, and finally found himself in a sitting posture in the ditch. He says he was dazed, and hardly knew what had happened yet, but feeling something warm running down his face and neck he thought to himself, "it must be blood; I am badly hurt." Says he felt no pain. Then he put up his hand and felt for the wound—it was bright moonlight—and, as he brought his hand down in front of his eyes, he saw that the clotted stuff upon it was white instead of red. "It is my brains," he said to himself, "and I am a dead man." He said then he saw the lights of the train coming back for him, and wondered if he would live till they got there. They found him seated so, and kind hands lifted him tenderly into the baggage car. With a trembling voice he gave the engineer a message for his mother and a certain girl that lived three doors west of his home, and bid his old friend good-bye. About this time a small man elbowed his way through the crowd, and the conductor said: "Here is a doctor." "Bring a good light," said the new master of ceremonies. It came, and the doctor commenced to feel of the victim's legs, arms and shoulder blades. "I'm all right except my head," said Fatty. The man of pills run his fingers lightly through the clotted mass on the bushy head and said: "The skull is not fractured; why, this is grease—tallow." Well, then that engineer just let out one war whoop and went into hysterics, and everybody laughed till our fleshy friend got mad and broke out of the crowd and went to the engine. It seems that when he fell, the tallow-pot, as usual, fell on top, and from that day to this he has gone by the name of "Tallow-pot."

Getting Left.

Where engines run, "first in first out," it is a very good and safe scheme to go home and go to bed as soon as in, even if you can figure that you won't get out for twenty-four hours or more—you may get fooled; other engines ahead of you may not be repaired in time, accidents may happen to others going out, men may be sick, and before you have closed your eyes the caller may be after you. Don't get left. Sleep first.

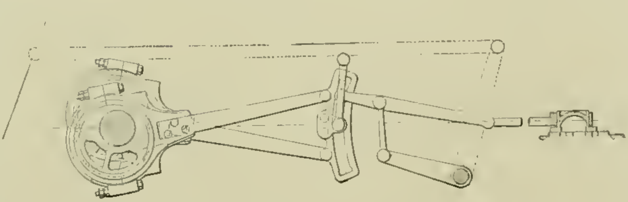
In riding over several lines of road during the month we failed to strike any cars so well heated as those on the Reading road. They use a common stove hung under the car.

Art Critics on the Locomotive.

Sometimes it is comical to hear criticisms on road matters in a roundhouse, and sometimes the most critical of the critics learn a thing or two on little matters which they before thought they knew about all there was worth knowing.

Sometime since the writer was an interested listener to some rather severe and comical remarks about a large, colored advertising picture of a locomotive. The boys poked fun at the artist's arrangement of parts in cab, when really we have rode on and run locomotives arranged much worse. One young man pointed out the fact that the link was curved toward the front end instead of back, and then the laugh on the artist was long and loud, but was suddenly checked by the discovery that the branch pipe from pump entered the smoke arch instead of the side of boiler. Then you ought to have heard the comments. About this time an old-time engineer came in to register, and the boys pointed out the paper engine with the links "crooked the wrong way." The old man glanced at it and remarked that it was all right, and told them all to look again. They did, but nothing was right as far as they could see. "Where is the rocker box?" asked the old man. They laughed again; the picture showed no rocker arm. The old engineer told the boys he had run engines like that, and drew on the bulletin board a rough sketch something like the one below, and said:

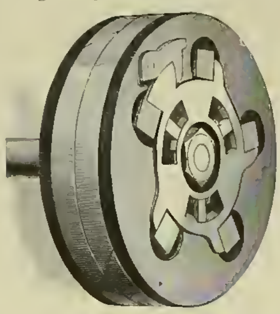
"Boys, that is a direct-motion engine. Do you see the top of link hanger is pivoted to the frame instead of arms of tumbling shaft, and the block is moved in the link instead of the link over the block; the link, of course, is curved the other way, and its radius is as a part of a circle drawn from the joint in valve rod to center of link. The tumbling shaft arms are connected by hangers directly to valve rod." The boys said no more about link, and the old-timer gathered up his dinner-pail and a roll of dirty overclothes and said: "As for that check on side of smoke arch, you have only to go over the other side of the creek and look at some of the old switch engines there; their feed pipe goes through arch and into flue sheet above flues and back about half-way to fire box, and was supposed to be a feed-water heater; you fellows want to 'cast about' a bit and pick up some different ideas than these new-fangled ones on this new road; study up, and when you 'get stuck' come to the old man and—lend me a chew of the golden leaf!" The weed was produced, sampled, and the boys gathered around the stove and told lies about fast runs their mills had made, and the aged educator buttoned up his corduroy coat and waded out into the snow.



DIRECT MOTION VALVE GEAR.

New Piston Head Bolt Lock.

The cut represents a new, novel and cheap lock for piston head bolts, the invention of Jos. Wormald, Missoula, Montana Territory. It is made of iron or brass, generally the latter; it is cast and



needs no finish whatever, not even filing up.

It is held in place by the three bevel-headed bolts, which are cast on the follower head of new pistons and tapped into old ones; the hook is driven in and keeps lock plate tight against bolt heads. It takes up no room—engines using it having the same clearance as before. It is very handy, needing no special tools to apply or release it—can be done in two minutes with a soft hammer.

It is in extended use on the Northern Pacific R. R., and is the invention of a practical mechanic and shop foreman, whose address is given above.

Is There Any Hope?

We are in receipt of a well-written and interesting letter from a young man on one of our Western roads, who says he is a fireman and has been for over three years, is temperate and loves the work, but ends by saying:

"It is the custom to promote the oldest firemen, regardless of any other qualifications, except in a few cases. Now I do not think I have got the throttle fever at all, but I feel as if I could run an engine better than many men who have merely shoveled coal for seven or eight years and never spent a day about the shops trying to learn how the engines were made, repaired, etc, or who never read or study the business. I acknowledge that I am ambitious to be an engineer, but I want to be a first class one or not at all. Had I better go to some new country and begin again? Is there any use or any hope in staying here?"

There are many young men in the same place that our young friend finds himself. We want to give this young man the right kind of advice, and let all who find themselves in his place profit by his case.

That it would be better to remain at home there can be no doubt. Take a trip next summer, study the engines and men in other parts of the country, and you will come home better satisfied with your own lot. Keep up your reading and study of your business—it will become useful to you when you least expect it. Study your business from your own standpoint, observe closely, and above all, be so busy that you will not have time to think of those years yet to fire; do your work well on the road and keep your engine clean. Be *conspicuously useful* to your engineer and to the officers of your department. You will be promoted because you are a good fireman, not because you are a good engineer.

Watch your work and chances to improve yourself, and do not think of its results. Somebody else will be watching you.

Do not put your nose to the grindstone, but take a certain amount of enjoyment—select your pleasure as you do your clothes—it will pay better to spend $2 to see a good play than 25 cents to see a low variety show. Buy books, not all mechanical, but good, wholesome story books, entertaining and instructive. If a fine painting is on exhibition in town, take it in and let the circus go. Seek the company of ladies, and avoid that of mere females. Take needed rest as soon as you come in, and be ready to go in an emergency, and thus establish a good reputation at the roundhouse. Promote discussion on locomotive subjects among fellow firemen, and thus inform yourself and establish a reputation as an intelligent engineman among a class you will work with. If you have a room, make it a home; have a fire in it, have books, pictures, magazines, and you will soon come to seek the comforts and enjoyments of that room rather than the streets. Your life, your conduct, your abilities will soon be noticed, and promotion follow. If it comes only with age and your "turn," you will find yourself a better informed man and a better engineer. There is hope, there is a chance for earnest workers in this line. The next generation of locomotive engineers will be a better one than the present, as the present is better than the past. Strive to be near the masthead of the craft, not a mere muscle clinging to its bottom.

Many of the locomotives now being built have the entire back boiler head lagged and jacketed. It makes the cab more endurable in summer.

New Application of Tire Heater.

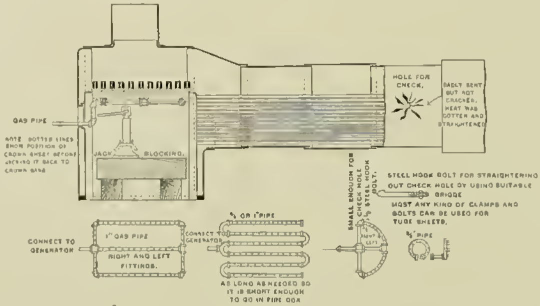
The tire-heating apparatus patented by Messrs. T. W. Gentry and G. W. O'Brien, of the Richmond and Danville Railroad, and manufactured by Pedrick & Ayer, of Philadelphia, Pa., is proving itself to be a very valuable and economical appliance for locomotive and other repair shops, where a quick and cheap heat is needed to straighten iron and steel boilers, crown sheets, tube sheets, smoke boxes, extension fronts, tanks, etc., where engines have been in collision, or crown and tube sheets sprung, from burning or other causes. The fact that the gas for heating is so cheaply and easily generated, and safely handled, and can be conducted in ordinary gas piping of any size from ½" to 1¼", within a reasonable distance of the generator, makes it the most convenient means for getting a quick heat in any place which would be inaccessible to the ordinary charcoal pan and bellows.

The great advantage this apparatus has over all ordinary gas heating appliances is, that the jets, when lighted, will stand a pressure of 25 lbs. to 40 lbs. of superheated compressed air as a blast, and, owing to a peculiarity in the extremely rich gas generated, this air is conducted through the same pipe that takes the gas to the burners.

Every mechanic who has had a *burned* or *buckled* crown sheet, or a *sprung* tube sheet to "get back," knows what the old charcoal, or coke pans, or hearths, with their clumsy supports, and the old bellows, or even small hand bellows, are; and he also knows that after he had worked hard to get the heat where he wanted it, and was ready to strike, or jack, as the case might be, he found his fire of glowing coals, and his old irons and fire pans, etc., right in the way, and all to be moved before he could get at his work; meanwhile his heat was waning and growing beautifully less each moment. With the tire-heater attachments, it is very different. A cheap burner of any desired shape can be made of ordinary gas pipe and pipe fittings; the pipes forming the jets being simply drilled with $\frac{1}{16}$" or $\frac{3}{32}$" holes. In this manner, a square, oblong, oval, or round fire may be gotten, and by suitable bends, elbows, returns, etc., any size or shape may be given to the fire.

This jet, or series of jets, are connected to a stem, or pipe, and this in turn to the gas pipe leading to generator by a union joint placed convenient for uncoupling quickly, and a cut-off cock having been provided near at hand, the whole thing is under perfect control.

The following jobs, all familiar to repair shop men, have been successfully handled by this means of heating, viz., crown sheets of 16 x 24 and 20 x 24, locomotives with sheets 60 x 35 and 100 x 40 that have been badly burned and forced or sprung down, were heated and jacked back with hydraulic jacks to their original positions without cracking or straining. Tube sheets which have been bent in from collision were heated and pulled out to original position; smoke boxes and extension fronts, which were stove up from butting, were heated and straightened; and one job that deserves special mention, which was neatly and successfully accomplished, was restoring to its original form a portion of the barrel of a locomotive boiler of ½" Otis steel, which had been badly bent in by the *checks* having been driven back, and wrenched off in collision. So nicely was the heat gotten in the exact spot needed, that it only required the threads in the hole to be freshened up, and the new checks set as square as before the accident.



Engineers to the Front.

Under this heading some papers and magazines have been lauding the great invention (?) of a new railroad reformer who is going to put another cab on a locomotive—immediately back of the stack—and place therein a new thing, for locomotives—a pilot. The inventor describes him as "a man to study the time cards and rules and to merely think of his train rights, receive all running orders, etc. This relieves the engineer of all trouble except to look out for the manipulation of the locomotive itself; the two cabs are connected by speaking tubes, etc., etc." It is needless to say that the inventor is not a practical railroad man. There is scarcely a change that we can imagine that would be harder to make and a bigger nuisance when made than this.

Engineers are already well aware how men will advise trials on runs that they would not dare attempt themselves. How many a conductor will tell a five-act story in the telegraph office and then rush over to the engine with orders in one hand and watch in the other and ask if you "can make it" to the next station for some fast train; if you have about as many miles to go as you have minutes to go in and decline to try, he will tell you of half a dozen engineers who have made it in less time.

The pilot in his front cab would be able to figure out what the engine *ought* to do on the run, but as to what she *would* do he cannot know. It would help matters a great deal for the front engineer to bawl through the speaking tube to the back engineer, "Come on; we can make it; it is only six miles and a half, and we've got ten minutes," while the rear man was feeling for water in the lower gauge, with steam at sixty pounds, and four or five flues squirting like a fire engine.

The pilot cannot know the condition of engine, track, train, quality of fuel, abilities of firemen and a thousand other conditions that are always there and always different. It is a poor idea to divide the responsibility of command too much. In a case of this kind there would always be a fight between the pilot to make a record for speed, etc., and the engineer to not overtax his engine. The decision to "go" in a tight pinch must be decided in a second—the decision must be based on experience, knowledge of the condition of every part of the locomotive, how she steams, how the train handles, etc., as well as a thorough familiarity with every foot of the distance to be gone over, the rules governing trains under the circumstances, and the chances of success. If the front engineer and the back engineer agreed on these things through the medium of the speaking tube, the opposing train would be liable to run into them where they stood. There is time for no consultation; it must be decided in one brain and the start made before the thought has had time to get out from under the engineer's hat.

The precaution of another man on the engine to think of these things can be greatly augmented by giving the fireman an insight to orders, train rights, etc.

Make repairs on locomotives so good and so carefully that an engineer can put his head out of the cab window and care nothing for the working details of the machine under him. Let him *use* the engine knowing that she will steam, that the injectors will work, the air pump supply air, and the brakes hold, and he will have time to think of his orders and the rules and figure out his run beforehand.

Do not work him three hours for every one he sleeps; do not pay him such wages as will oblige him to chop his own firewood between runs, and we will risk the engineer alone rather than be hampered with all the pilots on earth.

The Baldwin Locomotive Works are now using a plate cast especially for the place, to mount air pumps on side of boilers. It prevents sparks and dirt from accumulating behind the pump, and, as the jacket is cut out around it, there is no place behind the pump to clean. The old wrought iron brackets were unsightly, unhandy and expensive.

Correspondence

A Boycott Raised.

I am a blacksmith and foreman of a shop on a large road, and I have always thought and said blacksmithing was too hard work and my boy should learn an easier trade; since I read John Alexander's article on fighting against nature, I have been looking around and thinking. I have twenty blacksmiths and as many helpers, most of the latter are middle-aged men and have been laborers; only one boy in the shop who wants to learn the trade. Dudes and women do not take kindly to blacksmithing; others think it hard work. There is now more need of good blacksmiths than ever, and where are they coming from? I honestly believe that in ten years from to-day a first-class machine blacksmith will be getting more pay than workmen in any other kindred trade. Only three of my men are first-class, and they are now getting fifty cents per day more than machinists. I have raised the boycott on blacksmithing; it is a hard, honest, healthy, honorable calling—my boy can be a blacksmith. If he hunts for an easy trade I shall be disappointed.

N. Y. City. ANVIL.

Some Shop and Road Kinks.

The extension smoke box, while it may have some advantages over the short box, yet it has its disadvantages; and while I have never been a friend to it, I am willing to give it its due. We used to think the old Bell stack was a great deal of trouble, it required so much beating to get the sparks out; we had a round club and a piece of 2½-inch gum hose put over it, so as not to bruise the iron too much; but it was a spark catcher, and the extension smoke box is nothing more. One of its disadvantages is the use of the baffle plate; it cannot well be dispensed with; but it throws the flame down to the joints of the steam and exhaust pipes, causing the bolts and nuts to become red-hot. I have seen them almost welded together; then the bolt expands, and the steam-pipe joint leaks. I have known cases where they have had to be tightened every trip, often causing much delay along the road. I tried a cement made of asbestos, fire clay, and cast iron borings, and put a coat three or four inches thick all around and over the joints, which answered a good purpose. It was very hard to keep the joints of spark pipe and door tight, and the least air would kindle a fire that would warp and burn everything it came in contact with; sometimes the joints between the cylinders would let air in, and had to be calked with iron cement.

Another source of trouble was the sand box; the way some of them are made, every time it rained the sand was wet, and it was not a small job to empty four or five bushels of wet sand; the trouble was, the sheet iron rim went inside the cast iron base, and as the boiler maker did not make a tight fit, water ran down the sheet iron and in the cracks at the bottom. If the sheet iron was made to fit on the outside of the casting, it would run outside, and not affect the sand. A valve in the casting at the top of sand pipe (Fig. 1) answers a good purpose, often saving the taking off of the pipes; a wire rod can be run up or down, dislodging anything that may stop them up. A few ¼-inch holes drilled in the sand box lid will let the steam out if the sand is damp, but they must be drilled up so as not to let the rain in.

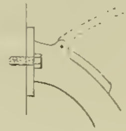


Fig. 1.

Relief valves should be on every steam chest, whether balanced valves are used or not, especially on shifting engines, where they are reversed so often; the pistons act as air pumps, and draw smoke and sparks down the exhaust pipes. A very simple valve, like Fig. 2, I used with good effect; and as it was short enough to go between steam chest and casing, a stranger would never know there was one on; six or eight holes ⅜ or ½ inch were drilled in the steam chest, leaving the center solid for the end of valve to strike against, to regulate lift of valve, and a lot of inch holes ¼ drilled in sheet iron casing opposite end of valve opening.

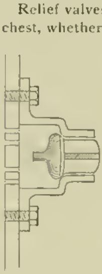

Fig. 2.

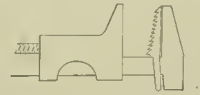
J. J. BINGLEY.

An Engineer's Kit.

Plumbers, carpenters, machinists, draftsmen and shoemakers all have a "kit" of tools, but locomotive engineers very seldom own up to one, yet even a rather poor and careless one will get a pet torch or perhaps a towel of his own.

I have got a kit. I believe all engineers should have one. I will give you a list of some of the tools in mine. I have a fine clock; it cost $20, but I would not do without it for $80. I have a good torch and a stand to put it in, a little box with soap and towel, a small mirror, a hook to keep my orders on, and a little box of tools. This contains an extra screw top for oil cups, two or three corks, a ¼ inch



rod threaded at one end and bent into a circle for a handle at the other end; this is about 8 inches long, and its use to take out the steam valves of air pumps if anything gets wrong on the road, a couple of steel wires to clean out oil holes, a scraper, a couple of small files, a small piece of emery cloth, an extra feeder for oil cups, a ball of wicking, some extra gaskets cut ready for throttle, water hose and other pipe connections, a box of matches, a screw driver, a pair of pliers, a small alligator wrench and a little steel jaw like cut, just as wide as jaw of my 15-inch wrench; by putting it into that I can handle any pipe up to 2 inches; a few assorted sizes of nails, tacks and screws. On the cab I have tacked a calendar, a tin box to hold my time card, and another to hold the coal checks. I find use for all these little things very often and find room for them all. I do not find room for the half-naked pictures of prostitutes that are so common. I do not want them in my home—the cab is my home.

Philadelphia, Pa. A KIT.

Naming Engines.

Your remarks in the January number in regard to the practice of naming engines being revived, will strike a sympathetic chord in the breasts of many persons both in and out of the railroad profession. I remember, some years since, while firing on the Hartford Division of the N. Y., N. H. & H. R. R., where all the engines were named, how passengers and others who were at the depot on the arrival of the "fast line," would descant on the relative merits of the "Adonis" and "Venus." This road formerly ran some of the most beautiful engines on this continent. The tendency now, however, is toward a plainer, though none the less sightly and certainly more serviceable locomotive. The "Arcturas," "Atlanta," "Altair," "Mercury," "Saturn," "Hercules," "Regulas," "Andromeda," and many similar names, are still familiar to the travelers over and persons living along the line and their appearance never fails to excite admiration. Mr. John Henney, the master of machinery of this system, used to derive much satisfaction from the pleasure it afforded his wife, in being allowed to select names for the new engines he built. Let the old custom be put into effect again is the wish of more than besides

"RED BIRD."

The Oily Engineer.

I was interested in an item in your first number on "the oil fiend," as it reminded me of one of the runners I know. He was an oil fiend in the fullest sense of the word—never thought a cup or box had enough oil till it run over. He used to say he would rather waste a little oil than take chances. Oil was his cure for everything—he even put it in the pop or safety valves.

He often came in off the road and said his engine was played out; wouldn't "mind her throttle," "something wrong with her eccentrics," etc.; it was lots of trouble to us roundhouse men until we found out that the eccentrics were all O. K., and that our oily engineer used valve oil and tallow as he did engine oil. We found the exhaust nozzles so badly stopped up by burned oil that the engine could not do her work on account of back pressure. After we got used to the man we always opened the smoke arch door to set his eccentrics, as we generally found one of them stuck in the nozzles (so to speak). A new wiper once remarked to me: "This engineer is going to run her all winter, ain't he?" I said I did not know and asked why he thought so. "He has oil enough on her to last to spring," answered the green hand. I always noticed that these wholesale oilers need more repairs than men who are careful about oil—I guess if a man is careful about one thing he is careful about them all.

ROUNDHOUSE.

Broom Straw Feeders.

I run a very heavy "hog" and for hot pins she was a caution, for about four months. If her pins let up on me for a day, her crossheads would commence. The side rods had common brass cups with wool feeders, the main rods had Dreyfus' plunger cups and the crossheads needle feeders. I changed cups, oil and habbitt, to no purpose; one day the pins would get hot in five miles of a run and the cups would be full of oil; the next day they would get just as hot in the same distance and the cups would be empty; one time I would take out a cup and the plunger would be free, the next time it would be stuck—I got tired. I came to the conclusion that a single small grain of sand would wedge in beside the wire plunger and stick it; the heat from pin expanded the cup and pin different, and that might stick it; the oil was thinner when hot and run through faster, etc.

When I got in I had one cup taken out and a small pipe soldered into it and coming up within a quarter of an inch of the screw cap; this pipe I filled with common broom straws. They do not work in the cup and never stick; they are not affected by the heat or cold; they are easily changed to feed, more or less, by taking out or inserting a straw or two; they catch all the dirt; the oil cannot run out when the engine stands still; they cost nothing; the feeder merely carries down oil thrown upon it. I have them in every cup, on rods and crosshead, and I would not trade them for all the fancy cups on earth. I took out all the screw tops on my cups that required a wrench and put in those with a taper thread and milled heads. I can take any of them off without a ton of monkey wrenches, and they never jar loose.

JOHN REYNOLDS.

Kansas City, Mo.

Packing Hooks.

When Watt and Trevethick and some of those old builders of the first species of steam engine got up hemp packing rings on the piston head and hemp filled boxes on the piston rods, it was thought a great invention. The trouble with the thing was the packing wore and burned out; now in those days steam engines using twenty-five and thirty pounds of steam were called "high pressure," and a piston speed of one to two hundred feet per minute was lightning. Hemp packing did very well then. Iron rings soon exiled it from the piston head, but a lingering delight in a few relics of barbarism has kept up its use for piston rods and valve stems great enough to drain the market till rope-makers had to get out iron ropes and paper strings.

When the first hemp-stuffed box commenced to "blow" and send up a cloud of steam and a few dark flakes of chewed hemp at every exhaust, history tells us that Watt or Duesenberry or What's-his-name tried to repack it, and found that the hemp had burned on to the casting of the stuffing box. The herein-before-mentioned inventor then sat down on the oaken gudgeon of a slippery-elm connecting rod and scratched his head; twenty minutes later he was out in the "smithy" pounding a piece of small iron; thirty-four minutes later he was sitting straddle of the piston rod of that engine, digging out mortified hemp with a modern packing hook.

About 2,000 engine builders are still making stuffing boxes like What's-his-name made, and about 250,000 engineers are probing after lost hemp with the same old packing hook.

There are better stuffing boxes and better packing, but if builders make miniature baling presses for hemp, engineers will keep on destroying good stuff that ought to be used to hang horse thieves and car stoves.

Locomotives with the What's-his-name's packing are a nuisance, first, last and all the time. On steamboats a great many engineers use a packing hook—so-called—that has a corkscrew on its business end, very handy and good on large work. I have found that a sharp, straight rod is better than a hook; it never breaks off; it always gets hold of something, and in prying over the piston rod or valve stem it comes in contact lengthwise, and is not so liable to scratch the rod. I will be glad when good metallic packing will allow me to take home my old packing hook and pickle it in spirits of turpentine and a long-necked bottle, as a relic of about 'steen years of sweat and profanity that are charged up to me on the silvery leafed ledger of the chief time-keeper in the great subsequently.

JOHN ALEXANDER.

Why Flues Leak.

I am a fireman and do not claim to know much about locomotives—firemen have no license to know very much—but I have been keeping my eyes open, however. Last year I fired in Texas, where the water is bad, it is bad enough so that engines only run three hundred miles before boilers are washed out. I fired for two different engineers; the first one was eternally having his flues calked, and I seldom saw the engine go over the division without leaking; almost all the other engines were the same way, and I came to the conclusion that it was a hard country on boilers—and it is. Finally I got changed off on to another engine with a young engineer. The day I was marked up my old engineer remarked: "Going out with the kid, are you? Well, he's a pretty good fellow, and may make an engineer in time." I went out expecting to have a hard trip.

When I came to engine in the yard the engineer was there; we talked pleasantly till the time came to start; he was no older than myself, and had been promoted there. As we coupled on to the train he turned to me and said: "Don't think I am a crank, but I never talk when running; I am busy." I liked that.

We pulled out with a heavy train, and as soon as the engine "popped" the kid runner put on the injector; I fired carefully and the engine steamed well; I kept watch of the water in the gauge glass and it seemed to stand at one point; the kid watched it, too; I noticed on hard pulls he touched the lazy-cock handle, and when the road became level again, and the throttle had to be eased off, he eased off the lazy-cock too; we stopped for water, and side-tracked for the express; he tried his water as he shut off, had a flutter in the top gauge and solid water in the second; he let the injector work till we got in siding and shut it off, told me to open the door.

My old engineer never touches the lazy-cock; he works the injector full until glass is full, or it commences to rain, and then shuts it off; of course I have to keep a big fire when it is on full. As soon as it is shut off the pop commences to throw steam and the stack water; then I open the door to cool her down, then the fire gets low—so does the water—and on goes the "squirt"; then I have to rustle, then the flues leak.

I was with the "kid" two weeks, and the flues did not get hammered once. It is down grade for over forty miles into headquarters, and sometimes the flues would simmer all over, but not squirt. The "kid" always looked at them and said: "They will take up with a new fire; I don't want them rolled unless they squirt, it only makes them thin and weak."

I asked the boss boiler maker about it and he said he didn't see how the "kid" did his work; every other boiler was doctored a dozen times to his once; said the M. M. was speaking about it the day before.

I came to the conclusion that the "kid" will not have to wait for time to make an engineer of him. I came to the conclusion that he is one of those men who think about their work, and I found myself trying to fire better to keep up with his intelligent running, and I would have been firing for him yet if I had not been smart and coupled the engine to train for a lazy brakeman and coupled on to a pair of fingers. I will be all right before your next issue, and back with the "kid," and I will write you a letter from

TEXAS.

Baltimore, Md.

At the Lehigh Valley shops at Weatherly, Pa., they still make frames for heavy engines with jaws bolted to frame. They are extra well fitted and finished, and give no trouble at all. We were shown a frame so made that had been in constant use for twelve years without the least sign of being loose. They cost more to make, but are handier to repair.

Hogeland's Safety Jack.

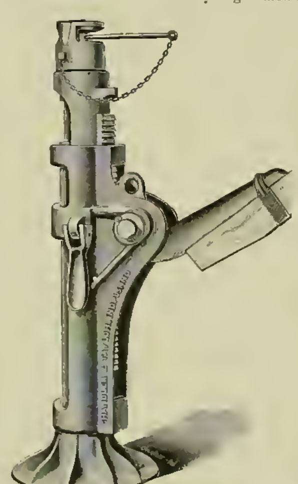
The designer of this new railroad jack aimed to combine the rapidity of movements found in the ratchet jack and the safety in sustaining loads found in hydraulic jacks.

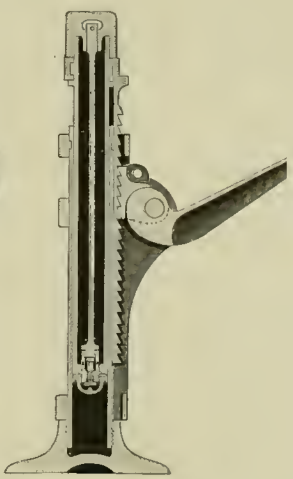
Referring to the detailed view it will be seen that the jack consists of two steel cylinders, one operating inside of the other in a manner similar to a plunger inside of a pump cylinder. The outer and larger cylinder is attached to a base of malleable iron which sustains it in an upright position. Around this cylinder, and resting on the base, is a jacket of malleable iron, to which the lever dog is pivoted. This jacket is free to revolve around the cylinder so as to permit the use of the lever from any position. To the upper end of the inner piston is attached the lifting rack, into which the lever dog operates, and by means of which the load is raised at will. The lower end of the inner cylinder is closed, and a valve inserted therein is free to open or close on the least movement of the lever being communicated to the piston. This valve can be forced open by means of a rod that is operated from the top of the jack. The object of this valve is to permit the flow of a fluid from one cylinder into the other, and thereby avoid the use of pawls.

When a load is to be raised the jack is placed under it, the lever dog thrown into contact with the lifting rack, and the valve rod turned to the *left*, leaving the valve free. A downward movement of the lever raises the plunger or inner cylinder, and causes the valve to open and the fluid to flow into the outer cylinder to supply the vacancy, and as it cannot escape back again it supports the plunger and its load until the next movement is given it; the fluid follows it and securely holds all that has been gained.

To lower the load, all that is required to be done is to disengage the lever dog and turn the valve rod to the *right*. This allows the fluid to flow into the inner cylinder, lowers the load fast or slow and releases the jack.

The jack shown has a capacity of ten tons and is built by the Indianapolis Hydraulic Jack Co., Indianapolis, Ind.





Seeing Through Other Men's Eyes.

If a man is sued by his neighbor he seeks the advice of his lawyer. If his liver is out of order he don't say a word to his lawyer, but calls in a physician. Men cannot learn law, physic and railroading all in one lifetime. A master mechanic cannot ride on engines night and day to watch the working of every kind of device used. If he tries a patent piston packing, he puts it on one or more engines run by engineers in whose common sense and judgment he can rely, and lets their verdict settle its merits and demerits. If master mechanics do not see through the eyes of their men, why do they appoint representative engineers as road foremen of engines, or traveling engineers to look after trials of new things, watch and instruct new men, order repairs on engines that they, themselves, have not seen, condemn engines, and give them advice about everything on the road? A traveling engineer is the confidential clerk of the master mechanic, and that official sees through his eyes. Some of the greatest and most successful superintendents of machinery have a general traveling engineer, and one for each division, to see, think and judge for them—and yet unthinking men often say enginemen have no influence.

Bad Cinder Slides.

Many roads, in adopting the extension front end, took any slide or opening that came up first, and worked in the shop without finding out how it would work on the road. We were on an engine recently that "got full on duty," that is, the front end got full. The boiler had a chill, the train was delayed, and the engineer and fireman mad—so were the passengers. Inquiry proved that the slide was under the front end and handled by a large screw with a brake wheel on it; a cow had got on the track and also the front end, breaking off the screw. The engineer said it was a nuisance anyway, as it could not be worked unless the engine was standing. A slide that is handled from cab by one movement of a lever, and also having the jet cock in cab, is far better than any outside arrangement, as the runner can take advantage of open road, favorable wind, etc., to "blow out."

Useless Sacrifice.

Locomotives that are so constructed that firemen are obliged to go under them to clean out ash-pans are an unnecessary and an uncalled-for element of danger. There are many legless and armless men who can testify to this; there are many graves filled with mangled victims who cannot testify at any tribunal here. No designer, builder or owner of any locomotive need tell any intelligent man, who has fired or run one, that they cannot all be arranged, at very slight expense, so that their ash-pans can be cleaned from the side. Engineers and firemen are beset by a thousand dangers, half of which are unnecessary and can be remedied. This is one of the easiest reformed. Reform it.

A New Steam Brake.

D. Clark, M. M. of the Lehigh Valley R'y at Hazelton, Pa., has adopted a new steam-driver brake of his own. It is operated by a button on footboard of cab where runner can easily reach it with his foot. It will apply brake to drivers only, to drivers and tender, or to tender alone, at will. When in use it does not interfere in any way with use of hand brake, and is very simple. The trouble with the automatic brake is, that it releases very slow and on heavy grades the train gives a jerk back before the driver brakes allow the engine to start at all. With the new brake the steam releases as well as applies the brake, and is held on till the automatic on train is fully released and the train is free, then the steam brake is thrown off and train starts easier. A gauge is attached to brake cylinder that shows the runner how much pressure he is using on drivers.

Then and Now.

There has been a big change in the morals of locomotive engineers and firemen in the past thirty years. In those early days running a locomotive was a rough and ready side experience to the shop, and the man who went out to run and could not hold his companions level in drinking bouts, etc., was not rated very high as a runner. Now, locomotive engine running has come to be a very high grade of skilled labor, and better men are required, more temperate, more intelligent, and more skillful. The future demands will be greater than now—let the best men prepare for the demand.

STANDING NOTICES.

☞ *We invite correspondence from Locomotive Engineers and Firemen, Roundhouse and Repair-Shop Employes, and Railway Master Mechanics, on practical subjects connected with Locomotive Operation, Maintenance and Repairs.*

☞ *Manufacturers of proprietary devices and appliances that are novel, and properly come within the scope of this paper, are also invited to correspond with us, with a view to showing their engravings of same in our reading columns. Such illustrations are published without charge and without reference to advertising considerations.*

☞ *Correspondents should give name and address in all cases, though not necessarily for publication.*

☞ *Mailing address of Subscribers can be changed at any time. Both old and new address should be stated. Prompt notice should be given whenever papers miscarry.*

☞ *Entered at Post Office, New York, as Second Class Mail Matter.*

NEW YORK, MARCH, 1888.

CONTENTS

WE are pleased to announce that arrangements have been made with the American News Company and its wholesale branches by which copies of THE LOCOMOTIVE ENGINEER will be regularly supplied to and kept on sale by retail newsdealers in all parts of the United States and Canada. This is a convenience which is sure to be appreciated by many readers.

Pending Investigation.

Around every shop and division head quarters there are always loafing one or more engineers or firemen "pending investigation" for some slight violation of rules. Perhaps the victim lives a hundred miles away and is there on expense, earning nothing, and, perhaps, blameless. The superintendent who should do the investigating is deliberate; he knows he can get the men mad this way, and perhaps so "rattled" that their evidence will get tangled. Some roads allow half pay when the men are found blameless, but when an official has tortured men four or five days before the court martial, he generally finds all hands guilty enough to screw down on the half pay.

The laying-off system of punishment for minor offenses is a crude, inhuman, Pagan punishment. Depriving a man of the opportunity to work, increasing his expenses, running him into debt, stinting his family and making him the creature of the whim of some petty official.

There ought to be some other mode of punishment devised that at least has a little more humanity in it. Make the punishment fall on the individual, not his family. Don't contribute to the over-full ranks of idleness. Set him back and make him work harder for less pay, or something like that, but don't say: "You can't work for thirty days, that will put you behind financially so you can't catch up for a year; your old overcoat will have to do this winter, your wife won't get a new cloak, and if you don't look out your oldest boy will have to stay out of school and, maybe, after awhile you'll learn not to run off a switch."

Who will offer a remedy that is human and where the "punishment fits the crime"?

Unwilling Heroes.

It has become the style, now, for the press and public to laud the deeds of dead engineers and call them heroes and martyrs, etc., and while they live treat them with silent contempt and as nothing but greasy, ignorant laborers. Naturally engineers cling to life as much as anybody and few of them care to die just to be called a hero and have his grave covered with flowers. He had rather be treated as a man and an intelligent mechanic and receive a few flowers now.

Engineers are never dead heroes from choice; they are sacrifices on the altar of duty. It is just as natural for an engineer to do all in his power to stop in an emergency as it would be for a woman to scream under the same circumstances. It is their training. Like veterans in battle, who obey any order unflinchingly because they are used to obeying. Any engineer who has done all in his power to stop, for instance, in a collision, is very foolish to "die at his post" if he can get off. Engineers' lives are too valuable to throw away in this manner. Men become so used to emergencies that require prompt and quick action that applying brakes, reversing engine and opening sand lever is but the work of a few seconds, and is, in ninety-nine cases in a hundred, done before the engineer thinks that the first law of nature is self-preservation.

It is the years of experience that engineers get in the front of danger that makes them the factor of safety to the train that they now are. It is this training that makes them skilled mechanics of a high order. It is this training that makes it impossible to supplant the engineers of this country by any other class of men in any emergency. The engineers of this country may be depended upon to do their duty regardless of circumstances, and will be dead heroes only because there is no time to escape after that duty is performed.

A soldier who had fired his last shot would be foolish to throw down his musket and rush to death upon the bayonets of the enemy. So is an engineer, who has done all he can, foolish to refuse safety—if safety can be found.

There is a Man Looking for You.

This is the warning we would pour into the ears of all young men who are ambitious to get ahead and cannot see the rounds of the ladder from their present position. All successful business men and railroad officials are constantly on the lookout for some good, reliable, man to take off their own shoulders some of their responsibility. There are very few superintendents who are not watching their conductors, and fewer master mechanics who are not watching their engineers with a view to finding out who would be best to take some position of responsibility if a vacancy should occur. Master mechanics, roundhouse foremen and traveling engineers are watching firemen to discover the best man to promote. To every man we would say, attend to every detail of your business, study to do it better, more economical and easier, and some one else will be taking notes of your actions; they may say nothing about it, but the good is all placed to your credit.

You have been surprised before now, the men themselves have been surprised, to find a foreman or master mechanic, superintendent or train master asked to take a similar but better position, at more pay, on some distant road, that the man himself knew little about. He had never thought of seeking employment on that road, but had been attending carefully to the details of his present job—there was a man hunting for him. He had an important place to fill and he wanted to put in a practical man who knew and studied the details of that business, and when at last he found him in Maine, he opened a higher position for him in Oregon. Do not hunt for the man with the position to give—you will lose him in the crowd. Make every action of your life and work so suspicious of honest endeavor to be an expert at your business, that the man hunter will find you by your acts, your record or your words.

If you have new or different ideas of economy in running, firing, or repairing engines, or of making or using tools, think out the details of your scheme, look at it from all sides, and if you think it fairly novel or in any way better, let it be known; write about it—you may make a mistake; who has not? You may call out pointed criticisms, but you will be learning something, and the man on the watch will count you as a thinking man and ask for your pedigree of results—if they are fair he will ask for you.

Guarding Against the Unforeseen.

This is the engineer's first great duty on the road. This is the duty that keeps his eye riveted to the track ahead, noting every signal and every sign. This is the duty that makes the fireman keep an extra lighted lantern ready for use in case of trouble. It is this duty that makes the careful engineer inspect his locomotive every trip to see if any single bolt or screw shows any sign of weakness. This is the duty that calls for lunch pails as big as a boarding-house—there *might* be a snow blockade or a burned bridge. It is this uncertainty of what will turn up next that makes an engineer's life the nerve-straining one it is. A man walking over the road may expect to find different conditions, but he can stop in a single step and the risk is only to himself; an engineer cannot stop for a considerable distance, he is going at a rate of speed that is moderate if all is well, and dangerous if anything is wrong; and a hundred lives, instead of one, are in his keeping, and depending upon his instant ability to cope with any emergency that may turn up. These emergencies are turning up many times a day to every engineer, and that so few signals are disregarded and so few fatal accidents happen from this cause speaks well for the careful guard kept on every detail and the ability of the men in charge to guard against the unforeseen.

Useless Discussion.

We are in receipt of a somewhat lengthy but well written communication from a machinist who takes exceptions to our article on the "Coming Man." We do not wish to shut off free discussion in these columns when the discussion can give any information or do any good, but as this article would only open an old and interminable argument between engineers and machinists, we do not publish it. The article referred to was penned to show that engineers had a great influence in the introduction of new devices or supplies. Our correspondent denies this influence, and then goes on to show that the reason they have influence is because they are organized and stand up for each other and *kick* for new devices, engineers' promotions to foremanships, etc., instead of for machinists.

The controversy about machinist runners is again opened; this has been settled long ago by most all roads promoting firemen only—we know of no good reason why a machinist would not make a good fireman, and, in time, a good engineer, provided his shop experience did not make him bigoted enough to disdain, instruction from a "cornfield engineer" with road experience only.

Of two men, equally adapted to railroad service, one from a machine shop and the other from a farm, the man from the shop ought to make an engineer before the man from the farm.

There is no more reason why a machinist "who knows how to build locomotives," as our correspondent puts it, should be competent to run one than there is reason that a sailmaker could manage a ship at sea or a blacksmith who makes picks should know how to mine coal.

Dangerous Bribery.

Loud whispers go around from time to time that railroad men, holding certain important positions, are bribed, or receive (so called) commissions, from manufacturers for getting their wares used on roads with which they are connected.

Proofs of such things are always hard to obtain, yet there may sometimes be a moral certainty that they do exist.

One thing is clear, if a manufacturer sells boiler tubes, for instance, to a railroad, not on account of their quality, but because somebody is bribed to recommend them, the bribe money comes out of the railroad company's till, in the end, as, of course, bribery, or the mere suspicion of it, stifles competition.

And this is not the worst of it. Defective boiler tubes mean defective, unreliable, and often dangerous service.

There is another inference. The roads which pay the most attention to the experience of their enginemen, and employes generally, are least likely to suffer from this cause. A manufacturer may bribe an individual, but he can hardly afford to bribe a whole railroad.

A. J. Stevens, for many years superintendent of motive power of the Southern Pacific and Central Pacific roads, died at San Francisco, Feb. 11. Mr. Stevens was a locomotive engineer for some eight or ten years, and reached his high position through regular stages of promotion.

An interesting feature of the progress that is being made by THE LOCOMOTIVE ENGINEER, is found in the number of subscriptions which are being received from superintendents of motive power, master mechanics, general managers and their chief assistants, as well as in the appreciative tone of the letters accompanying these subscriptions, and the pains some of these officials are taking to make the paper known along their lines. Repair shops and roundhouse foremen and employes are being heard from in like manner. All of this, taken in connection with the prompt recognition that the paper is receiving from engineers and firemen, goes to prove that it is rapidly realizing one of the prime objects for which it was founded—that was, to establish an open channel through all the departments of locomotive service, available for the mutually beneficial interchange of ideas and information.

ASKED & ANSWERED

(7.) W. Hartley, Milwaukee, Wis., writes: What is the Belpaire fire box? *A.* What is called the Belpaire fire box is merely the method of staying the fire box and form of boiler shell over it. The wagon top is square instead of round, and the crown bolts go straight from shell to crown sheet and the sides by straight bolts across from one side to the other.

(8.) Fireman, Slater, Mo., asks: What makes packing rings in a cylinder revolve—is it the shape of cut? I heard a roundhouse man telling a wiper that the rings were cut slanting so that they would turn and thus wear even. *A.* You had better get the roundhouse man to tell you *why* they turn; the steam going through the opening would turn the ring, perhaps, if it had any place to brace against; the "slant" is balanced by the other end of the ring. We never knew of any that did revolve.

(9.) F. S. E., Raton, N. M., asks:

How are the different sizes of injectors determined? We have almost every kind here; how is it some are numbered 16 and others 7 and 8? *A.* Injectors are numbered by the size of delivery tube—the smallest nozzle in the instrument—and are numbered to correspond to number of millimeters in diameter of this tube The only injector that has as high numbers as you mention, that we know of, is the older style of Little Giants. Locomotive injectors were then numbered ten more than others, to distinguish them from stationary injectors; 16 would be the same as 6 of other makes. The works now number same as all others.

(10.) Helper, Albany, N. Y., asks:

What is the chief advantage and disadvantage of double tube injectors or inspirators? *A.* Double, or, as they are called, double tube injectors or inspirators, deliver the feed water several degrees hotter than single tube instruments; this is their chief advantage. The hotter the water is heated the more lime will be deposited in using bad water; this is the only disadvantage we know of. All injectors, single or double, lime up ahead of the combining tube only.

(11.) G. H. E., Atlanta, Ga., asks:

Where does the air go to that is drawn in at overflow pipe of an injector? *A.* Into the boiler. What is the difference between the principle on which a non-lifting and a lifting injector works? *A.* There is no difference; the lifting features are merely auxiliaries or attachments to take the water to the injector; in a non-lifter it runs to it.

(12.) Snow Bank, St. Paul, writes:

I am a roundhouse machinist, and in repairing Baldwin locomotives I have noticed a chisel mark near center line of driving box and one corresponding nearly to it on jaw. What is its use? *A.* The mark is placed on box and frame to show the center line of axle, and its use to guide workmen in adjusting spring hangers. It is customary on some roads to adjust new engines so that mark on the box is about a quarter of an inch above the one on the frame, and as the brass in box wears away the marks approach each other, and by the time the engine is worn out, the box mark is not more than a quarter of an inch below the mark on frame. Allowing an engine to run too high or too low will affect the valve motion, especially if the engine has very short eccentric blades.

(13.) X., Minneapolis, writes:

Please state what unseats the steam valve, allowing pump to start in automatic pump governor, when air pressure falls below that required. I cannot see through it, except that *velocity* plays an important part, and velocity in this part of the world is an unknown quantity. *A.* The pump governor has a balanced steam valve, the top area, in steam space, being larger than the bottom, where seat is located; on top of this valve is a piston, and a small port allows steam to accumulate above it, and, being larger than valve, it forces it down and open, thus sending steam to the pump; above this piston is a small valve that closes upward. Above this is a diaphragm, and a coil spring holding it in position; above this diaphragm the air from main pipe is admitted. When air pressure exceeds the tension of this spring it forces the diaphragm down, opening the small valve, and allows the steam above the piston on steam valve to escape to the air, and the steam from below will force the valve up, thus closing it. If the air is reduced, the spring carries diaphragm back to position and its own spring closes the small valve, the steam entering through the small port then accumulates on top of piston and forces it down and opens steam valve. Velocity has nothing to do with it.

(14) E. B. M., The Dalles, O., writes:

Will you please explain the manner of testing boilers, and also state what is the equivalent steam pressure for 100 lb. hydraulic, in testing boilers by that means, or if there is any difference? *A.* Boilers are usually tested by hydraulic pressure, by pumping or forcing water into boiler with an injector made for that purpose. It is customary to apply from 25 to 50 per cent. more hydraulic pressure than it is expected to carry steam. The object of such tests is principally to find leaks. There is no practical difference between hydraulic and steam pressure.

IN THE ROUNDHOUSE AND REPAIR SHOP.

If Midland will send his name, will publish his article.

* * *

The C., B. & Q's new passenger engines have Belphare fire boxes.

* * *

The Strong locomotive is getting a new pair of fire boxes at the Wilkesbarre shops of the L. V. Ry. It is claimed the trouble with the old one was a badly designed seam in the combustion chamber.

* * *

The simple widening of driving brake shoes, grooved to cover flange of wheel, was a happy thought and has increased the retarding power of driver brakes and lessened the wear of tire in a wonderful degree.

* * *

The State railway council of Germany has forbidden the employment of men in railway service for more than eight hours. Something to make the limit at least eighteen in this country would be a big improvement.

* * *

On most coal roads of the East and on many New England roads, four wheels are rated as a car. This is because there are so many four-wheeled coal "jimmies" in use. We found this out by doubting an engineer's word when he said he had 170 cars in his train.

* * *

We have noticed a number of roads are putting a small headlight on back of cab. They are a very useful thing where engines are obliged to back up, and are a better marker for light engines when running ahead than small colored signal lamps carried on back of tank.

* * *

The Pennsylvania Railway's solid ended rods are well liked by the engineers on the fast runs. The boys say they rattle, but none have ever come up through the cab, as the old ones used to do. No one blames the engineer for "monkeying" with rod keys if they run hot.

* * *

At the Pennsylvania shops in Philadelphia we noticed several engines with long patches on sides of crown sheet. Inquiry developed the fact that they had some crown bars that rested at the ends on the edge of side sheets that were made to extend up above crown. It was a weak spot.

* * *

Mr. Jos. Hoefecker, M. M. of the Lehigh Valley R'y at Weatherly, Pa., uses a double truck in front of consolidation engines, and has flanges on all drivers but main pair. The road is a crooked one and has very heavy grades, but we failed to find one engine that had even touched the flange on any driving wheel.

* * *

The man who runs a locomotive has no business to drink intoxicating liquors before he goes out, or while on a run. If a man is at home and going to bed, a drink, if he feels like it, is not so dangerous. Total abstinence is the true and safe plan for any man with as much depending on his cool head and steady nerves as the locomotive engineer.

* * *

A. K. Mansfield, of 280 Broadway, this city, has invented and put on the market a very simple water crane that has provisions for relieving the extra pressure in pipe caused by sudden closing of the valve. They are returned to position and held there by springs that can be adjusted to any tension desired. One man can handle crane from tank alone.

* * *

Some of the finest locomotive castings we have ever seen are turned out at the Weatherly, Pa., shops of the L. V. R'y, Jos. Hoefecker, M. M. Cylinders and driving wheels come out as clean and smooth as the patterns. The foundry is well kept, with clean floors, clean windows, and a place for everything. This is the reason they do good work.

* * *

The antics of the French syndicate who are cornering the tin and copper markets of the world, make some of the manufacturers of journal bearings squeal. Of course railroad buyers don't like to pay any more for the brasses on account of their increased cost, and the temptation will be to use those of an inferior quality—a possibility which is of special concern to enginemen.

* * *

Steam reverse gears are in extended use on many Eastern roads. Some are simple and some very complicated. The Reading road has about as simple a one as we have seen. It uses a small reverse lever to handle the gear, a pointer telling where engine is working; to reverse, the lever is merely shoved forward or back, and, when the indicator shows where it is desired to work engine, the gear is locked there, by simply moving lever to center notch.

* * *

One of the fast line engines of the Reading road attracted quite a number of railroad men at the Ninth street station in Philadelphia recently. She had a line of pipe running all around under the water tank with a **T** over every truck box; a short piece of hose with a pipe nipple allowed the runner to cool off any box while running. Each box cover was drilled, to admit the piece of pipe; provisions were also made to irrigate the engine trucks also. This engine was one of the world renowned "dirt burners," but we noticed that her tank was full of the very best of coal.

* * *

The Lehigh Valley road has no general master mechanic. Every division M. M. builds engines to suit himself, and the road has some of the best locomotives we have seen East or West. There are more improved devices patented and invented by employes in use in the shops or on the engines than we have noticed elsewhere. If one M. M. gets out an engine that is better, or does better work than those in use, the man on the next division tries to beat him. Cheap material or inferior devices are not used under the excuse of being "standard."

* * *

All engineers know what a grand nuisance it is to have an engine troubled with the disease known as "sweating in the sand box." This is often caused by poorly dried sand, but where a sand-box cover fits tight it is very likely to occur. Sand-box covers that set up on little feet, or ribs, allow a driving storm to force water into the box. Some engineers have a "pig-tail" put in the cover or box with good results. This is a piece of ½-inch pipe screwed in and bent into a coil with open end down—steam and hot air can go out and the storm cannot blow in.

* * *

The Pennsylvania Company use an oil cup on driving boxes that is the best thing of the kind we have ever seen. It is a cast box with a hinged cover, and has three small copper pipes tapped into the bottom, one to the waste in center of box and one each to wedge and shoe; the box is fastened to spring saddle. In some cases a pipe to cab allows boxes to be oiled while running. Single pipes to boxes do not oil wedge and shoe, and the screw top cups are generally too small and too slow. The box described does not require to be touched by wrench or hand—the cover can be raised by spout of oil can.

* * *

The Reading Railway shops at the City of Brotherly Love are certainly model shops—models of filth and dirt. On a recent visit to the Ninth street roundhouse we found a number of locomotives and cars under cover, the floor was half mud, half plank, water stood in pools, scrap iron and car repairs in stacks, and smoke, steam and fog combined about the ceiling in great gobs of gloom. In one corner a group of men sat on timbers about a fire built on the ground. It is no wonder this road has got a new head to its mechanical department, and we know enough of G. W. Cushing to think the place mentioned will have a house cleaning day declared as soon as he sees it. Men working in a place like this will naturally get like the place after a while—no matter how good when they went in.

* * *

The Pennsylvania shops at Philadelphia have a small upright boiler fitted up with a set of boiler washers and testers made by the Rue Manufacturing Company, where all boilers are washed with warm water and pressure applied where wanted to test repair work. This company *double crew* all engines, and every mill is expected to make from six to ten thousand miles per month and often do make more. By washing out with hot water the boiler sheets are not cooled so much, and when filled up with hot water save lots of time in firing up. The foreman of the shops speaks very highly of the efficiency of the device, as it occupies no space and has no working parts, requires no foundation, and can be carried any place by one man; it is cheaper than any steam pump for this purpose.

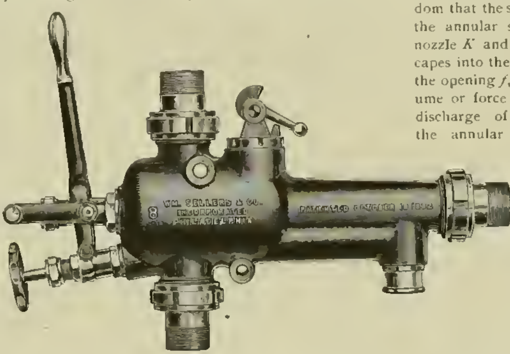
The Locomotive Engineer.

Devoted to the Special Interests of Locomotive Engineers and Firemen and to Locomotive Maintenance and Repairs.

VOL. I. NO. IV. | NEW YORK, APRIL, 1888. | $1.00 per Year, or 10c. a copy.

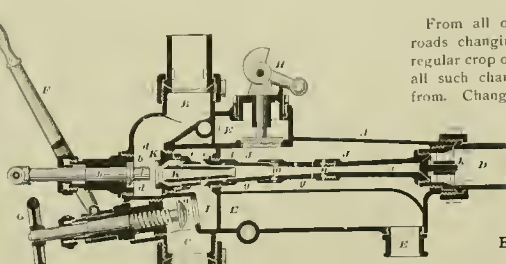
New Re-Starting Injector.

The accompanying cuts show the form and details of a new injector just brought out by Wm. Sellers & Co., Incorporated, Philadelphia, Pa. It is very handy, being started and stopped by simply pulling out or pushing in the lever.



Referring to the sectional cut, it will be seen that this injector consists of a case *A* provided with a steam inlet *B*, a water inlet *C*, an outlet *D* through which the water is conveyed to the boiler, an overflow opening *E*, a lever *F* by which to admit steam, start and stop its working, a hand wheel *G* to regulate the supply of water, and an eccentric lever *H* to close the waste valve when it is desired to make a heater of the injector. The operation of the injector is as follows:

The water inlet *C* being in communication with the water supply, the valve *a* is opened, to allow the water to enter the chamber *I*. Steam is admitted to the chamber *B*, and the lever *F* is drawn out to lift the valve *b* from its seat and permit the steam to enter the annular lifting steam nozzle *c* through the holes *d d*. The steam issuing from this nozzle passes through the annular combining tube *e* and escapes from the instrument partly through the overflow opening *f* and partly through the overflow openings provided in the combining tube *g g'* through the overflow chamber *J* and passage *E E*, and produces a strong vacuum in the water chamber *I*, which lifts the water from the source of supply, and the united jet of steam and water is, by reason of its velocity, discharged into the rear of receiving end of the combining tube *g*. The further movement of the lever *F* withdraws the spindle *h* until the steam plug *i* is out of the forcing nozzle *K*, allowing the steam to pass through the forcing nozzle *K* and come in contact with the annular jet of water which is flowing into the combining tube around the nozzle *K*.



This jet of water has already considerable velocity, and the forcing steam jet imparts to it the necessary increment of velocity to enable it to enter the boiler through the delivery tube *j* and boiler check *k*. If now from any cause the jet should be broken—say from a failure in the water supply—the steam issuing from the forcing nozzle *K* into the combining tube *g* will escape through the overflows *m* and *n* and intermediate openings with such freedom that the steam which returns through the annular space formed between the nozzle *K* and combining tube *g* and escapes into the overflow chamber through the opening *f*, will not have sufficient volume or force to interfere with the free discharge of the steam issuing from the annular lifting steam nozzle and escaping through the same overflow *f*, and hence the lifting steam jet will always tend to produce a vacuum in the water chamber *I*, which will again lift the water when the supply is renewed, and the combined annular jet of steam and water will be forced into the combining tube *g* against the feeble current of steam returning, when the jet will again be formed and will enter the boiler as before.

Changing Rules.

From all over the country, reports of roads changing rules, together with the regular crop of accidents, that comes with all such changes, continue to be heard from. Changing running rules is almost as bad as changing engineers. Those roads that adopt good rules and raise good engineers, and hang on to both, are the safest and best.

Exhaust Nozzles.

There is probably more "monkeying," as it is called by engineers with exhaust nozzles—and as much excuse for it—than anything else. Steam is absolutely necessary to pull cars, and when other means have been experimented with a little, with no satisfactory results, it is perfectly natural for a man to try a little strangulation. There are no engineers in this country, that we have ever heard of, who do not know that an engine will work better and do more work with a large nozzle than a small one. But nozzles will not pull cars, no matter how huge; some steam is also necessary.

Round nozzles, single or double, especially if provided with removable tips, present too good a chance to be turned out or bushed, according to the notion or ideas of the engineer or roundhouse foreman.

Some roads use square nozzles that won't turn out, and are more of a job to bush; but if they are too large for steam making, it is little satisfaction to runners.

A nozzle that can be varied from the cab would seem to cover all the desirable features, and would doubtless be of service to most engineers on the road. There are few engineers who would not gladly shove a small lever ahead, and run with a large nozzle when the train, fuel, fireman and other circumstances could keep, or allow to be kept, steam enough; and it would be some satisfaction to know that he could make the draft cut the fire right by the same means.

A very simple nozzle of this kind is the old one with a taper plug in the center, that can be raised or lowered as desired; it does not cost as much as the ordinary double stand, and has a wide range.

On the Right Track.

The Locomotive Firemen of Chicago have organized a mechanical club, and publish as their aim "To bring together the locomotive enginemen of Chicago for the purpose of discussing all matters relating to the management, care and construction of the locomotive." That there will be good results from this club, and all others like it, there can be no doubt.

Manufacturers of all devices used on locomotives cannot do better than to furnish such clubs with working models of their devices; the results are bound to be fruitful. Many a good device has been condemned on roads just because the men did not understand its working, or the principle that it worked on. Many men, especially after they get to running, avoid this kind of discussion, for fear they will expose their ignorance. This is all foolishness. A few hours per week in this kind of self-taught school gives a man lots of problems to think out, and, if he thinks, asks questions, and tries to post himself, it can but benefit himself, the company for which he works, and the public that he serves.

Success to the mechanical club, its officers, and its aim.

Keep Up.

A railroad company who have built their own cars for a good many years recently gave a big order to a car manufactory, and, as they wanted standard cars they sent their patterns to the works. In a short time the master car builder of the road got back the pattern of a very important casting, and a note saying that the pattern was *more than a year behind the times*—a moulder being able to get out but sixteen of the castings in a day, while with a pattern made on a new principle it was possible to make thirty-eight of the castings. Keep posted.

Special Chuck for Turning Locomotive Packing Rings.

BY WM. H. HUBBARD.

Invitation to air some of our shop kinks in your valued paper duly received; and, while I am not troubled with an over-supply of modesty, I do dislike to hear men shout "that's old." Still, I am satisfied that where these repair shop rigs are old to one they are new to hundreds of

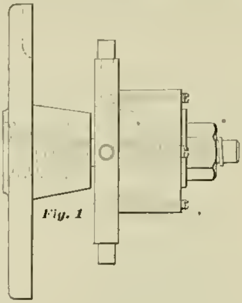


Fig. 1

others, and as you name especially one "makeshift" of ours, viz, a mandrel for facing parallel the "bull" rings and spring rings of locomotive pistons, I send you a sketch of same, but am not the originator of the principle, unless it may be in the combination and materials used in the construction; for it is made of old piston spider heads and follower plates—no new castings being necessary.

The range of work being limited to just what it is made for, it may not seem of great value; but in this respect it is like the pistol in Texas, and it does the work nicely—which is the proof of value in all shop kinks.

The work done on this mandrel must be bored in a common chuck. In making

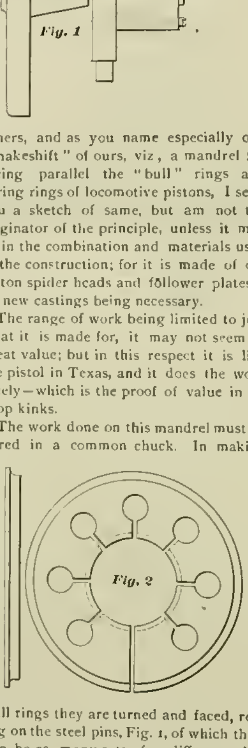

Fig. 2

bull rings they are turned and faced, resting on the steel pins, Fig. 1, of which there can be as many sets, for different sizes of cylinders, as may be required.

In facing spring rings we use expansion plates, made as shown in Fig. 2. These are bored to fit the cone of the mandrel near the face plate, and are brought up square by the follower and nut. The amount of expansion we find to be not over one-eighth inch, but as we make our rings standard sizes, we do not need a large number of plates.

While a common chuck is theoretically true, a machinst who has run a "packing lathe" knows it is impossible to chuck such work true, as the tendency is to spring the work out and away at the jaws. On this mandrel the strain in tightening is towards the plate in all cases.

The thread on the stud is ½ V, leaving the top flat, so as not to wear loose in the follower, which should fit well to hold everything central.

We make a slot in the face plate to admit of a caliper or templet for gauging the spring rings.

As the expansion plates are made of old follower plates, any shop can afford one for each sized cylinder in service.

The Pittsburgh Locomotive Works.

Superintendent Wightman, of the Pittsburgh Locomotive Works, has one of the most complete systems of measurements that we have seen. No mechanic in the works is allowed to use a scale or caliper of his own; there are complete sets of templets, guages and distance pieces for all work. The tool-room is provided with full sets of Whitworth guages and all fine measuring tools; from these the distance pieces, plugs and rings are made. No piece of work is made to fit another piece but a standard measurement piece. For instance, if a man has to make a taper fit of a piston rod in a crosshead, he goes to tool-room and gets a ring, ground to the right size and taper, and makes his rod fit that; the man who finishes the taper hole in the crosshead draws a taper plug and makes the hole fit that. It is an admirable system of manufacture, well worked out, and is shown in the work of this concern. Fifteen years ago Pittsburgh locomotives had a very hard reputation, owing to bad design, but under the management of the present superintendent they have come up, and now compare favorably with any engines built in America. There is not an old-fashioned machine in the works; everything is new, and the latest improved methods of doing work and handling material are in use. The foundry is exceptionally well arranged.

A Tool Breaker.

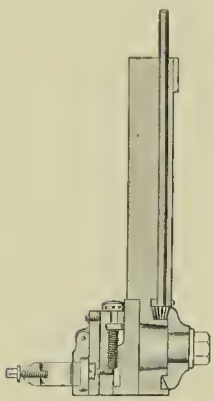
That expensive tools, like taps and reamers, are not broken by unknown causes entirely, was proven to us recently by seeing a cow-puncher using a reamer on a locomotive frame. He was turning the tool with a solid-ended wrench and every half turn he would pull the wrench off and hit the top of the reamer a sharp rap, spit over his shoulder and turn again. The tool was often forced into the work so tight he could not turn it, and the head of the wrench looked as if it had been to a dog fight and got licked. This artist might do to chip rough castings, but putting him to using tools reminds one of the fairy story of the crazy bull in an egg-shell foundry. There is one tool that this kind of a man should always use, and no other—a shovel.

Planer Tool for Locomotive Driving Boxes.

This invention, built by Pedrick & Ayer, of Philadelphia, Pa., is applied to an ordinary planing machine having a longitudinally moving bed and a vertical adjustable crosshead.

The tool is made of a forged bar, heavy and strong, to withstand the strain to which it is subjected. At the lower end of the bar is a circular enlargement, and at the rear of the bar is a groove and a shaft or spindle, upon which is mounted a gear. At the front of the bar is a face plate or head, with a vertical guide for tool carrier. The carrier is made with a vertical adjustment by means of a screw and nut. The gear, fastened to face plate or head, is driven by the gear pinion upon end of rear shaft, which rests within the groove at rear of the bar which gives the rotation of face plate and tool holder, and can be driven by hand or feed gear wheels.

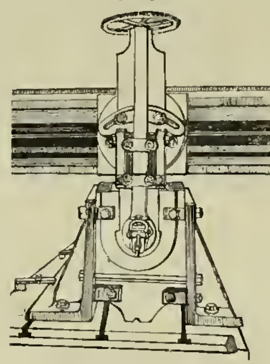
Supposing it is desired to plane out a number of driving boxes; they should be suitably placed in line and fastened be-



tween angle irons to planer bed. The bar or tool is then placed in planer tool post and properly secured and adjusted. The planer is then set in motion, and, at every stroke, a suitable partial revolution to the shaft may be given and a corresponding movement will be given to the tool which moves around the center formed by the spindle, and the entire circular part of the driving boxes, by repeated movements of the planer bed or table, will be planed out. Should the operator prefer, both shoulders of the driving boxes may be squared up before the circular part is begun.

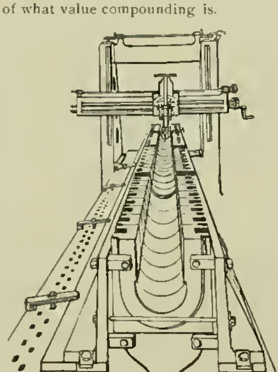
The number of boxes operated upon at one time is limited only by the length of the planer table, and the work will be done with greater accuracy, which will make the boxes interchangeable. This tool is not confined solely to the planing of driving boxes, but can be and is used for performing any similar work Tests prove that it is a big improvement over slotters for this work.

This tool is in use on the Chicago, Burlington and Quincy Railroad Company, giving most excellent results. At their Aurora shops they have a 25-foot planer, upon which is placed 32 driving boxes at one time. The planing for the cellars and shell bearing is finished complete in 36 hours, at the rate of 24 cents per hour—making the cost of all planing 27 cents per box.



Compound Locomotives.

Great interest has been shown of late years, especially in Europe, in the compounding of locomotives—expanding the steam twice. This is advantageous only in high pressures, and as the average locomotive's boiler has made a jump from 120 to 160 or 175 pounds' pressure in the last few years, it is plain, therefore, that there would be an economy in two expansions of the steam. Mr. Webb, an English master mechanic, has built a large number of compound locomotives, and is now building one for the Pennsylvania Railway that will be subjected to a comparative test with some of the best standard American locomotives, with a view to determining of what value compounding is.



Mr. Webb's locomotives have a pair of high pressure cylinders located where cylinders ordinarily are, and having their connecting rods coupled to the back pair of wheels. Between these high pressure cylinders is located a very large low pressure cylinder, whose connecting rod is coupled to a crank in the center of the forward axle. The engines are, therefore, independent of each other, there being no side rods.

It would look to a road man as if this was a complication of parts that could be avoided.

There have been one or two experiments in this country where the high pressure cylinder was on one side and the low pressure cylinder on the other.

We should think that placing a low pressure cylinder at the end of the ordinary locomotive cylinder, and extending the piston rod through to carry its piston—as is done on many ocean-going vessels—would be at once the easiest and best way of accomplishing the desired results. Whether the saving made by compounding will pay for the increased cost to build and repair the engines remains to be determined by experiment and the trials soon to be made on the Pennsylvania will go a long way in this direction.

There is no great mechanical difficulty in the way of compounding locomotives if it can be proven that it will pay.

Clark's Valve Gear.

David Clark, M. M. of the Lehigh Valley R'y. at Hazelton, Pa., has invented a new valve motion for locomotives. It consists of a second valve, riding on top of the regular valve, that cuts off the steam. This valve is controlled from the cab by a second reverse lever. When this is thrown out of gear the engine works as an ordinary plain slide valve engine. The gear is driven by a separate eccentric for each side. If there is anything in indicator diagrams, the motion will do more work with a given amount of steam, and therefore save fuel. Complication is not objectionable when it accomplishes results; whether this gear will save fuel enough to pay for its increased cost and maintenance remains to be proven by long tests in actual service. If Mr. Clark's gear is not better than the link, there is little use of attempting to improve that well-known gear—taking the theoretically correct indicator diagram as the ideal to be reached.

Interchangeable Locomotives.

Building machinery to gauges and templets, so that their parts are interchangeable, has its advantages and is desirable, but it does not go far enough. There is no doubt that it cheapens the cost of manufacture, and is, therefore, a good thing for the builder. After a locomotive has been rebuilt or overhauled at the shop on its home road, the interchangeability disappears as slate pencil marks disappear under a wet sponge. If the shops had a full set of the builder's templets, it might be kept sight of—but a full set of these gauges would cost as much as the motive power on some roads.

We do not believe in standardizing everything. We do believe in standardizing many things. Car, tender and engine trucks can easily be kept to a standard, and always be interchangeable. Pistons, piston packing, valves, links, eccentrics or straps, rod brasses, crossheads, driving boxes, etc., cannot be easily or cheaply kept to a standard, or entirely interchangeable.

Standard shapes and sizes for everything prevents multiplication of parts in repairs.

Established standards prevent the inventive genius of men from trying to improve the power of any road.

There is a happy medium in all such things, and we believe that is the field to occupy.

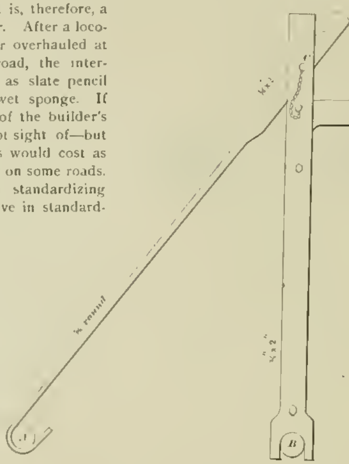
Interchangeable standard men see all the advantages of their system, and are liable to overlook the advantages of others. Men who have bought or run locomotives built to standards and guaranteed interchangeable, have become disgusted with the system when they tried to use a link or a rod strap of one engine on another, and found that they "wouldn't gibe."

If we were buying locomotives, we should buy those built to gauge; when repairing them, we should try to preserve some of the sizes and let the rest go.

Engines are not worn out alike, and after a year's service many of the best made parts would not work well on other engines.

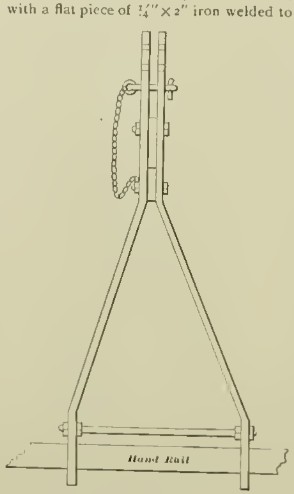
Engineers, Beware!

The New York *Post* is the father of, and deserves all the credit for, the new order of things that will dawn on the country within six months. It proposes to teach locomotive running in the public schools. Everybody will be engineers. People have had an idea for years that locomotive running was a trade learned only by several years of close application and hard experience as firemen, but the *Post's* easy way out of the strike trouble knocks an old and time-tried custom in the head. It is so simple that it is a wonder that some other 22-caliber idiot never thought of it before. First class in locomotive engineering, stand up! Jimmie *Post*, this is not your class, a boy has to have *some* sense to learn engineering. You belong in the primary class of wipers.



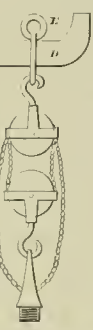
Portable Hoist for Air Pumps.

The advantage of this hoist consists in its being easily and quickly adjusted to almost any engine. It is attached to the hand rails, as shown at *A* and *B*. The tension rod is made of ⅝" round iron, with a flat piece of ¼" × 2" iron welded to



its upper end, with several holes in it, so that, by inserting the pin *C* in the proper one, the bar *D* may be brought to a horizontal position. The pin is attached by a small chain to one of the bolts in upright piece, so that it will not get lost. A short hook to attach to whistle stem may be used where the dome comes immediately in front of pump brackets. A sheave, *E*, runs on bar *D*, and to it a differential pulley block is attached, which hooks into an eye plug having a thread cut on its lower end, to screw into top cylinder head of air pump, in place of reversing valve cap, which may be temporarily taken out for this purpose.

With this arrangement one man can easily take off or put on a pump in a short time. By using the chain pulleys, the pump may be drawn up and left suspended, and the man can have both hands free to move the pump in or out and adjust the bolts in their holes. Any shop that has one lathe and a blacksmith shop can make one very cheaply.



Hiram R. Jones.

A Lost Art.

On a recent visit to the home of an old time engineer we saw on top of his book-case a pair of large brass eagles, and wondered at their being there. The old-timer leaned back in his chair, and said: "Your hair is hardly gray enough for your experience to date back to the time an engineer used to have one engine for years. I used to run a pet engine, and those brass eagles rode beside her headlight for thousands of miles. She was a brass angel, anyway, and I'll bet there has been two years of solid work, and $200 worth of cleaning compounds wasted on those eagles by the many firemen who have groomed the old girl. I had more brass than a little; fine pair of flag staffs (they are out in the wood-shed now), and a dozen brass traps for the cab. One day my pet came out of the back shop a "Black Maria," and I rescued those eagles and some more gew-gaws from the brass foundry. It was but a few years more and I was running an express engine on the 'chain gang,' 'first in first out,' 'catch as catch can.' Brass statuary for locomotives is one of the lost arts."

Looking Over Your Shoulder Without Turning Your Head.

Many engineers, on roads where long trains are hauled, have a small mirror hinged to outside of cab, in front of and above the engineer's face; a sliding rod and set screw allows the glass to be set at any angle, or folded up entirely. When set out at right angles to the cab it shows the rear of train, night or day. By a glance at it, on a curve or other favorable piece of track, the runner can see if the train has parted, if signals are being given, or if anything is wrong with the train without turning around to look back.

The B. & O. have many locomotives, especially heavy freight engines, that have a ¾-inch relief cock in the steam chest connected to cylinder cock rigging.

Special Locomotives.

We recently paid a visit to the locomotive works of H. K. Porter & Co., Pittsburgh, Pa., and found their large shops very busy on light locomotives for various grades of service. This company make light locomotives, of all gauges, and with cylinders from 5 x 8 up to 14 x 24. They had in the shops some street-car motors for California, several wood-burners for lumber roads in the South, a Forney for suburban traffic, one little engine of 20-inch gauge for a Lake Superior copper company, and a number of odd sizes ranging in gauge from 36 to 42 inches. These works have developed the light locomotive business in the United States more than any other makers, as they have made a specialty of this branch of manufacture.

Their engines are made to standard sizes, and a large stock of "extras" are kept on hand to send out to owners. They have a large trade in driving boxes, links, eccentrics, springs, tires, etc.

The engines are put together with a view to their easy repair by men in charge of them and away from shops. Tire on drivers are put on on a taper and held by bolts; these can be removed and the tire taken off with a sledge cold; all parts liable to wear have means for taking it up, and in case of pins there are always bushings put in when new, that are easily replaced.

We believe this is the first firm making locomotives that have introduced the profit sharing principle into their works. Two years ago, Mr. Porter started on a small scale to get some data to work from, and last year set aside a certain per cent. of his profits to divide among his men. This was apportioned to each man in proportion to the amount of wages he had earned in the year.

Last year the amount each man received was about ten per cent. of his wages. Foremen got from $300 to $125, machinists from $120 to $70 and laborers from $60 to $45. This is an inducement for the men to put in as much time as possible and to work as honestly and avoid errors and mistakes as much as if they were working for themselves. General Foreman Frank Lackner says he finds a big difference in the men and their work since the new order of things. Every man who earns a dollar for the company during the year is entitled to his share of the profits, and the company have in their safe, checks made out for many different men who worked for the firm sometime during the year. After the distribution of profits this year, the employes of the works presented Mr. Porter with a very flattering testimonial of their esteem, and passed resolutions showing what they thought of the system. One of the items we noticed was that, in the estimation of the men, it was a cure for strikes, as they could ill afford to strike against a business that paid them good wages and in which they had a dividend-paying interest.

During the year the works had 440 men on the pay roll, the regular working force being about 265.

New Steam Heater Coupling.

We illustrate herewith a new steam hose coupling, the invention of James B. Clancy, of Springfield, Mass. Most hose couplings use two pieces of hose between the cars, a coupler head on each; in this coupler but one piece of hose is used. On each end of this hose there is a coupling piece, like Fig. 3; this has taper lugs on each side, to enter the slots in the union nut, with a handle, shown in Fig. 4. The end of the hose piece has an octagon opening that fits over a projection on the

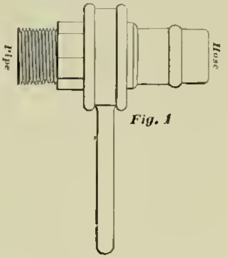


Fig. 1

pipe end of coupler. This serves to prevent the two pieces from turning from each other when the clamp nut forces them together, and also to carry the steam past the joint for about an inch. Any kind of gasket can be used between the

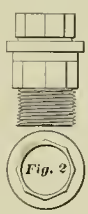

Fig. 2

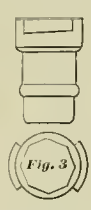

Fig. 3

butt joints. A coupling before us has a thin copper one, that has been doing service for five weeks on the Connecticut Valley Railway. By using but one piece of hose, two clamped hose joints are gotten rid of. Extra pieces of hose are cheap, and can be carried, and if a joint should

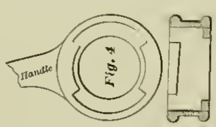

Fig. 4

leak, a change of gaskets is but the work of a moment. A quarter turn of the handle locks or unlocks the clamp. The coupling has been tested for some time, and as yet has shown no weak points. Its simplicity, and provisions for keeping a tight joint, should make it a lively rival for more elaborate devices.

At the Pittsburgh Locomotive Works we noticed several engines going out with Krupp tire not turned off on outside. It is unusual for tires to be put on and be true on outside.

A Rod Key Kink.

The key in front end of main rod on most locomotives, especially those not having the four bar guides, is generally a source of annoyance to engineers. The first single beam guides had a slot through them, and also the crosshead and gibs, to allow a bar to be placed through them to drive down the key. This weakened the guide, crosshead and gibs, and was hard to get at, as the engine must be placed in a certain position to make the slots "gibe." The next move was to put the key in from the bottom and drive it up, if the set screw worked loose—and it will if the crosshead needs lining up badly—the key was lost, tne brasses might have enough play to let the shock shear off the strap bolt or knock out a cylinder head, or both. Then they made a solid front end to rod and tightened the brass by a taper key *drawn* in from the back side by having a thread and nut on the outside. This permitted the use of a large key, but it took two men to keep them properly set up; they *would* work loose. The Pittsburgh Locomotive Works are making a solid front end on rod, the brass being tightened by a large key driven in from the outside and held in by a set screw on top of rod. The upper side of key has a slot as wide as a set screw, and about 1/4 inch deep, and running to within 1/2 inch of each end of key. On the bottom of this slot the set screw grips; if the key works loose it can only get out to end of slot, and the pound will notify the engineer by telephone. It is a simple kink, and as good a one as we ever saw. Why not slot the side of all rod keys? There would be fewer keys thrown at people along the route.

Compulsory Labor.

One would think, to read some of the daily papers, that the Government of the United States was a despotic monarchy, and that the said newspapers were the reprint of royal decrees. One of them tells how a little "judicial thunder" from some petty judge out West scared a lot of U. P. engineers from thinking of striking to help the Burlington men. According to them, there is, and should be, a law to prevent a man from stopping work if he wanted to. Such stuff is nonsense, pure and simple; such utterances are calculated to do a world of harm in widening the breach—already too wide—between labor and capital.

We heartily commend to the thoughtful consideration of every locomotive engineer and fireman in America, the noble and honorable sentiments expressed in an article headed "Hiring Engineers," in the March number of the *Locomotive Fireman's Magazine.*

Arrangements have been made with the American News Company and its wholesale branches by which copies of THE LOCOMOTIVE ENGINEER will be regularly supplied to and kept on sale by retail newsdealers in all parts of the United States and Canada.

A Valuable Tool.

Pedrick & Ayer, of Philadelphia, manufacture tools especially for railroad repair shops, and, knowing the want of a tool to plane up and finish driving boxes, truing brass as well as the box itself, they got up designs and patterns for a heavy tool for this purpose, built on the shaper plan. The tool did nice work, and the firm had great hopes of it, but about this time their attention was called to the planer attachment for the same work, shown in this issue, invented and patented by C. F. Geyer, general foreman of the C., B. and Q. shops, at Aurora, Ill. They saw the utility of the invention, and at once made arrangements to manufacture it. It could do work faster and cheaper than the regular tool, and could be sold for about $150. The special machine just got out was abandoned and the patterns laid on the shelf. It sold for $2,000, and the firm knew very well that no shop would pay that for a machine when they could get a better one for less than $200. Shop kinks are often valuable—have you got one?

A Hand Blow Back.

Our valued correspondent, J. J. Bingley, gives his idea of a fuel saving device in a valve and connection to send surplus heat to the tank. This is doubtless a very good idea—much better than the scheme that attached the pipe directly to the safety valve and obliged the extra steam to go to the tank always. There are times—lots of them—where, on account of low water in tank, or heat stored up there till the pumps or injectors would not work, it is very desirable to let an engine "blow." Mr. Bingley's idea appears to be the happy medium that we all want to reach.

The B. & O. have condemned all the old camel-backs that will require an expenditure of $1,700 for repairs.

Correspondence

A Lesson on Valve Motion.

When I was a "cub" around the shop we had lots of old locomotives, hook motions as well as links, and I got pretty handy at doctoring valves that were "out." A few years ago my engine was in the shop, and I worked for a couple of months in the roundhouse. One day an engine was ready to go out that had just got a half rebuild in the roundhouse; the foreman asked me to set her valves. I did so, proceeding in the usual way; got her dead centers, made her port marks on valve stems, by using tin in ports and a good steel tram, divided the travel very carefully, and pronounced her O. K.—but she was not. Her engineer took her out into the yard and she started off, holding up one leg, as if some one had stepped on her corns. He brought her back and I went over every point again, but could find nothing wrong.

They got the pet valve man out of the back shop; he was an English machinist, and had his nose at an angle of 45 degrees at the very idea of letting a "driver" set valves. He explained to me that an engine at work had a big load on her valve, and he had a couple of coil springs that he rigged up each side of the rocker box to keep up all slack, and after it all did not change a bolt I had set—and still she limped.

They examined her nozzles, her valves and valve seats, and all were as they should be. All hands were stuck. The division master mechanic sent out in the yard for an old engineer running a switch engine. He had lost a foot in some former wreck on the rail. He hobbled into the roundhouse on a cork foot, and the master mechanic said: "Peggy, the cob chopper won't chew her cud square; I wish you would take her out and see what is wrong. Take John along and give him a few pointers." I had fired for old Peg, years before when he had the use of both hoofs. We went out and up a long side track, and Peggy turned to me and said: "Jack, are you sure you have her all right—line and line?" I was sure. I set the tank brake and ran the engine slowly, and Peggy hobbled along beside her, looking for her limp.

We stopped, and the old man came to the gangway and said he guessed he had it cornered, and asked for a half dozen coal checks. I got them and got down. "Now, Jack," said Peggy, "you see, as sure as you live, one of these link motion engines has got to be right, and I believe this engine's valves are square as a die; she ain't lame at all; she's *lopsided*. Get a monkey wrench." I got one. "Now, Jack, you stand down here and squint across the top of them arms to the tumbling shaft; looks like they was straight, and yet it don't; may be they are, may be they ain't; but we'll get this here scrap square, all the same, by the tumbling shaft. You see, if one of them arms got bent a little in kicking around the shop or being put up, or if one of the pins was wore more than the rest, or one of the hangers was a trifle too long, or one of the rocker boxes were a leetle high or low, it would make it impossible to find where she was out by the trams; it would be jest the same as if she had two reverse levers and one of them was working a notch harder than the other. Now, you loosen up this tumbling shaft box on this side, and we'll block her up a trifle with card board and see how she acts."

We did so and she was better; we gave her a couple more tickets and she was square. The old man trimmed off the card board outside the box and smeared the edge over with black grease. We went down in the yard and got hold of a string of cars and pulled by the shop with every exhaust just exactly like its twin brother from the other side. To the valve expert's questions the old man replied, "You fellers got her stack on wrong side before," winking at me. To the master mechanic he said, "I guess the boys made a little mistake in making that new rocker arm or box or in setting it, or perhaps the arms of the tumbling shafts are bent. It would be better to go over those points and correct the real fault, and take that gun wadding out from under the box of tumbling shaft; still she is old, and it won't hurt her to run that way. Next time you have a bad case of limp send for John here; I have been giving him a few lessons in the artificial leg business."

And, giving me a sly punch under the arm, he hobbled out into the yard and read a paper in the soothing shade of the water tank, keeping his weather eye on the motions of his fireman, who weighed coal cars and played engineer.

JOHN ALEXANDER.

Encouraging Master Mechanics.

The master mechanics are a valuable set of men in their own estimation or while in convention, but fall very short of convincing large railroad corporations of the fact.

A well qualified master mechanic gets a good salary, say from $150 to $250 per month, while his engineers make from $180 to $190 per month.

Now the M. M. gets his $150 or $250 per month providing he has some good friend to put him in position.

Remember, they are all paid by the month, so they can be fired out at any time the management may wish to do so; while cooks, waiters, etc., are paid by the year.

I am only surprised that, while a master mechanic is of so little use, that they are employed and paid such enormous salaries, when they could be so easily done away with. I am sure the traveling public could do away with them better than they could with cooks.

I am sure any of your $10,000 cooks could keep the world in motion without being bothered with the high-priced mechanics. If a man is a good judge of beefsteak why should he not be a good judge of iron and steel and of engineers and firemen?

I wonder if those $10,000 cooks get annual passes over the different American railroads. I am sure master mechanics do not. I can answer for that myself, being one of the unfortunate M. M's, and ex-member of the Master Mechanics' Association, caused by being refused passes from Philadelphia to Boston. My thirty-three years' experience does not count in machinery department of railroads, therefore I am not entitled to passes, and this after spending and devoting my lifetime to railroads. Oh, why did I not learn to be a cook, and keep out of conventions and mechanical departments of railroads?

I was told by a traveling man three or four days ago in my office, that two very liberal managements in Iowa gave their master mechanics the privilege of attending the last M. M's. convention—providing they would pay their own expenses and lose their time while gone.

This is generosity and kindness personified on the part of the management toward men who meet in convention solely to discuss methods to do their work cheaper and better—profiting by each other's

experience. How long will this continue so? E. A. Campbell, M. M.
Houston, Texas.

Babbitt.

I have had considerable experience with babbitt metal, and the conclusion I have come to I sum up in the following lines: I have known two identical cases on different roads and different build of engines, one a Schenectady, the other a Baldwin, where the main pins ran warm enough to cause considerable anxiety to engineers for several weeks, and in each case the remedy has proved effectual, which was to remove babbitt and substitute leather.

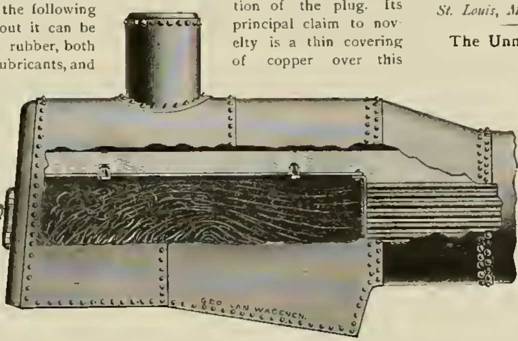
I believe that babbitt in any case is unadvisable on back-end bearings of main rod brasses, even when put in near top and bottom of brass, a strip dovetailed, say of ¾-inch wide; and when put in the way just stated, is the best for the following reason: In case of melting out it can be replaced by leather or sheet rubber, both of them good absorbents of lubricants, and they can be re-babbitted easier than other ways; the most objectionable way is to drill holes all over brass, including crown, for the reception of babbitt; in this case, when brass has been hot enough to melt it, there is no other way but to re-babbitt, which takes time, or to do as I did once with a brass, which had bothered us a great deal, on a ten-wheeler main pin—drill holes deeper in crown of brass, tap them and put in brass plugs, then slot brasses as aforesaid, and put in leather; the reason for filling up the crown with plugs was the want of bearing in the right place; we were never troubled with that brass after. But if babbitt is objectionable in rod brasses, it is much more so in driving box brasses, when they become hot enough to melt the babbitt, which they do sometimes (every mechanic who has had to remove it from driving box while engine was in round-house, and, as is generally the case, engine wanted as quick as possible, will agree with this), they fill up oil holes, and the metal, which was put in to save the brass and make it last longer, is the cause, in that case, of wearing it in one trip more than one year's ordinary wear would do.

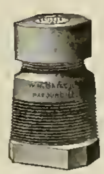
It is of course understood that the rod brass, from the same cause, has the same effect, only in this case it can be got at easier, and in consequence, as a rule, less profanity ensues. This has been my experience with babbitt in the negative; in the affirmative, I have found babbitt very useful in conjunction with copper plugs for taking up lost motion laterally, on crossheads and driving boxes, next to hubs of wheels; have also applied it with success on tops of crossheads, where it does good work, and is not as expensive as other metals to apply, taking labor into account; have also used it to advantage, taking up lateral motion, on rod brasses, by drilling holes around brass and driving in every alternative hole copper plugs, leaving them as much longer as required, to form a dovetailed head by riveting with hammer; this not only helps to hold babbitt in place, but makes it wear longer and gives good satisfaction.
Missoula, Mont. Jos. Wormalo.

The Bailey Soft Plug.

We show herewith a new style of soft plug, the invention of W. H. Bailey, an English engineer, and being introduced in this country by Geo. Van Wagenen, of 233 West street, this city.

As will be seen by the perspective view, the top of plug has a removable nut that holds the cap of fusible metal in place. The section shows the general construction of the plug. Its principal claim to novelty is a thin covering of copper over this fusible gasket. It is claimed that the action of the water changes the character of fusible metal, making it impossible to melt it at the proper heat. The inventor of the new plug has aimed to avoid this trouble in the copper cover. The action of the soft plug in protecting the crown sheets in cases of low water is perfectly familiar to all engineers, who can readily see the advantages of this particular plug.





The large cut shows two plugs as applied to very long fire boxes.

Points on Air Pump Repairs.

When air pumps are repaired in the roundhouse they often get mixed up in their bearings and act queer on the road.

The other day my pump was overhauled, and I was called out in the night to go to a wreck, in a hurry. The engine was in the yard and hold of the wrecking car, and as soon as I arrived I filled lubricator and started air pump and got down to oil. In a few minutes the pump began to labor hard, and slow down, and finally stopped. I thought the exhaust was stopped, and disconnected the exhaust pipe, but the pump stood still; I got up in cab and the gauge showed 80 pounds of air. I tried the cock on air drum, and there was no pressure there; then I started to take engine to roundhouse, and found the tank brake was set. I investigated a little further, and found that the machinist had connected the reservoir hose to the train pipe, and the train pipe hose to the reservoir, between the engine and tank. The pump could only fill the length of pipe on tank and the brake cylinder. I traded hose connections, and all was well. We use straight air. I find it good practice, if a pump works hard, to investigate exhaust pipe; they often stop up, and for pounding I find the air valves are the cause of most of it.
St. Louis, Mo. John Veroer.

The Unnecessary Half-Notch.

In your March number you had a little item on the half-notch that shows how inferior the American locomotive is to our British built machines. We use a screw and hand-wheel to suspend our links, and it gives us a chance to cut off at any point we choose, even to splitting your *half-notch* into eighths. English.
Jersey City.

[The remarks of our correspondent as above are very amusing, if nothing else. The British locomotive, with its screw reverse gear, may *split* hairs or anything else in point of cut-off, but how long does it take to get one from full gear forward to full gear back, when in a hurry to avoid an accident? One English built locomotive that we are familiar with, came to this country to surprise the natives—and it did. It took ten revolutions of the wheel to get it from full forward gear to full back, and was continually getting through the roundhouse or off switches on this account, although run by an imported engineer from across the salt-lick, who was used to the "critter."]

Stopping Locomotives.—A Question for Roundhouse Men.

The boys are much pleased with the paper—it is just what they want. Some pointers, a little logic, and no algebra. There is always something to learn about a locomotive, and no man knows it all; but lots of engineers are too proud to acknowledge this, yet it is often proven to them in little mishaps on the road.

I see by the first number that you have a few practical railroad men for railroad commissioners in the States. I wish we had some in Canada, as in many cases here our companies have to pay big damages because there are no practical men to question the assertion of witnesses and jurymen who may never have been on a train, and seem to think that a locomotive can be stopped in a few yards at the outside. I have had farmers race with me for a crossing, and if by chance they got across before the engine did they turn around and laugh at us; but if it happened the other way and horses were killed or a wagon shivered, they immediately sued the company, and *prove* that the engineer should have stopped. I have been running on the Grand Trunk for the past fifteen or sixteen years, and have had many different firemen in my time, and have watched them closely. The ones that require to be told to do everything every time you want it done, that never think of picking up a broom unless told to, who clean their lamps, fill the oil cans or do any other of their duties only when asked, whose oil, clothes and tool boxes are half full of cinders and coal, and their engine always dirty, who work only to get in their trips on the engine and keep their pay up, are the men who make our incompetent, careless and ignorant engineers.

On the other hand, the boys who seemed to take a natural pride in keeping things neat and handy, and, by taking advantage of time in delays, have kept things in such shape that they made it very pleasant for the engineer, and easier for themselves—they are the men who are our best engineers. John Alexander was right when he said good firemen make good engineers.

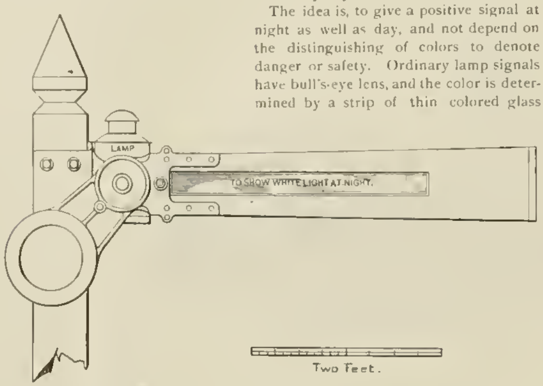
I hope the question and answer column will be freely patronized by the boys. There are a number of items I should like to see shown up myself. One I will ask now: What good does it do to book repairs when the boss fitter will cross it off and tell you he will "keep his eye on it"?

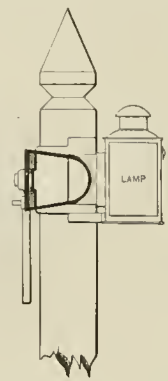
Montreal, Canada. JOHN ALLAN.

Illuminated Semaphore Signal.

The engravings represent a new illuminated Semaphore Signal, as manufactured by the Union Switch and Signal Company, of Swissvale, Pittsburgh, Pa. The larger cut is a front view of the signal, in place on the post. The strip in the blade is fitted with glass, through which the light from the lamp is reflected by means of suitable reflectors, shown below. In this signal the only duty of the lamp is to render the blade visible at night, and the slot in the blade is so proportioned that it presents a broad band of white light at night, of the same general form as the blade by day, making a positive signal at night as well as by day, no colors being used.

The idea is, to give a positive signal at night as well as day, and not depend on the distinguishing of colors to denote danger or safety. Ordinary lamp signals have bull's-eye lens, and the color is determined by a strip of thin colored glass





slipped in behind this lens; should a red glass break, and they often do, the lamp shows white, or safety, where it should show danger This signal avoids the use of colors, and is safe with color-blind men.

Air Pump Conundrum.

I want to see air pump and brake discussions in THE LOCOMOTIVE ENGINEER, and, to start the ball rolling, will give a little of my own experience.

Some time ago an engine came in with her air pump working badly; the piston would move upward very slow and would go down very fast; the first thing I did was to examine the top discharge valve seat, thinking perhaps it had worked loose, so as to prevent the valve from lifting; but the trouble was not there. I then took off the top cylinder head, but found nothing there. I then put the head on again and started the pump, and when the piston was on the upward stroke I shut off the steam, took off the reversing cylinder cap to see if reversing piston had forced the main steam valve down. I found it had; but to be sure that the reversing piston was all right, I put new rings in it; I also put new rings in main steam valve, put everything together again, but the pump acted just the same. I then took off reversing valve cap to see if reversing piston had performed its work, and found it had. I then took off the head for the third time, and found—what?

If any one working at air pump repairs will guess what the trouble was, I will send him a good cigar, care of THE LOCOMOTIVE ENGINEER. W. F. R.

The Richardson balanced valve is being applied to about 75 locomotives per month. Several roads that have had a few in use for a year or two are putting them on all engines that come in.

Some Pointers for Firemen.—A Barometer and a Blow Back.

It is said by someone that the steam from the locomotive is a good barometer; for if the steam remains long in sight, it proves the air is saturated with moisture, and rain may be expected. But if the steam evaporates quickly, it proves the air is dry, and fair weather will follow. But I have often seen steam from locomotives so full of moisture that there was a kind of fog falling all over the train. Indeed, I knew an engineer who was so accustomed to watching the exhaust steam, that he could tell when to put on and shut off the pump, without trying the gauge cocks.

Many engineers would be surprised if they could know the difference in the coal bill, by carrying one gauge too much water, beside the cut valves and cylinders by carrying water too high, as it washes out all cylinder oil.

Some firemen have an idea that to always have the steam blowing off is a sign of a good fireman; it is just the reverse. This is a matter that is being looked into more than formerly; I knew a R. R. President who said it cost five cents every time the whistle was blown. It may not have cost that much, but it shows that these things are noticed.

The heater can be used when standing, to blow the surplus steam back in the tank, and if firemen only knew how much difference it makes to have the feed water heated twenty to fifty degrees, they would watch every chance to put on the heater, instead of blowing it off at the safety valve. This cannot be done so well with the injectors or heaters blowing into the feed pipe, as it injures the hose. I used to put a $\frac{3}{4}$" angle valve for a heater and run a pipe under the footboard, also under the front end of tender, and through the floor and up the side of and into top of tank, and down into the water, connecting the engine and tender pipe with a piece of air brake hose, and a union, allowing slack for oscillation, and whenever the fireman saw the gauge hand was going to the blowing-off point, he would open this heater, and it saved the annoyance of blowing off, and gave him a chance to store up power for a hard pull.

It is the ambition of all good firemen to get to the right side of the footboard; but how few of them try to qualify themselves for advancement; they can do wonders, to hear them talk in the roundhouse; but if the engineer has got some work to do about the engine, and needs a little help, they often grumble about always being at work, and skip off, when they might have learned something there that would have served them well in after years. I heard an engineer once say (who had been running, I think, seven years) that he had never seen the inside of a steam chest. A man with no more ambition than that, could not run for me. He had been one of them sooner fellows —sooner not work. Remember, there is always room at the top, and persistent climbers generally get there.

J. J. Bingley.

An American Railroader Off the Reservation.

I am a Yankee fireman and on a visit to England with my father, who was a former subject of herself, the Queen. This morning I got a paper and it told of an engine recently brought to the repair "shed," that had experienced a peculiar accident. It read: "In striking the tack spline at the west point in Cranshire, the little end of connecting bar unhobbled, knocking off siphons, clacker, trailing splashers, and spring shackles, letting the engine so low that the life guards caught the next spline, and turning the locomotive into a goods train on siding, derailing several wagons; the driver was scalded by escaping steam and the stoker was badly burned in reducing the furnace fire. The break-down van was several hours in clearing the wreck."

I made a pilgrimage to the said shed to see the cripple, and found that the front end of the main rod had come down or broken at the frog of west switch at Cranshire and knocked off the check, wheel cover, oil pipes and spring hangers, letting the big hooks in front—there are no pilots—catch the next frog, ditching engine and crashing into a freight train on side track; the "wagons" are cars, and the "break-down van" the wrecking car. I also heard a "driver" telling the foreman that his "cistern" leaked, and I went to see them look at it—it was the tank. It seems to me this is railroad English, "as she is spoke."

Yank.

London, Eng.

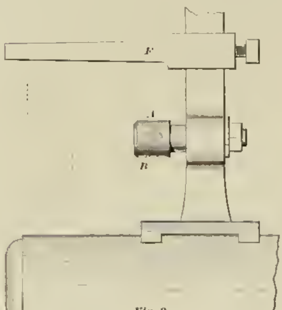


Fig. 2.

Handy Ratchet Drill Frame.

We illustrate herewith a very handy ratchet drill frame, specially designed for boiler work. It is the invention of John Lee, foreman of the Lehigh Valley shops at Hazelton, Pa., and was patented by himself and Master Mechanic Clark some time since.

Shop men are perfectly familiar with the makeshift frames and braces often rigged up to use ratchets.

As will be seen by Fig. 1, the standard of the frame has a slightly curved base plate, about twelve inches square, with a sharp steel point at each corner. Above the plate a few inches is a heavy bolt *A*

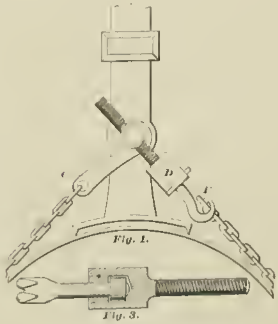

Fig. 1. Fig. 3.

(Fig. 2), that can turn in the standard. This has a threaded hole *B*, through the head, and a recess turned back of head to receive the hook *C* (Fig 1). This hook is attached to a cable chain of the proper weight. The bolt *D* (Fig. 1), has a swivel hook in its head, as shown in Fig. 3.

The brace can be set on the top, side or bottom of boiler, or any other work, the hook *C* attached to bolt *A*, and the chain passed around the work, and the hook *E* grappled to it. A few turns of the bolt *D* draws the chain tight enough to hold the frame firmly where wanted. The brace arm is held by a set screw in any position required. The device takes up little room, and is not in the way of other workmen.

A mechanic who has had to rig up to drill a hole in the side of a locomotive dome can see what a handy rig this would be.

Wedgeless Locomotives.

I am an old fogy. I can't help it. I am only old fogy about some things, however. I believe that many of the earlier ideas, properly worked out, are as good and better than some of the would-be improvements of later days. I like improvements, however. I believe one good injector is worth four pumps. I believe one good sight feed lubricator is worth a dozen tallow cups. I believe solid rod are better than loose straps. I think anything that saves work in repairing engines, or prevents the necessity of repairs, is good. I have rode an engine for many years, and I have been foreman of a shop for many more. There has been considerable said and written in the past few years about "monkeying engineers," etc. Now, I am old fogy enough to take square issue here. The engineers do not intend to "tinker;" they are *too good*, they take too much care of their engines. The men try to keep their machines up, and they will adjust rods exactly right, but they cannot adjust worn driving boxes and brasses, and the wheel cramps and twists about, and the closely adjusted rod comes off the pin. If the rods were solid they would wear loose as the box wore loose, and the engineer would not be blamed if it did pound or rattle.

If I were building locomotives to my own notion I would never have a driving box wedge except on main box. A runner naturally keeps his wedges set up just as snug as he considers safe, and is, therefore, careful to oil them. Let him lay off and a strange man go out on the engine; he forgets or neglects to oil as carefully as the regular man, and the box begins to chatter as it gets dry; as it sticks it gets warm, and by the time it expands a little it is cutting and sticking, turn about. After a box, shoe and wedge are once cut there is no more close adjustment with them. Now I contend that a driving box that has no more lost motion than a thickness of tin is all right; when they would take this much I should put a shim behind the shoe. I think this would prevent stuck wedges, cut wedges and boxes, relieve the engineers of an irksome, yet necessary duty, be cheaper to build, run and maintain, and do just as well or better than the *too good* devices we now have. Locomotives are expected to do rough, heavy work, and I think there is such a thing as making them too nice, and too finely adjusted.

Primer.

The big Strong locomotive has solid wrought-iron driving wheels, made by Krupp at Essen, Germany.

CONTENTS.

The Coal Record Farce.

Every month nearly every road of any consequence in the country posts up in its offices, shops or roundhouses a bulletin showing the expenses of each locomotive in service ; how much coal she burned per mile run, how much oil, tallow, waste and repairs were needed, and many other items of equal interest. As ordinarily kept these records are worse than useless.

The general plan is to require the engineer to give a check for all fuel received, and he does. The coal is piled into chutes, buckets, dump cars, or is shoveled on to the tender, and in every case it is a matter of guesswork just how much is put on to tank. Often an engineer requires a full tank of coal, and the man in charge of coal chute agrees with the enginemen that fifty bushels will fill it, but he has no chutes except 75 or 100 bushel chutes, and rather than go "short," the engineman gives a ticket for it, and receives half of it—the rest runs off, or is shaken off as soon as the engine gets to running.

Again, the engines are coaled up and sent to the roundhouse, where they are robbed to keep up stoves, boiler makers' forges, etc. This is about as fair for one engineer as another, but it is not as fair for the engines.

Guesswork is uncalled for. We are satisfied that good and efficient coal chutes can be devised, where all the coal is received from one chute, in any quantity desired, and while the tender is standing on a pair of scales that weigh the tank *before* coaling and *after;* in this manner the engines will be charged with the amount of coal actually received. Stop the shop robber and let the engineers see what records they can make on a fair basis.

We know positively that many roads must account for every pound of coal *purchased*, and all losses by theft or other causes in transportation, in handling, in amounts used in shops and offices are *averaged* and charged up to the locomotives in service. This is encouraging to the men who try to make a fair mileage record.

The officials of a road who go on the supposition that there is no waste or shrinkage in coal or oil in handling are very impractical railroad men. Charge shrinkage to shrinkage, and give the boys and the engines a show.

We hear lots of "taffy" for English locomotives as being much lighter on fuel than American locomotives. Perhaps they do not have to account for coal lost, stolen and burned in roundhouse stoves.

Graded Pay.

The great strike on the Burlington system has called out a great many so-called editorials—from all classes of writers—on the above subject. The "hustler" who carries the reportorial Faber on the daily press has just outdone himself when he could interview the railway manager who would explain to the world—through the reporter—that if it were not for graded pay the railroads would never promote firemen and take the loss of their first year's blunders ; they would hire competent and experienced engineers always. The manager, or the reporter, forget to mention the place where this great supply of experienced men is coming from. According to them the "woods are full of engineers," experienced, competent, and always out of work.

The idea of the manager is to get the firemen to think that graded pay is their only hope of promotion. The action of the firemen in the Northwest troubles shows conclusively that this class of men are intelligent, posted, and know that the man who manages a railroad in the interest of stock gamblers cares not one iota whether the firemen are ever promoted or not.

If all managers could have four or five grades of pay they would soon have the country full of engineers, as they would take pains to find an excuse to dismiss men as fast as they got to the full pay notch.

With the country full of half-starved engineers, the management could cut wages down to the rate they would like, and once down they would remain down.

If one man runs an engine on freight, and daily goes over the road with fifty cars, getting therefor $3.00, it hardly looks fair that another man should do the same work for $2.00.

On any road where graded pay is in vogue, the company are just as willing to use a cheap man on an important train as a full pay one. If the company is sued for damages in case of trouble from incompetency, the manager is always ready to swear that the third-class pay engineer is a first-class engineer in every particular—but he pays him third-class pay because he is inexperienced. Like Mickey Flynn's whisky, "it will keep you warm in winter and in summer it will freeze you."

The Burlington manager was very particular to cite some isolated cases of light passenger runs on branches and compare them to main line runs, stating that they could not pay men as much for such runs as for the hard ones on the main line, because they did not do as much work. He offers no excuse for three grades of pay for pulling freight over the same division.

As a rule, promoted firemen do not make the mistakes on the road that hired engineers off other roads do ; they know the road. The firemen would rather remain firemen a year or two longer and then become engineers and receive engineers' pay, than be promoted to a great responsibility without pay in proportion, and with a premium on his discharge as soon as he reached full pay.

Pay men on switch engines less per day than men get on the main line—if some form of graded pay must be kept up—but do not pay a man half wages for doing as much work, taking the same responsibility and earning the same money for the company as another man getting first-class pay. We have noticed for years that newly promoted men who made bad breaks on the start were speedily "set back" and made to fire a few years more or else discharged. The officials did not charge up the expense of his developing experience to the fact that they would get his services for from one to three years for less than he was worth. They demand and receive first-class service for third-class pay. Is it right? Is it fair? Should a man who has started a new grocery, as an experiment, be expected to sell sugar, flour and other staple goods at two cents per pound when the ruling price was three cents? If he furnishes the staple, does it make any difference whether he has had a number of years' experience in handling it? Is not labor the king staple of the earth?

Graded pay is not a fatherly endowment for the education of locomotive engineers. It is a reduction of wages, pure and simple, with no other object in view. If any human being on earth is entitled to good pay, without previous servitude, it is the locomotive engineers and firemen of America.

Shop Experience before Promotion.

Promotion of firemen to the responsible position of locomotive engineers is a matter of great interest to a very large body of men who are directly interested, and to the public at large, as on the efficiency of these men, and the thoroughness of their schooling, depends the safety of travel.

Many master mechanics think it is best—and no doubt they are right—that a man should have some shop experience, and therefore take boys into the shop as helpers, with the idea of letting them go out to fire in a year or two. The insight that they get to the construction of the locomotive often gets them to thinking that they know considerable more of the mills than the men who originally designed them.

When a young man with a year or two of shop experience starts out to fire a big freight engine on a night run, he often finds that he does not know *all* about locomotives, and he always finds out that a fireman has several other things to do besides ringing the bell and smiling at the ladies on the depot platforms.

Many engineers prefer a perfectly green man to one out of the shop, as the new man will receive the necessary instruction and try and do his duty to the engineer and the engine. As the engineer teaches him to fire first, then to clean, and do his other work, he becomes a good fireman, because he has commenced at the bottom and learned the rudiments only; hence has learned them more thoroughly than the boy who knows, or thinks he knows, how to set valves.

No one questions the utility and improvement that follows from the shop experience; it is the delay in making the shop boy a good fireman and in making him think of his work, not the engineer's.

Mr. Henry F. Colvin, manager of the Rue Injector Co., an old engineer and a man who has had many years' experience in charge of railway shops, proposes a slight change in the usual shop programme, that has several advantages.

He proposes that men be put on to engines to fire first, and learn firing, get their several years of road experience, then be taken into the shop, but still remain extra firemen. Their shop experience, on running repairs, would be intelligible to them then, and do them great good, and the officials of the motive power department would know right where to put their hands on to an experienced fireman in an emergency. Extra firemen going out on all kinds of engines, on all kinds of runs, should be experienced men, and they can be kept on the extra list in no other way. Let shop experience come just before promotion, instead of just before firing, and we believe a vast improvement would be made.

Mr. Colvin's idea is an excellent one.

Unlucky Engines.

There are few men on locomotives who are really superstitious, but many do believe in such absurdities as certain engines being unlucky; where there is one accident there will always be three, etc. A good many of these half-developed beliefs are inherited by firemen from their early engineers. That some certain engine may have had more accidents than others is no reason why she will continue to have them. People who are inclined to be superstitious will be sure to mention the fact that an engine that just fell through a bridge came out of the shop on Friday, if she did, but always forget to count up the other wrecked engines that did not come out on that unlucky day. They also forget to count up the many mishaps that come singly—but let three come together, and then the "I told you so's" are thick. The writer was in the office of a master mechanic once when a young engineer applied for a position. The M. M. looked at him for a minute and said: "I have nothing for you to do unless you want to run an unlucky engine. The 49 has been running less than a year and has killed three engineers, and been rebuilt twice. The boys call her the 'man eater.' She will be out of the shop to-morrow, and not a man on the division wants her." "I would rather have her than any other scrap you have got. I don't believe in spooks," said the engineer.

That engineer is running that engine yet, and her former bad record has been wiped out. A bridge that wants to burn, or a freshet that wants to wash over the track will not wait for the "49," or the "13," or any other certain engine. Don't be superstitious.

If So, Why So?

The discussions of master mechanics, and the experience of shop and road men, as recorded in mechanical papers of the day, tend to show how good one device is, and how successfully it works in one place, and how poorly in others. We can easily see how different conditions of service would change the results, but cannot see why it is that on two paralleled roads, using the same class of engines in the same country and on the same service, one will have perfect success with cast-iron guides, while the other has no end of trouble with them. One finds it cheap and easy to use solid piston heads and snap rings; the other is obliged to use Dunbar or other sectional packing.

One cannot run its consolidation engines without one or more pairs of blind drivers; the other has flanges on all wheels and they do not cut.

One claims to save oil and repairs by the use of sight feed lubricators; the other says they are not worth using, and not reliable.

We do not believe this is because the engines are "cranky" or object to any new-fangled arrangements on them. There must be a good, practical common-sense reason "why these things are thusly."

The reason solid pistons do not work on some roads may be found in the style of crosshead in use; it may not be so proportioned that it helps to keep the piston head up off the bottom of the cylinder, or some other similar reason. The reason the cast-iron crosshead, or cast guides do not work, may be found in the design, insufficient bearing surface, or in the quality of the metal itself.

The lubricator may be troubled by poor or dirty tallow, or the engineer with ignorance or prejudice. Don't be superstitious, don't believe that anything about your engine is so unless the "why so" is proven.

Get at the bottom of these things—study, talk, write. "In ignorance there is bliss" was not written about railroad men.

ASKED & ANSWERED.

(15.) R. R., Plattsmouth, Neb., asks:

What is a scab? *A.* Railroad men call a man a scab who takes the place of a man who is striking or in trouble about wages. A man who works for under pay. A man who defeats the aims of workingmen in demanding good pay or fair treatment.

(16.) J. J., Leadville, Col., writes:

I run an engine with small wheels, and I notice that center of cylinders are higher than center of driving wheels. What is the object, and how does it affect working of the engine? *A.* It is generally found desirable to raise the cylinders two or three inches to get them up out of dust and snow, and when the engine rolls the frame is thrown down, bringing the center of cylinder about on line with center of driving-wheel. Its most noticeable effect is on valve motion; provision is always made to meet this.

(17.) O. N. T., Delphos, O., writes:

I am firing an 8-wheel engine, Rhode Island build. When she first came from the works she was so logy or slow you could hardly get her started; now she is the quickest engine on the road, and she has never had anything done to her; in fact, has never been in a round-house or shop since she was built. Can you tell me the cause, as her lead has never been changed? *A.* The engine was probably fitted up so nicely that she was stiff, and the friction of her own parts made her slow to start. It requires six to eight times as much steam pressure to start a new engine as is required to start an old one.

(18.) Student, Topeka, Kan., writes:

Our road has had the automatic brake for years, but we have not used it, always using the straight air until recently. I notice now that with eight or ten cars, when we use the brake quickly, that the head car or two and the tender brake will *release*. I cannot understand this. *A.* The shock caused by closing the three-way cock too quickly, thus checking the flow of air, increases its pressure at the front end of the train enough to force the triple valve piston up and release the brake. In using the automatic it is best to *open* the brake valve quickly and *close* it slowly. If you use the later design of engineer's brake valve instead of the three-way cock, it would obviate this trouble, as it cannot be closed so quick. Engineers like the old three-way cock because it handles easier.

(19.) W., Broad street, Philadelphia, asks:

Why is the back of many locomotive tenders made like a wedge? *A.* To enable men in cab to see switchmen on ground behind the engine and to make it easier to get over. Only yard engines are so built.

(20.) Elevated, Brooklyn, asks:

Why is the vacuum brake better for roads like the "L" than the air brake? *A.* It is quicker to act and release, having almost no friction at all in its working parts.

(21.) Reader, N. Y., asks:

What is the composition of the Mason locomotive bell? *A.* The bell mentioned is composed of four (4) parts of copper to one (1) part of tin.

IN THE ROUNDHOUSE AND Repair Shop.

The B. and O. still use the old clamp screw coupling on air hose—the same as they used with the Loughbridge air brake, before the introduction of the automatic.

***

Pittsburgh engines have the steam chest casing and cover in one piece, cast to fit the place, with round corners, and no creases of fringe to collect dirt and grease.

***

The Reading road are having a number of engines built at Baldwins that have a large fire-box, but only about half the size of the Whooton. Has same grate surface, but no combustion chamber.

***

Readers who do not find THE LOCOMOTIVE ENGINEER on sale at the news stands where they are accustomed to trade will confer a favor on us by dropping a card to this office, giving location of stand.

***

Some of the new roundhouses in the East are heated by large radiators between the stalls. The old idea of placing all the steam pipes in the pits was a good scheme to cook oil from about October to May.

***

H. K. Porter & Co., builders of light locomotives, at Pittsburgh, Pa., do a large trade in rebuilding engines for firms who have no shops. They had an engine in the shop, the other day, that was burned. She came from the pineries of Michigan.

***

D. Clark, designer of the Clark valve motion, at Hazelton, Pa., uses a throttle whose stem enters side of dome and is worked by a bell crank. The throttle lever in cab stands up like a young reverse lever, and is just behind that lever on side of boiler.

***

Consolidation locomotives have a long extension of the frames from the back box to the tail piece, also from front box to cylinder saddles. Engines are now being built with a cast wedge fitting between these frames for some three feet, and strongly bolted in.

On L. V. pushers they use a pony truck with a pair of heavy flat coil springs set immediately over the truck box. It makes it possible to shorten the front frames, allowing short enough buffers to prevent them from passing and locking with those on cars on heavy grades.

***

In answering Question 12, last month, we made a mistake in saying the mark on box should be placed *above* mark on frame. A moment's thought will show why it should be placed *below*; as the box wears, the frame, boiler, etc., settle down; the wheels or box do not work up.

***

Wm. H. Hubbard, foreman of the D. & R. G. shops, at Pueblo, Col., gives our readers the benefit of one of his shop kinks in this issue. Mr. Hubbard enjoys the reputation of making some of the most perfect rings at the least expense of any shop on his road. Such kinks are just what we like to get hold of.

***

The variegated, complicated and intricate signal system of some of the big 2, 3 and 4 track roads of the East looks Greeky to a Western engineman off a single track road, but put an engineer of the Pennsylvania or New York Central on to a Western line, and the time card, book of rules, "rights, etc.," is just as hard for him to understand.

***

It is strange that so many repair shops, locomotive works, etc., are equipped with such poor blacksmith shops. Crowding work into small forge shops and requiring forgings to be got out in a hurry to keep men busy in other departments is bad policy. The blacksmith shop is the foundation for the machine shop, and is as important as the foundry.

***

One of the "fast line" engines on one of our New York roads recently broke down on its main line and "held everything," for nearly three hours, all because the solid rod was held on by a loose collar that had concluded to stay, the end of the pin having been badly battered. Had the collar been in the shape of a nut it could have been forced off.

***

The Pittsburgh Locomotive and Car Co. are building 25 large 10-wheelers for the Atlantic & Pacific. They have 60-inch boilers with an 8-foot fire box, extension fronts, rigid front trucks, and tenders with a capacity of 4,000 gallons of water. They have solid-ended rods, Krupp tire, air brakes, comfortable cabs and good paint. They weigh over 100,000 pounds, 90,000 of which is on the drivers.

***

We notice some of the large consolidation engines over in Pennsylvania have both ash-pan slides arranged to pull *back* instead of to one side; they are connected together by a rod, and a lever on the back one opens both. Slides that open to the side are hard to get around to clean pan, and if the wind is strong on one side, it is often a great privilege to pick sides.

***

It is too bad the Rotary Snow Plow Co. did not have one of their rotary snow shovels to send out during the blizzard, to show its range and practical use, in the East. We have very flattering reports of its work in Montana and Dakota. The recent storm found several thousand miles of road without a single plow. Some of the roads had an engine or two with a little boiler-iron shield on pilots, that the boys out West call a "weed cutter."

Engine truck wheels, especially pony trucks under consolidation or mogul locomotives, would be very much handier if a spoked wheel were used. It is almost impossible to pack or oil these boxes where a solid wheel is in use.

***

Railroad men, young or old, cannot do better with their savings than to invest them in real estate; get a little home, stick to it if you move away, rent it; buy another and pay for it as fast as you can, you will soon own two. A little rent coming in every month will be a big help. It is easier to save money after you have made a start. Make the start.

***

A great many of the engines in the East have a neat, black painted board clamped to hand rail just back of the stack. It can hardly be noticed from the ground. It is very handy to paint or repair the stack, and keeps the men who sand up the engines from standing on the jacket and scratching up the paint work on the sand box. It is also very comfortable when you have to crawl out on a stormy night and dig down real estate.

***

One man runs and fires switch engines in the Cumberland (Md.) yard for the B. & O., and receives therefor but $2.50. Some day one of those old camel-backs will kill somebody, because the engineer could not see both sides of his engine, and the company will have to pay heavy damages; but this will not pay for the loss. There should be an international law, that at least two men should be on all locomotives. It is dangerous enough then.

***

If a man wants to see some old veteran engines, that ought to be pensioned, he should go over to the B. & O. road. The old "camel-backs" are improved now over what they once were, but are very crude affairs yet. They have old slab frames, no wedges, cast-iron tires, small sloping fire boxes, a low deck or "pit" for firemen to stand on to fire, old half-stroke pumps back of fire box, cab above boiler and large dome in it, no lagging or jacket on boiler, a lever to open smoke arch door to keep her cool, bell on boiler back of cab, Loughbridge air brakes, steam scales, eccentric throttle movement and a thousand other old schemes. They have injectors now and steam gauges, and link motions; they used to have hook motion and some of the old gear is retained—especially the old heavy cast rocker arms.

***

The B. & O. have a few old Perkins camel-backs still at work in its odd corners. We noticed one at the Cumberland Rolling Mill. These engines have the cab well back, more like an 8-wheeled engine than the old camels. They are equalized on four 20-leaf springs of heavy pattern. They have 8 wheels connected and no trucks; the wheels are small and have cast-iron tire. There is no cylinder saddle, each cylinder being separate and bolted to the center of the smoke arch and laying at an angle. All the rods are round, and the main connections are on next to the back pair of drivers; the back end of main rod has a knuckle joint and the side rod to rear wheel is connected to it. The main rod connects next to wheel, and outside of it the side rod to pair of wheels ahead is placed, and from the forward to next pair of wheels another rod is used; thus each connection is independent, except back one, and that is tied on to the main rod. These engines formerly had hook motions, but now have links, connected through two pairs of rockers and any amount of hangers and reach rods. These old pelters make a man think of his great-grandfather.

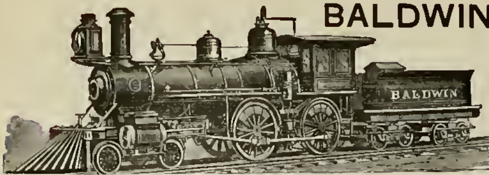
And now, as a fitting sequel to the headlight war that has been raging for the past year and a half, some of the manufacturers are talking of organizing a pool, or trust, or whatever they may choose to call it, for the purpose of putting up the prices of locomotive headlights. Of course the natural result of this course will be to stimulate competition in the manufacture of the goods. Perhaps, too, if the prices should begin to go up, quality may cut more of a figure than it does at present.

***

A MANUAL OF STEAM BOILERS—THEIR DESIGN, CONSTRUCTION AND OPERATION. By PROF. R. H. THURSTON, of Sibley College, Cornell University.

This book is a very complete treatise on the steam boiler; beginning with the history of the earliest contrivances, and giving accounts of all developments in steam-generating devices from the first to date. Every style of boiler is illustrated and described, and its advantages and disadvantages pointed out. A vast field of experiments in construction is reviewed and the causes of failure and explosions are gone into very fully and very plainly. The book is exact and complete enough to be used as a text-book in schools of engineering, and yet is so eminently practical that it must impress the mechanic as being, for his purposes, complete and reliable. Prof. Thurston has had a better chance than almost any other man in this country to study and experiment with steam boilers. The book would make a first-class reference for any mechanic desiring such a reference.

The price is $6.00, and they are for sale by the publishers, John Wiley & Sons., 15 Astor Place, New York.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

ANNUAL CAPACITY 650

LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable.

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, Etc.

Illustrated Catalogues furnished on application of customers.

BURNHAM, PARRY, WILLIAMS & CO., Proprietors, PHILADELPHIA, Pa.

PITTSBURGH LOCOMOTIVE AND CAR WORKS, Pittsburgh, Pa.

Manufacturers of

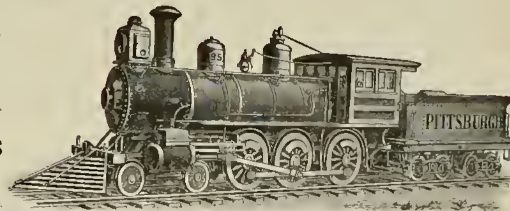
LOCOMOTIVE ENGINES

For Broad or Narrow Gauge Roads.

From standard designs, or according to specifications, to suit purchasers.

Tanks, Locomotive or Stationary Boilers

FURNISHED AT SHORT NOTICE.



D A STEWART, Pres. D. A. WIGHTMAN, Supt. WILSON MILLER, Sec. & Treas.

LOCOMOTIVE BOILER TUBES.

ALL TUBES WARRANTED.

Special Semi-Steel Tubes, combining High Tensile Strength of Steel with Ductility and Welding Qualities of best Iron.
Standard Tubes made from best Cold-Blast Hammered Charcoal Iron.

SYRACUSE TUBE COMPANY, SYRACUSE, N. Y.

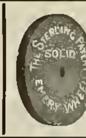
THE RICHARDSON & THE ALLEN-RICHARDSON

BALANCED SLIDE-VALVES.

Used by 140 Railroads. 8,500 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

Estate of F. W. RICHARDSON, Troy, N. Y.



Sterling Emery Wheel Co.,

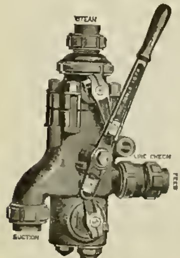
L. BEST, Manager,

MANUFACTURERS,

22 Warren St., New York.

Our Wheels for Machine Shop Work and Tool Grinding superior to all others.

Over 115,000 Inspirators Sold.



THE "NEW IMPROVED"

Hancock Locomotive Inspirator.

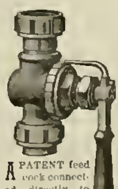
Awarded the FIRST PRIZE, A GOLD MEDAL, at New Orleans Exposition, 1885.

The Most Perfect Locomotive Boiler Feed.

Most Durable.

Most Economical.

Most Convenient.



A PATENT feed cock connected directly to Inspirator in the cab

Send for descriptive circulars to

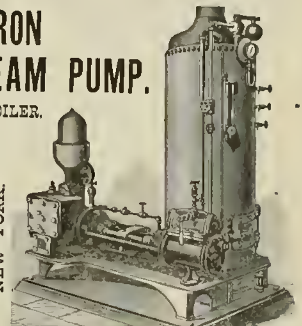
THE CAMERON STEAM PUMP.

COMPLETE WITH BOILER.

Send for Illustrated Catalogue.
THE
A. S. CAMERON
Steam Pump Works,
Foot of East 23d Street,
NEW YORK.



BAILEY'S PATENT

COPPER CAP FUSIBLE PLUG.

A Cheap Means for Preventing Accidents to Steam Boilers through Low Water.

Highly recommended by American Railway Master Mechanics, and others. Over 150,000 sold in Europe since first introduced, with increasing sales. Highly recommended also by the U. S. Board of Supervising Inspectors of Vessels at Washington, D. C.; by Prof. R. H. Thurston, and many other eminent expert engineers, as superior to any now in use, and filling all requirements.

GEO. VAN WAGENEN,

233 West Street, New York City,

SOLE AMERICAN LICENSEE AND MANUFACTURER.

Illustrated Pamphlets on Application.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. V. NEW YORK, MAY, 1888. $1.00 per Year, or 10c. a copy.

A New Reverse Lever.

The reverse lever shown on this page is the invention of George W. Cushing, Supt. M. P. & R. E., of the Philadelphia & Reading Railroad, Reading, Pa.

It will be seen by a glance at the cut that this lever is designed to give just what the locomotive engineers of the country have been wanting—a reverse lever that could be instantly thrown from full gear forward to full gear back, or *vice versa*, by the use of a latch, same as now used, but still allow a very close adjustment.

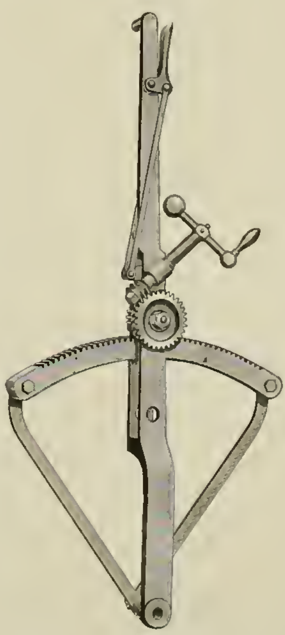
Mr. Cushing seems to have met this want very fully in the present invention. The quadrant is cut full of teeth, instead of notches, into which a small gear meshes. This gear is located between the two sides of the lever, and is shown just behind the worm wheel, which is on the end of same shaft, and shown fully in cut. The worm on the handle engages the teeth of this wheel. This worm shaft is held by a box on the side of reverse lever, and its axis or shaft goes through the lever and is secured by a nut. In the center of the shaft is fastened a short crank arm, and to this arm the long links are attached below, and reach to the thumb latch above. It will be seen that if the thumb latch is pressed to the lever the worm will be tipped out of gear with the worm wheel, and the lever can be thrown to any position as quickly as can any reverse lever. For comparatively short movements the handle is rotated, and the point of cut-off is as closely regulated as any man can wish.

Another thing will strike the observing engineman; the gear in the quadrant can be easily kept tight, and the worm, being on a taper, is always tight, doing away with the lost motion and chatter of older devices.

The desired results seem to have been simply and cheaply reached.

The Water Hose Trouble.

One of the meanest acting little details of a locomotive is the water hose from tender to feed-pipe of engine. The usual design has a "goose-neck" fastened to the leg of tank by tap bolts through a flange on said goose-neck; this is, of necessity, very close over front wheel of tender trucks, and is in the way of air hose, steps and brake rigging. The working of the brake works the joint loose, and to tighten it up on the road is next to impossible; in winter the leak covers the wheels and running gear of tank in an overcoat of ice; the hose "kinks" at its shortest turn and finally breaks there, shutting off the



supply of water; it is stiff and mean to connect or disconnect, and altogether an undesirable scheme. The B. & O. have the goose-neck attached outside of tank frame and back of the step; if it leaks a man can get at it by standing on the ground; it requires a little longer hose, but there is no short kink in it; the brake cannot touch it, and it looks—to a man who has been lying on his back trying to reach a rusty bolt in a hidden corner, while a stream of water ran down his arm and froze on his funny bone—like a blessed good thing.

Side Rod Cups.

The writer recently rode over one line of road and found the engines well supplied with modern appliances. We talked with an engineer on a freight consolidator, and he was in a stew because some of the needle-feeders—glass cups on the side rods—were not doing just right. We went right over onto another road where consolidators are in use, and rode on one; there were no cups on the side rods, and never were, there was only a drill hole, and the engineer spilled a little black oil around this hole when he oiled the rest of the machine. There is a good deal in the way a man is brought up how he takes these things. We are for side rod cups, because we are used to them, yet the men who don't have them seem to think a simple hole is good enough for a side rod.

Kicking Against the Wrong Thing.

We recently ran across an old-time engineer, and he was very busy cursing the right hand injector, and wishing he had his "good old pump" back again.

Investigation proved that the throttle or steam valve attached to the injector was leaking so badly the instrument could not prime. By leaving it wide open and using the steam valve next to the boiler, it worked all right; good enough for one trip. Injectors get blamed for many mysterious tricks that are really the antics of throttles, primers, checks or hose strainers.

The modern injector is one of the best, if not the best, improvements put on locomotives since they put on a stack to carry off the smoke, instead of having the fireman catch it in a bucket, and carry it out and dump it in the ditch.

We are in receipt of photographs of the Rotary Snow plow at work in the drifts of Montana. Makes a man shiver to look at the way nature lavishes the beautiful out there.

Locomotive Feed-Water Heaters.

We are in receipt of several questions about the work of feed-water heaters on locomotives, and asking us to explain certain things.

One correspondent from Canada states that he ran an engine some years ago that had a feed-water heating device, through which the right hand pump fed water; this heater was a coil of pipe on the inside of front end. He states that, with this pump, the water was so hot that a person could not hold the hand on feed pipe, but when the engine was at work the hardest, he could shut off this hot water pump and put on the left pump, that pumped cold water direct from tank to boiler, and it would make no perceptible difference in the steaming of the engine. He is at a loss to know why hot water is not better than cold water to feed a boiler, and if heaters save from 10 to 20 per cent. on a stationary boiler, why they don't on a locomotive.

A locomotive is altogether a different case from a stationary engine and boiler. The stationary boiler has a natural draft, and the engine exhausts into the atmosphere; if heat can be taken from this waste steam and returned to the boiler in the feed water, it is a clear gain.

On a locomotive the exhaust and all the heat in the front end or smoke arch is used to create a draft. If we take out a certain quantity of heat and return it to the boiler we have robbed the steaming capacity of the boiler just this much; we have lost one place to gain in another; we have taken a sum of money from one pocket and put it into another. If we take out exhaust steam to heat the feed water we rob the exhaust of so much heat, and hence have gained nothing.

You cannot take out one degree of heat from the front end without a loss. Locomotives are now crowded in every possible way to make steam enough to do their work; to take out heat from the front end in any shape means to further contract the nozzles to make up for the loss, smaller nozzles means less work exerted by the engine to pull her train, and more to burn her fires. Work is heat.

We have yet to hear of a single feed-water heater that has let the engines work at anywhere near their full capacity with larger nozzles, yet they all claim to save fuel and reduce back pressure.

Where any saving has been shown we are convinced that it is where the locomotive was not worked to anywhere near its full capacity.

The successful locomotive feed-water heater must take the heat from the gases after they leave the stack. Taking it any place between the fire-box and the top of stack is robbing Peter to pay Paul.

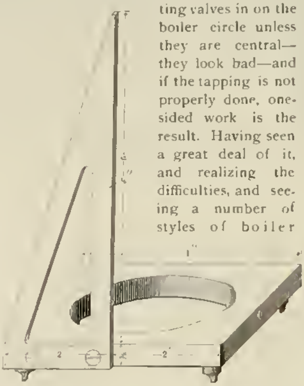
An Example.

The London and Northwestern Railway, of England, has 55,217 employes on its staff. With one of the fifty-cents per-month hospital schemes of America, the yearly receipts from this quarter would be the neat little sum of $331,302 "Hospital fund" is railroad English for a "hold up."

Handy Boiler Square.

BY WM. FOSTER.

I send you a print of a boiler square which I made, and which has proved a good tool. There is great difficulty with the average mechanic in drilling holes in a boiler to get them central, and in putting valves in on the boiler circle unless they are central—they look bad—and if the tapping is not properly done, one-sided work is the result. Having seen a great deal of it, and realizing the difficulties, and seeing a number of styles of boiler



squares, all imperfect, for the reason of the difference in the size of boilers, necessitating a different square for each size To overcome all difficulties I made this square, which will enable anyone to drill holes and tap them central with the boiler. The sketch explains itself, the projecting feet on bottom being of equal length, when placed on the circle of the boiler, squares itself, as the tongue of the square is exactly in the center and square with the feet. Now if the tap is brought on a line with the tongue of the square, it will be right every time.

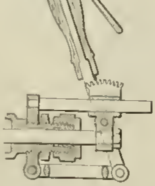
The sizes in inches are given on the drawing, so that any mechanic can make one.

One other advantage this square has, it can be used on any sized boiler, from 10" up to the largest size.

Providence, R. I.

New Valve Handle.

The cut shows an attachment to lever valves, whereby they can be held in any position. The idea was gotten up for throttle valves of injectors, and is in use on a number of roads, the B. & O., and the Canadian Pacific especially. This lever and arrangement can be held at any angle or be worked upside down as well as any other way.



We are indebted to Eugene V. Debs, editor, for a bound volume of the *Locomotive Firemen's Magazine* for 1887. The *Magazine* is the ablest labor organ in America.

Cure for Leaky Lubricators.

The tramp editor was taking an inventory of the inside of a locomotive cab the other day, and his attention was called to a new style of air pump lubricator. The device had no internal pipes, but drilled holes through solid casting; the holes were straight and a small iron screw was tapped into them, so that a wire could be used to clean out the passages. The oil used contained plenty of acid (the fireman said it was composed of sun-cured mule oil and old rubber boots), and its action on the fine thread of the iron screws was seen in the leaking indulged in around them.

The engineer said that all the cups that had run a month or two had blown out a screw if they were not removed soon after commencing to leak. Tapping out the hole and putting in a brass screw cured the disease.

Burlesque Examinations.

There is scarcely a road in the country where the engineers and conductors do not have to pass an examination. This examination is generally conducted by the division superintendent, and in half the cases might just as well have been omitted.

Division superintendents are made of all kinds of timber—conductors, station agents, office men, etc., and, except in the case of the first mentioned, know nothing of road service; the ones who know the least are the ones who want to appear to the men as the cutest—a sort of railroad encyclopædia. They get hold of and learn by heart a lot of difficult and unlikely problems, and spring them upon the unsuspecting victim.

If the practical man undergoing examination asks a knotty question the official looks wise, and asks: "Don't you know that? Well, now you think that over and let me know how you figure it next trip"—he wants to consult some oracle himself.

One local big-wig, whom the writer stumbled across in his experience, was in the habit of getting young men up in his office and propounding some of his tangled problems. If the answer was right he would look the young man in the eye for a second, throw down his book of rules, pick up his pen and say: "If that is all you know about railroading *we* can't use you on *our* road." If the now rattled man would start to go the superintendent would call him back, and, without telling him that his answer was right, go for him again. There was at this time a young man throwing coal into one end of a big boiler that the writer was taking out at the other, *via* the exhaust. One morning he got a notice to wash the coal dust out of his ears, pull off his overalls, and stand in the august presence of Himself for examination for promotion. That night he bearded the lion in his den, and the writer slipped into the roadmaster's office next door, to hear what was said. Himself wrote about ten minutes after the candidate arrived—this to get him nervous. He finally read his note from the

M. M., and settled himself to do the youth up—but he didn't.

He fenced a little and finally asked:

"What is rule 18?"

"The rule is rendered useless by rule 93," said the fireman.

Himself commenced to thumb the leaves of the book of rules, and the fireman asked:

"What are you looking for, rule 93?"

"Yes."

"Well, there is only 84 rules in the book, and besides that, I don't know a single rule by its number, and I see you don't. Take a train or engine on the road and cite any case or complication that can come up, and I will tell you what I would do. Now in the case of the wreck last week, both crews think they were right, and so far the men are about equally divided. Now I am a little shaky to know which side is right; I think the man coming East had the right of the road, don't you?"

Himself could not decide that, as the case was before the general officers.

The candidate asked that his examination be deferred till these cases were settled.

Himself couldn't do that.

Then the victim pulled out a book of rules with a dozen rules checked, and asked light in each case, but he didn't get any. Then he pulled out a division time table—made up by Himself—and pointed out several conflicting rules and as many fatal blunders in the time table, and wanted more light, but he got a certificate of examination, with the parting injunction to "run slow."

Himself had not asked a question but had been asked many, and he could not answer one.

While the writer was wondering to himself what earthly use such jim-crow examinations were, the victim came out with the flush of victory upon his cheek, and ye scribbler fell upon his neck and wept tears of great joy.

Tallow Pots.

There are few enginemen who will not recognize their own tallow pots in the photos given below. Fig. 1 is a bird's-eye view of the inside of a standard tallow pot, furnished by a well-known locomotive works, and in use on dozens of different roads; it is about 14" long by 4½" or 5" square, with a loose cover in the center, a small spout at one end and a small handle at the other; it is not, as a rule, provided with a strainer, and was intended to use where valve oil is used instead of tallow. The builders send out an iron bracket that just fits the tallow pot; this is sometimes bolted to the cab, and at other times to the boiler head; in either event, at each lurch of the engine it pumps out a small quantity of oil. To handle it is like a man trying to carry an axe with the handle horizontal and the weight extended far out in front, by main strength. As a tallow pot, it is not a thing of beauty, or much use either. Fig. 2 is a step-brother of Fig. 1, but is shorter and larger other ways; it generally has an inclined perforated sheet of tin in front at *a*, that gradually gets full of dirt and stays full, as there is no way to get at it. They slop over easily, and when they are half full of unmelted tallow you can't use half the stuff that will run. The stiff, pasty lumps slide down and shut off the screen holes. Then the engineer or fireman gets in a hurry and sticks the spout under overflow of injector or waste of air pump and tries steam as a melter, generally succeeding in blowing off the cover and getting a

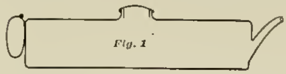


Fig. 1

shower bath of possum fat, condensed steam and foul odors. Then they get a shovelful of hot coals and set the little refrigerator on that, or set it in the fire door; this melts the tallow, and generally the spout or handle fastenings. Some roads use this same pot with wire bail, which is of some use, not much.

Now, what is wanted on a locomotive is a tallow pot that has a large bottom surface to insure its melting the tallow easily; it wants a handle that a man can hold on to and keep the pot right side up with a greasy hand, and no other effort than to sustain the weight; one that has a strainer that can be taken out and cleaned, one that will not slop over at every lurch of the engine, one that can be cheaply made, easily repaired and easily cleaned, one that can fall without break-

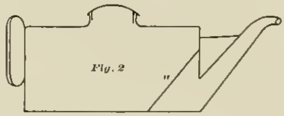

Fig. 2

ing off a handle or spout, and one that can be set in the fire door or on a scoop of coals with only one inch of grease in it and not melt something.

Such a tallow pot can be found in Fig. 3. The top is pressed tin, the filling cap is well back, so as not to waste tallow there when pouring from a full pot, the spout screws into a brass nut soldered into the top of pot in front, and to the bottom of spout is soldered a cone strainer, easy to take out, clean or repair; the handle is made of cast brass or of wood in a pressed tin depression; it can't be

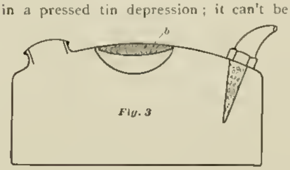

Fig. 3

knocked off, melted off or bent; it is close to the weight and easy to handle; it gets hot, perhaps—all of them do—but it is just as easily cooled. Because the old tallow pots have been made like 1 and 2 for years is no good reason why they should always be made so.

On eight-wheeled or open cab locomotives there is generally a small shelf on boiler head over the fire door, to carry the pot; as this is generally narrow the pot may have to be made oblong to fit it; on engine where boiler comes through the cab a good practice is to cut a hole just the size of the pot through the jacket and lagging, and fit a neat rim into it, letting the tallow pot set directly on the boiler sheets.

How and Why Injectors Work.

We are in receipt of many letters from practical men on the roads, asking for some plain explanation of an injector. Almost every one states that the writer has read or studied the principles in books, but is not up in terms and mathematics. One says: "I know an injector when I see it, but I don't know any algebra, and I don't know anything about foot-pounds, initial pressure, latent heat, etc. Would an injector work with compressed air as well as steam?"

The ground has been gone over many times by able men, but we will try to make the principle plain to the practical men whom we address. In the first place, no work is done on earth without heat. The exertions of the horse or ox are only accomplished by the use of heat. It is the heat of the sun that causes the grass to grow and the corn to ripen; it is the heat of the sun that draws the water from the earth and returns it in rain, or that sends down the streams from the mountain that turn a hundred water wheels. It is the heat of the sun stored up for ages in the shape of coal that we burn to-day. Work requires heat; heat, properly directed, is work. An injector does work, and to do it, it expends heat.

Compressed air will not work an injector, because the air would not condense on coming in contact with the water, but remain air, prevent a solid jet from being formed, or maintained after it was formed. There are many kinds of injectors, but all are essentially the same in their working parts. A non-lifting injector is different from a lifter only in wanting attachments to lift the water to it. The fixed-nozzle injector is one without moving internal parts, and differs from the adjustable instrument in the method of controlling the range of work only; the principle on which they all work is the same.

Steam issuing from an opening in a boiler travels at a very high velocity, while water escaping from the same sized opening will travel only about one twentieth as fast; this is due to its greater weight.

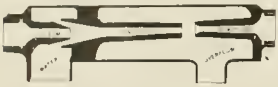
The simplest form of injector is shown in the cut; and water must be supplied to it either by placing it where water can flow to injector or be brought to it by lifting jets.

Suppose water flowed to this instrument, it would fill the space around the steam nipple and flow through the combining tube and out of the overflow; it cannot flow into boiler, because it has not force enough to lift the check. Now if steam is admitted in small quantity it will force its way through the combining tube and carry considerable water with it; it would produce a current that becomes stronger as more steam is admitted, until the velocity of the steam, combined with the weight of the water, will form a jet that has sufficient weight and velocity to cross the space between the combining and delivery tube and force its way through the latter to the boiler.

The steam, by coming in contact with the water, has become condensed, and in imparting to the water its velocity has lost its heat, or most of it. If more steam is sent to the injector than the water can condense, air will be drawn in at the overflow up to a certain point, then steam and hot water will issue from the overflow, the steam through the combining tube will be hotter and less solid, until the velocity will be out of proportion to the weight, and the injector will break; on the other hand, if more water is supplied to the instrument than the amount of steam supplied can carry with it, the surplus water will escape at the overflow.

If a pound of feathers were shot at and struck a house with a velocity of 1,000 feet per second, it is not likely that it would do the building so much harm as a pound of iron would, traveling at the same velocity.

Water from the boiler will not work the injector, because it has not the velocity to impart to the water to be fed. The steam can only do the work by sacrificing heat and velocity to gain weight; or, in other words, it has sacrificed heat and velocity to pick up and carry with it a certain amount of weight in water.



Experiments show that with a boiler having a pressure of 100 pounds, that from an inch opening in the steam space steam will flow at the rate of about 1,870 feet per second, while from the same sized opening in the water space water will flow at but about 100 feet per second. These figures may not be exactly right, but the proportions are nearly so.

If, for example, we assume that the steam is condensed until it consists of but ⅛ of the amount of heat and water returned to the boiler, we will find that it has taken up the other ⅞ in water. It has gained that proportion of weight and has lost a corresponding amount of velocity, which, in this case, would reduce the velocity to about 234 feet per second, leaving out all fractions, which velocity has to overcome the 100 foot velocity that would issue from the raised boiler check if there was not the stronger jet rushing in to overcome it. It is plain, from this condition of things, that an injector would force water into a boiler of even greater pressure than that from which it took steam.

There are exhaust injectors that work, using steam from an open exhaust pipe with pressure only equal that of the atmosphere, but it will not work with certainty at boiler pressures above 70 pounds per square inch. The reason for this is that steam at atmospheric pressure flows at a slower velocity than at higher pressures, though the velocity does not increase in the same proportion as the pressure, and its imparted velocity is but little above the resisting pressure at the check.

Fastening Shoes and Wedges.

Early locomotives had no wedges to take up lost motion between driving boxes and jaws of frame, and so the men who ran, repaired, designed, built or owned those locomotives had no trouble about holding wedges in a certain place. Their trouble was because they had no wedges or any other means of taking up the "thump."

When wedges were invented they had no wings or side pieces, and to hold them in place sideways they had a rib on their backs and a slot in the jaw of frame for it to work in; they were held in various ways, but one of the first was a tap bolt, top and bottom, but the top one was always getting on the time of a spring hanger or something, and had to be pulled off. Some of those old wedges are running yet; they have different ways of holding them, but the rib is there and the sides are gone, and the sides of the boxes have chawed a slice out of the jaw on each side, as a trade mark, or else to show that the frame belonged to the box.

After awhile some one stumbled on to the fact that wedges and shoes could be made cheaper than frames, and then commenced to make wedges that went each side of the jaw. After this they schemed for some way to hold the wedge after they got it there, and their schemes are holding, or trying to hold, in dozens of different shapes, all the way from Sweden to Missouri.

There was the plain little old bolt that was screwed into the bottom of the wedge and was fastened with a pin; it stuck through a larger hole in the pedestal brace, and had a nut top and bottom. It held the wedge from wandering around, but the top was loose, and the nut on top of pedestal brace was hard to get at, especially on the boxes next to eccentrics. Then they screwed the bolt into the brace and put its T head into a T slot in the wedge, and held the bolt by a jamb nut; the wedge soon elbowed around till it got room on top of that T idea.

Then they drilled a hole through the back of frame; yes, even made a slot, and put a bolt through there and into the middle of the wedge, but the driving box was bigger than the wedge bolt, and the latter, believing that discretion is the better part of valor, slacked off. Then the wedge danced around again, and, having nothing else to do, enlarged the T slot.

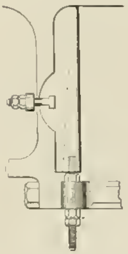
Then the box "thumped." Then the engineer "set up the wedge," and oiled around. Then the box worked up and down and hugged the wedge, got warm and expanded and hugged harder, and finally, at a bad frog, the box went up, and the wedge went up, as far as the slack in the T business would let it, and it stayed there.

Then that engineer sawed blocks next time, and, when the wedge had been screwed up where it belonged, he put the block under and screwed *down*. The T scheme was gone, but the top of the wedge was loose, and everybody said that was a bad idea, but it couldn't be helped.

Then the fellow who got up the cast-iron thimble, in place of the pedestal brace, came along, and, as he had a bolt through the middle of the thimble, they couldn't hold the wedge up by a middle bolt, so they put one each side. By getting the wedge where it was wanted, and jambing one bolt up and the other down, the wedge couldn't move lengthwise, but it wouldn't hold its tongue at the top of the box. They put in the gag bolt through the frame, but she spit them out; or, if they were located where the stopper and starter couldn't possibly reach them with a wrench, she took the lockjaw and held on to them for dear life.

All these schemes are in use, right in this country, now. What is wanted is something to hold the wedge where it is put, solid, and some simple way of raising and lowering the wedge. There is often as much necessity to draw the wedge down as there is to force it up.

The back tap-bolt is in general use to hold the wedge against the jaw, but is very unsatisfactory, especially on roads using small-wheeled engines.



William Wilson, Superintendent of Machinery of the Chicago & Alton Railway, designed and has in use a very efficient device for this purpose. The sides or wings of the wedge and shoe have a projection, and in this a T slot; T-headed bolts hook into the wedge each side of the frame, and a piece across the frame makes an efficient clamp. If there is a brace or bolt in the way the bolts are made a little longer and the clamp put on top of the projection. It is about the surest thing we have seen, and its simplicity and get-at-ability recommend it above any of the older devices.

Economizing Pieces.

A few years ago locomotives had only a few attachments; there was little in the cab but a lever, a throttle and a fire door; now there are few boats running but what are fitted with most of the new devices for oiling cylinders, pumps, etc., from cab; air pumps have added many handles, injectors, and all the smaller attachments have made the locomotive more complicated, but more efficient. To offset some of this, there are now many castings made alike for both sides of the engine. Years ago if an eccentric strap was broken an order would call for a "left forward" or "right back," and that meant entirely a different casting than the others; now many builders cast their straps all alike.

Then all the change that is called for from one side to the other is to drill the oil hole on the proper side. This calls for but one pattern for this piece, thus they are cheaper; it also calls for a smaller stock of castings to be kept on hand.

Right and left hand cylinders are now cast from the same patterns, both ends being alike.

Many steam chests were made with the stuffing box out of center, and a pattern for each side was deemed necessary, but it was soon found that if the gland was placed in the center of the chest, up and down, it would work just as well on the

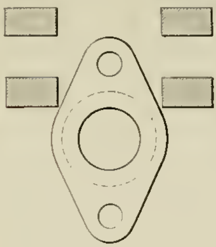


Fig. 1.

other side, turned over. Solid rods are throwing away many pieces about side rods ; solid piston heads have exiled bushels of small pieces from our cylinders and injectors, and inspirators have retired thousands of trappy pumps from active service.

It is good practice to never use two pieces where one will do the work ; it is poor economy to use two patterns where slight changes will let one pattern make a piece fit either side.

The Water Brake.

Some one expressed a desire to know how this simple device worked some time ago, and the answers from correspondents in the journals that published the questions are very conflicting.

We notice one thing, however, that is some satisfaction, and that is that all the men know how to handle the brake ; they invariably state this part right. This is the trouble all over the country, the men know how to handle many devices, but don't know why the devices work. That they could reason out failures far better if they did know goes without saying.

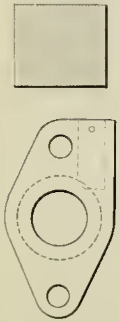

Fig. 3.

One man writes clear from the sunny land of the Montezumas to tell the readers of the *Engineer's Journal* that the water pipes are tapped into the steam-ways in cylinder saddles. As a matter of fact, the pipes enter the exhaust passages, and the water is drawn into cylinder by the engine being hooked back of center while running ahead.

The Reading Railway Company use gas lights in their new cars. It is carried in a steel cylinder under the car, and compressed to 1,500 pounds per square inch.

Piston Glands.

There are about as many different kinds of piston glands as there are railroads—more or less.

Four-bar guides that are so arranged that the piston is below them—and most of them are so made, because the lower inside guide is in the way of the truck wheel —are usually fitted with a gland like Fig 1 or Fig. 2 ; single or beam guides generally call for a gland like Fig. 3, or one without the oil hole attachments.

In nine cases out of ten, if . and works off, and they often do, the first stroke of the crosshead finds the gland partly turned over, drives it against the studs, stripping the threads, bending or breaking studs off, or breaking the gland itself.

Where the piston is in the center of guides, a large gland, like Fig. 4, is a good pattern ; it can come off if it wants to, but can't get out of shape or strike the studs, and the nuts are away from the guides and easy to get at. This style, or one very much like it, is in use on the B. & O.

Where the piston is below the guides, a gland like Fig 2 is often used, and where

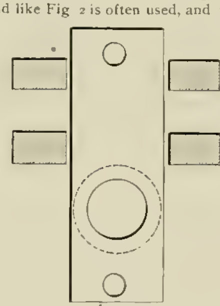

Fig. 5.

so arranged should be fitted close enough to guides to prevent its turning enough to strike studs in case it came off ; the long gland, like Fig. 5, is good, and easier to get at. The losing of a gland nut or stud is a very common occurrence on many roads, and if a form of gland can be used that will make such incidents no more costly or cause no more delay than the replacing of a few nuts, it will pay to make the change of glands as the engines go into the shop

Practical or Nothing.

Engineers and firemen in England are "kicking" against a bill that has been introduced into parliament providing for their examination and carrying certificates. Something of the same nature has been disturbing the enginemen on this side of the water. If the law will provide that all examinations be actually made on the road, that no employe shall be asked to distinguish shades of color, but only flags and lamps used by the roads, that all rules about brake handling shall be made where the candidate can actually handle the brake, that all examples of train rights shall be cited on the road and division of the road with which candidate is familiar, and numbers of trains be numbers of trains actually on the road ; that examples in fine-drawn theories be abolished, and only practical questions that *could* come up, where candidate would have to act, be asked, we will guarantee that the enginemen of this country (or any other) will safely pass.

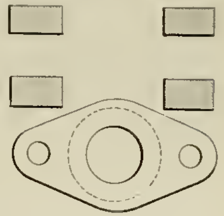

Fig. 2.

Deep-laid schemes of railroad puzzles and color-blind dead-falls would catch almost any man. If no official examiner was allowed to examine men whose engines and runs he could not himself care for, there would be few of the boys "stuck"

An Undershot Snow Plow.

The inventor of a new rotary snow-plow shows up an imaginary and ideal half-page cut of his invention in one of New York's railroad papers. The picture shows the excavator wading along in about four feet of snow, and sending a solid stream of ice and snow clear over into the next township. The wheel runs in front of the plow, and looks for all the world like the stern of a Monongahela river steamer, the wheel having vanes and paddles, being some nine feet across and about the same in diameter, running "under," and is supposed to throw the snow out at the top. It looks to a man who has pushed snow plows in a country where they have snow, as if good-sized drifts would fill the wheel up solid, and then at the first ice-spot lift it off the track. Every obstruction that it strikes must go under.

There has been a number of good articles and interesting queries come to us during the month that we were loth to

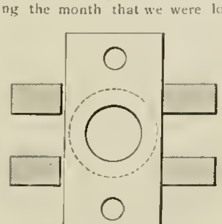

Fig. 4.

crucify ; but as the writers signed simply "E. C. Centric," "Subscriber," "Reader," "J. G. W.," etc., and did not also give their own names and addresses, they had to go. Your own name is not necessarily required for publication or to forge bank checks to, but we insist on 'em in self-defense, in case of breach of promise, and to show that you really mean it.

Air Brake Practice.

BY J. F. PHELAN

First Paper.

In dealing with air brake practice, we need not know how to build or rebuild an air pump, an engineer's brake valve or the triple valve, or other parts. It is always desirable to know as much as possible of the construction and workings of all parts. It is mainly desirable to know the principle on which air acts in doing its work, to insure good practice. For an individual to attempt to explain the intricate workings of the triple valve on all occasions, or by cuts or figures, leads to confusion in the inexperienced mind. Let it be understood, however, that within the triple valve lies the principle of automatic air brake action, and the student who wishes to understand it thoroughly must witness air brake repairs or get at a triple valve with sections cut out so as to display the mechanism in action. At all division terminals of railroads such sectional views should be on hand for study and practice.

Up to the present time it has been a difficult matter to get down to definite rules in governing air brake appliances. For the future, until the new Westinghouse triple valve and latest improved automatic brake appliances come into general use, there will be more or less distinction and varying opinions concerning straight air and automatic air practice. With the new equipment in use, straight air will be doomed, and then definite rules will have force, only limited by the condition or state of repair of the brake appliances in use, and the intelligence of the individual handling the same.

There is a general desire to learn more of the workings of air brakes, and the future will develop a general knowledge beneficial to all concerned.

To begin with, there is always an air pump, or small engine in itself attached to an air pump. The small engine, composed of steam valves and piston within a cylinder, worked from steam connection with locomotive boiler, is for the purpose of working another piston and set of air valves within a cylinder in connection with steam cylinder, common terms of expression being steam cylinder and air cylinder of air pump. The steam piston, working the air piston, draws air from the atmosphere, and forces it into a fair-sized air reservoir located at some convenient point about the locomotive, where the air is stored, and from there distributed to auxiliary reservoirs, or brake cylinders, as may appear further on.

The volume of air stored in this way depends on the size of the main air reservoir. The pressure per square inch thus stored, as indicated by good judgment and practice, should not exceed 90 to 100 lbs. in reservoir, and but 70 to 80 lbs. working pressure in train pipes and auxiliary reservoirs, located under tank and each car.

From the main air reservoir, a pipe leads to the engineer's brake valve, located in the cab, convenient to engineer, to use in handling the brakes. From the engineer's valve, a pipe leads back under tank and all cars on which air brakes are used. Under tank and each car, this pipe is connected with an auxiliary air reservoir and brake cylinder, through the medium of a triple valve, wherein lies the principle of automatic work.

The auxiliary reservoir is for air storage, supplied from main air reservoir on engine. This auxiliary reservoir, at all times when brakes are in working order, contains a supply of air pressure, to act on piston in brake cylinder to apply brakes, when action of triple valve is prompted by reduction of air pressure in main air pipe, by action of engineer releasing it through engineer's brake valve, or from any other cause, such as hose parting, air pipe breaking or springing bad leak, or any similar cause. To state the matter in plain English, reduction of pressure in main air pipe causes triple valve to move down, and opens a passage for air to flow from auxiliary reservoir to brake cylinder. In the new triple valve this reduction of pressure causes air to flow from main air pipe into brake cylinder, until pressure is equalized in both, when the brake cylinder receives supply from auxiliary reservoir also. It is needless to say that air going into brake cylinder sets the brake.

In the original Westinghouse system, straight air, there was no triple valve or auxiliary reservoir under cars. There was simply a brake cylinder connected with main air pipe. To apply brakes, air passed from main air reservoir on engine, through engineer's valve, back through main air pipe, flowing into brake cylinders and applying brakes. When stop had been made and engineer's valve been changed by engineer, the air returned through same pipe, escaping to atmosphere through an opening in engineer's valve. Originally for this service, the engineer's valve was a simple 3-way cock, and the same is yet in use for straight air and automatic on some roads. This 3-way cock might be termed a sort of improved beer faucet set at junction of two pipes, with a third opening for exhausting air, when contents of pipes were to be emptied into atmosphere. Its main function being to keep air supply in main reservoir from escaping, until wishing to use the supply in setting brakes, handle and plug would be turned to allow air to flow from main reservoir to main air pipe and brake cylinders. Returning handle and plug to regular position, supply would be confined to reservoir again, and that in main pipe and cylinders allowed to flow back and out into atmosphere, thus releasing brakes. Using the same 3-way cock for automatic air, its function would be changed, and in regular position would keep supply of air in main air reservoir in constant communication with main pipe and auxiliary reservoirs. Turning it around to correspond with releasing brakes in straight air, would simply shut off supply flowing from main reservoir to auxiliaries, and allowing that in train pipes to escape, start the triple valves and allow supply from auxiliaries to flow into brake cylinders. Throwing it back again to allow air supply to flow from main reservoir to main air pipe, would release brakes by action of triple valve, and recharge auxiliaries, the quantity having been used in brake cylinders, in setting brakes, being allowed by action of triple valve to pass out into atmosphere directly from each cylinder.

Too Much, Indeed.

In speaking of the examination of new men by the "Q.," the *Railway Master Mechanic* says that the question:

"What course would you take in order to run into station if both front cylinder heads were blown out? was too much for most of them. The proper method would be to remove the steam chest covers, block up the front ports with wood, and, after replacing the covers, go on as usual."

The circumstance is a very unlikely one in the first place, and the answer a misleading one. The taking off of both steam chest covers, and the work of nicely blocking both front steam ports, is the work of more than one hour. Tools to make the fit a good one are not furnished, the port is small at the seat and larger and irregular, half an inch below it, and it would be almost if not entirely impossible to fit a block in it, keeping it away from the valve, so tight that it would not be blown out. An attempt to do this, in practice, would delay not only the engine crippled, but many other trains beside. The engineer who did it would also run great chances of further damage by the blocking working out and catching the valve.

This is one of those railroad problems that is often done in an office and on paper, but when it comes to doing it on the road any engineer who attempts it runs a chance of doing the road more damage than there is any call for, and would be reprimanded or punished by almost any master mechanic in the country. If you find yourself with both front cylinder heads out, protect your train, send for assistance, disconnect your engine, get out of the way as quickly as possible, and be "towed in." The idea that there is a disgrace about being towed in, when you can't help it, without delays to trains, and taking uncalled-for chances of heavy expense to your company, is all humbug.

The spectacle of a locomotive with both front heads out proceeding with her train *as usual* is one of the things we would like to see. A locomotive in this condition would be much more helpless than a locomotive "on one side."

Double Fire Doors.

Double fire doors, some that slide to each side, English style, and others that open each way from the center, are being adopted on a great many Eastern roads. They occupy less room, and there is no good reason why they should not be better than the old swing doors that are noted for their habits of "not staying put" in any position but shut.

Correspondence

That Air Pump Conundrum.

Editor The Locomotive Engineer

In reply to W. F. R., in your April number, I want to say that if W. F. R. had looked in the air cylinder instead of the steam end, he would have found his terrible pounding. If he found the steam end just as he says he did, I think that one of the air valves had got corroded fast, and the pump was only pumping air on the down stroke. F. M.

Greenbush, N. Y.

Gun Barrel Boilers.

Editor The Locomotive Engineer

One of your correspondents speaks of gun barrel boilers, and the remark pleased me, as I am sighting over an old smooth bore boiler of 12 gauge. This small boiler has her gauge cocks within 8" of the top of shell, and I think here is the main trouble; the boiler has a large fire box and enough flues for a larger shell, but there is no place for the steam, as the dome is very small.

One of these engines recently went into the shop and got a new fire box and a new dome, much larger and higher than the old one, and it helped her wonderfully in carrying her water and in steaming. I don't think locomotive boilers, as a rule, have large enough domes.

St. Louis, Mo. JOHN VERDER.

Wants That Air Pump Cigar.

Editor The Locomotive Engineer:

In answer to Air Pump Conundrums, by W. F. R., in your April issue, I think he has set the ball rolling in the right direction. I have not worked much on air pump repairs, but have studied it a little with what spare time I have at my disposal, so do not consider myself a very competent person to answer the many little mysteries concerning same

I can only answer for the pump working as described on account of the top exhaust port of steam cylinder getting foul, or partially stopped up, and not allowing the steam to get away properly, thus creating back pressure on piston, and consequently making piston to return quickly on down stroke. I trust if this is not correct W. F. R. will kindly tell us what he did find.

I think your paper the best of its kind I have ever read.

Schreiber, Ont. T. J.

Retarding Power of Brakes.

Editor The Locomotive Engineer:

In your March issue, under heading of "In the Roundhouse and Repair Shop," you say that the simple widening of driving brake shoes, grooved to cover flange of wheel, has increased the retarding power of driver brakes and lessened the wear of tire. I agree with you so far as the lessening the wear of tire, but not in increasing the retarding power. The bearing surface of the shoe is widened 1½" to cover flange, and is grooved 2" wide to prevent it wearing where tire comes in contact with the rail. The shoe only bears out parts of tire that do not come in contact with rail, thereby keeping tire worn almost as true as when turned, but reducing surface of brake shoe 12 square inches. This I do not think affects the retarding power of brake. The power of any brake is in the power that forces the shoe against the wheel, and not in the shoe or rubbing surface exposed. The above are my views of the matter; if I am wrong am willing to be convinced.

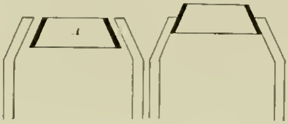
Allegheny, Pa. JNO. HOWARD.

[In the main our correspondent is right; the retarding power of a brake is the power applied to the shoe, and the distance from outside of tire to center of wheel. In the case we noted the engineers had told us the new shoes held better; we believed them then and believe them yet. The principal braking is done on the flange, which gives more leverage, and the wheel surface presented to the brake shoe is rougher than the tread, giving more friction.]

The Variable Exhaust.

Editor The Locomotive Engineer

In your issue of April you speak of exhaust nozzles that can be regulated by a rod from the cab, and also mention the use of a plug in the nozzle. That is a very simple arrangement, but I think a nozzle like the one here shown is a little better, as there is practically nothing in the path



of the escaping steam. The tip *A* is raised up or let down, according to circumstances.

2156 Second Ave., N. Y. F. HOCHBRUNN.

Care of Locomotive Jacks.

Editor The Locomotive Engineer.

I am a fireman, and throw black diamonds at a hole in a Baldwin consolidation that belongs to a road whose master mechanic holds the fireman responsible for care of jacks, frogs, switch chains, pinch bars, etc.; in fact, all the tools in the big tank box. Just why I am expected to clean and look after these things every two weeks is not yet clear to me.

We carry a little of everything in our back box, hemp packing, stack paint, old oil can, extra air hose, old pair of overalls, extra brass for tender-box, a few pails of cinders, some wool waste to pack boxes, extra scoop and shake lever, an old lantern frame, and a general assortment of extra spring hangers, bolts, nuts, spring keys and rusty nails. My engineer says all of these are handy.

I found that with this collection it was next to impossible to get anything to lay still, and the way they dance and rub and tangle up is a caution. If I oiled the screws to our big jacks the oil collected dust till it was a paste; then, when we wanted to use them, they wouldn't come up. I took the screws clear out and wrapped them in oily waste and an old pair of overalls, and I thought I had them pat. I looked at them once a week for a month, till one day we wanted to use them, when I found that a big hook on the switch chain had worn a hole through the armor of one, and made a mark on the thread big enough to prevent us from getting the screw into the base; then I went and had a piece of ½ inch board turned up just the right size to fit the circular hole in the bottom of base piece I painted the edge of this with white lead, and, after pouring in about a pint of black oil and coal oil, I forced the wood into the hole; the oil soaked the wood up and made it tight, and I have had no more trouble; the oil can't get out altogether, and the dust and cinders and water and rust can't get in. I oil them about once a month or six weeks, and keep the screws down. It is a little trouble to fix up, but it pays. SCOOP.

Sedalia, Mo.

Coal Records.

Editor The Locomotive Engineer

I was pleased with your article on coal records, more especially as I had just had a little odd experience in that line At the terminal station, the coal chute fiend has been kicking for bigger checks—and got them. The other day, at a chute out on the road, I took 100 bushels of coal, and the chute man said: "Never mind the check, I am 2,600 bushels ahead of the cars this month."

The boys must have been liberal with checks, or more likely the *guesswork* had been poor: this man had checks for 2,600 bushels more coal than he had received. If managers are as careful (?) with their ticket receipts as they are with coal it is no wonder that some of our roads are in the hands of receivers, and English locomotives posing as the most economical coal consumers on earth. The enginemen of this country are more anxious to show economical results than their officers are anxious to have them shown.

Denver, Col. H D. DOYLE.

Oiling Driving Boxes.

Editor The Locomotive Engineer.

Any runner who has watched his engine carefully and has had any experience at all, has had hot driving boxes, and tried to think of some way to help the matter.

Some engines are built that have such small driving box bearing that they are continually hot. In cases of this kind about all the engineer can do is to oil, pack, experiment and swear.

Some engines are built that have babbitted boxes, and when one of these gets hot enough to melt the babbitt there are no more oil holes, comfort or safety.

Some engines are built that have little or no packing space in the cellar, and no matter how well proportioned, are chronically hot.

Before now I have had hot boxes caused by the top oil holes being stopped up, and always found that if I could take out the inside cellar bolt and tip the cellar in enough to put in some fresh waste, and oil there by reaching across from opposite side of engine with a long-spouted can, they cooled off. This led me to think; thinking led me to an experiment.

I was coming in one day on the "Hummer" (humming along about fifteen miles per hour, with one car more than a train and a Dutch clock), when the fireman said: "John, there's a hot hub over here"

I was tired—born so—but I slid off the seat and went over to his side; something did smell hot; I looked back at the tank boxes, and there was ice on them; there was a box smoking on the second car, however, and I turned to that smutty-faced youth with a visage wrapped in stern reproval, yet a heart full of fatherly love. I am not a man of words, but of actions, and I took that student of smoke by the ear and led him to the gangway and pointed back to that hot box, that wasn't mine, with the same kind of a look upon my classic features as must have sat on the phiz of Sir Isaac Newton when he discovered that apples fall down instead of up. I resumed my vacant seat with a sigh, and hooked the finger beam down a notch when the boy wasn't looking, just to get even with him for causing me extra exertion.

At the next water tank you could cook steak on the left forward driving box of our old mogul, and I compromised with the smoke shoveler by giving him the last and only cigar I had

The oil hole was stopped up and I couldn't unstop it, and I did not waste much time trying; I let down the cellar on the inside, put in some clean waste, a lot of cold tallow, and went on. The box cooled off—so did I.

The next day was my lay-over, and I took that cellar out and had a hole tapped into one corner on back side and threaded for ½ inch pipe, and an elbow put in; then I had a piece of 1-16 iron cut to go into bottom of cellar, a loose fit; it also had several ¼ inch holes in it, and a flat brass spring under it; this was to keep the wool up against the journal always.

I put this up well packed, and screwed into the elbow a piece of pipe just long enough to come above top of driving box; then I made pine plugs and stopped up top oil holes for sure. I ran that engine until she was condemned, and that box never got a drop of oil from the top holes; it was never hot, and it was never petted; I packed its cellar only when I packed the others.

I believe that if driving boxes had no holes on top, but had a long drill hole through box to each side of cellar, and the cellar arranged to keep its packing in constant contact with the journals, that we would have fewer hot driving boxes.

JOHN ALEXANDER.

Early Experience with Balanced Valves.

Editor The Locomotive Engineer

In reading over the April number of THE LOCOMOTIVE ENGINEER I ran across a little item about the extended use of balanced valves. About thirty years ago I ran an engine that had a balanced valve—or rather what they called balanced. The valve itself was planed off on top, and scraped to fit a plate fastened to the cover; there was no springs, packing strips or rings at all. I started out one cold day with the engine and a train of railroad officials, also the inventor of the balanced valve. The engine worked nicely, and after a few hours' run we stopped for breakfast. I left the engine on the train, the reverse lever in the center notch, and struck for the dining-room.

It was fully thirty minutes before the party were ready, and after oiling around I got a signal to go—but I didn't. It was a very cold morning and the frost king had got in his work. I could not get the reverse lever out of the center, and the longer I waited the larger the crowd got around the engine; it was full ten minutes before the "balanced" engine got away, and then only after a vigorous warming *via* the throttle.

When we got to the shop the balance plate was raised, and after that I could see no advantage over the old D valve. I suppose the contraction of the sides of chest and the studs came down enough to pinch the nicely-adjusted valve. I remember the clown fireman remarked that the valve had swelled—if it did steam unswelled it.

ELMIRA.

Elmira, N. Y.

The Fixed-Nozzle Injector.

Editor The Locomotive Engineer

In Forney's Catechism of the Locomotive, page 123 (1881), questions 136 and 137 are answered in a way to muddle younger students of the injector. I see Mr. Forney has not changed these answers in his revision of that work now appearing in his paper. That I may not be misunderstood, I repeat the questions and their answers.

"*Q. Will a 'fixed-nozzle' injector, such as has been described, answer as a boiler feeder on locomotives?*

"*Answer.* It will answer at some one pressure of steam, to which pressure it may have been adapted in making the instrument, and at that pressure it will work admirably; but it will not work satisfactorily at any other pressure, either higher or lower, and has not much range in quantity of water delivered.

"*Q. What is required to make an injector work at different pressures?*

"*Answer.* The instrument must be so made that the water passage between the receiving tube and the combining tube can be varied in size. This is usually done by making the combining and receiving tubes conical and moving the former to or from the latter, thus contracting or enlarging the water space. Such adjustment must be made at each change of steam pressure in the boiler."

Now when it comes right down to a matter of theory I am not there; my life has been spent on a locomotive in practice; I know from actual personal practice that a fixed-nozzle injector will work very satisfactorily on a locomotive with all the different steam pressures that we are ordinarily called upon to use, and that without hand adjustment. I have run a heavy ten-wheeled engine with fixed-nozzle, non-lifting injectors alone, and have supplied the engine when pulling a very light train or a very heavy one, by simply adjusting the lazy cock and steam throttle. I have also done the same with a Monitor and a Hancock Inspirator, both fixed-nozzle instruments. This proves to me that this class of instruments have a great "range."

The load to be moved, not the steam pressure, determines the amount of water needed. Injectors of every class have to control this by the amount of water supplied to the instrument, but not necessarily by moving the combining tube.

If this is not "range," the practical men on the road do not understand the term. I can start my Monitor No. 7 with 40 pounds of steam, and, leaving the lazy cock in the same spot, it will start again and work at 150 pounds' pressure by opening the steam valve the same as at 40 pounds. It will just supply the engine running 30 miles per hour with a heavy train; I can adjust it to just supply, when running a light train 15 miles per hour. If this is not range, and adaptability to all practical purposes on a locomotive, what is? To be sure there is some difference in the amount of water delivered at 40 and 150 pounds' pressure, but this amount can be regulated by the water and steam supply cocks. This supply does not change as much as one would suppose. Again, if a locomotive "goes back" on her steam 20 to 30 pounds, any runner will shut off his water supply to let her catch up if he can. The way we are loaded now don't admit a variation of more than 20 pounds. It seems to me wrong to tell young firemen, or engineers either, for that matter, that a certain thing *must* be so; for instance, that an injector must be made so that the water passage between the receiving tube and the combining tube can be varied in size to make the instrument work at different pressures, when their daily task is in doing the work successfully in entirely a different way. They are either mystified about the operation of the practical things in their own hands, or begin to doubt the soundness of the theories laid down by eminent writers in their line.

I know that our Sellers and Giant injectors, that regulate by moving one of the tubes, break very easily when trying to throw a very small amount of water, and the latter can be regulated finer by using a lazy cock than by using the adjustable tube.

I am not arguing for or against any particular kind of injector—I can use any of them and get all the water I want—I am only arguing against trying to teach men that a fixed-nozzle injector will not do what they are seeing it do on a thousand different locomotives every day.

Engineers and firemen are just commencing to study and read, and are hunting high and low for correct information. If Mr. Forney does not mean to convey the idea just as I have stated it, he should change the language, as it is so understood by all the engineers and firemen of my acquaintance.

Kansas City, Mo. JOHN REYNOLDS.

Poor Tank Brakes.

Editor The Locomotive Engineer:

What engineman is there who has not at some time tried to set the tender brake, and when most needed the thing wouldn't work?

If in winter time the staff gets frozen into tank deck, ratchet and pawl are covered with coal and cinders, and if it should be summer, instead of the staff being frozen it often gets so tight it can scarcely be moved, on account of deck being water soaked.

Now this can easily be remedied, and it is surprising to us that it has not been done.

Some builders still put brake on left side of tank, where the fireman can bark his knuckles when not otherwise engaged. The right side is the place for it—handy for the engineer to use, so as not to trouble his partner.

In place of having the ordinary bracket to hold top of staff have a plate instead, and made wide enough to hold pawl and a light spring to keep the pawl against ratchet wheel. Then have a piece of gas pipe, large enough for staff to pass through, bolted or riveted to the plate and running down through tank deck. This would always keep the staff free. The ratchet being on top of tank instead of at deck, it would never be covered with dirt or coal, and having the pawl held against ratchet by the spring, the brake would always be in working order unless some of the parts under the tank were "out of kilter" Many roads use air or steam brakes on the tenders, but these sometimes fail, and a good, reliable hand brake, always ready for use, is a handy thing to have around.

Denver, Col. H. S. H

Railroad Promotions.

Editor The Locomotive Engineer:

In my exceptions to the article on the "Coming Man," the point of argument is misunderstood. I take no exceptions to the class of men that are promoted to engineers. In regard to machinists runners, I brought that up for this reason. How can an engineer get shop experience on the road, any more than a shop man can get road experience in the shop. Can't a first class locomotive machinist (qualifications being equal) get road experience just as soon as an engineer can get shop experience? Don't you know any engineer that never fired a locomotive? I do. I can send you the names of four in the employ of our road. One is M. M., another is foreman of the machine shop. Had shop experience for 15 years before he ran. The other two got $3.60 and $4.50 per day, while they were getting *their* road experience. There are but few shop men that would go on the road, that would make good runners. All firemen don't make runners. But I *do* think that shop experience, after a man has fired a reasonable length of time, makes the man a better runner. Another reason that machinists are not promoted is this: when they find him to be a first class shop man, they feel that they need him there, more than on the road.

Now, Mr. Editor, just give the poor machinist a fair shake and I will not argue machinist runner any further, for it is not my point. The point that I object to is this. From the tone of your article on the "Coming Man," you seem to think that there are no class of railroad men that are competent to be superintendents, M. M, or foremen, except engineers. This is the point that I take exceptions to. Now, you claim that you have had shop experience, don't you know of any man (with shop experience only) that you would trust to take charge of a railroad shop, if he had served 10 to 15 years in that shop? Suppose he knows where all tools are. Has run shop. Knows the system of the shop (if there be one). Knows what men do their work well, and what men slight their work, or what men will kill time on a job. Isn't he just as competent to take charge as the engineer with road experience only? This is the point that I argue; and whenever there is a vacancy in a shop, if there is a machinist with the qualifications he should be promoted in preference to an engineer. It is a job that a shop man feels that he has a right to. Qualifications being equal, a machinist has just as much right to rise in the railroad world as any other class of men.

Your paper is for all men connected with the machinery department of a railroad; don't boom one class, but give us all a show. I don't deny the influence of engineers in regard to supplies or improvements, but I do deny that they are the only class of railroad men that have the qualifications for any promotion. Machinists make just as good M. M.'s or foremen as engineers. Road foremen, traveling engineers and superintendents are another class of railroad men, and out of scope of shop or roundhouse service. C. W. L.

Columbus, O.

[We agree that a shop man can get road experience as soon as a road man can get shop experience—road men, as a rule, do not desire the shop experience, they do not want to be machinists. We do know men who are running who never fired. Men used to run, years ago, who came from the shop; conditions have changed; men cannot learn the duties of the road now in a few months; it takes years. Machine shops should be under the foremanship of machinists certainly; roundhouses can be easily placed under a machinist or a runner—either will be poor enough to suit the engineers and the roundhouse men too.

No one disputes the fact that any employe has a right to rise in the world. Superintendents and master mechanics are all the better fitted to fulfill their duties, if they have road experience. Machinists certainly should be promoted to positions they are better qualified to fill than engineers, and *vice versa* We know successful M. Ms. who never ran an engine a mile; we know others who never worked a day in a shop.

The point made in the article on the "Coming Man," was, that the engineers were the men who tried and decided on the merits of any device on a locomotive —and they are. That so many engineers have been promoted to high positions of late years, has shown only that their knowledge of road service made them valuable men for the business of the company—pulling cars over the road.]

Pittsburgh Locomotive Works test their boilers with steam up to 225 pounds.

An Invention Wanted.

Editor The Locomotive Engineer.

Why is it absolutely necessary that the sight feeds on cylinder lubricators should be within an inch of the cup itself? They used to go outside to pour tallow into the chests, but they soon found they could pour it from the cab just as well by using a pipe.

Now there are a great many sight-feed lubricators on the cab end of those oil pipes, but the "sight" is right next to the cup, and this is often placed where the engineer can't see it very well in the daytime, and not at all at night.

It seems to me that some inventor ought to get up a scheme that would let the "drip" and the glass be located any place in the oil pipe; this would allow the two glasses to be brought between the engine and the gauge lamp, and the cup could be located any place out of the way. If some more fortunate brother will tell me how to keep my headlight from smoking, so I will not have to clean it every trip, I'll invent the rig myself.

Minneapolis, Minn. "Soo."

Modern Improvements.

Several instances are on record where railroad men have recovered damages for being crippled on account of the company's refusal or neglect to furnish improved appliances of one kind or another. Some of the towns in Minnesota, Dakota, and other Northwestern territories are suffering from the same cause. Many of these towns voted bonds to get the roads there, and the roads were glad to get the bonds and all the stock and grain they could haul in the fall, but when the snows were deep this winter they did not make an effort to relieve the suffering caused by being isolated from the world, short of fuel, no mail, and no chance to buy or sell. If the town was on a branch, all the worse for the town.

In some places up there when the snow plow did reach town there was a regular jollification parade.

Mechanical devices for clearing snow from railroad tracks are now very reliable, and there is no possible excuse for any company under any circumstance to leave any town on its route shut up for weeks at a time.

All Are Not Alike.

On some roads where there are in use for years one certain kind of engine, the men become so used to the handling of them that another make, equally as good, is condemned as radically wrong on first trial. We remember one instance where the new make of engine were condemned for slipping, and the engineers kicked till they got bigger sand boxes put on them. A year after, the engines slipped no worse than the rest. The trouble was that the new throttles were wide open by an inch movement of the stem, while the old ones only opened about ⅜ of an inch for the same movement.

The Hospital Steal.

There are many roads that have a hospital and a doctor corps. That regular, sworn in, company surgeons are very handy things to have (for the company) in case of wreck, there is little doubt; dead men are only worth $5,000, while cripples come higher. When it comes to letting the doctoring of the employes of a whole railroad out in yearly contracts, God pity the sick.

Investigation will show that half the roads, where a hospital system is in force, have fine hospital buildings and a lot of salaried surgeons to use in case of accident, supported entirely by taxes on their men.

It is the general custom to assess each and every employe of the company 50 cents per month for the hospital fund: this is $6 per year for every man, and calls for many thousands of dollars every year.

A man may pay his regular monthly tax for years, and if he leaves the employ of the company or is discharged he gets not one cent.

He may be discharged from the service of the company and cut off from hospital benefits because he is about dead with consumption, cancer, or some other lingering disease, after paying assessments for years.

We know of several cases that have come under our own observation that will tend to show some of the evils of this illegitimate tax.

The senior surgeon of a big road was called to a freight train wreck, and assisted the local surgeon to amputate a leg for one of the unfortunate employes; there was another railroad man badly hurt, but he was not in the employ of that company; he was dead-heading over the road in search of work; the senior surgeon asked if he was a passenger, and when told who he was offered to amputate his limbs if he had money to pay for the service; he had not, and died. The employes petitioned the management for a change of physicians, but the brutal senior was a fixture.

In another city the regular appointed doctor was so disliked, and was so careless of his duty, that all the employes of the company at that place signed a petition asking for his removal—but were informed that he had been appointed for a year, and he stayed.

Under such circumstances men will employ their own doctors and buy their own medicines.

If a man will go to a hospital in case of serious sickness he is entitled to his board, attendance and medicine, but men who have homes will not go to hospitals.

Men who have paid for years for medical attendance that they have not needed, are obliged to use one kind of medicine when they have faith in another, or hire their own doctor. This they do, and the company want them to do it. We know of one railroad hospital, built from this drain upon labor, at an expense of many thousands of dollars, that had, on its opening, a big "housewarming," a supper and a ball. The mayor of the city made a speech, the manager of the railroad danced in the head set, and the morning papers told how the great and good railroad was *caring for its men.* Not one employe of that company, except officials, was asked to tread a measure or partake of one mouthful of that feast, or look upon the walls of that magnificent building that the company had built *for them*—and made them pay for.

When there is a great wreck these hospitals are filled with dead and maimed, and the working men on that road pay for it—not the company.

A single man without means is taken sick or is hurt, and receives treatment in the hospital; you say this is good work. The company could afford to have him treated at a pay hospital, or the men would do it voluntarily.

Engineers, firemen, conductors, brakemen, mechanics, section men and laborers are all human beings—to the contrary notwithstanding. This is a free country, and no man, be his pay $10,000 or $10 per month, wants any guardian placed over him. He wants and has a right to expect pay for all his work. He wants to employ his own doctor, butcher and grocer, and pay them himself. He don't want to pay for service he does not receive. He don't want to insure his employer—the company—against loss if anything happens.

It would seem to be a fair scheme if the railroad company would put in every month as much money as all the men did. This would not be the snap it is now; still, it would be wrong.

Where men are obliged to pay for service, why would it not be nearer square if the men elected their own doctor and their own druggist? Railroad men have good and efficient beneficiaries and insurance in their brotherhoods and unions, and assess themselves heavily for mutual benefit. To assess them for the benefit of a hospital grab is taxation without representation. It is demanding something for nothing. It is extortion. It is robbery.

Unfair Treatment.

There is and always has been a constant demand from the management and transportation departments of all the railroads of the country for better locomotives and more economical service. They have always wanted more and heavier cars hauled at higher rates of speed than in the past or was hauled by rival roads. They expect all this to be done with less fuel, less stores and less repairs than the old engines received or needed. They want men to run and fire the engines at less pay, for longer hours or more miles than is safe.

The management lets the head of the mechanical department order or build a locomotive that it is hoped will eclipse all others, and in many cases if it does not do all and more than is hoped for, the master mechanic is often asked to resign, to give some other man a chance.

These very managers are very backward about granting passes to master mechanics to attend the yearly meetings of the American Master Mechanics' Association to exchange notes and bits of experience. These discussions are productive of much good, and have saved many an M. M. from experimenting on ground already found barren. The entire object and aim of the association is to make its members better posted mechanics, and the good results from these meetings can finally come to no other place than to the profit of the companies the men serve.

It is high time that the general practice of laying all the wrecks, failures and delays in practical railroading to the motive power department was stopped.

It will pay any railroad company to be a little liberal with the officers and men in its machinery department. Give them chances to discuss vital questions with others in the same walk in life. Let the master mechanics and the engineers go around a little and study up.

A little liberality in the pass business, and the retiring of the system of docking the master mechanics for time lost in attendance at these association meetings might result in considerable good to the roads.

When all roads are under the management of men who have seen service in the ranks, we will have better managed roads, better engines, better service and more contented men.

Bridge Accidents.

There has been considerable printer's ink used in the last month trying to explain how trestles and bridges are neglected till they let trains fall through them, on one hand, and how no amount of care will prevent trains from jumping the track just at a bridge, on the other.

One man, perhaps over zealous, or even malicious, wrote an article for the New York *World*, just after the fearful accident at Blackshear, Ga., making some very damaging statements about the condition of bridges on the Savannah, Florida & Western Railway, where the accident happened. Since the appearance of this article, H. S. Haines, general manager of the above company, has published a long communication in several papers, giving the details of the mode of inspection of bridges on his road, which, if true, is as complete and careful as can well be devised. An ex-civil engineer of the road now publishes a letter verifying the manager's statements, and showing more fully the system of examination. In speaking of the accident he says:

"*First and foremost, no trestle or bridge ever built could withstand the tremendous strain put on that at Hurricane Creek, be that trestle or bridge wood, stone or iron.* Private dispatches received by parties in this city state that the baggage car was next to the locomotive. The front axle, or one of the journals of the front truck under that car broke. The truck was slewed around directly across the track, dropping down on the cross-ties. The weight of the train behind that baggage car was 240 tons, driven with a momentum of 45 miles per hour. With this condition of facts there was but one of two things which could happen, namely, either the 'immovable mass should succumb to the irresistible body' or vice versa; or, in other words, either the train should reduce itself to kindling wood and remain on top of the trestle, or else the trestle must succumb to the momentum of the train and go down with it."

If the first statement is correct, there would seem to be no use in building a bridge stronger than was just necessary to sustain the weight of trains. That bridges have been built that sustain shocks similar to those mentioned by the above writer is well known.

Wooden bridges have stood up under truckless cars at great speed, not, perhaps, so much on account of the strength of materials used, as upon the safety appliances of the bridge. Guard rails placed outside the tracks, also between the rails, keep "slewed" trucks from getting a hold, and allow any sort of wreckage to slide over, instead of being sure to find a butting post and a trap-door at the first bridge. Stone arches are generally covered with earth or stone ballast, and a wreck on them would be the same as on the ground anywhere.

As to the condition of this particular bridge, or any on this line of road, we know nothing; we do know that trestle work is, as a rule, weak for the work it does.

We should think the right thing to do would be to either make the "immovable mass" (the bridge) strong enough to stand up under broken axles or derailed trains—the general excuse given for bridge accidents—or make some provision to prevent the cars from "jumping the track" just at the bridge—or slide them over when they do jump.

Accident reports are showing all too often how trains running at even more than 45 miles per hour have been suddenly checked, as in case of collision, without all of them being "reduced to kindling."

Brake Improvement Needed.

Locomotives on some roads of the United States wear out more brake shoes on freight cars when the brake is supposed to be off than as many locomotives of England do when they are on—another side light on the difference in coal records.

In this country we have much heavier grades, use more power brakes, and keep them up better. On our grades, especially where continuous power brakes are used, it is desirable to have the brake work with as little slack as possible, and means are provided to take up this slack, generally located under the car. Our brakes are, as a rule, hung from the body of the car and the shoes grip the wheel well below the center; this keeps the brake beams from "climbing the wheel" and entangling the whole gear.

When the car is loaded down with from 30,000 to 50,000 pounds, the shoes are a considerable distance from the wheel, and, if the grade is heavy, the boys get under the car and take up the "dead lever" a hole, or screw up a nut, or any other means provided to take up slack. The brake works well, but when the car is unloaded the springs pull the body up and the shoes tighten on the wheel or are so close that the swinging of the car keeps a lot of cast-iron shoes in contact with the wheels. It costs money to pull cars under these circumstances. They may look all right and the brakemen swear brakes are all off, but, if you look back after night, you will see a torchlight procession following you.

Eight-wheeled cars, having brake beams hung as above mentioned, ought to have some easy means of taking up the slack, without going under the car. An easily moved lever under sills and in center of the car would fill the bill.

Master Mechanics' Association.

The twenty-first annual convention of this association will be held at Alexandria Bay, N. Y., June 19th. The place selected is in the world-famous Thousand Island country, June, one of the most enjoyable months, and the M. M.s an extraordinary lot of men. If in this selection of one of the finest Edens of nature, the virgin queen of months and the cream of railway brains, we get no new or good results, this talk of good company is all bosh.

ASKED & ANSWERED.

(22.) J. C. W., Pittsburgh, Pa., asks:

Do you think it possible that the corrugated fire boxes in the Strong locomotive boiler will expand by buckling in its corrugations. *A.* No.

(23.) Union Jack, Toronto, Can., asks:

Are there any locomotives in the United States that have brakes on the front truck wheels? *A.* Yes, a few; the Beals brake puts two shoes on every wheel under engine and tank.

(24.) Quiz, Como, Col., asks

How do you make a heater of Hancock Inspirator? *A.* Shut off valve in steam pipe, bring operating lever to position for working injector, and then apply amount of steam required to keep water in pipes and hose in motion.

(25.) R. A., Rutland, Vt., asks:

What would be the result if checks were tapped into steam space instead of below the water line, and has it ever been done? *A.* If it was near dome it might interfere with working dry steam; it has been done, some old engines had two domes, and the checks went into the forward one.

(26.) Car Repairer, Baltimore, asks:

I find in all the air brake cylinders I take down a slot about three inches long in the bottom of the bore of cylinder. I thought at first it was to hold oil, but it can't be that. Don't it leak air? and what is it for? *A.* The slot is to let a little air leak past the piston, to prevent the brakes from "creeping on" from some slight leak. When the brake is applied quickly the piston passes the slot and closes it.

(27.) Sub., Alexandria, Va., asks:

Do you think it possible for an engine to slip when running with steam shut off. *A.* If our correspondent wants to know if it is possible to *make* an engine slip when running with steam off, we would answer, yes; by reversing, the pistons will pump up air enough to slip the wheels backward or blow the chests off. If he wants to know if a locomotive is liable to slip under ordinary circumstances while running shut off we would answer no.

(28.) Boiler Maker, Weatherly, Pa., asks:

What is the "drifting test" for boiler plate, and how is it done? *A.* The drifting test is the practice of drilling a certain sized hole in the plate to be tested (usually a ⅝ hole) and then enlarging it with a taper drift till the metal breaks; metal that will stand an enlargement to double the size of hole without breaking is considered good. Different users demand different degrees of this test. The Northwestern Railway of Great Britain demand an enlargement to two inches. This test is used more in Europe than in this country.

(27.) Tenn, Knoxville, Tenn., asks:

Why could we not compound our ordinary locomotive by shutting off steam to one cylinder and piping exhaust from one to the other, using one side for high and the other for low pressure? *A.* Because the pressure on the piston of the low pressure cylinder can only equal the back pressure on the high pressure cylinder. In order to gain by two expansions of steam the low pressure cylinder must be much the largest

(28.) Blacksmith, Chicago, writes:

In our shop we have a large blower and an independent steam plant to run it, by recent additions to the shop we needed more wind, and belted up to run the blower just twice as fast as before. We expected this would double our coal consumption under boiler, but were not prepared for the results that followed—burning over four times as much coal What is the matter? *A.* You are now moving twice the *amount* of air you formerly were, and at twice the *velocity*. You are doing four times the amount of work The coal consumption is about what should be expected.

(29.) S. H., Quebec, Canada, writes.

I am a boiler maker in the C. P. R. shops, Quebec, and we have some Portland engines on this end of the road, and I find the third row of stay bolts up from the foundation ring drilled through with a ¼-inch drill. Will you or some of your readers please explain the object of this, and the object of copper rings on fire box end of tubes? *A.* On many locomotives in the United States one or two rows of stay bolts are drilled to admit air over the fire, to aid combustion, though the size is generally not over ¼ inch. Copper rings are put on fire box end of tubes to keep them from leaking it is very seldom done, late years.

(30.) Stoker, McCook Neb., asks:

What makes the clicking noise in steam chest or cylinders when the throttle is closed and the reverse lever not hooked down, and why does it stop when lever is hooked down? *A.* The clicking is caused by the valve being raised off the seat at each end of the stroke, when the reverse lever is left near the center the end of the valve covers the port about eight inches before the piston reaches the end of the cylinder, and the compression of air there raises the valve off its seat before the inside of valve opens the exhaust port. When the lever is at full stroke the exhaust port opens before enough compression to raise the valve takes place.

IN THE ROUNDHOUSE AND REPAIR SHOP.

The bill providing for the licensing of engineers and conductors failed to become a law.

* * *

The Londonderry Railway of Ireland is equipping two engines and a train with air brakes.

* * *

Correspondents must let us know their own name and address if their articles are expected to be used.

* * *

We wish some one would get out that cheap valve gear model we spoke of a month or two ago and put it on the market. We have had letters about it from everywhere and Arkansas.

* * *

William W. Hills, of Cadalac, Mich., has been granted a patent on the old idea of a valve in the spout of a long oiler. The device, to all intents and purposes, just as shown in the patent office reports, has been in use for at least twenty years.

Since the Old Colony has got hold of the Boston and Providence road they are repairing the engines, substituting numbers for names and straight-shot stacks for the diamond breed.

* * *

Superintendent Wightman, of the Pittsburgh Locomotive Works, has adopted the single admission port for steam chests. It does away with extra space at ends of chest, and admits steam at the arch end of valve seat. No doubt the proper place.

* * *

There seems to be a tendency on the part of many State legislatures to pass laws compelling railroads to adopt some form of continuous brakes and automatic couplers, to be in use after a certain date, generally about 1890. Let them come soon.

* * *

In this issue will be found the first of a series of papers on "Air Brake Practice," by J. E. Phelan, general road foreman of engines of the Northern Pacific. These papers promise to be the most complete, simple and practical instruction yet given on air brake practice.

* * *

Engineer Robert Patterson, Salida, Col., sends us the largest paid up club yet. Ninety-one names is not so easily picked up in a small place. W. H. Thomas, Superintendent of Motive Power, E. T. V. & G. Railway, Knoxville, Tenn., comes second, with sixty-four names.

* * *

A Wisconsin genius has got up a trunk that is not a trunk, but a cross between a chest and an express truck. This may make it a little easier for baggage masters, but what enginemen want is some sort of trunk that will let the conductor report a delay of five or ten minutes as time lost unloading baggage, instead of saying the engine did not steam.

* * *

Elijah McCoy, Detroit, Mich., has patented the idea of attaching lubricator pipes to the steam passages as well as to the chests The oil pipes on steam chests are used when running down hill and those on steam passages while using steam. It is claimed that oil pipes on chest are not effective where balanced valves are used, although we do not know why.

* * *

A fatal collision occurred on the "Q.," at Creston, Ia., on the 16th of the present month. The reason given was that the conductor had been on duty 54 hours, and fell asleep, thereby neglecting to take a siding. Before the strike the engineer would have been blamed for running by the siding—they must not be blamed for anything now. There should be a law against 54 hours' service or 24 either.

* * *

An Illinois inventor proposes a headlight in each end of passenger coaches, with their light reflected down the aisle. One reflector behind would no doubt let passengers read a little more than the murky glims now in use. But if an engineman was dead-heading over the road and went to sleep he would jump through a window when he woke up if a young headlight was shining in his face.

* * *

The general practice of the day seems to be to see how many flues can be crowded into a boiler. Recent orders in several shops place the distance apart at $\frac{5}{8}$ of an inch This is considered good practice where the number of flues does not exceed 150, but where there are over 200 2-inch flues crowded into a 60-inch shell the space is not enough. An old rule, and one that seems to bear out its correctness within the range of locomotive practice, is to allow $\frac{1}{8}$ of an inch space for every thirty flues Boilers whose flues are too close together are the ones that drop their water so bad when shut off, after working hard.

* * *

European railroad papers are publishing as "great improvements in railway carriages," an item stating that the Southeastern Railway of England are building "115 carriages with six-wheeled trucks, upholstered seats, lavatories and water coolers; they will also be heated." The poorest cars running in the United States have closets, ice water, etc.; our best roads have water in cars used to haul live stock. There would be a howl go up very quick if every passenger car was not heated just about right.

* * *

An English inventor has secured a patent in this country on the idea of extending the link slots past the blade connections. He uses this to open the port when the engine is "blind." An engine is called blind when she has no lead; that is, when on the center she will not open the port, if she has no lead ahead she generally has too much back, and it is customary in this country to slack back then go ahead when an engineer finds his engine in this condition; but he only stands it one trip. She is squared up at once. The best way out of the blind business is not to make engines blind. Eccentric blades have been connected to links almost everywhere, and that a man could patent a place to put them seems curious.

* * *

We are in debt to unknown friends in different cities of Illinois and Iowa for over a dozen papers, giving accounts of accidents on the Burlington road, also several pages of testimony before the Railway Commissioners of Illinois. Some of the new engineers (?) testifying that they did not know the signals in use, that the reverse lever lengthened and shortened the stroke, that they had been running without any examination at all until the morning of the investigation, and then had been told the answer to questions they could not answer, etc., etc. Some of the new men's own children testified that they had not been beastly sober since they could remember. These facts have been kept from the public by the meek and holy daily papers, with a telegraph franchise, who do not want to widen the breach between capital and labor (?)

* * *

At a certain station on a Western road there was a foolish boy always about the trains and engines. He invariably wanted to "run the old thing" a little ways. The enginemen were always hiring him to run or making a bargain to sell their jobs to him. One day there was a big crowd around, and he asked one of the men what he would take to get him a job running an engine. The engineer looked serious and said: "Now, no fooling, are you a real engineer?"

"You bet," said the embryo.

"Well, now, I'll tell you," said the plug puller, "down here at C—— there are over 40 steamboats tied up (C—— was on a sand bank, and not a decent drink of water in ten miles), you get right on here with me and I'll take you down there and get you a good job at $10 per day."

"No, I don't want any job, I can't run," said the big fellow; "I was on a steamboat once on the Missouri, and it takes a man to run one of them, but any darn fool can run a railroad engine. Why I've seen 'em go through here without anybody on 'em at all."

This boy has all the qualifications of a great general manager.

Human Sacrifices to Greed.

Thousands of young, able-bodied men are killed annually on the railroads of this country by the old hand brake and man-killer coupler, that could be saved by the application of automatic brakes and couplers to freight cars, and yet nothing is done to remedy the evil. If an equal number of horses or cattle were killed, a law would soon be passed to prevent further slaughter. If something is not done for the protection of these men, they will find means to compel the adoption of these safety appliances.

One hundred and sixteen brakemen were killed on the railroads of Michigan last year. If such an enormous number are killed in one State in a single year, what is the annual slaughter in the whole United States, and what shall be done with legislators who encourage this terrible butchery, by killing every measure presented for the safety of brakemen?—*Railroad Brakemen's Journal.*

There are now in use on American railroads 26,415 locomotives, 19,252 passenger cars, 6,325 baggage cars, 845,914 freight cars. The total cost of this rolling stock is $700,000,000. If made up in one train it would be 5,600 miles in length, or stretch twice across the continent.—*Express Gazette.*

CAST STEEL WORKS

OF

FRIED. KRUPP, Essen, Germany.

AMERICAN OFFICE, 15 GOLD STREET, NEW YORK.

P. O. BOX 2878.

Represented by THOMAS PROSSER & SON.

These Works cover an area of 1200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

LOCOMOTIVE TIRES, CRANK PINS, PISTON RODS, SPRING STEEL, &C.

STEEL-TIRED WHEELS.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

Straight and true to size, within the one-thousandth fraction of an inch. All ready for the most accurate purposes.

All sizes to 8 inches, varying by sixteenths, kept in stock.

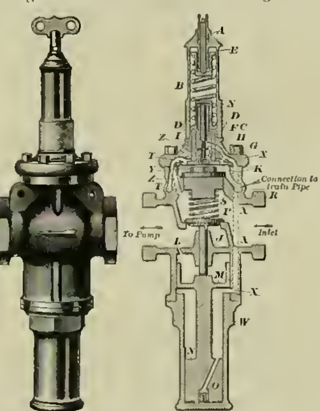
The Mason Air Pump Pressure Regulator.

The accompanying cuts represent the outside and sectional view of a pressure regulator designed by the Mason Regulator Co., of Boston, for automatically controlling the pumps used on air brake systems. It is well known by railroad engineers that a certain pressure (about 70 pounds) in the reservoir is most effective for controlling the brakes; higher or lower pressures causing very uneven working. On long runs, where the brake is used but little, some means that will prevent the pump from working itself to death is needed, and on local runs, where the brake is used a great deal, a pressure regulator that will run the pump fast until the required pressure is gained, and then ease it off, is almost an absolute necessity with automatic brakes. The regulator is placed in the steam supply pipe to the pump, the steam entering at the point marked "inlet," holding down to the seat the main valve *P*, and passing up the passage *Z Z* into the chamber *I*. The auxiliary valve *F* is held open by the tension of the spring *B* by screw *A*, which is operated by a key. The steam, after leaving the chamber *I*, passes through the valve *F*, along the port *X X*, under the main piston *M*, which has twice the area of the valve *P*, which rests upon it. Piston *M*, being twice the area of valve *P*, forces it from its seat, thus allowing the steam to pass through the valve *P* into the outlet, thence into the pump. When the pump has forced up the desired pressure in the reservoir, it acts through a one-quarter inch pipe, connected from the train pipe at *R* into the chamber *K*, forcing up the phosphor bronze diaphragm *G*, and the cricket *D D*, thus allowing the valve *F* to close with the aid of the spring *I*. Steam is shut off from under the piston *M*, and the valve *P* is forced onto its seat by the initial pressure, thus stopping the pump. The pressure already under *M* exhausts around it, and escapes through *L* into the outlet side of the regulator. The piston *N* at the bottom acts as a dash pot, its object being to prevent sudden movement, and consequent "jumping" of the pump. The passage *T T* is to afford an escape for whatever small leakage may have passed around the valve *F*, and through the holes for the cricket *D D*. The distinguishing feature of this regulator is that the pressure chamber is entirely separate from all working parts, so that dust, or any foreign matter from the air tanks, will not disturb the working.

A Chance for Arbitration.

Notices have been posted in all division roundhouses of the Chicago, Burlington and Quincy Railroad that after May 20 all engineers not able to run their engines



without the aid of pilots will be dismissed—an order which, it is said, will take off about 60 per cent. of the engineers.—*Chicago Inter-Ocean, May* 19.

Last week we were informed on every side that the "Q" had a full hand of the "best engineers to be had in the land," and now, after two months, those "good men," who can't stumble over the road without a pilot, will be discharged. This simply means that the loss of business of something in the millions since the strike, and the fact that the public are still steering clear of "Q" ticket offices, has caused the stockholders to outline a plan to re instate about 50 per cent. of the old men, but without appearing to give in. Stockholders, who have "nothing to arbitrate," will not keep on losing a million or so a month without hunting around for something to arbitrate.

An Abomination.

If there is one abomination worse than another on the average locomotive, we think the blow-off cock should wear the medal. A big, taper plug cock, located where it can fill up with sediment, and chronically leaking—one that you must loosen the jamb nuts to open, and then can't get near to close—is about as near nothing as mechanics can devise. Where there is bad water it is a great help to blow out on the road occasionally. If there is any good reason why a better cock can't be made for the same money the plug is, we would like a photograph of the reason.

Little Railroads.

Most railroad men employed upon well-known "systems" forget that there is in this country many small, almost unknown but important lines doing business and employing many men.

There is a railroad interest in the United States that is almost unknown to operative railroad men, and entirely so to the stock market. We refer to the logging, lumber and mining roads owned by individuals and firms. These roads are not incorporated, yet are of considerable importance to the communities where they are located.

There are 439 different roads of this kind in the United States, none of them over 30 miles in length. They have 2,812 miles of track; 441 locomotives, and 5,810 cars.

This equipment represents a large outlay of money, and the employment of a young army of railroad men.

None of these little feeders amounts to very much in itself, but put them all in a string and they make quite a "system."

Mysterious Pounding.

Some years ago the writer was running an old pelter that was about as loose-jointed as the average circus contortionist. She got a roundhouse rebuild—flues calked, rod brasses filed and stack painted, and the crew was told that they ought to keep her out two years.

The first trip out she crawled up hill

without making any fuss, but when we came to drop down there was a succession of pounds that made us think of a broken frame or a trip-hammer. An examination of the anatomy of the beast disclosed nothing out of place or broken; we started again; all went well just as long as steam was used, but shut off the throttle and the pound started. By observations made from the footboard while the engine was running, we came to the conclusion that the trouble was in the right cylinder.

At the first station, where we had time, we got the piston in the front of the cylinder and disconnected the back end of the main rod, but could not push the crosshead ahead at all; it was solid.

In putting up the rod, the roundhouse men had made a mistake in the guide marks, a heavy liner taken from in front and placed behind the box shortened the rod and cured the pound.

The rod was put up at just the right length to tap the front head when running shut off; while steam was being used the pre-admission, or cushion, took up the lost motion just enough to keep the piston from striking.

Rules for Reading Employes.

Following is a copy of the rules posted by the general storekeeper of the Reading Railway Company

All the employes are expected to be at their posts before the whistle is blown.

Any workman caught talking during working hours will be discharged.

Any person incompetent to fill an order will be dismissed.

When orders are given to the men by bosses they must be brief in their conversation.

Any person making a mistake in filling an order will be discharged.

Any workman who leaves the shop without reporting off will be discharged.

When employed outside and cannot be given work inside, during rough weather, must report off duty.

It is the duty of the foreman to see that every man does a full day's work.

Any person caught eating during working hours will be discharged.—*National Labor Tribune.*

The above, if true, is ample evidence that the emancipation proclamation has not been heard of or has been disregarded by the above would-be slave-whipper, by courtesy called a storekeeper

Special Notice to E. C. Centric.

Editor The Locomotive Engineer:

You do not appear to take much notice of my query as to a correct way of placing eccentrics on the shaft of a locomotive before the wheels are put under the engine, to have them come right for the lead and lap of valves. I hope the question is not too much for a journal that claims to be authority on such matters. I will anxiously wait your next paper.

Buffalo, N. Y. E. C. CENTRIC.

[Notwithstanding our advertised rule to ignore anonymous communications, and specially advertising for E. C. Centric in our reading columns last month, we are in receipt of the above query for the third time from the same E. C. Centric individual. If he will send his correct name and address we will gladly answer his question. We will take an oath not to publish his name—if that is what he fears.]

A Handy Tool.

BY J. H. COOPER.

I enclose you a sketch of a handy little tool I made to face off gauge cock plugs

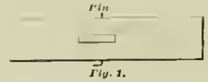


Fig. 1.

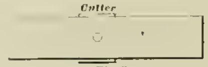

Fig. 2.

and plugs to lubricators. It is made with a piece of iron or steel, with holes drilled in ends the size of plugs, and slotted out at center for a cutter, which is held in place by a pin. The Rose reamer is used to ream the seat of gauge cock, and, using a bushing, it is used to form the cutter, which is then taken out of holder, given clearance and hardened. By this mode the seat and plug, when faced up, are exactly the same, and, I find, do not need any grinding. The holder can be made

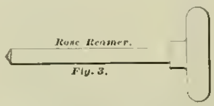

Fig. 3.

Fig. 4.

for two different sizes, as per sketch. This is not patented, and I give it to the public as a handy little tool.

Rochester, N. Y.

Friends (?) in Need.

A month or six weeks ago, there was scarcely a railroad paper in the country, that treats of everything in the railroad line, but that were vieing with each other to see who could condemn the striking engineers and firemen of the Q. in the most scurrilous manner. How hard they could condemn "organized revolution" that could "threaten the safety of the country," the "despot authority of one man," etc., was a free-for-all race for official favors that these papers hurried into. The organs of the different orders of railroad men, excepting the O R C., were, of course, with the men. Some railroad papers that are purely mechanical said nothing—which was right. But the past two weeks we note a change in those sheets that were ranting the worst; sales have been falling off, and the railroad man's own paper (?) wants him to subscribe, and now they are wishy-washy on the "unfortunate complications that drew so conservative a lot of intelligent mechanics into an unnecessary struggle with the Q."

They devote columns to lists of managers, etc., who have "come up from the ranks," pointing out the prosperous times coming that must force men now at the bench, the scoop or the throttle, up to the desks of high officials.

In these assertions they are right, but if we do not miss our guess by a long way, this late trouble has shown to the engineers and firemen of America just what friends they have in the newspaper line.

Those papers whose policy has been to stab at labor, organized or unorganized, with one hand, and accept annual passes and advertising contracts with the other, should expect no quarter at the hands of engineers and firemen.

Such papers as consider the Brotherhoods of Engineers and Firemen as organized anarchy, and a pool of railway managements a business combination, who declare that the public has no sympathy for striking workmen unless they are "actually striking for bread, or hours of rest enough to sustain life," that any body of strikers is a mob, and Pinkerton's standing army the salvation of the country, should disdain to notice the individual members of mobs.

The two Brotherhoods have not "received their deathblow," to the contrary notwithstanding.

They are organized on principles of honor, manhood and integrity beyond the conception of the lick-spittle sycophants who have assailed them.

They have put too many hundreds of thousands of dollars worth of food into the mouths, clothes upon the backs, and roofs over the heads of widows and orphans.

They have raised the standard of temperance, ability and honor of their membership too high.

Their members have become too trustworthy as guardians of human life.

Their only crime is that they have sought to obtain fair compensation for the labor they peform and the dangers they encounter.

This, then, is the curse that will throw down two institutions founded upon three such virtues as Benevolence, Sobriety and Industry.

Let the outcome of the strike on the Q. be what it may—even should every man who participated in it be tried and executed—the twin brotherhoods would recover from the blow as a locomotive rights herself after lurching at a low joint.

As well might you expect the United States to turn up its toes because the city of Boston had sunk in the Atlantic.

That there shall never be another strike we hope, that there shall never be such cause for one we pray.

The loss of over a hundred lives at Chatsworth has cost the Toledo, Peoria & Western about $166,000. All claims were settled without a lawsuit.

A Big Hole.

The great tunnel of the Northern Pacific Railway, through the Cascade Mountains, is done. It was commenced in 1886, is 9,843 feet long, almost entirely through solid rock. It cost over $2,000,000.

'Twas Ever Thus.

What has become of the locomotive with the hundred or more flat spots on each tire which was built down Boston way a few months ago? When are we to hear its cheerful hippety-hopping along the rails? There is whispered rumor to the effect that the flat spots or "facets" won't keep flat, but persist in getting themselves rubbed out, leaving the tire just like any ordinary tire without any patent on it. This would appear to be another illustration of "the total depravity of inanimate things." If you want a tire to keep round it will get flat spots on it; but if you want it to have flat spots it will get round. —*Master Mechanic.*

A Leaky Throttle.

Once upon a time there was a scrap-heap that had a leaky throttle; some of the wipers swore that it was so used to leaking that steam would continue to blow out of cylinder cocks when the boiler was cold.

This engine used to stand in the roundhouse and hiss at everything that was said. Then she would go out on the train and sizzle away till leaving time.

Once in a while the engineer would stop at a tank, get her just right, and then start on a tour of lubrication, forgetting to open the cylinder cocks. The leaker would stand this for a minute or two and say nothing, then she would swell up with indignation, and, when the long oiler was after a far-off eccentric through the spokes of a driving wheel, make a sudden lunge ahead, put a compound fracture in the snoot of the long oiler, a crimp in the water tank spout, and freeze the spinal column of the engineer as the fireman yelled: "Hold 'er there, you crazy loon; are ye trying to kill everybody?"

About twice in a while the hostler would forget the cylinder cocks and put her in the house, but if she did not have a cord of wood under her wheels she used to hook off doors or kick out brick.

All the machinists at the place had ground in her throttle, and one had gone over dry pipe and connections.

The best machinist in the place, bet a $100 dog he could grind that throttle so it wouldn't leak, and he would have lost, if a dog worth that much could have been found. He tried again, and made up his mind to grind in everything, from the mud-ring up. He elevated the dome cover, and Barney, his helper, who was no bigger than a piece of waste, wormed himself down among the braces and lay on his back on the flues, while the machinist went to hunt a certain wrench. When he came back Barney said: "Mr. 'obbins I want to h'ask you a poser; what is the hobject of this 'ere vent 'ole in the long pipe? Hits only about a 16th, but what good does hit do?"

Barney had found a hole in the dry pipe caused by the breaking out of a small piece of iron where a chaplet had been used to hold the core in casting the pipe. A copper plug in the "vent," cured the leaky throttle.

The Vance Flue Cutter.

The cuts shown herewith represent a device for cutting out boiler tubes, and is

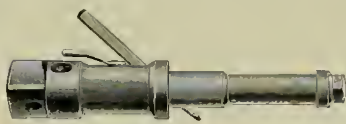

Fig. 1.

the invention of James R. Vance, a well-known boiler maker of Geneva, N. Y.

Fig. 1 represents the tool as it appears away from the work. Fig. 2 is a sectional view showing the tool in position. The body of tool *A* is arranged at inner end to hold a washer *r* of any size to fit the flue to be cut; this is to keep tool central. *C* is the cutting tool, and *e* a thumb clamp to keep it from working out of its slot; at *d* is shown a collar that serves to keep the tool in place and protect the tube sheet. The point of the tool is shown full size in Fig. 3.

Fig. 3

In use, the cutter is withdrawn until the tool is in place, then a sharp blow of a hammer drives the cutter through the flue, and the whole tool is then revolved by levers inserted in holes on shank of tool.

We have before us a piece of a flue cut off by one of these tools, and it presents a clean cut and tapering end; it is just the

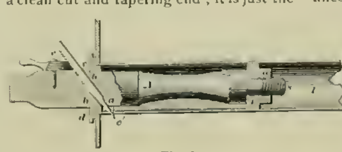

Fig. 2.

right shape for welding on safe ends, as it needs no scarfing. Tubes taken out by this cutter leave a clean flue sheet, and there are no holes to file. One man has cut off 400 tubes (one end) in ten hours. It is made in all sizes, and is especially adapted to locomotive work.

Any further information will be furnished by the inventor, as above.

To build an average locomotive in the best works in the country requires 1,300 days of labor. In another establishment 1,400 days are required; in another 1,450, and in some, where inferior machinery and appliances increase the time required, it takes as long as 1,900 to 2,100 days. Therefore it would take the labor of one man from 1,300 to 2,100 days to build a first class locomotive.—*Exchange.*

Repair Shop Hints—Good Light.

BY HIRAM R. JONES.

A dark shop with smoky windows and dingy walls, almost always has dirty floors, greasy, broken-down tools, and piles of scrap in every direction to make fit company for each other. The workmen catch the same spirit of dirt and disorder, and the work turned out will be on a par with its surroundings. "The wicked like darkness rather than light" —so do dirt and disorder.

Let in the light. Put in more windows if there are not enough. Clean up those you have. Whitewash the walls and ceiling. There is nothing like a beam of sunlight to reveal what is under the bench or down in the engine bed. Some shops are so dark that it is necessary to burn gas to see in the day-time This is all wrong, and poor economy.

A word about the kind of light. North and south windows are the best to work by, and for general shop light; east and west windows—especially in the long summer days—let the early morning and late afternoon sun directly in your eyes, which is not pleasant.

Never put a machine or kind of work that is particularly dirty in a dark place. If you do, a "hog pen" will be the result.

If a wash sink is in front of a window, it is much more likely to be cleaned every day than if in a dark corner, "suitable for nothing else." You don't see the dirt, but you can smell it.

A piece of tin or sheet iron painted a bright red and put inside the engine bed will show every drop of oil, and the engineer will see and wipe it off. It is much better than old greasy waste or sawdust.

A grindstone is quite an important tool; but because it is rather dirty and uncomely in appearance, it is stuck in a corner, with the nearest window twenty feet away, and then perhaps on the opposite side from where it should be. I have seen them put out in a shed, where the "muss would not matter," and, as a result, shunned by all. Who wants to stand in a mud puddle while he is grinding a thread tool, and then take it to the window to see if he has got the right shape to it? I say give the emery wheel and grindstone a good light.

Machinery and tools in a light place will be better taken care of and last much longer. There will be better work and more of it. A bolt or journal in a dark out-of-the-way place is quite likely to work loose or wear out before it is discovered to be out of repair.

I have in mind a model plant in this respect — shafting, hangers, belts and pulleys in a room so dark and cluttered up that a man would nearly break his neck in moving about; pumps and pipes in a pit soft with grease and mire. Verily, the man in charge delights (?) to care for such a lay out. "Let there be more light."

Staten Island Road.

The shops of the Staten Island Railroad at Clifton, S. I., are merely old board sheds, unsightly, inconvenient, small, and poorly equipped. The company operate 20 miles of road, and have 14 locomotives in service, some of the older machines being pretty ancient. The new engines are Cooke build, and of the Forney type admirably adapted to the work the road does. The road uses a good system of distance signals; the cars are heated by steam and controlled by vacuum brakes. Very bad water is used, and the writer noticed sheets of tin hung over driving boxes on some engines and eccentrics on others, to keep leaks from fire-box from cutting the bearings. There were three engines in the shop, and a set of flues just taken out showed the space between lower ones almost solid with scale. Bad water also keeps the engines dirtier than looks well for the service they are in.

Company Time.

There seems to be a desire on the part of many superintendents and managers to advertise their roads and their management by making rules governing the inspection of watches (for which the men have to pay), in many cases going so far as to name the particular watch the engineers and conductors must use. When it goes this far there is a job in it—a steal.

Most engineers buy good watches, paying from $40 to $200 for them. They are expected to regulate these fine watches by a big but inferior clock in the dispatcher's office.

Here is an engineer who has invested $150 in a fine Howard watch; it may be in a silver case, but it has got fine "in 'ards" and he knows it; it is warranted, and he knows by actual comparisons that it is keeping right on the tick with a chronometer in the jeweler's window; he goes out and the watch is 45 seconds "off" by the dispatcher's clock; he don't move it—he would be foolish if he did. The next day it is just right, and in a week it may be a minute or more the other way.

Under circumstances of this kind, considerable variation of different watches on the road is sure to exist; where the variations of watches is but three minutes in handling trains this is dangerous.

The only way out of the difficulty is for the company to own and supply to engineers good, reliable watches that are turned in the same as a report, at the end of every trip, placed in charge of a reliable watchmaker, regulated and set by him, and issued to each engineer as he goes out, just as his running orders are. A few years ago the Pennsylvania company owned the watches and furnished them to the engineers and conductors, taking receipts therefor, and allowing them to keep the watches as long as they were in the employ of the company, or the watch in good order; this plan offers little improvement over the one now in use, as it only changes the ownership of the timepieces; what is wanted is some arrangement that will insure all the watches on the road being set to one standard time and compared each trip.

New Tube Expander.

The expander here shown is the invention of T. Beverly, a boiler maker in the shops at Ellis, Kansas, and has several new and good points.

By reference to Fig. 1 it will be seen that the body of the tool is in one piece, numbered 1, in both cuts, and has plain straight recesses to receive the rollers; it has three recesses for springs that are shown in Fig 1, marked 2. They are held in place by a projection on spring in a recess marked 3; the sleeve 4, is a plain steel band kept in place by one spring shown at 5. The rollers have a small hole drilled through the center, and into this hole the ends of the springs are introduced, thus keeping the rollers from being lost.

It will be seen that by pressing down

Fig. 1.

Fig. 2.

spring 5 and removing sleeve 4, the rollers may be easily removed or replaced.

When the tool is complete there is no shield or collar, the rollers being as large as any other part of the device, and it can be used in a corner, or close up to a side or crown sheet. The tool is easily repaired, and can be made in any shop where there is a lathe. Further information will be furnished by the inventor, as above.

How to Start.

We are not going to tell how to start a train—if you don't know how, it is not likely you will get much of it to do.

We are in receipt of letters from young men all over the country, saying, that it is and has been the ambition of their lives to become locomotive engineers; some of them have had experience in machine shops or in charge of stationary plants, and all state that they have tried several places to secure positions as firemen, but the master mechanic always declared they had more men than they needed. Some of them think it strange that men so anxious to follow railroading cannot get a chance, while on the roads there are many dissolute, and perhaps ignorant men.

Replying in general to all of these writers, we would say that they all aim too high; because firemen become engineers, they wish to become firemen.

Master mechanics, as a rule, have several men employed in the shops, who have the promise of a chance to go firing, and as he wishes to keep those promises, he turns away men who apply for places ahead of men who have his word for "a show," when there is a vacancy.

If you are a young man, not an employe of the company, seek to get on the pay roll in the motive power department, in a lower capacity; leave the M. M. alone—he is busy; seek the foreman, a mechanic or a wiper, make their acquaintance, tell them you want to get to work in the shop or roundhouse *at anything*, wiping, calling, wheeling cinders or helping a machinist. Once at work, show by that work that you are in earnest and willing to do your whole duty; you cannot do this unnoticed, and you will soon have a better job; you will learn something every day; it will not be time thrown away.

When you are known a little, ask your foreman's help to get you out firing "extras"; if he forgets it, remind him once in a while, but don't hound him for a chance when it is plain that there is no chance and business is dull.

Get acquainted with some of the engineers and take a trip with some of them, on freight in the night—perhaps you won't care to go firing then.

Remember the M. M. has enough to see to with the engineers and firemen, and let him alone; recognize your foreman; be a conspiciously useful man, and let your ambition be known.

First of all get to work for the company where you can be seen; commence at the bottom—clear down—and then struggle for the gratification of your ambition.

If you were shooting snipe you would not discharge your gun until you were within range—near enough the game. Get behind some good mechanic in the shop, and thus approach the roundhouse foreman; keep on the windward side of the M. M., and don't give him both barrels until you are so close you "can't miss him."

No matter what your former experience in shops, on the water, or in stationary practice, do not try to impress your engineer with your profound knowledge of mechanics; tell him you are green as a Hottentot about locomotive running or firing, and tell him you are there to do just what he tells you the very best you can.

All you know about the strength of materials, setting valves, running or firing stationary plants or designing machinery, won't make you a good locomotive fireman. Your engineer knows this, and not to acknowledge it is simply saying that he don't know his business. The footboard of a locomotive on the road is absolutely different from any other place on earth.

If you make a first-class fireman and live long enough, you may become a first-class engineer.

Doing Work.

There are a great many locomotive engineers who seem to think it an evidence of proficiency to be constantly "doing work." They are always at the roundhouse and up to their ears in work. Not only do they pack cellars and boxes, doctor oil cups, clean headlights, and pack pistons, valve stems and cab cocks, but they set up wedges, monkey with side rods, line up crossheads etc., etc. Somehow they have got the idea that every point of the engine needs re-adjusting every trip; they never get through experimenting in the front end. They very often undertake to close up eccentric straps or file brasses, or do some other work delegated to machinists, and it is an insult to infer that perhaps the machinist could do it better; this class of men are always in trouble.

This is the man who has hot pins and break-downs, and has to open the front end on the road in order to get the chill off the water in the boiler.

The best engineers we ever knew, were men who took pains to key up their rods on the road when the engine was hot and in working condition, and then left them alone; that got the front end so that the engine steamed well, and then kept out of it; that did not report work till they knew it was needed, and then insisted on its being done; that did not do machinists' work, and did not ask machinists to do theirs; men that could get a thing about right and then let it alone.

We recently went through a roundhouse with the general foreman in charge, and as we passed an engine there arose from the pit a specter of grease, blue overclothes and perspiration that appalled us—it was the engineer. We passed on and the foreman said: "That man works night and day on his engine, and we do more work on her than on any of the rest; here is an engine run by a man whom I do not see once a month, never seems to do anything, but you can't find any brasses loose in his rod straps, his headlight is clean, his rod cups full. He does just what he is required to, does it well and lets it alone; he does all his work when he is laid out on the road or at the other end of division. His home is here and he stays at home, and when he puts a report on the book you can depend that it is no case of imagination—it wants doing." There is a goodly lot of runners, with road experience only, who think they know more about repairing locomotives than machinists; there is a big batch of machinists, with shop experience only, who think they know more about running locomotives than engineers—both of them are very much mistaken.

If you are a machinist, try to be the best one the company has got, handle the engines when they are cold and let the engineers handle them while they are hot.

If you are an engineer, be a careful, sober, everyday man and an expert runner, and when you get in go home and to bed, and let some miserable machinist actually take down the rods and file brasses on your pet engine, thinking that perhaps he will do it just as well as you would yourself.

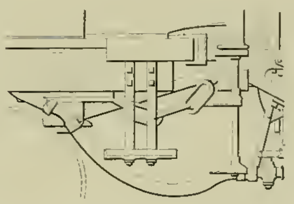
A Theoretical Advantage and a Practical Nuisance.

The accompanying cut shows the draw bar arrangement of a new express locomotive built by the B. & O. Ry. In describing the engine the *Master Mechanic* says:

"One of the most noticeable features of the design of this locomotive and tender can be seen in the angle of the draw bar between the locomotive and tender. This angle is 18 deg., and it is quite evident that, during a heavy pull, a considerable vertical pressure is brought to bear upon the back of the locomotive, thus increasing the weight upon the drivers and lessening that upon the trucks. This we suppose is the purpose of the design, and it seems as if it would make an efficient automatic traction increaser."

The writer of this article has fired and run locomotives with this breed of draw bars, and can sympathize with othe. men who have it to do.

When an engine is pulling hard, there is no doubt that this draw bar lifts up the front of tank and transfers its weight to



the drivers, but it opens the space between the friction plate and the tank wedge, and causes a pounding and jerking that makes the engine ride very uncomfortably.

The tank is raised up in front and becomes a little see-saw sideways over the draw bar, and a fireman wants to be a sailor to be able to stand up.

On paper they help to pull cars; on the road they are elements of "grief" to the men. Make them as near straight as possible.

Improved Link Motion.

A writer in the *Engineers' Journal* tells the readers of that paper that he has gotten up an improvement on the link motion. He claims to have slotted the lower end of his rocker arms and put therein a movable block that moves up when the engine is hooked up between the 10 inch and center notch, but when lever goes back of center the new block returns to place.

He claims to have given this motion a practical trial, and says it is the thing for high speed, as it makes the valve release earlier.

If it were possible to do just as this inventor says he does—which we doubt—his slot arrangement, when in gear, would simply be handling the valve about as the link would do at 10 or 12 inches. The woods are full of men who are improving the link motion—in their minds.

We would like to know how this change affected the lead on our inventor's engine and how much lead he thinks of benefit to an engine.

Air Brake Practice.

BY J. E. PHELAN.

Second Paper.

Straight air appliances have not altered any, or improved in principle, to date. Its use is rendered possible with automatic appliances by a 4-way-cock used in connection with all triple valves excepting those recently improved. This 4-way-cock, when handle is in horizontal position, places triple valve, auxiliary reservoir and brake cylinder in communication with main air pipe and air supply. When it is turned midway, it cuts off triple valve, auxiliary and brake cylinder from air supply, and renders brake useless for air appliances. When the handle of this cock is turned down, it cuts out triple valve and auxiliary, rendering them useless, and opens passage from main air pipe and air supply to brake cylinder, for straight air, same as though triple valve and auxiliary had not been invented.

This 4-way cock attachment to triple valve is left off from latest appliances, and evidently straight air practice with it; and in light of such circumstances, the triple valve and auxiliary reservoir in future are for use and not for ornament.

With improvements, the principle of the engineer's brake valve has not altered. But as improved, and in use now generally, it is the medium through which auxiliary reservoirs are supplied with air, and when handled right, retains 20 lbs. more air pressure in main air reservoir than it transmits to train pipe and auxiliaries. This 20 lbs. reserve pressure in main reservoir is desirable and often necessary in insuring release of brakes by its action on triple valve in forcing it up to its true position for releasing brakes, and receiving supply of air. The 20 lbs. reserve is always insured, with engineer's valve clean and in good order, by having spindle or lower point of spring in handle, rest against middle stop in its travel around outer rim, or top of valve chamber. This relates to engineer's valves in general use. The new engineer's valve has still another stop, and its principle of improvement may be explained later.

With automatic air, custom and practice of some engineers has dictated the cutting out of at least ⅓ of brakes in train, after every alternate car, in freight trains of 20 cars. When brakes are in good repair such practice is wrong, and only demonstrates poor practice on part of those favoring such methods. Brakes should apply throughout the entire train. The stop-cocks in end of pipes at ends of cars just back of hose connection should receive special attention, and always be open—handles pointing down—when brakes are in use, excepting the one in rear of last car, that must remain closed.

Many failures of air brakes could, no doubt, be accounted for by knowing probably, but one of these stop-cocks, not far back of engine, being shut off. The best way for engineers to detect such neglect is when trying air brakes, before starting from terminals, or points where air couplings may have been coupled.

If engine is coupled and air connection not made, in setting brakes air escapes through engineer's valve lightly, and air pipe being quickly emptied of air, the air gauge indicator acts quickly in going toward zero. The indications correspond in degree for one or two cars, and can be quickly detected by an engineer acquainted with conditions. When full train is connected, air flows out with indications of having a volume of pressure back of it; air pipe is not easily emptied of air, and reduction of pressure, as shown on air gauge, is so much slower, and each let up in escaping air is followed by gauge indicator rising again from effect of pressure coming from rear cars. The new engineer's brake valve will alter such conditions, so far as not showing effect on gauge, of air flowing from rear cars to increase pressure on forward cars. This flowage of pressure from rear to front cars by improved triple valve is utilized by passing from main air pipe to brake cylinder, thus going to set brakes; at same time continuing reduction of pressure throughout the train and causing prompt action of all brakes.

Handy Tender Step.

On many engines the step on side of tank is in the way of hose, and is often trappy because its hangers are loose. A step that any one can easily make and put on is a square piece of ½-inch iron, as shown. Drill holes to fit long bolts that hold box on front tank truck to angle irons, and bolt the plate to top of box. No hangers in the way. When truck is too far back, a step on front box in addition to the regular step is a convenience and often an element of safety. Such steps are in use on the elevated roads of New York and Brooklyn.

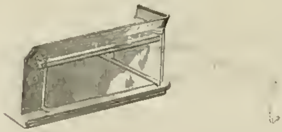
A Safety (?) Jumper.

A Wisconsin inventor has got a patent on a device to let railroad men jump a good distance from the track.

The device is so novel we illustrate it. As will be seen, the arrangement consists of a barn-yard gate hinged to side of tender, one on each side (we suppose). In case of a wreck, collision or derailment, the bold engineer gets his dinner pail, coat, and time card, places his foot on the step, pulls the string, and swings safely toward a field of high oats; the fireman grasps the tallow pot and leaps into the darkness, *via* the gate.

Of course they always have lots of time for gate swinging. There is a self-regulating windlass concealed in the gate frame, and the jumper can take hold of the ring shown and it will lower him gently and drag him as long as he has breath to hold on.

We imagine that if any of the boys would practice on this scheme of escape, that by the time the victim had been dragged through a few patches of brush, knocked over a couple of switch stands, dove through a cattle guard, and butted his brains out against a bridge, that he would



prefer to just simply fall out of a side window and take his chances with the mud-hens in the ditch.

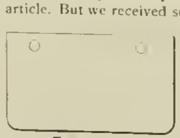
Correspondence

A Hospital Victim.

Editor The Locomotive Engineer.

I read with interest the article on Hospital Steals, and in support of the truthfulness of that article I would like to give you a little of my experience with corporation contract doctors. While in the employ of a certain company I had my hands scalded and the backs blistered badly (I am a boiler maker.) The doctor gave me a bottle of lotion to wash them with. He gave me strict orders not to cut blisters or let the water out until they broke. I went to his office daily for a week; my hands seemed to be just the same as when I went to him at first, and showed no sign of breaking. I suffered terrible pain all that time. I was prevailed upon by friends that witnessed my suffering to try an old lady that made a specialty of such cases. The first thing she did was to let the water out by cutting the blisters. I was relieved of all pain immediately. She showed me what caused the pain—the water had eaten into the flesh and formed matter. She said I must not take blistered skin off, as it would peal off as new skin formed underneath.

Now, the rules of this company in the matter were practically as stated in your article. But we received so much cash per week while disabled. If not a hospital case we must go to that contract doctor, as he has to give you the order for your pay. I



TENDER STEP.

had to wash off the salve, the old lady put on, every day before going to see the doctor. After a few days he was astonished, my hands were getting along so nicely. At the same time he would pat his bottle of lotion with his fingers and proclaim it could not be beat for scalds; but that bottle went into the first vacant lot I passed. But one day, just as I considered my hand all but cured, he ripped the blistered skin off before I discovered what he was doing, and took the new skin with it. That was too much for me. In my anger I went for him, and told him he would never get the chance to do that again, and I had been receiving other treatment. I got no pay for those four weeks. We held several meetings (there were 2,000 men interested) and tried to dislodge that doctor, but we found he was a Gibraltar.

JAS. HERON.

Buffalo, N. Y.

Drivers, Stokers, Fitters and Blunders.

Editor The Locomotive Engineer:

Having become a subscriber to your valuable paper I would wish, through its columns, to say a few words in regard to a matter I have heard debated many times. Many old and experienced drivers advance the theory that mechanics, that is, locomotive fitters, make indifferent drivers. Now I would like to know how such theory can stand? Who, I would ask, should know better what is under his feet than he who makes and places it there? Who should have a better idea of the strain and tension on every bolt and pin in an engine? Why, I have heard a good driver ask a turner who was turning up piston rings, if they were cast or wrought iron. Imagine, then, what idea he had of metals in general. It is ridiculous to assert that a man can, after a time firing, be competent to take charge of an engine. Is it the case on our ocean steamers? An engineer should be an engineer in every sense of the word, mechanical, practical and theoretical; outside those necessary attributes I consider any driver but a laborer. Every man, in my estimation, who wishes to drive a locomotive, should, like engineers on vessels, pass an examination as to their fitness for such position. It will, I am sure, be the means of securing more safety in travel, and the saving of a large amount of capital.

MECHANIC.

Quebec, Dom. Can.

[Engineers are not sent out to test strains on bolts or pins, but to pull cars. If the officials of the road put on trains too heavy for the bolts or pins, the engineer is not expected to argue about the strains, but to pull the cars or break the pins. Engineers do ask foolish questions about shops, but they do not get much the best of shopmen on the road. Engineers on vessels pass examinations on the engine only; the captain, mate and pilot have to pass another on the handling of the craft, signals used, etc. A locomotive engineer must pass *all* these and more. To pass an efficient examination on *handling* an engine over the road, would debar the best mechanics from becoming engineers—unless they had road experience. Engineers are foolish to say a machinist cannot learn to be an engineer. Machinists are equally foolish to think a man with road experience only cannot be anything but a laborer.]

The Way the Road Men Feel.

Editor The Locomotive Engineer:

I was pleased to read your article on "How and Why Injectors Work;" for there is a large number who do not think the real cause has ever been discovered yet. The chap I sling coal for, a good, practical man, told me, when I tried to tell him he could find the principle explained in some good work on the steam engine, it was all bosh, for it was a mystery to-day as much as it was twenty years ago. I heard an M. M make a statement not much better a short time ago. The paper on the air brake is another good start for the boys, for that is a thing we should thoroughly understand. I hope you will soon be able to make THE LOCOMOTIVE ENGINEER a weekly paper.

Halifax, Nova Scotia. FIREMAN.

Care of Locomotive Boilers.

Editor The Locomotive Engineer:

In making out reports of repairs required, and general condition of, locomotive boilers, it is a disagreeable duty to me to have to report water spaces mud blocked, more especially so when the diagram with report shows the mud block to be in close proximity to an inspection plug, where ordinary care could have prevented its formation there. I am willing to admit that washout plugs are sometimes put where there is little chance of being taken out, except when the engine is in the back shop for repairs, and freely grant that the time allowed for doing the important work of washing out a boiler is frequently too short to allow of its being well done; but no reason exists why plugs easy to get at should be allowed to remain untouched for months at a time—except, perhaps, a morbid dislike to too much work on the part of the washer-out. This individual should be supplied with a set of water space torch rods, and required to use them. If a boiler-maker is around, he should examine the water spaces with a light, after the boiler is washed, and see that everything is O. K. Staybolts are often found broken, and some that sound good under the hammer test are found to be defective when the water spaces are examined with a light. A piece of clean waste, well soaked with benzine or kerosene, makes a good light to use on a rod.

In your Roundhouse and Repair Shop Notes for May, you state that the practice of the day seems to be to see how many flues can be crowded into a locomotive boiler. In my humble opinion, this practice is wrong. I think more economical results would be found if the spaces between flues were wider apart—say seven-eighths or one inch—than where flues are kept so close together. Any one knows, who has ever been inside a locomotive fire-box, that an engine is not in service long before some of the flues in the outer rows are choked with cinders, etc., rendering them practically useless for the purpose they were intended for, namely, heating the water surrounding them, and converting it into steam by conducting hot air, combustible gases, smoke, etc., from fire-box to smoke-box. If the flue area thus lost by choked flues was distributed through the boiler in water space, by allowing wider spaces between flues, circulation and ebullition of water would be more evenly diffused through the boiler, and no loss of heating surface follow, as compared with present practice. Where flues are crowded together, the outer rows are plugged with dirt, the heat centralized, ebullition is more violent and leaky flues common.

If I was a fireman, and wished to save the railroad company money, and myself lots of hard work, I would try and keep the crown sheet free of those hard, gritty lumps of incombustible matter which adhere to crown-bolt heads, safety plugs, etc., until the crown sheet is covered with it to a [illegible] of several inches. Sometimes the [illegible] are nearly choked with it. This stuff, as a non-conductor of heat, will rate A 1. It must be evident that a lot of good heating surface is lost on the crown-sheet, and in the reduction of effective flue area, by its being allowed to remain on the ends of flues. It is not hard to remove at first, but if allowed to remain for a time, considerable difficulty is experienced in removing it. A BOILER MAKER.

Hamilton, Ont.

Another Wedge Fastener.

Editor The Locomotive Engineer.

Some of the new engines on our road, the B. & O., have the wedge bolt fastened in the wedge, and the bolt extended through the brace to a separate bracket, as shown. It seems to work well, and you can screw the wedge down as well as up. 631.

Baltimore, Md.

Another Air Pump Question.

Editor The Locomotive Engineer

In reply to F. M., Greenbush, N. Y., I would say that I did examine all air valves of the pump in question and found them all right. Furthermore, that I did not say anything about a "terrible pounding." From the tone of his answer I should infer that he (F. M.) had jumped at his conclusions without giving the matter proper investigation. Now T. J., of Schreiber, Ont., takes the right course in giving the subject proper thought, and the result is that T. J. has won the cigar, and I will tell him with pleasure what I found.

Some one at the other end of the division had been working at the pump, and while the top head was off had in some manner dropped a pine plug (probably a substitute for a cork in the oil can which was used while working on the pump), in the exhaust port or cavity on the side of cylinder, which almost closed the exhaust passage from upper end of the cylinder, causing no small amount of back pressure. After removing the obstruction the pump worked all right.

I will join T. J. in praising THE LOCOMOTIVE ENGINEER, and add that I hope it will prosper and grow to that extent that you will be obliged to issue it every week, and that very soon too.

Now here goes another conundrum for the boys. Sometime ago Engine 600 came in, and Uncle Rube Allen (who ran her at that time) said his air pump stopped working very *abruptly*, and he could not start it again. Well, I went to work at it, and, as I had always done, I loosened the reversing valve and cylinder caps before loosening the head (because the caps sometimes stick pretty hard), and on removing the reversing cylinder cap I noticed that the reversing piston was at the top of reversing cylinder; I pressed it down, put both caps on again, gave the pump steam, then the main piston moved up to end of stroke, returned to the lower end of stroke, and stayed there. I again took off reversing cylinder cap, found reversing piston up as before; I pressed it down, put on the cap, put on steam, and it acted the same as before; I then removed the cylinder head, thinking perhaps the steam passage leading to the lower end of the reversing valve bush was stopped up, but found it all clear. Then I thought perhaps the wings of some of the air valves might have broken off and worked under the air piston, which would prevent the main piston traveling down far enough to draw reversing valve stem down and reverse the motion of piston. I took off bottom head, found nothing; took out main piston and found nothing. I put everything up again, tried the pump, but no go. It was now about midnight, and I was tired and mad, but would not give up, so off comes the top head again, and I found the trouble, and it was so simple that I could have kicked myself for not discovering it before.

Another cigar for any air pump repairer who will tell me what the trouble was.

Syracuse, N. Y. W. F. R.

How They Do Us Up.

Editor The Locomotive Engineer:

Not long ago I was in a large machine works, and was being shown around by one of the proprietors. I was somewhat interested in a large three-spindle drill.

It was merely three drill presses mounted on the side of a 20-foot bed, and they could be moved along its length, or be used in any place independently of each other. An attendant was in charge of one, and on one spindle was drilling a lot of castings; on another he was drilling and countersinking holes in long wrought-iron straps, and on the third he did any odd job of drilling that was wanted. As I looked so interested, the owner said: "That tool was intended for long work, where a lot of holes are needed, and all three spindles could be working at once, but we find it pays to keep them on little work; one man will run them and not realize what he is doing, but ask him to run three separate drill presses and there would be a strike."

We went out into the yard and saw a great consolidation "hog" go by with 60 loaded freight cars, where the old eight-wheelers only hauled 28 loads a year or so ago.

The engineer receives the same pay, and while his responsibilities have been increased he does little more actual work.

But with the fireman it is different; where he formerly burned from two and one-half to five tons of coal in a hundred miles he now burns nine; he not only has to break up this much more coal, but he has to lift it, and he has to throw it 11 feet, instead of four. He also has to clean an engine as big as three of the old ones. Now these firemen are getting the same pay they got on the little engines. Here is a case of doing at least three times the amount of work, and in furnishing steam to haul over twice as many cars, for the same money. If these men killers were not so big and so hungry for coal I should say give the fireman more pay, but it is really too much work for any one man to stand up under and protect his health at all. All locomotives having fire-boxes ten feet in length, or all locomotives burning over ten tons of coal in ten hours, ought to have two firemen, and the law ought to say so. H. D. DOYLE

Denver, Col.

Where It Is Better Managed.

Editor The Locomotive Engineer

In looking over the columns of your journal I see some correspondent writing on the Railroad Hospital, in which he terms that institution a swindle.

Now, I fail to see his point in calling it a big steal. I have paid hospital fees for the last ten years, and have never had one cent's worth from a hospital as yet, but I do say it has saved me many a dollar, for if one of our men comes in from the road sick or mashed up we send him to the R. R Hospital. Now, can any one say he has not a good room to stay in? You certainly know he has. Is the writer aware that the man is not compelled to have a hospital doctor if he or his friends are able to pay for a doctor? Now, if he wants another doctor they can, of course, get one, and the prescriptions are filled gratuitously at the expense of the hospital. Board and washing are also furnished the patient while in the hospital. Is this nothing for our money? I am surprised that our railroad men are so blind as not to see where their own interests lay Now, I am a married man; suppose I get sick and want my family doctor; he prescribes for me, and then I can send it to the hospital drug store and have it filled. Such is the arrangement at our hospital, and I for one do most cheerfully endorse it for the benfit of my fellow workmen.

My men on this road wanted me to have it done away with. I explained to them the benefits of it, and they have all concluded it is a good thing and wish to continue it. It is to be remembered that doctors are like engineers and machinists, they like good wages after spending thousands of dollars to learn the profession, besides several years of labor. Let gentlemen weigh this matter well, and if I have committed any error in this article it is more of the head than the heart. I will close by saying that I consider the R R. Hospital a godsend to poor homeless railroad men. E. A. CAMPBELL, M M.

Houston, Texas.

[Our correspondent is where the men have a little latitude; as a rule men can get medicine from a company drug store only on order from a company doctor. What the writer objected to in the original article was the fact that the men pay the expense of repairs for "mashed up" people, instead of the company.]

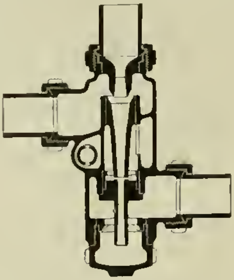
There has been an unusual number of locomotive boiler explosions this spring.

Injector Currents.

Editor The Locomotive Engineer :

The interior of an injector has always been a mysterious interrogation point to me. Just about as soon as I come to the conclusion that I have got the right idea, along comes something that shakes my faith in my own information.

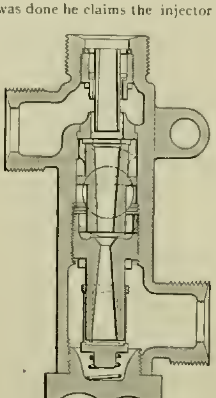
The last issue of THE LOCOMOTIVE ENGINEER had two articles on this subject that seemed to me just right; but I have



SELLERS' "NON-LIFTER."

had a little experience lately that has got me "off" again.

There is an old runner here, and he is considered extra well informed, who insists that the range of an injector depends in a great degree upon the turns in the feed pipe and the obstructions the water meets with after it leaves the delivery tube. On his engine they put up an injector, with an elbow in the pipe only about a foot from the injector, and he kicked about it till he got it out, and had all the turns made nearer the check. Since this was done he claims the injector does



RUE "FIXED NOZZLE."

better in every way; on top of this comes an article in another paper, telling how an injector failed to work because the brazing of a joint in copper feed pipe was rough and broke the current. Now if all this is so, how is it that the fixed-nozzle injector, made by the Rue Injector Co., and the non-lifter, made by the Sellers folks, will work when their delivery tubes send the water directly against a cap and the feed pipe is at right angles to tubes and *above* them, so that the current has to turn clear around?

I wish you would print a view of the *innards* of these two squirts, so that us fellows who have got currents on the brain can see what is what.

Tyler, Tex. TEXAS.

[Cuts asked for by correspondent are published, and show change of current as he states; nevertheless they work admirably.]

Fastening Follower Bolts.

Editor The Locomotive Engineer :

While men are scheming to get some form of lock that will prevent follower head bolts from working out, I should like to remind some of them of an old scheme—and a good one. It is in use on some Eastern roads, and is much used in Europe, both in locomotive and steamship practice. Each bolt head has two one-eighth inch drill holes through the head, and the follower has a channel cast between each bolt hole, just deep enough to hold a one-eighth inch copper wire. After the bolts are all in, the wire is strung around through all bolts and fastened. A bolt cannot work out without shearing this wire. I believe that this device is as simple and efficient as can be devised for this purpose. But all the ingenuity that can be put into a locomotive piston cannot compare with a good, solid head—that is, in the opinion of your SUBSCRIBER.

The Dalles, Oregon.

Problems from the Footboard.

Editor The Locomotive Engineer.

The nozzle of a locomotive plays a very important part in hauling trains, still, as you say, in your April number, steam is necessary to pull cars, but every pound of back pressure on the piston means one pound less hauled. I always went in for the largest nozzle possible, and rather than reduce them have put in smaller blast, or petticoat pipes, sometimes putting liners in the bottom of the stack, ten or twelve inches long, reducing the diameter from two to three inches, and by so doing have been able to open the nozzles ¼", and making plenty of steam on far less coal. On some roads I have known the boys to put a piece of ⅜" round iron, wedged tight across the center of the nozzles—a "split." It did not reduce the area very much, but it worked wonders on some engines. There was only one way I could account for these results, that was that the strip of iron split or spread the current of exhaust steam, and made it fill the stack, thereby producing a greater vacuum in smoke arch and tubes, and more complete combustion. The trouble with many engines to-day is the stacks are too large, and the exhaust acts like a very loose plunger in a pump—not doing more than half its work. Some years ago we got a Wooten engine, Baldwin build, it had a 5" single nozzle, with a plug in the center that could be raised or lowered from the cab; there was a register in smoke box door, the grate was 96" x 102"; we used Cumberland coal; it made steam very free. I took the plug out of the nozzle, then commenced cutting off the top to enlarge it, and finally made a new pattern, and when I left the road that engine was running a six and five-eighth inch ($6\frac{5}{8}$") single nozzle. Mr. Angus Sinclair said it was the largest nozzle in the United States. It was a picnic to fire her. But her good qualities were spoiled by the M. M. ordering the fireman to shovel snow in the fire-box during a snow blockade, to dampen the fire; this made a steam inside the flues, and the smoke and ashes formed a scale inside, and the nozzle was reduced to 5", and she was like a waterlogged ship. Jones' portable hoist, in the April number is good; it can be used to lift steam chests off also. I am glad to hear so many praising The Locomotive Engineer as the spiciest little paper out.

Considerable has been said about sight-feed cylinder oilers; they are good when kept in good order, but if the oil gets gummy, or anything gets in the valves, they get stubborn, and refuse to work or else work too fast. I once saw an engine with a quart Dreyfus cup screwed into a cross on top of smoke arch behind the stack, and a pipe led to each steam chest; in winter time, when very cold, a box was put around it, to keep it from feeding or condensing too fast; this cup worked first-rate for many years, and gave very little trouble.

It is often thought to be a disgrace for an engineer to have his engine towed in, and he ought to use every effort to bring his train in, but this is often a risky business on roads where traffic is heavy. But some men soon get badly scared and go off at half-cock, or make no effort to help themselves. I once went after a broken-down engine and found train on main track and engineer sitting on fence. When asked what was wrong, said the flues leaked, and he was afraid he would burn her. An oak sapling was cut down and a plug pointed and drove in, and very soon she hauled the train at good speed. At another time we had the back driving axle of an 8-wheel engine break, just outside the R. B. box, the wheel fell over, twisted off the side rod, and rolled down the bank; the engine staid on the track; being but two miles from town, the brakeman was sent in for help. We took a hand car and ran down, looked around, took in the situation, got a chain and made fast to the bracket on right side at back end of engine, and to the left front corner of tender, took a twist on it and drew the engine over tight on L flange, making the tender bear hard against right rail, and pulled out and went in on three legs. It is always well to be prepared for these things, and if an engineer don't make some preparation, by having chains, extra blocking, bell cord, saw and ax, etc., he will find the road a poor place to hunt for them.

Watertown, N. Y. J. J. Bingley.

Link Blocks.

Editor The Locomotive Engineer:

Whenever you or your readers get tired of my growling, just get out your cheese knife and guillotine my effusions.

I had a little experience the other night with a link block, and ever since I have felt mad.

I have had considerable experience with different kinds of link blocks, but most of my trouble was to keep any kind of waste or wool in the holes, and the first builder that fixes a simple arrangement in the block, that will stay, and keep the hole full of waste, and come in contact with the sides of the link, will receive a vote of thanks from the undersigned.

A good kind of a block was the solid one like Fig. 7; it was always there and was simple; but, of course, it couldn't be used with a solid link; the next breed was in two pieces put into the link and riveted there. It looked like Figs. 2 and 3, and I thought it was a poor scheme if riveted into a solid link. The common kind, to me, is like Figs. 4 and 5; it is made in two pieces, the block proper with one side plate solid, and the other, next the rocker arm, loose, but held in line with the block itself by a dowel pin, shown at *a*. Now, all this family of blocks would look like Fig. 6, if they were sawed in two through the pin.

I took out a new engine some time since and helped a train over the road, returning "light." It was night, and the road

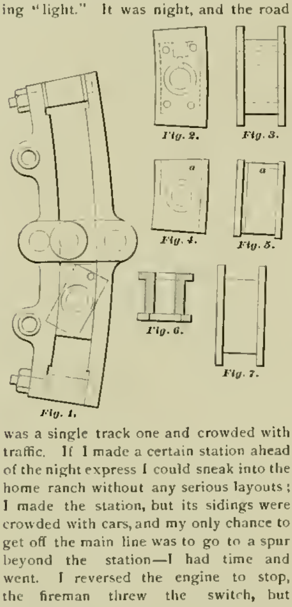


Fig. 1. Fig. 2. Fig. 3. Fig. 4. Fig. 5. Fig. 6. Fig. 7.

was a single track one and crowded with traffic. If I made a certain station ahead of the night express I could sneak into the home ranch without any serious layouts; I made the station, but its sidings were crowded with cars, and my only chance to get off the main line was to go to a spur beyond the station—I had time and went. I reversed the engine to stop, the fireman threw the switch, but when I tried to get the reverse lever pointed toward the stack it wouldn't point—something was striking solid, and my first thought was that it must be a broken valve yoke or a cocked valve; still I could move the lever for a notch or two in the corner. About this time the headlight of the express jumped around a corner about two miles behind, and made straight at me at about forty miles per hour. There was not much time to think, and very little to act, but before you could say John Spoopendike, the fire-boy, was making passenger train time down the track with a red lamp, and I was on the ground with a torch, looking for the cause why. I found it the first look—the dowel pin on that measly link block plate had come out and the plate was tipped ahead, as shown in Fig. 1, and caught a bolt in the link saddle. As long as I was working the engine near the center it was all right, but as soon as I pulled her into the corner the block came below the saddle and caught. I straightened it up, but it would not stay, and I looked for something to hold it; the first thing I saw was thick mud, and inside of a second a handful of this was holding that plate up straight; I lost no time in getting into siding and shutting the switch. The express passed, and I made up my mind to get even with that block. The first thing I came across in the tool box was a round file, and the end was just about as big as that hole; I drove it in with a soft hammer, and about 4,000 pounds of bad temper, and then broke it off flush. I reported a new pin needed, but they could not get the one out I had put there very easily, so they left it, and for all I know it is there yet. I don't like them.

John Alexander.

Packing Air Pumps.

Editor The Locomotive Engineer:

Of all the mean things to pack on earth, a Westinghouse air pump is the champion.

If you pack the lower or air gland first, you can't get the other gland down far enough to get a knife into the cavity.

If you pack the upper one first, you are stuck, for the lower gland and the big nut around it has to be held up while being packed.

In eleven cases out of ten, the pump will not show a sign of needing any wading till you have the scrap well out on the road, then she will blow and you will have to "put in a ring" at the first stop, while you are standing on tip-toe on the end of a rotten tie, and the pump registering about 400° in the shade.

Ordinary packing hooks and irons are too big to use, and, prying and twisting around, scratches the rod and jams up the nuts; the threads at the ends are the only ones in use, and, being soft brass, soon wear until they will not hold until they are on about three turns. The loose gland inside the nut sticks to the latter and turns on the packing, disarranging it.

A much better arrangement would be to discard the gland or collar, and the present stuffing box, make the brass fit the piston rod closely, and make the nut as deep as possible, putting all the packing into the nut; it would be easier to get at and cheaper to make and repair.

The Westinghouse company make a metallic packing which they sell for locomotives; if it is any good, why don't they put it on their pumps, and let us see a good thing in a place it is needed, and needed bad?

Kansas City, Mo. John Reynolds.

H. K. Porter & Co., builders of light locomotives, Pittsburgh, give the following rule: To compute the number of tons of rail needed to lay a mile of track, multiply the weight of the rail per yard by 11 and divide by 7. All rails are sold in tons of 2,240 pounds.

CONTENTS.

Blacklisting.

On April 5th the Iowa Senate passed the House bill forbidding railroads from blacklisting their employes. It makes exception in the case of employes discharged for gross negligence or drunkenness, but provides a stern penalty for attempting to prevent employes discharged for other reasons from obtaining similar work elsewhere. It is designed especially to cover the case of railway employes who are blacklisted for engaging in strikes, or who for any reason incur the disfavor of their superintendent.—*Railway World.*

Most States make blacklisting a crime and punishable by imprisonment, but there are still a few cringing, cowardly men who get into petty offices, who, for personal spite, will prevent men whom they have discharged from obtaining employment on other roads.

Railroading is as much of a trade as stone-cutting, and as much of a profession as dentistry. If any man could vent his spite on a dentist or a stone-cutter by preventing him from working at his trade or profession, and thereby rendering lost and useless his years of apprenticeship and study, there would be war. Yet this is done to railroad men all the time.

Honorable and fair-minded men who are railway officials do not use or approve of the practice, yet they do not condemn it as they should.

We should like to see some railroad manager that is man enough, brave enough, hero enough, to nail upon the bulletin-boards of his road an order something like this:

Notice.

TO WHOM IT MAY CONCERN.—While the undersigned is manager of this road, no employe leaving the service of the company, *under any circumstance*, will be blacklisted. Ex employes of this road may seek employment elsewhere, and if officials of other roads ask for reference of this road, I have instructed all officers to reply that such a man was employed for a certain length of time in a certain capacity, without other comment of any kind. The laws have made blacklisting a felony, and it is such, and due notice is given that I shall uphold the law. Any official of any road who sends a blacklist to this road may expect that I shall at once place it in the hands of the person so blacklisted, and furnish all evidence in my power tending to the conviction of the criminal.

Signed, —— ——.

We hope that every railroad official in this free land who ever again uses the blacklist to prevent any man from earning his bread at his chosen calling, may find his just deserts in a prison cell.

When some official comes out in well-set terms and declares war upon the damnable practice, we want to show up his picture on our front page, surrounded by a garland of laurel, as a hero in a class where heroes are not supposed to exist.

About Brake Leverage.

In commenting on the remarks of a correspondent last month we omitted to fully qualify a certain statement on the retarding power of brakes that might lead to the formation of wrong ideas in the mind of earnest students.

Referring to the practice of putting driving brake shoes over the flange of the wheel, we said: "The retarding power of a brake is the power applied to the shoe, and the distance from outside of tire to center of wheel." This statement is altogether too broad. In the case cited, the brake on the driver flange gave that brake more retarding power than if it was on the tread of tire, and so it would have more power the higher the flange was; but coming down to brakes as usually applied to the same place on wheels that comes in contact with the rail, the distance from outside of tire to center of wheel has nothing to do with the retarding power of the brake.

The size of the shoe has nothing to do with it. It is entirely a matter of how much pressure is forcing the shoe against the wheel.

Suppose a locomotive to be running at the rate of 30 miles per hour, she has six-foot drivers, and three-foot truck wheels, each wheel under the engine, regardless of size, is traveling 30 miles per hour; if you apply a brake shoe to each wheel with a pressure of 100 pounds each, the three-foot wheels will hold just as much as the six foot ones. Because while the six-foot wheel has rubbed its shoe through one revolution, the three-foot wheel has rubbed its shoe through two revolutions, representing the same retarding power in the same length of time.

The Car Coupler Row.

The Master Car Builders' Association has adopted the Janney type of automatic car couplers. It appears now that there is a quarrel between the Janney coupler folks and some of the car builders, or their managers, about just what constitutes a Janney coupler. The contour lines adopted do not exactly coincide with the lines patented in 1879 by Mr. Janney. The litigation likely to grow up out of this controversy will very likely extend the time that will ensue before the general adoption of automatic couplers will take place.

If the patents of Mr. Janney, taken out some twelve years ago, cover the opening head principle, he is entitled to the profits of this invention, and nine years of expense in demonstrating that that class of automatic coupler was the best. The howl about paying royalties is the last kick of the companies against adopting a safety appliance that the public demand. As to the difference in the contour lines, there is very little, and we have yet to hear it disputed that the Janney lines are the foundation on which all modifications are built. The Janney coupler folks should not be considered home missionaries. If they have an invention that the railroads want, let the railroads pay a reasonable price for it.

While the managers and the coupler companies quibble over a matter of dollars and cents, the ghastly harvest of life and limb goes on.

Automatic Brake Lessons—Written in Blood.

Two fearful accidents have occurred within the past month by the explosion of giant powder or dynamite loaded in cars. According to the press reports both accidents were caused by trains breaking in two. In the accident at Locust Gap, Penna., the broken sections of the train came together, causing an explosion of several hundred kegs of powder and 12,000 fulminate caps, tearing down almost all the houses in a little village, and killing a number of people.

Near Fountain, Col., a freight train broke in two, and five cars and a caboose ran back down a heavy grade, striking a passenger train and bursting an oil tank car and setting fire to the wreck. In one of the cars was 17,000 pounds of giant powder, and its presence was discovered by the passenger train conductor, and warning given, but too late for many; several people were killed and many wounded. Had either of these freight trains been equipped with a reliable automatic brake, the runaway cars could never have started. Either accident will cost the companies enough in damage suits to equip the entire system with reliable brakes.

The daily harvest of dead trainmen has attracted little attention from the press or the public, but a few awful lessons like these will practically boycott all roads, not using reliable automatic brakes on freight as well as passenger trains.

Two Kinds of Scalpers.

That philanthropic and self-sacrificing body of men, the "American Ticket Brokers' Association"—called by the scoffing world "scalpers"—is holding its tenth annual meeting at Detroit this week. The call declares that "the ancient enemy of the honest broker"—meaning doubtless the necessarily dishonest railway officials who oppose ticket scalping—"has been routed, but his hosts are rallying for renewed assault, and the brokers must show him an unbroken front." Certainly. And why not secure the passage of State and national laws prohibiting railway companies from selling their own tickets, and putting the business, including the fixing of rates, in the hands of the always "honest broker"? —*Railway Age.*

If all railroad managers would make all tickets "good for one passage" from one station to another without limits of time, trains, conditions of signing same, and all the other "ifs," there would be little business for brokers. When the ticket goes out of the possession of the company they receive their own rate for carrying a passenger a certain distance, and they should be compelled to perform their part of the contract upon presentation of their ticket. No one fixes their rates; it is their own scheme to avoid delivering goods that they have sold, and received their cash for, that causes the trouble.

Vanderbilt pays his cook $10,000 a year and his engineers $3 a day each. Difference between a cook and an engineer, $8,905.—*Solid Muldoon.*

Shop Rules.

How many shops and roundhouses are there in the country where there is not posted some rule or set of rules to govern the men. If there is nothing else, "No smoking" is pretty sure to stare you in the face.

In very few cases are the rules lived up to—especially by the foremen.

Men are not school children, and do not need a standing notice how to walk, act and talk.

A set of cast-iron rules are a standing insult to the intelligence, manhood and independence of workmen.

If you are in charge of a shop and must have rules, tear down your old ones and substitute one reading:

"Employes are expected to do what they consider just, fair and honorable to the company, the foremen and themselves. Men not capable of judging between right and wrong will not be retained in the service."

There is no standing insult to manhood in this; you put every man on his honor, and a man who will not do twice as much work on his honor as can be got out of him by case-hardened rules, threats or tyranny, is not much of a man.

License in Alabama.

The Supreme Court of the United States has recently rendered a decision in the matter of the law enacted by the State of Alabama requiring locomotive engineers to be licensed. The court holds that the law is not a regulation of the inter-state commerce law, is constitutional, and the fee required is payment for service rendered, and not a means of raising revenue, nor a tax upon transportation. It looks as if the boys, in one State at least, would have to carry papers. Make the examination thorough and of a practical nature, and the men will pass. If this is done, anything that flies in cannot take engineers' places—unless the examiners could be bribed.

No man, or organization of men, ever built up a reputation, increased their pay, or added to their own self respect, at the expense of any other man, or organization of men. He who can only hope to go up after he has pulled some one else down, deserves to stay down—and he will. Deserve success and advancement. "By their fruits ye shall know them," is railroad law.

ASKED & ANSWERED.

(31) Button Sett, Topeka, Kan., asks:

What is the use of copper ferrules between flue and the front tube sheet? *A.*—To prevent the tubes from leaking; as a rule, all tubes are put in from the front end, and where the holes in sheet are as much larger as the thickness of ferrule the tubes are easily put through them.

(32) Throttle, Stewart, Iowa, asks:

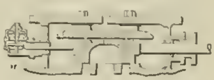
What advantage is claimed for the throttle arrangements used on the Rock Island road—and how is the dry pipe arranged? *A.*—The dry pipe is placed in the boiler as usual, but the end is open, the throttle valve being located in the T-pipe, or "nigger-head," in the smoke-box. The advantages claimed are that it is not necessary to go inside the boiler to grind in or examine the valve. All connections being outside, any derangement of the actuating levers can be doctored without blowing off steam.

(33) J. H., Buffalo, N. Y., writes:

Will you please advise, through your paper, a way to keep car wheels from sliding? I am conductor of a train on the "Belt Line" at Buffalo, and although but 60 pounds of air is carried, we are continually flattening wheels, and I cannot account for it, so I appeal to you to enlighten me. *A.*—It has been found that to obtain the best result from air-brakes the leverages should be so proportioned that 50 pounds of air in the brake cylinder will force the brake shoes against each pair of wheels with a force equal to the load carried by the wheels. Fifty pounds of air per square inch in a 10-inch cylinder gives about 4,000 pounds, and for an 8-inch cylinder, about 2,500. We should judge from the name of your road that its service was light, and, without knowing the exact conditions, would say that you have too much brake power for the loads carried. This can be avoided by carrying less pressure or decreasing the brake leverage.

(34) T. L., Alexandria, Va., writes:

I am running an engine 18x24 on passenger train with Richardson balance valves. I was asked what would you do in case you should break a valve yoke,



to cover the ports and not take chest cover off, and hold valve in place. My answer was, take relief cup out of chest and work valve in right position, and then put relief cup in chest again. Take oil plug out of top of chest, and have a bolt made to screw down on top of valve to hold it in place. Do you think I am right? *A.*—Our correspondent will see by the cut of Richardson balanced valve here shown, that screwing a bolt down the oil pipe hole would only bear against the balance plate, unless the bolts holding the same were loosened, in which case steam would blow around them, and a bolt cannot be made out on the road. Valve yokes are seldom broken so that the stem will not hold the valve; but in case it was so broken, we should think the simplest and quickest way would be to take out relief valve and push the valve to center of seat, disconnect the stem, push it up to valve, and cramp the gland to hold it there, then saw off a piece of the broom handle, or any other similar stick, and place it against valve, leaving it long enough to extend into the relief valve, to keep it in place, as shown at *a*. Should the relief valve be on cover we know of no better way than to take off cover and block. Where metallic packing is used the gland cannot be cramped, and a bracket, like Fig. 2, is often used. It is made of one-sixteenth iron, and is put on studs holding packing gland, and the key dropped through slot into valve rod connection.

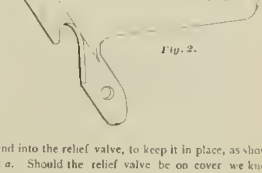


Fig. 2.

(35) T. E. W., Marquette, Mich., writes:

Can you tell me how to set a petticoat pipe properly—how it should be set for an engine which works on a hilly road, where you have to "knock it to her" to get to the top most of the time, and how it should be set if an engine runs on a comparatively level track, with long runs between stops? What is the principle governing the setting of the pipe? *A.*—The question is not an easy one to answer, as no set rule can be given of all, or even the general run of cases. This is one of those points that must be settled by the engineer, and in doing so he is required to bring into use his past experience. He must take into consideration the size of his cylinders, wheel, nozzles, fuel, the work to be done, the kind of boiler, shape of fire-box, etc. The office of the petticoat pipe is to conduct the exhaust directly to the center of stack, and to *control the source from which the gases are drawn.* In other words, the draft or petticoat pipe is to make the fire burn evenly all over the grates. If the fire-box is long and shallow this is harder to do than if it is short and deep. As a rule, the stack of a locomotive should be about the size of the diameter of cylinder, and the draft pipe about 75 per cent. of that size. The lower flues control the draft on the front of the fire, and the upper ones the back. By raising the bottom of pipe up you will give more room and more draft there, and by lowering the top of sleeve you will cause more draft through the top flues, and hence burn the fire harder at the door. Should you get your pipe too low at the bottom and too high at the top, yet in the right proportion, the side flues will suffer. Knowing nothing of your case, we should say set the top of pipe about four inches from the stack opening, and the bottom level with top of nozzles, and go out on road. Watch the fire; if it burns fast and dances merrily at a white heat near the flues, and tries to tear a hole there, it shows that there is too much draft through the lower flues; drop the pipe a little at a time, and watch; turn the scoop upside down in the open door while the engine is at work; this will deflect the air onto the fire, and allow you to see how it is burning. Very clean flues show fierce draft, and soot and ashes show little draft. Get the pipe to clean all flues nearly alike, and clean out the front end, and it will be all right. Actual experiment only will determine just where pipe belongs. It may be safely said that when the locomotive burns her fire evenly all over the box the petticoat pipe is in the right position and performing its functions.

(36) Embryo, Galveston, Tex., asks:

How should an engine be disconnected when a steam chest or cover has been broken on the road? Tell me just what to do, and why to do it. *A.*—Shut throttle and apply brakes, or call for them, and stop; send out flagmen, to keep other trains from running into you; disconnect the valve stem rod at rocker; take down the main rod; shove the piston to one end of cylinder, and cramp the gland enough to hold it, no need of blocking, as no pressure can get in cylinder to move it; take off nuts on such studs of steam chest as are left; take off cover, pieces of chest and valve; lay sheet rubber (if you have it) over the steam passages to chest, and a board on top; block up over this, using the valve or any other handy blocking, and put the cover, or pieces of it, or fish plates, over the studs, and clamp them down hard enough to prevent steam from blowing out of steam ways, load up your main rod, etc., take all the train you can handle, and proceed, leave enough of your train at the first siding to let you handle load easily on one side; report accident to your M. M. at first telegraph office.

IN THE ROUNDHOUSE AND REPAIR SHOP.

The new engines for the Brooklyn L roads have the DeLancey balanced valve.

* * *

Classification of wages has been abolished on the St. Louis and San Francisco road.

* * *

James Gillett, senior editor of the *National Car and Locomotive Builder*, died May 13.

* * *

Twenty inches is the narrowest gauge of road doing regular business in the United States.

* * *

Torpedoes should be carried in an iron box on back-board of cab—never in seat boxes or near the heat.

* * *

The Kings County Elevated road, of Brooklyn, is open for business on its Fulton street line.

A little tallow put on while the glass is hot will clean your gauge glass of lime and alkali deposits on the outside.

* * *

Many of the big lines of road are placing heavy orders for cars. Must expect to do a land-office business this fall.

* * *

The shops of the Central and Southern Pacific railroads, at Sacramento, Cal., employ 2,200 men, and will be enlarged this summer.

* * *

On consolidation locomotives it is quite a convenience if the blower is so arranged that it can be handled from the cab or the tank deck.

* * *

An old Turkish towel, cut in two lengthwise, beats waste for cleaning brass work in cab; you can get around hot cocks without burning the hands.

* * *

Engineers who are mean and overbearing to their firemen are the ones who would be mean and overbearing to all men under them, if promoted to any higher position.

* * *

If you were asked this question when being examined what would you answer? "If a flue should burst and let the water and steam all out of the boiler, how could you fill the boiler by the injector?"

* * *

Large orders for new cars are pouring into the shops; all of them are busy; the Indianapolis Car Company will build 2,000 gondola cars of 60,000 pounds capacity, for the Santa Fe. An exceptionally large order.

* * *

The cigar promised by our air pump man at Syracuse has been received at this office, inspected, and forwarded to the winner at Schreiber, Ont. Judging by the Flora del Cabbage odor, if it don't kill the guesser he will live forever.

* * *

The New York, New Haven & Hartford Railway will put in the scoop trough water tanks this summer. The troughs between the rails will be about four inches deep, fifteen inches wide, and 1,500 feet long. The engine tender is filled without stopping.

* * *

The new engines built by the B. & O. have the lower rail of frame bolted in. In taking down one pedestal brace, or binder, it is necessary to loosen and remove nuts from four bolts, and these are the same bolts that hold frame splices. Without having much experience in building locomotives we should call this a faulty design.

* * *

The baptismal name of the "Graphite Smear Grease," made by the Dixon Crucible Company, of Jersey City, will hereafter be "Graphite Pipe Joint Grease," the latter term better describing its use. Any of the stuff that the roundhouse boys have left over in packages, bearing the old name and label, will make just as good joints, however.

* * *

The locomotive builders who don't know any better than to place lifting injectors so low on boiler that they are below top of tank ought to ride on some of their cob-choppers. When the tank is full and the injector shut off, the runner has to shut off the water, or it wastes at the overflow. This kind of work takes time, calls the attention of the engineer from other and more important duties, disarranges the feed when once set, is an annoyance, a nuisance, and entirely unnecessary.

A recent issue of a railway paper says that the length of locomotive fire-boxes is only limited by the distance it is possible for a fireman to throw coal. The way we look at it, this limit has already been reached, and men who are daily breaking up and throwing from ten to twelve tons of coal per day into an eleven-foot fire-box ought to get better pay than they do.

* * *

Everybody knows plenty of enginemen who have risen to the high places of railroading. Some ex-locomotive engineers "get there" outside. Like his friend Colvin, of the same city, J. E. Lonergan, of Philadelphia, is turning to good account in the manufacture of locomotive and steam engine appliances, information gained by active duty at the throttle. Mr. Lonergan ran an engine for a number of years on the Central Pacific, under the late A. J. Stevens.

* * *

Our contributor, James Heron, of Buffalo, enclosing several subscriptions, writes us: "I see in your last issue an M. M. leads in getting subscribers. If all have sent the money who promised me they would subscribe, I think it would put me in the lead. The names here sent I got on your explanation of the injector. I propose to make as thorough a canvass of the large railroad shops in my neighborhood as a responsible foremanship will admit, and to take that banner from the M. M. before 1889."

* * *

Isn't it about time that that tramp that always lets off brakes when cars get away and do damage, who sets fire to all the bridges that burn who robs stations and fires the depot to cover the theft, who wrecks all the trains that strike misplaced switches or ties standing on their heads in cattle guards, etc., etc., was caught and hung? A few years ago all bridges that burned were set on fire by careless engineers, and by discharging the engineer who came over the bridge last the responsibility was fixed. Then there was the farmer whose stock had been killed—and not paid for—and then it got around to the tramp; and it is time he was caught. Like the insanity dodge for murderers, it is getting "too thin."

* * *

This is the season of the year when the boys take down the back boards and remove the storm glass from the front windows of their cabs, put up screens, and take the chinks out from around the boiler head. On many of the Western roads the boys put up awnings of oil cloth or canvas, tacking to top of cab, and sewing the bottom to a rod of iron made in the shape of a bail, and sprung into staples on side of cab, about even with the face, and arranged to tie up out of the way of roundhouse doors, etc. This keeps off sun, rain and cinders, and, if made the full length of cab, and without end pieces, they do not obstruct the view front or back, and are a great comfort.

* * *

The Erie Railroad has discharged the conductor and brakeman of the train that was run into while waiting for the signal to proceed at the approach of the Bergen tunnel recently. This has been the way of fixing the responsibility of railroad accidents, and it is a poor one. In the first place, the approach to this tunnel is on a curve—not protected by a distance signal. In the second place, there was but one brakeman on the train, and he had duties to perform there. The engineer of the following train was coming in too fast to stop in time, and the first train was held unexpectedly. The company itself, or its management, is to blame for not providing distance signals and a flagman on all trains.

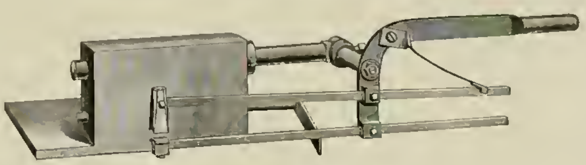
A Simple Flue Welder.

The accompanying cut represents a flue welder of simple construction that is the invention of Jno. N Buchanan, Batavia, N. Y.

The base of the machine is a simple cast-iron block with a large flaring bottom, and it is permanently placed on the right side of an ordinary blacksmith fire; it is not high enough to be in the way; through this block is a drill hole, that admits the shaft of the machine; this shaft carries a head, and this head a cross shaft, to which is fastened a lever that swings with the cross shaft and carries the long steel helve of the lower hammer; this helve can be lengthened or shortened by a set screw in the lower lug; the top helve is hung the same as the lower one, except that it is pivoted to move independent of the lever, the spring shown having a tendency to keep the two hammers apart.



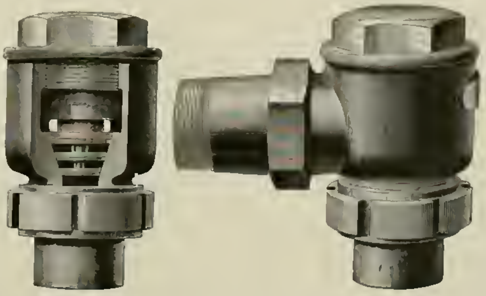
In use the flue and the end designed to be welded to it are placed in the fire, and not removed from it until welded; when hot enough, the lower hammer is inserted in the flue, and the helper holds it up by the lever; the safe end is held by coming in contact with the guide or stop shown below the shaft; the blacksmith strikes the top hammer with his ordinary striking hammer, revolving the flue at the same time. By this process the thin flue is not allowed to cool, as by other processes where it is taken from the fire.

The flue welded, the machine is thrown over by revolving the main shaft through block, and its levers are thus taken away from the fire. The set screw in the main shaft and the one in the block act as guides to bring the rig to the proper position for working. Without loosening a bolt, the whole rig can be pulled out of the block and put away. By using long helves very long pieces can be welded together.

The device is so simple and easily transported, as well as being cheap, that it can well be used where a machine could not be afforded For further information address the inventor, as above.

A New Check Valve.

The check valve shown on this page presents some very novel features, and, it would appear, many advantages. It is the invention of A. B. Glace, foreman of the Rockland, Cal., shops, and has been in use for two years on the Central and Southern Pacific Railways. These roads were troubled with checks sticking up on the desert divisions where the water is very bad and the present form of check was designed to avoid the trouble.



The cage is of the usual pattern, except that below the seat of the main valve there is a taper opening toward the water pipe, into which two extra valves fall and seat. These valves are guided by a round stem running into the main valve from the valve under it, and the bottom valve stem running into the middle valve. The main valve has wings working in the guide cavity in the cap.

The principal reason check valves stick up is that small pieces of foreign matter, scale, etc., get under them, and prevent their seating, but it is hardly possible that something should get under all three valves at once. The fact that the engineers all want this valve, and the company have adopted them, after two years' trial, is pretty good evidence that they do the work

J. E. Lonergan & Co., 211 Race street, Philadelphia, Pa, are the manufacturers.

Bad Signal Practice.

On several roads we have noticed that distance signals and semaphores are very often placed on the inside of curves, because they are easily seen by the engineer, but are entirely hid from the view of the man who turns them. All he knows is that he has moved the lever and the signal ought to be set; ropes, wires and rods often break, or bolts work loose, and the signal fails to turn, and the engineer might plunge ahead while the signal man thought he had him stopped Place the signal where the tender can see it, even if it is not so easy to see from the engine.

The new express engines of the Reading road are the heaviest passenger engines running into Philadelphia. They look like locomotives beside the Wooten fire-box mills—"bake-oven attachments," the boys call them. They are too modern for the Reading, and will probably be discarded.

Setting Eccentrics Before Wheels are Under Locomotive.

BY HIRAM R. JONES.

Some years ago I experimented on this problem, and constructed the machine shown in Fig. 1. The beveled openings rested on the journals, and were just far enough apart so that the two side pieces would reach from the center of one journal to the center of the other journal; this would give a side play to the whole machine nearly equal to the length of journal. The vertical straight edge welded to the cross-bar is in such a position that it may be set opposite either eccentric by sliding the machine sideways.

The beveled openings are accurately planed, and their centers coincide with the center of axle, and are a given distance from inside edge of straight edge. In use the crank-pin is placed on its center nearest the straight edge. The machine is so set that it will be level on top, which will bring the straight edge perpendicular. (See Fig. 7.) Now to set eccentric, subtract the sum of lap, lead and ½ diameter of eccentric from the distance straight edge is from center of axle; this will give distance to set ball of eccentric from straight edge. This rule will apply if the arms of the rocker are both the same length. If they are of unequal length, multiply the sum of the lap and lead by length of bottom arm, and divide by length of top arm, add this to ½ diameter of eccentric and proceed as in the first case.

Now, after this machine was made and used a time or two, a fellow machinist showed me a simple stick and string arrangement which accomplished the same result just as correctly, and can be made by any intelligent man in an hour.

I made one and laid aside the machine, which, of course, was rather humiliating after the thought and labor put on it.

The stick is constructed as follows: Take a piece of clear pine three or four feet long and 1½" square, Fig. 2. Lay off a line in the center at *A*; lay off another line at *B* as far from *A* as the sum of lap and lead multiplied by length of bottom rocker arm, and divided by length of upper arm. Set your dividers to ½ diameter of shaft, and with *A* as a center lay off lines *C* and *D*. Set dividers to ½ diameter of eccentric, and, with *B* as a center, lay off lines *E* and *F*. To use this rig set crank-pin on center as before. Place the stick—resting on a support of some kind—under the eccentric, with the face of stick projecting a little beyond side of eccentric, as shown in Fig. 3, which is a plan view. In this way it will allow the plumb lines shown in Fig. 4 (one of which is thrown over the axle and the other over the eccentric) to fall each side of the stick, and close to it at the points indicated by the dots in Fig. 3. Adjust the stick so that the lines *C* and *D*, Fig. 2, will coincide with the plumb lines *C* and *D* hanging over the axle. Then turn eccentric so that the plumb line hanging over it will correspond with the lines on stick at *E* and *F*.

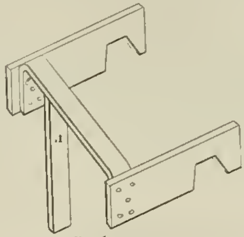


Fig. 1

There are one or two important points that should be noted. The crank pin is not necessarily on its center line when its center is level with center of axle. The crosshead pin is usually an inch or two above center line of axles, which would bring the crank-pin above said line on forward center, and below it on back center. This may be more fully understood by reference to Fig. 5, in which *A B* represents a center line through centers of axles. *C*, the center of crosshead pin at mid stroke; *D*, the center of main driving axle; *E*, the forward center of crank-pin, and *F*, back center of crank-pin. The height of *E* above center line may be obtained by multiplying height of crosshead pin above center line by ½ the length of stroke of crosshead, and dividing by length of main rod, or, simpler still, draw the lines in Fig. 5 on a board and measure the distance at *E* or *F* with a rule. Set crank this distance above center line of axles.

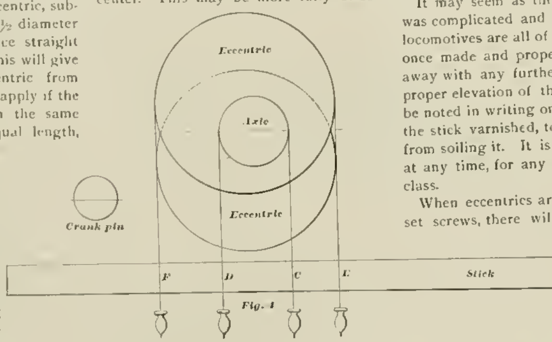

Fig. 4

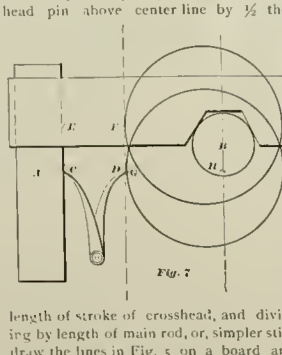

Fig. 7

Another thing: If the pin in bottom rocker arm is above center line of engine it will necessitate a new position for crank-pin in using this arrangement.

Referring to Fig. 6, let *A B* represent a line through center points of crank-pin (not center line of axles). *C*, center of main axle; *D*, bottom pins of rocker arm, and *G*, forward center of crank-pin.

Now for the sake of illustration, the elevation of the pin *D* above line *A B* is somewhat exaggerated. It will be seen that, in order to bring the eccentrics in their right positions, a line *E F* drawn across the front edge of eccentrics will be perpendicular to *C D*, and not *A B*. Now, as the line *E F* represents the direction taken by the plumb lines in Fig. 4, and the eccentrics must be set in that position, and the crank-pin *G* must be kept in the same relative position, we lower the point *G* to *I*, a point as much below *A B* as *H* on *C D* is above it. This distance may be obtained by drawing a diagram on a board, as before, and measuring with a rule.

It may seem as though this procedure was complicated and intricate, but when locomotives are all of one class, a stick once made and properly marked will do away with any further calculation. The proper elevation of the crank-pin should be noted in writing on the stick, and then the stick varnished, to keep dirty fingers from soiling it. It is then ready for use at any time, for any engine of the same class.

When eccentrics are only fastened with set screws, there will be no particular advantage in adopting this plan; but if they are to be keyed on, especially for a narrow gauge locomotive, where there is little room, it is a decided convenience.

From South America.

John J. English, an experienced and well-known locomotive mechanic, has recently returned from a two years' sojourn in South America, where he has had charge of the long but successful trials of the Baldwin locomotives in competition with the English locomotives in the Argentine Republic and Uraguay. Mr. English says that the Atlantic coast countries of South America are very poor places for railroad men to go to; many English and native engineers are running down there for $35 per month, and $4 per day being the highest wages paid, even on the Pacific side—this being the exception rather than the rule.

One road, in the Argentine Republic, over 1,000 miles in extent, uses the worst water on earth, it being necessary to replace all flues in a few weeks, the boilers being thoroughly washed every trip.

Copper fire-boxes and stay bolts are used in all makes of locomotives.

Mechanics in charge are largely English, and American manufacturers have to combat their prejudices, one of the most stubhorn being their utter lack of faith in the strength, adaptability or safety of cast-iron centers for driving wheels. They declare that they won't and can't stand the work, regardless of the fact that the hardest service known is being daily ground out of thousands of locomotives in the United States, all riding on cast-iron drivers.

Mr. English has great faith in the staying qualities of the American locomotive and believes that their peculiar characteristics will make them the cheapest, easiest repaired, and best working engines in South America, and that they will eventually supersede all others. He expects to return to South America soon with another installment of Baldwin engines.

Injector Practice.

BY PRIMER.

The more we know about the notions of a woman, the easier it is to get along with her—in this respect women are like injectors. The less we know of a cranky woman, the less we know what to do to get her to work—same as an injector. You can reason with a woman—same as an injector (and it will do just as much good). You can know so much about a woman or an injector that either one dare not "act up," and if they do they are easily cooled off; it all depends on knowing what to do and when to do it.

If your injector breaks easily on the road, look out for your strainers. If it breaks when you throw the engine over, or in stopping suddenly, look to the dry pipe inside the boiler; it may be disconnected, or the "fountain" or "duck's-nest," may have no dry pipe, and the water enters the steam pipe and breaks the current.

If it primes slow and poorly, look for leaks in suction pipe below injector, that let the air leak in, and prevent the formation of a vacuum. If your primer leaks don't report check ground in or *vice versa*. If you primer is leaking it will not prevent the quick formation of a starting jet; if the check leaks it will. If a Monitor primer leaks it will not stop blowing at overflow if you screw down the heater cock; if the check or ram leaks it will stop and go back to the tank; if an independent primer "Little Giant," pull regulating lever back; this will put combining tube against delivery tube, and send steam and water from check to tank, if steam still blows at overflow grind in the primer.

If your Hancock Inspirator blows so at overflow that it won't prime, shut off throttle next to boiler; if blowing stops, grind in operating valve under main cap at steam connection; if it still blows, look to the check.

Work your injector so as to just supply the boiler; do not work it full head with a light train till you have the boiler full, then shut off.

When you lessen the quantity of water by the lazy cock or tube regulator, lessen the quantity of steam at the same time.

Once a week shut off steam, close water supply and overflow, and put in a few tablespoonfuls of black oil and let it cook there by giving a little steam, it will remove scale, oil all the internal screws and soak the fibrous packing so that all cocks and plugs will handle easily.

Sometimes roundhouse men or others doing work in cabs shut off the globe valves next to the boiler, leaving them open

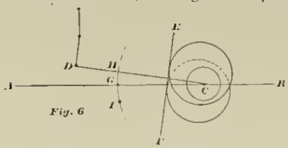

Fig. 6

just enough to prime the injector, but without volume of steam enough to make them work.

Often the loose ball-valve on steam ram comes off by its nut working loose, and it drops into the water space below; steam will blow full head at the overflow, and will not stop when ram is screwed clear in. If you are on the road, and it is important that you get your train in, don't try to fix it then; shut off steam valve next boiler, get left hand instrument to work, and then take off the valve-stem box, cool the injector with a pail of water, and fish out valve and nut, replace and go ahead.

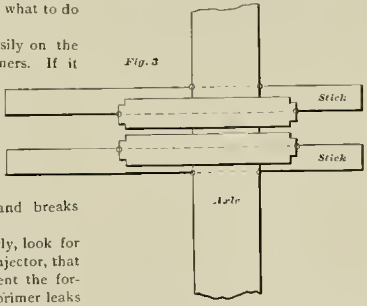

Fig. 3

In extremely cold weather injectors will often refuse to work because the manhole cover on tank has frozen solid and a vacuum is formed above the water in tender; put on your heater for a few minutes and break cover loose.

Use left hand injector daily, to insure its being kept in working order. If it is a non-lifter let the water run through it for a few minutes to cool it off and secure a current, open steam valve very slowly and just enough to notice that water is being

Fig. 5

thrown from overflow pipe a little faster than it will run, then open steam valve full and quickly, throttling down steam

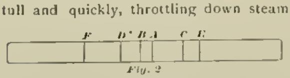

Fig. 2

and water afterward. Try to use your feed water arrangement when the engine is at work and the fire bright; avoid "cooling off" when standing still with water, unless to keep up level in boiler.

In starting out on a run, have water enough in the boiler to allow you to run without using pump or injector until fire is at full heat.

Don't try to see how hard you can shut primer and steam valve—shut is shut and it can't be no shutter.

Don't pound an injector for any fault—it will do no good.

If a check sticks up, tap the top of cage lightly with a soft hammer or a piece of wood—not the coal pick.

If tapping it smartly will not bring it to its seat, a pail of cold water poured onto it will often do so.

Don't expect a ¾ pipe to carry off the overflow from a big injector—make the waste pipe ¾ the size of feed.

If there are many crooks and turns in branch pipe, use a size larger pipe than the fittings.

Don't expect a No. 7 injector to go into an engine with No. 6 pipe, check and feed pipe, and do No. 7 work.

Oiling Bearings.

There are bearings and bearings. One has got in the habit of being oiled every trip, from two to ten times, and will get hot if not attended to, and the other runs several months, making many thousand miles, and don't seem to care much whether it gets oiled or not. One is on the engine and was raised a pet, the other is on the tender and has been neglected. Just why a bearing on an engine truck needs oiling every two hours, while the same sized bearing, under the tank, carrying fully as heavy a load does not need oil oftener than every two months, is a question that does not seem to have been probed into very deeply.

The writer is of the opinion that the engine truck gets too much oil and the tank too little.

Oiling a locomotive is, as a rule, done more by habit than by any study of the requirements of the service. Every drop of oil that runs off and away from a bearing is wasted; all the oil used that leaks out of boxes or cups after the run is over is wasted. Study the work your bearings have to do, and experiment on how much oil you can use and not waste it, yet have enough. One of our big railroads investigated the oil business two years ago, and found a difference of over 100 per cent. in oil used by different men. They took the ten most economical records and averaged them, and then limited the amount of oil served to engines to that amount. There was a kick, but the boys soon learned to do with less oil, and all had enough, while some who studied hardest on the problem had a little left over to sell. The officers of the company claim that the limited rule saved the company over $50,000 last year. All problems of economy on a locomotive deserve the careful study of every engineman, whether he believes in them or not; the day is fast coming when a man's record will be of value to him.

The extension front, straight stack and brick arch have evidently come to stay. The majority of the master mechanics are in favor of them.

Starting Non-Lifters.

Non lifting injectors on locomotives are usually large sizes, from 7 to 12, and have large connections. The globe valve used as a throttle is usually a large one, and it is very often well-nigh impossible to open this just a little, while the engine is running in order to catch water and produce a current before giving it a full head of steam to start the thing to working. Non-lifters are usually on the left hand side, and seldom used unless wanted badly, and in opening the valve the current is often broken several times, and once broken a non-lifter is surprisingly easy going about starting the stream again. If globe valves used for throttles on this class of injectors had a plug below the valve seat that nearly filed the hole, when first opened they could only give the injector a very small dose of steam, and, we believe, would start easier and with more certainty.

How to Make Fast Time.

Conductor William T. Jordan, of the New York Providence and Boston Railroad, who has charge of the Shore Line train from New London, due in this city at 5:25 A. M., made some fast running on Friday morning. The mail train drawn by locomotive No. 39, S. D Babcock, arrived at Wickford Junction fifteen minutes late, leaving there at 5 06 A.M., instead of 4:48 o'clock. In spite of this delay, the train rolled into the Providence depot at exactly 5 28 A M. only three minutes behind schedule time, having made the run from Wickford Junction to Providence, nineteen and a half miles, in twenty-two minutes.—*Providence Journal.*

Wonder what that useless luxury, called an engineer, was doing all the time "Conductor" Jordan and the 39 were making their fast run. According to some authorities, the mere fact that a slick conductor is back in the chair car, with his eagle eye on the rail, will just make a locomotive hum.

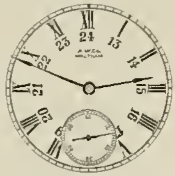
Insure Before You Burn Out.

We recently saw a note written by an engineer to his M M. that read: "I have already been on duty 18 hours. If I go out this trip I cannot reach a terminal station until I have been on duty over 30 hours. This I cannot do and keep awake. I would rather be discharged for refusing to go out, than for having an accident for want of sleep—do not send for me until I have had ten hours of rest; I shall not go." This is the right stand to take—an ounce of prevention is worth a pound of cure. The officials of the companies hold men responsible for everything that happens on the road, regardless of the hours of rest he may have had.

The 24-Hour System.

Slowly but surely the 24-hour system of computing time is gaining ground in railroad circles. It is a reform, a safeguard, and all such reforms have to fight their way, but, like truth, they usually come out on top.

People opposed the establishment of standard time, and kept all kinds of time in the same house for years, but they would not now go back to the catch as-catch can time of the '70s; and we confidently believe that, in ten years, railroad men will wonder why they risked the old A. M. and P. M. system as long as they did.



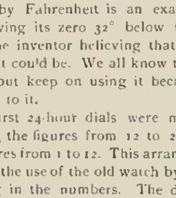
Several roads now use the 24-hour system, and like it; among these are the Union Pacific and the Canadian Pacific, two of the largest trans-continental lines.

When changes are made it is customary to adhere to the first form of the new device, and these when once established, are often adhered to, even when they are known to be wrong. The thermometer invented by Fahrenheit is an example of this, having its zero 32° below freezing point, the inventor believing that was as cold as it could be. We all know that it is wrong, but keep on using it because we are used to it.

The first 24-hour dials were made by marking the figures from 12 to 24 under the figures from 1 to 12. This arrangement allowed the use of the old watch by merely marking in the numbers. The dial here shown made in this way is the one in common use, and was kindly furnished us by Robbins & Appleton, New York agents for the Waltham Watch Company. The device is crude,and opens as big a field for blunders as the A. M. and P. M. system.

H F. Colvin, of Philadelphia, a man of wide experience as a locomotive engineer, has been for years an advocate of the 24-hour system, and some years ago ordered a watch made, on which he had taken a hand at the details.

A few real 24-hour watches are made, but from habit, or lack of thought, the 1 and 24 are at the top.



Mr. Colvin's watch, as here shown, has the 12 at noon, 24 at midnight and the 6 at daylight, so that the hour hand always represents the sun. From 6 to 18 o'clock it is daylight and from 18 to 6 it is night. There can be no possibility of a mistake in looking at the watch—if the hour hand is in the lower half of dial the sun is in China, New Zealand or Australia, and it is night; if it is in the upper half it is on our side, and it is daylight.

The idea is simpler to teach, simpler to understand, and on its face looks sensible and reasonable. It is just as easy to commence right as it is to commence wrong. Is not Mr. Colvin's idea right?

Air Brake Practice.

BY J. E. PHELAN

THIRD PAPER.

When an engine is coupled to an air brake train, maximum pressure should be on hand with which to work or release brakes if train is on continuous trip. It should always be known that it requires equal or greater pressure to release brakes, than pressure on hand in train pipe and auxiliaries when brakes are applied. If engine is coupled to a train where all pipes and auxiliary reservoirs are empty, the engineer must know that enough air must be pumped to supply pipes and auxiliary reservoirs under all cars with uniform pressure, before brakes will do effective work Because a train man asks for trial of brakes immediately after coupling engine to train, is no reason why air should be wasted in useless trials before uniform pressure is supplied to engine and all cars alike, and engineer's brake valve held in proper position to provide greater pressure in main reservoir than that supplied to train at time of setting brakes. After coupling to an empty train, supply of air expands back into train pipe and auxiliaries, and pressure reduces accordingly as indicated by air gauge. When pressure stops reducing and gauge indicator commences climbing again toward maximum pressure even though it be but 50 lbs., brakes can be tried and can be depended on usually as indicating proper condition. It is always desirable to have maximum pressure before starting on a trip, and then brakes can be relied on without doubt, if properly inspected.

Knowing that an air pump with a cylinder but 8 in x 10 in., or an air cylinder 6 in x 15 in., must pump air into a main air reservoir usually 25 in. x 28 in. or 25 in. x 32 in., and this main reservoir in turn must supply from 6 to 12 passenger cars, having each auxiliary reservoirs 11¾ in x 30 in., it can be recognized, without further figuring, that the source of supply and the economical handling of the supply is a most important point for study and practice.

This study and practice should lead to maintaining the proper or maximum supply of air pressure at all times, and the use of this supply in such a way that effective work shall *always* result without discomfort to passengers; and positively without injury to rolling-stock or freight or live stock in transit on freight trains.

To insure good air brake practice it must be known that every time brakes are applied, air flows from auxiliaries into brake cylinders 8 in. or 10 in x 14 in. usually, and when brakes are released air escapes from cylinders into atmosphere, and is wasted; and auxiliaries are again recharged from main reservoir and air pump, through the medium and automatic action of triple valves attached to each auxiliary.

For brakes to release promptly, the reserving of greater pressure in main reservoir is provided for and insured by proper handling of engineer's brake valve, as explained in former paper. There is in use an improved air brake gauge. Practically a double gauge in one casing, with one pipe leading to pipe connection with main reservoir, and second pipe leading to connection with main air pipe. Each pipe acts on separate indicators on face of gauge and while one records the pressure on main air pipe and auxiliaries, the other records pressure in main reservoir. It is most novel and important, in recording variations of pressure in accordance with the practice in force, and forcibly shows whether practice is skillful or awkward.

Another important assistant in good practice, but condemned by many engineers, because they do not know better, is the air pump regulator or governor, that works automatically in preventing air pressure running higher than maximum allowed.

Running on the road with maximum pressure and all appliances in good order, the main object is to do most effective work with least quantity of air.

The engineers who do the most effective and smoothest work with the least quantity of air are the best air brake men.

After accomplishing effective work with economy of air supply, the next consideration should be to have brakes release without discomfort to passengers from the back-lurch, so common on many roads, by having brakes remain set and not being released until after train has stopped. To avoid this back-lurch requires accurate judgment in releasing brakes while train is in motion, so that *brakes will all be released at the moment stop is made*, thus avoiding rigid stopping of trucks while body of car has gone forward with motion of engine, causing the disagreeable jerk when returning to proper position on trucks. Engineers should so handle brakes that trucks will move to accommodate body of cars, and not have body of cars move to accommodate rigid position of trucks held in such position because brakes are not released in time.

Putting Water on Hot Pins.

There is probably no other cause of delay so annoying to engineers as hot pins. They feel a certain personal responsibility for them, and a desire to get over the road with as little delay as possible, that can be laid to the engine, makes most runners extra anxious to not have hot pins, or, if he does have them, to be able to get rid of them as soon as possible.

For this reason some runners put water on hot pins to cool them off, and for the very same reason many other runners will not put on water to cool them off; claiming that it makes the brasses spring and the pin rough.

Another man will put water on a pin if he has the rod down and the brass away, but not while it is on the pin.

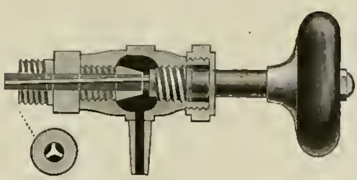
This is one of those points where an engineer will be guided and his belief settled by his own experience.

There is no doubt that it makes considerable difference whether a pin is made of steel or of case-hardened iron. As a rule, we do not think it good practice to use water on very hot pins; they can be cooled off often by slacking off key and using plenty of tallow or other heavy oil.

If a brass commences to throw babbitt do not stop; keep running until it is all out, then take out cup and clean oil hole if it is foul, and use a heavy feed of oil or, if it is thought best to take down the brass, scrape off the babbitt and fill the groove with soap, plumbago or with a strip of leather. It is almost impossible to throw babbitt as long as the bearing is getting oil. As soon as babbitt is gone, look to your feed.

Improved Gauge Cock.

The cut shown herewith gives a good interior view of a new gauge cock brought



out by Shaw & O'Toole, Girardville, Pa. As will be seen, the valve seat is immediately over the nipple, and is formed by the part that screws into the boiler being extended into body of cock, to meet the bronze valve. To the center of the valve is rigidly attached a three-cornered rod extending into the boiler. It will be seen that at every opening of the cock this rod is revolved, thus cleaning out the hole. The actuating screw is large, and is ahead of the packing, little of the latter being necessary.

The main part of cock and the piece that is screwed to the boiler can be taken apart, so that when repairing the seat it can be seen and got at; it is also a great improvement when threads are stripped or broken, as a new piece is much easier and cheaper made than an entire body. The cock is heavy and well made and finished.

Engineers Wanted.

A few years ago an engineer had fewer responsibilities, but took more risk. He had no air brake to take care of, but he might get killed for the want of one. If he wanted to stop bad he whistled "down brakes," put her in the "breechin," and waited for the brakesmen to get in their work. Now every improvement puts more cares on his head and hand. He has the care of and handles a complicated brake, he is responsible for the observance of a thousand signals, the heat of the cars has been asked from his supply, and he will soon have another little engine and a dynamo to care for; yet he is only a laborer in a soft snap; anybody can take his place; you can teach men to run locomotives in school (?) He is getting pay that belongs to the conductor, because the conductor is responsible (for the tickets). These brazen beggars have the impudence to ask for three or four dollars a day while they have got pie in their lunch pails. Some people want the earth—the engineers are some people.

What this country wants is a new set of ready-made engineers. They might not run the trains with surprising regularity, but they could be depended to keep down the excess population.

Will-o'-the-Wisps.

Few are the car hands that can't look back with a hearty laugh to some comical experience of his own or his comrades, where someone has mistaken something else for another train. The moon is sure to fool someone every time she gets full, which she does with painful regularity. Men have stopped before now and sent out a flag against a star that was peeping over the horizon right between the rails; and all of us have laughed over the Pennsylvania Dutchman who was running second section of a train, and coming suddenly upon a pair of red lights, came right down to three miles an hour, and followed a canal boat till daylight.

A few years ago the writer was firing for a genius who was sure to find all the will-o'-the-wisps that were out. One night we doubled an elbow rather suddenly and a bright headlight shone in our faces, looking as if it was not more than a quarter of a mile away. The old man jumped to his feet and exclaimed: "There! Half a minnit more and we'd a got 'em on this curve!" and as he spoke he aimed the starting bar at the caboose and commenced to choke our old hog to help out the air that was getting in its work from the start. At every hump of our engine he would let out an unearthly shriek for brakes, that would freeze the spine of a professional murderer. Said he: "Sliver, my boy, it was a close call; run down there with a red lamp, and tell them to get back to that siding quick; it's that 11 o'clock extra." The writer started out with Aladdin's lamp—and it needed rubbing—and no minister plenipotentiary ever felt more importance with the orders he bore; but just as we got about half way to the headlight, seemingly, it disappeared, looking for all the world just as though it had backed around a curve. From past experience ye scribbler had learned that it was not much use to chase a locomotive, especially if she had any great odds on the start; so there was a halt, and before you could catch your breath, a signal was blown recalling the flag. The entire crew was on the engine till we reached the next side track, but there was no train there. Suddenly the bright flash was seen again, and a vote taken declared that they were still backing up and now had several miles the start of us, as they were not dead ahead. Then my bold engineer tried to catch them, but as often as we seemed to get within signaling distance, the headlight would disappear, and about the time any of us had declared that they had blown it out it would show up again. Two miles from the terminal station was a new blast furnace, and it had been blown in that day and the gas check, or whatever they called the valve on top, that shows such a white blaze when they are charging the furnace, was what we had been chasing. It was too good to keep, bad as the old man wanted to preserve it, and the next trip the engineer got a message from the superintendent to send in accident report of his collision with the steel works.

Something About Lead.

The average man who tackles a job of firing soft coal for the first time, dreads it, and if he has never fired anything before he is apt to be a little nervous as to his ability to "keep her biling."

From an experience of several years with the freshmen class of these students, and having been one himself, the writer can think of no better way of illustrating the actions of the new fireman than to show him as a man under contract to empty the tank of coal into space through the stack as quickly as possible. No matter what happens, the scoop is his only remedy; he is not used to the noise, and can't understand the engineer, and if he so much as looks at the stoker, he jumps for the scoop; if she pops, he gives her more coal to keep her hot; if her steam gauge begins to get tired, he shovels as long as there is room between the grates and the crown sheet, unless the engineer stops him. One case came under our notice, that shows what an important thing 'lead' is to a new fireman. The cadet who wanted to be an engineer bad enough to fire several years first, went out with an old-time engineer, who could not keep him from shoveling coal and have any time left to run his engine, so he let him work and did the best he could with his train. They arrived at the other end of the division several hours late for the want of wind, and the engineer concluded to illustrate to the fireman what he had failed to make clear by word of mouth.

"Mike," said he "take that scoop into the blacksmith shop, and tell the boss blacksmith to give her less lead; tell him to take out a good bit."

The engineer's face was as calm as a summer sea, and looked as if it might have been a masterpiece of Michael Angelo moulded in shoemaker's wax.

Mike took the shovel into the shop and repeated his order. The boss Vulcan found out whose engine it was for, and resolved to have a little fun with the joking engineer, so he took the No. 5 scoop and cut off about four inches from the edge. He ought to have changed its number to 1½.

Mike carried it back and asked the engineer how it would suit.

"All right," said the runner, "that was the trouble; she'll steam to-night."

She did. Mike could not get more coal into the fire-box than she would burn, work as hard as he would, and after a few trips he got weak enough to tumble to the fact that a little judgment mixed with the coal was a good thing for a fire, and that, when he knew how, it was easy work to keep an engine hot with a scoop having any amount of 'lead,' provided he did not work it in the corner all the time.

Correspondence

Was This the Trouble?

Editor The Locomotive Engineer:

In reply to the air pump conundrum of W. F. R., of Syracuse, N. Y., I think he found that the nut on lower end of main steam valve became loose, thereby allowing the lower valve to drop down, thus preventing the pump from working.

If my solution is correct W. F. R. can send his "Havana" to

Laramie City, Wyo. Ter. F. E. R.

Is This Guess Right?

Editor The Locomotive Engineer

In reply to W. F. R., of Syracuse, "Conundrum" on Air Pumps in June issue, would say that the button on lower end of reversing valve stem had either worn or broken off, thus failing to pull the reversing valve down and admit steam to top of reversing piston. Your paper is more interesting than a novel, and I can hardly take time to eat until the paper has been read through. I wish you unlimited success.

Bennington, Vt. C. S. B.

The Cushing Reverse Lever.

Editor The Locomotive Engineer

In your May issue you show up a new, and I should think, excellent, reverse lever, the invention of Master Mechanic Cushing; something of the kind is needed. But I never see anything on a locomotive but I try and think of some improvement on it, and I want to suggest one to Mr. Cushing. Instead of the latch tipping the worm out of gear with the worm wheel, I think it would be better to arrange to lift the whole gear out of contact with the quadrant. This could be easily done, and I should think would be better. As now arranged, the gears revolve while lever is being moved by the latch, and are liable to catch clothing or dirt enough to clog them, and when in use at about the right place for service, the wear comes all in one spot on gear and worm wheel. If they could be lifted out they would seldom get back into the same place, and I think would wear longer and keep stiller. H. D. Doyle.

Denver, Colo.

Worse and More of Them.

Editor The Locomotive Engineer:

I guess the man who wrote that item about the taper plug blow-off cock has not been run by an engine with those old fashioned taper plug cylinder cocks as I have. There is but one blow-off cock (thank Heaving), but there are four of those low lying, dirty plugs beneath the cylinders; as a rule three of them can be got shut at once, but four very seldom. If you try to fix them yourself you get one to shut, but his partner on the other side will open, and you will be sure to get one loose in the cylinder and get the whole system into contortions. This 4-ply nuisance always leaks somewhere, they get full of dirt, the jamb-nuts work loose, they get out of line, if you strike a cow they get on a dead-center and won't open, and they get their backs up and won't shut.

Good, reliable, easily worked and tightly closing cylinder cocks are needed, and needed badly. They do not need inventing; there are a dozen valve cocks in use that are reliable, whose actuating levers do not tend to twist the cock in the cylinder, and that do not present three times as much surface in contact to move every time they are used as there is any need of. Locomotive builders, master mechanics and traveling engineers will begin to study up these things sometime from the road, and not from the shop, and when they do they will commence under the cylinders if they heed the kick of "Soo."

Minneapolis, Minn.

The Black Smoke Nuisance.

Editor The Locomotive Engineer:

The above-mentioned nuisance, if indeed it can be called so, is a question of great import with some of our leading officials A large number of roads require their passenger firemen to burn the smoke to as great an extent as possible, especially before coming into stations. There is one official of high standing that I know, who got the idea into his head that making black smoke was all foolishness. Any way, to think with him was to act, so he caused the M. M to post an order to the effect that all locomotive enginemen were to avoid making black smoke, and especially on coming into station. All who disobeyed the order were to be suspended. He made no distinction between freight or passenger men. The passenger engines did very well with the light firing required, but when it came to the freight engines, with thirty loads behind them, working the lever half way down in the corner, throttle out to the chain, injector working full, Mr. Official's orders, ideas and all went up in black smoke, and they never came down. But as every intelligent engineer and fireman well knows, this fogging the country with smoke, as too many of our firemen try to do at all times, is useless, and a waste of fuel. Let them study their work and try to learn something of the qualities of fuel and the science of combustion, and there will be a marked improvement in our firemen; and a great many of our engineers are in the same path—men who are content if they know enough to pull a train over the road and draw their pay, who could not tell why the crossheads wear on the upper guides in going ahead, or how to set a slipped eccentric, and in a breakdown would stay on the spot till some one pulled them in. We have too many such men running engines to-day. I hope the day is not far away when a man will have to be a first-class fireman before he is promoted, and will have to pass a thorough, practical examination (with all red-tape business left out) before being put in charge of an engine. I am not in favor of licenses given by State officials, as there are too many paper engineers, who never fired a day in their life, who would be turned loose to prey on the skilled men who have worked for the positions they hold.

WM. R. CLINE.

McArthur, O.

Helplessness.

Editor The Locomotive Engineer:

I can assure you your paper supplies a want among locomotive drivers, firemen and iron workers in general. Heretofore we have had no medium through which to voice our complaints or seek information, and I, in conjunction with a large number of my friends, wish your paper every success.

The division I am employed on can boast of a class of drivers second to none in America for intelligence and capability; not so on many other roads, where I have seen drivers who were so ignorant of what they were handling that it made my hair stand on end. Now, I will give you an instance which will, I think, go far towards proving my former argument correct. Some years ago, our road here, being in course of construction, my duty consisted in looking after the water supply. I was on the passenger express one day, when, coming to a station, we found the main line blocked by a wood train, the engine being dead. The driver of the express pulled him on to a side track and left him. My business keeping me at that station, I got off and went to inquire the cause of the trouble. The driver told me his pump had given out, water got low in boiler, safety plug, of course, blew out, as it should, and extinguished the fire. He had wired, he said, for another engine, but could get none, as there were no spare engines Now I went to work and took off his check valve, and found a piece of scale or iron jammed in the seat, which I picked off; made connections, went to a forge a short distance off, and had a taper plug made, which I drove into brass plug in boiler and got up steam, and he proceeded with his train. This was all accomplished in one hour and a half. Now I maintain that had he the requisite skill he could have managed all this himself, which goes to prove my assertion. I believe in the old saying that *when we learn a little, we find how little we do know.*

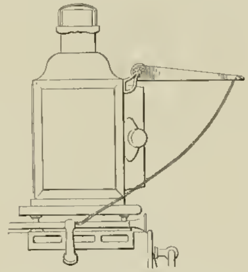
MECHANIC.

Quebec, Ont.

Improved Headlight.

Editor The Locomotive Engineer:

Sometime ago your paper told of the idea of blindfolding locomotives, but I think I have a better scheme. On our road we use the headlight to signal by; as long as it shows up at night it is on the main line; if we take a siding for another train as soon as we clear we cover the headlight, and have used a curtain inside, hung on a rod; but this made us go outside to cover it, and in windy weather the light was often blown out while monkeying with the shade. I had a light cover made for my headlight like sketch; it is hung from the top on a shaft that carries a stiff coil spring, always tending to keep it open; to one corner I attach a cord, as shown, that comes to the cab through the handrail. I can shut the "winker," as my fire-boy calls it, from my seat, and have a



hook to hold it shut; it keeps the glass clean, and the inside being painted white, it throws a brighter light on the track, and avoids another disagreeable thing—all runners know that when smoke and steam is driven ahead of the engine how the headlight will light it up and shadow the track. I find this reflector keeps the rays of light from getting very high till too far ahead to catch the floating steam.

Chicago, Ill. JAS. FENTON.

Boring Flues—A Cold-Handled Auger.

Editor The Locomotive Engineer:

I am back with the Kid in Texas, and I have recently learned something about flue boring and flue augers. A man that hasn't got sense enough to know that he can't read French until he has spent his good money for a French book is not very bright, but I am about in that fix. Of all the hard jobs that fall to a fireman's lot, I have found that keeping the flues clean where soft coal is used to be the worst, but the Kid has taught me a little flue science, and I find it was myself more than the work.

I had read advertisements of flue cleaners of one kind and another until I came to the conclusion that if, by spending a little money for one, I could save exertion, I would do so, and I sent for one. It is here now, bright and new, with crooked wings enough to fly through a flue, and back out itself, but it has as yet been uninitiated. I showed it to the Kid the day I got it, and he looked sorry for me, and said: "I make it a point to let a fireman do his work as he likes best just as long as he gets it done; I don't like to claim my way is best at all, but I have noticed for some time that you have worked to a disadvantage in keeping your flues clean—it's half a day's work, and hard, dirty work, too, every round trip. You wait till the engine is cold, and then open front end, move the petticoat pipe and bore and punch till you are tired out, and then readjust, and go home mad enough to fight a bulldog.

"Now let's study this thing a minute; a locomotive has a forced draft, and anything that don't stick in a flue goes through in a hurry, and it leaves the flue clean; you never saw soot burned into the inside of a flue in a locomotive like you do in a natural draft, stationary boiler, and for this reason your fancy scraper is of no use. The reason locomotive flues stop up is that a large cinder or clinker gets stuck in the fire-box end of the flue, and shuts off most of the draft in that flue, and what other dirt gets in stays, as there is not draft enough to pull it out. If the flue is left long enough, it will stop up solid from the other end, and 'bake in' and it is a hard job to get it out. What you want to do is to get rid of the clinker before it lets the flue get full of cinders. This being the case, you want to clean the flues every trip over the division. You want to avoid work—then clean your flues from the firebox end, and avoid opening the front door and elevating draft pipe. You can't work your flue auger when the tank is full of coal; do so when it is nearly empty.

"Now you get a pair of flue augers, one long and one short; use the short one every trip to punch out clinkers, and the long one about once a week to probe flues that will get full. When I was firing, I got a length of ¾ pipe and had a two-foot auger made to screw onto one end, on the other end I put a T and two six-inch pieces for a handle; one of these I stopped up at the end, and left the other open. I used it through the fire-box when we were dropping down long hills, and when it got hot I used to pour it full of water through the handle, changing water often enough to keep it cool. The pipe is stiffer than a rod, and you are surer of your aim when the engine is running. By doing a little of this work every trip, it will not get the best of you, as it does now."

The difference between this young engineer and myself is that he does nothing without studying on it, and I have been doing my work as others have done it, without thinking. I have followed his idea about keeping flues clean and it is not half so hard as the old way, and I do this much work while I am under pay, and not while I should be taking needed rest. I believe that, by thinking about the details of my business, I can save myself lots of exertion and the company many dollars. I shall think.

TEXAS.

Galveston, Tex.

Naming Engines.

Editor The Locomotive Engineer:

Some time ago you published an item on engine names, and I just came to the conclusion to give you a little scrap of my 30-odd years' experience on a foot-plate. In the earlier days of railroading in the United States, all engines were named and not numbered, but when the roads came to own a hundred or more locomotives the numbers were introduced more to classify the engines than anything else, as clerks, etc., could not remember just what kind of a scrap each one was. I also remember when passenger trains were all named and not numbered. I found that running an engine named after any of the general officers was easier than running one named for a town or anything else. If Gideon Gibbins is general manager of a road, and I am running a mill with "Col. Gideon Gibbins" in gold leaf on each side of her cab, I need not fear that she will need repairs very bad, or have a bad fuel record, or want for a soft run when Col. Gid. goes over the road seeking whom he may devour. Naming for towns or places does not always pay, either; I was out West a few years ago, and saw an irate plug-puller chasing a Hebrew drummer about a depot platform, because the H. d. had asked if his engine's name indicated her record for speed. She was named "Ten Mile."

Elmira, N. Y. ELMIRA.

The Extra Man.

Editor The Locomotive Engineer

Of all things firemen dislike, being on the extra list takes the lead. Now, while I don't blame a fellow for wanting a regular engine—one he can take care of and feel proud to be on—still, as a man serving his time as fireman is only learning to be a runner, there are chances for the extra man to learn, which the regular man seldom has.

To learn as much as possible, and to perfect himself, should be the aim of all; and right on the extra list is a good place for the pushing, energetic man.

To the boys who are thus situated, I would say: Don't be discouraged, but every time you go out see if you can't learn something; not only to be a better fireman, but something that will be of use when you step over to the right hand side. Avoid the faults and practice the good qualities of those you have been with. A man who is thoroughly in earnest will strive to please those with whom he works, and at the same time will study how to do work to the best advantage. If you are out with a man who likes to carry water so high it keeps slopping out of the stack, just note if he gets any more work out of the engine than the man who runs with a flutter in top gauge, or if he is any easier on the fireman.

If you strike a man who runs forty miles an hour and then has to wait for time at sidings, just think it over and see if he gets over the road any quicker than the man who uses the card time between stations. See if there is any difference in the amount of coal and water used, or if your back aches as badly with one as the other.

You will get on with some to whom it always seems hard work to get along. They are continually in hot water and make things unpleasant for themselves as well as others. The next man you go out with takes everything cool, and things always seem to run smooth him.

Find out for yourself the secret of the success of the one, and when you are promoted, see if you can't be a runner that all the "extras" will be glad to go out with. H. S. H.

Denver, Col.

"Drivers" on the Water.

Editor The Locomotive Engineer

How refreshing it is to read about the "drivers" and "stokers," and their abilities. It is hard to see what good it does to be extra well posted on the strength of material, etc., when, if you will not, or cannot pull those wagons, some other man will get the job, who is not so full of formulas. A little of the machine shop may be good in a "driver," especially if railroad companies would adopt the custom of sending a portable machine shop with every engine. What a lot of laborers there must be in the United States, and some of them are mean enough to walk off with $260 a month: pay sufficient for a good engineer. "Mechanic" mentions the engineers of ocean steamers as being criterions to cry by. My opinion is, that they are like any other class; some know their business and some don't.

I asked one of the engineers of the Cunard steamer "Cephalonia" how many times larger the low pressure cylinder was than the high pressure, and he could not tell. The engines of the "Pavonia" kept us all awake (going to the eastward) one trip with their pounding. Could it have been worse under the care of ordinary "drivers"?—not to any marked degree. Here's one nearer home: the engineer of the "Westfield," on his oath at the inquiry that was to determine the cause of the explosion on board, said that vacuum was *foul air!* Locomotive men ask some simple questions, sometimes, but shades of Watt and shadows of Stephenson! they can't and never will learn their business on the water or in a machine shop.

LITTLE BUTTE.

Albuquerque, N. M.

How Do Injectors Work?

Editor The Locomotive Engineer.

In your May issue there appears an article headed "How and Why Injectors Work," that I cannot let go unchallenged, although I may stand alone in the theories I advance.

If your theory—which is the general belief in the matter—is correct, how can an injector take steam from a boiler, make it take up water and deliver it into the *steam space* of the same boiler again? Is not the velocity caused by the pressure, and is it not as great at the check as at the injector throttle?

Now I have had some experience with injectors, and I claim that the size of the nozzles controls the range and action of the whole instrument.

If the steam nozzle is as large as the delivery nozzle, the instrument will throw lots of water—but not into the boiler. *Increase* the size of steam tube or *decrease* the size of delivery, and it will throw against the pressure of the boiler, and the larger you get the steam nozzle, and the smaller the delivery nozzle, the greater pressure it will throw against, taking steam from a boiler with 80 or 100 pounds pressure, and throwing water, in smaller quantity, into a boiler with 300 or 400 pounds pressure, the amount of pressure it will work against depending entirely on the difference in size of these two nozzles.

Do you claim that, by increasing the size of the steam tube, that you increase the velocity?

I look at an injector as a steam pump: the steam in an injector being the steam piston of the pump, and the delivery tube being the water cylinder; if the steam cylinder of a pump is twice as big as the water cylinder, it will force water four times as high, or against four times the pressure it would if both cylinders were the same size, making no allowance for friction. What is true of one is true of the other. The steam is a constantly moving series of pistons, always moving in one direction, and disappearing in their work, only to be reinforced by more pistons.

Without changing other conditions than the size of nozzles, you can make an injector do anything. Steam boiler testers are simply injectors with a very small delivery. Where does your velocity come in? LINE CHECK.

Germantown, Pa.

[The pressure at the check is at rest, confined, and is static force; the delivery of the injector is in motion, and is dynamic force; the blow of the water on the check is the action of a body in motion upon a body at rest. You can move a safe with a sledge hammer if the hammer has momentum enough.

By using a larger steam nozzle, you use more steam to force the same amount of water. An injector working with steam from one boiler, and forcing water into another boiler having greater pressure, is accomplished by using more steam to throw less water.

A hydraulic ram with but 10 foot fall will pump water up 100 feet; but by wasting water, until velocity enough has been gained to close a valve and strike the blow that puts water beyond the valve in the 100 foot pipe, so an injector wastes steam and water at the overflow until velocity enough has been gained to force the current of water and steam against the check.

If two horses of the same weight stand side and side, they do nothing; but let one stand still and represent static force—the pressure at the check—and let the other represent dynamic force, the force in motion—the current from the injector, and run against the horse at rest, the horse at rest will get moved, even though he were twice as heavy as the horse in motion.]

Help Yourself.

There has been considerable talk of late about mutual benefit associations and aid societies connected with shops and roads, and much good can be accomplished by such associations. Many engineers and firemen would organize, but do not know exactly how to go at it. We give below a copy of the constitution and by-laws of one of the most successful of these associations, conducted by the engineers of the D. & R. G. Ry. and A. T. & S. F. Ry., at Pueblo, Colo. On the first page should be a list of the officers and committees, and the name of road or divisions of different roads whose engineers are eligible to membership should follow the heading on the title-page.

CONSTITUTION AND BY-LAWS OF THE ENGINEERS MUTUAL BENEFIT ASSOCIATION.

ARTICLE I.

This association shall be known as the Engineers' Mutual Benefit Association of the —— Railroad.

ARTICLE II.

It shall have for its object the assistance of all members disabled by sickness or accident. The sum of twelve dollars per week to be paid, as the constitution and by-laws direct. Seven days to constitute a week.

ARTICLE III.

The officers of this association shall consist of a president, vice-president, an executive committee of ten members who shall be appointed by the president at the annual meeting in each year.

ARTICLE IV.

SECTION 1. It shall be the duty of the president to preside at all regular meetings. He shall have power, with consent of a majority of the executive committee, to call special meetings when and where he thinks best, for the best interest of the association.

SEC. 2. In the absence of the president the vice-president shall preside.

SEC. 3. The secretary shall give each member a dated and numbered receipt for each assessment as it is paid, and give credit on the books, or both; such receipt or credit shall be sufficient evidence of the good standing of the member, and entitle him to all benefits thereof.

ARTICLE V.

SECTION 1. The secretary shall act as treasurer and shall receive all moneys for this association, and hold the same subject to the order of the president and executive committee.

SEC. 2. He shall keep a true record of all the business and proceedings, and he shall also keep a record of all the members, and date of policies issued, and make a correct report of all receipts and expenditures, number of members and condition of association, semi annually, or oftener if required by a majority of the executive committee.

ARTICLE VI.

SECTION 1. All engineers running on the —— Railway shall be eligible to become a member of this association, and retain their membership for six months after leaving the employ of the company, if they remain within the jurisdiction, and then at the option of the executive committee.

ARTICLE VII.

When sickness or disability of any member of this association occurs, it shall be the duty of such sick or disabled member to notify the executive committee.

ARTICLE VIII.

SECTION 1. It shall be the duty of the executive committee to visit such sick and disabled members, and report the same to the president.

SEC. 2. Upon receipt of such reports the president shall order an assessment of twenty-five (25) cents or more per week upon each member of the association, to date from the day of such sickness or disability, or for the period of twenty-six (26) weeks unless otherwise ordered by a meeting of the association. Seven days constitute a week. In case the surplus fund be sufficient to pay assessments ordered, then the above assessment is not to be made.

SEC. 3. It shall be the duty of every member to bring the certificate from the physician when the executive committee demands it.

ARTICLE IX.

The secretary shall immediately proceed to collect the assessments when ordered by the president, and any member failing to pay any assessment within 30 days after ordered shall lose all rights in this association, and can only be admitted as new members. They will be governed by Articles 14 and 15 of Constitution and By-Laws.

ARTICLE X.

SECTION 1. There will be no benefit paid for less than two weeks, or the fractional part of a week, and such sickness or disability to date from the day of sickness, as per Section 2 of Article VII.

SEC 2. No benefit will be paid if sickness or disability is caused by immoral conduct, or the use of intoxicating liquors.

ARTICLE XI.

Expenses shall be defrayed by an equal assessment on all the members, but no assessment shall be ordered without the consent of the executive committee.

ARTICLE XII.

It shall be the duty of the executive committee to examine the books of the association and see that the accounts are correct and decide all questions of dispute that may arise previous to the meetings, and to fill all vacancies that may occur either in officers or committees.

ARTICLE XIII.

A fee of $1.50 will be required of every person on becoming a member of this association, the same to be paid over to the secretary, for the purpose of defraying the expenses of the association.

ARTICLE XIV.

Any member expelled may be reinstated by paying the admission fee, fifty cents, and a penalty of two dollars ($2) in addition, provided they receive a majority vote at a regular meeting of the association.

ARTICLE XV.

Any member forfeiting his membership the second time shall be governed by Article XIV, with this exception—shall pay a fine of $4, and if forfeited the third time shall never become a member again.

ARTICLE XVI.

Any member convicted for imposing upon this association in any manner, shall be expelled, and never again become a member.

ARTICLE XVII.

There shall be an assessment of one dollar for the purpose of a burial fund kept on hand, and an assessment shall be levied when it is used to replace it. The admission fee of one dollar shall apply on this fund.

ARTICLE XVIII.

Five or more persons shall constitute a quorum for the transaction of business.

ARTICLE XIX.

The secretary and treasurer shall be exempt from all assessments, as a compensation for his services as such officer.

ARTICLE XX.

This Constitution and By-Laws can be changed and amended by a two-third vote of all the members.

A notice blank is posted in roundhouses etc., when an assessment is to be levied, giving name of brother who has been sick, and number of weeks he was disabled; also if a brother has been killed—in which case a dollar extra is levied and kept on hand for a burial fund; this notice should be signed by the president and secretary. Annually the secretary and treasurer makes out and has printed a statement giving total amount of admission fees and assessments received to date, amounts of benefits and to whom paid, amount paid for printing, and balance on hand, amount outstanding and due from members, cost to each member for year, total number of members at beginning of year, new members received during year, number deceased, withdrawn or gone away, and total membership to date.

The second annual statement of the Pueblo association shows that they collected $1,031.00 during the year, paid benefits to the amount of $916.00, and $31.45 for printing; the total cost to members for thirteen months being $9.75, including one death assessment; total membership, 100. The assessments are rarely over $1.00, and as it cost but $9.75 during thirteeen months, it will be seen that for a very small sum an engineer can be assured of $50 per month if he is sick and disabled, and his family gets $100 for burial expenses in case of his death; as this amount is kept on hand and does not have to be collected the family have it at once, when it is so badly needed. The firemen at Pueblo have an association exactly like the engineers, except that their weekly benefits are $8 instead of $12, and assessments correspondingly cheap. Try it on your road. It is not a charity; you pay for it. Every brother on the road helps you to bear your misfortune and you help him in his.

Why Not?

There has been a number of runaways on roads where the automatic brake is in use, where part of the train was left on a grade while switching. The "tramp" lets off brakes. It would seem an easy matter to fix up some device that could be dropped on the track, or hooked to a rail, that would set the automatic if the train moved. A simple string or wire from the cock in the train pipe to a rail would pull the cock open and set the brake. But maybe the tramp would go along and "bleed" the brakes and let them slide just the same. There should be something on all cabooses to do this work. A man is the best thing, but the trouble is that he will have to do so many other things, the tramp gets the best of him. A string can't think, but it wouldn't have to flag or hunt links and pins.

New Idea on Flue Repairs.

The superintendent of machinery of one of the largest railroads of the Argentine Republic proposes to try a new plan of flue repairs. His road uses some of the worst water on earth, and, although boilers are washed out every trip, the flues soon become a solid mass of scale, making their removal costly and slow, and keeping many engines out of service for repairs. The plan proposed is to use separate flue sheets, front and back, into which all the tubes are expanded in the shop, and then the whole arrangement bolted into boiler by using tap bolts in flanges of heavy iron riveted in place of present flue sheets. The tubes and sheets would have to go in from the front of boiler, and the tap bolts on the fire-box end would have to go in from the inside of boiler; but by putting the flues in rows one above the other, and, perhaps, leaving out a few flues on the outside, the designer believes they can be got in; in removing he proposes to twist them out or twist the heads off. The man who proposes this novel idea is an intelligent mechanic, and does not think this a good thing for general use, but hopes that in his case it will serve to keep engines in service more months in the year. J. J. English, of the Baldwin Locomotive Works, who has recently returned from South America, says that the water in use on the southwestern deserts of the United States is no comparison to the stuff used on this road.

CONTENTS.

Revive the Practical Discussions.

Whatever else the organizations of engineers and firemen do—and they do much that is good, ennobling and charitable—they should pay more attention to the science of railroading, and discussions of the business of handling their engines, and doing the work of their employers. One of the main aims of any body of enginemen should be to make themselves better mechanics. They should study and discuss problems of the road, have models and books for general perusal that are too expensive for individuals to buy, and present such inducements that no good man could afford to lose the advantages offered by the brotherhoods.

It is well known that these discussions have fallen into disuse and decay, and the few lodge rooms that have valve gear models use them for hat racks more than means for information. The spirit of research should be encouraged to start, and made so interesting that none would wish to give it up.

It cannot be denied that there are in the country a large majority of engineers who would much rather condemn a thing than to honestly say that they did not know the principle of its operation. A little wholesome honesty with themselves would do all these men a world of good, and could do no harm to anyone.

Firemen, as a rule, are far more willing and anxious to study these subjects than are engineers, but why they should we do not see. There is a lot of honesty and force of character in an engineer who says frankly, "I don't know."

After a few years of running, the average engineer dreads to study or discuss questions where he knows he is on uncertain ground, and the more he avoids them the more insurmountable every molehill becomes.

No matter how much we don't want it, and don't believe it will ever come, the time is certainly coming when all firemen will have to pass an examination on adaptability, intelligence, sobriety, color blindness, etc., before they are allowed to fire; they will have to pass a rigid examination on time card rules, signals and the handling of engine and brakes, before they will be allowed to try their hands at the throttle. They will also have to be recommended by good engineers as first-class firemen. Men hunting jobs will have to pass rigid examinations; there will be no oldest man racket, no waiting for turn, but promotion on merit from top to bottom.

Let the enginemen of America be up and doing. It is their duty to so conduct themselves that they will court the examinations, and let them be so well posted that they can show and prove that nothing but an entirely practical examination is any protection to the public.

To be independent is to be well informed.

Study to be economical in supplies, and do the greatest amount of work with the least outlay of money. You would strive to do this if you were employed with a private firm, why is it a disgrace because you are employed by a railroad company?

Think of these things, men; they deserve your thoughtful consideration. Remember now these discussions in the days of thy youth, when the evil night run cometh not, and before you pull the plug on a scrap that has congestive chills, or the goose-neck is broken at the tender, or the wheel is busted on the right hand injector.

Scalping By Law.

A railroad company sold and delivered a 1,000-mile ticket to a purchaser who paid in money the usual rate to the class of travelers to which he belonged, and who secured it in ignorance of the following directions printed thereon: "Conductors will not honor this ticket unless properly stamped and signed by the purchaser, and will strictly enforce the above condition." Instructions of the company to its ticket agents, and the uniform custom regulating the sale of such tickets, required that the purchaser sign certain conditions printed thereon before delivery to them. The ticket in question was delivered to the purchaser and several times honored by the company's conductors without requiring him to sign the conditions. The Supreme Court of Ohio has just decided, in the case Kent *vs.* B. & O. Ry. Co., that. The company thereby waived such requirement, and its conductor was not justified in ejecting the purchaser from his car by reason of his refusal to sign the ticket and to pay the usual fare in money for his proposed passage.—*Ry. World.*

When the ifs and ands of ticket sales are done away with, and a ticket is good for the service it calls for, no matter who presents it, or how long after it is sold, so it has not been used, the better. "Good for this date and train only," "Good only when signed by the purchaser," etc., are a fraud and a curse. They leave many innocent purchasers with worthless tickets on their hands, for which they have paid full rates, then the managers weep because these tickets find their way into the hands of scalpers and say these men "fix their rates." Holy Moses!

Where is the Difference?

Senator Teller has introduced in the Senate a joint resolution declaring that all patents granted are for the actual use of the public, subject to the right of the inventor, discoverer or assignee, to receive the consideration for the use thereof, and must be put into actual use. Failure to put any patent into actual use within five years from the date of issue shall be held to be an abandonment of it, and thereafter the thing patented shall be public property and the patent ipso facto void.—*Ex.*

A great many papers are endorsing the above measure as a means of preventing inventors from demanding a tribute for merely thinking up a good thing, without actually manufacturing them, so that the public could have the benefit of their use. We do not see why an inventor has not as much right to hold his invention until the public necessities make it more valuable as a speculator has to hold vacant lots until the enterprise of others has made them more valuable.

The Wason Manufacturing Co. will build an $18,000 palace car for the king of Portugal.

The Master Mechanics' 21st Annual Meeting.

This meeting took place on June 19th, 20th and 21st, at Alexandria Bay, Thousand Islands, and was attended by a majority of the members. Mr. Setchel, the president, took occasion in his opening address to congratulate the association on reaching its majority, and to highly compliment Secretary Sinclair for his efficient work during the year. The secretary's report shows healthy condition of finances and an increase of membership.

The discussions were of an interesting character, but most of them show that the mechanics of the country are tired of the system long in vogue, of making inquiry by circulars issued by committees Reports based on the circular inquiry scheme were incomplete, and in many cases the committees complain that they received so few answers. Several committees were held over for another year for further consideration and study of their subjects. The master mechanics are very slow to adopt standards, but be it said to their credit that they have never been obliged to repudiate or change a standard once adopted.

It was shown that thousands of locomotives are now in service, whose running repairs are ⅓ less per mile run than the best practice 20 years ago; taking into consideration the increased complication, this item of itself would be good reason for the railroads to sustain this association at their own expense.

A great diversity of opinion and results in actual practice was noticed. This was especially true of the use of blind or bald tires on different wheels under 10-wheeled engines, in the use and advantage of extension fronts and the curving qualities of engines having rigid as against swing trucks.

The investigations of the committees, and the experience of such members as expressed themselves, seemed to be against the use of traction increasers and feed-water heaters.

By far the ablest and most important paper presented was the report of the committee to confer with committees of Master Car Builders and Wheel Makers' Association on the specifications, tests, and guarantee of cast-iron wheels. Chilled wheels are the cheapest wheels to be had, but the practice of contracting for wheels on the basis of price only has made it extremely difficult for makers of first-class wheels to compete in the open market, while the cheap wheels are constantly wrecking trains. In present practice the best wheel makers guarantee a certain mileage (from 50,000 to 70,000), and if the wheel gives out before that time—even by but a few hundred miles—the maker has to furnish a new wheel. Mr. Lauder, chairman of this committee, truly said this was robbery. On the other hand, if the wheel overruns its guarantee the maker gets nothing.

The new standard provides two tests, either of which may be used for each hundred wheels made; this test is to determine the strength and quality of material used, and of itself will exclude very inferior wheels, then the blank form of contract provides a certain price for each sized wheel, and a guarantee of service as follows:

36 inch passenger wheels,	70,000 miles.
33 " " "	60,000 "
36 " engine and tender wheels,	60,000 "
33 " " " " "	50,000 "
30 " " " " "	45,000 "
26 and 28 inch engine and tender wheels,	40,000 "
Refrigerator, through line and cattle cars,	24 months.
All other freight cars,	48 "

Should a wheel fail before this guarantee is reached, the maker is paid but a portion of the agreed price, based upon the miles the wheel has actually made; should the wheel run over the service guarantee, the maker gets a premium per mile over and above the first cost. The association put itself on record as endorsing this report for a future standard.

If it is adopted by the Master Mechanics and the Master Car Builders, the manufacturer of cast wheels will be stimulated to make the very best wheels they can, as the better they are the more money they get for them, while if a wheel falls just short of the gurantee, they get paid for the work it has done, instead of losing it entirely.

The report on guides was of interest, and favored the use of the Dean box-guide for 8 and 10-wheeled engines where it could be used, and the Penn. Standard open guides where the Dean could not be used, the Laird two-bar guide for consolidation, and the single beam guide for switching engines. Mr. Lauder, of the Old Colony Road, stated that he put a Dean guide on an 8-wheel engine five years ago last May, and the engine had been in service ever since, and he stated positively that the guide or crosshead had never been lined up since, nor did it now need it. This is, if true, the most remarkable record that ever came to our notice.

The association will meet in June next year, and the place of meeting will be decided within six months, by a committee who have the choice of Montreal, Niagara Falls or Chautauqua Lake.

The salary of the secretary was fixed at $1,200 per year, and all the old officers re-elected.

Many of the questions that came before this association will be discussed in future issues of this paper.

The Scribner Railroad Articles.

The long promised series of railroad articles have commenced in *Scribner's Magazine*, the June number containing the first article, by Thos. Curtis Clarke, entitled "The Building of the Railway."

From the high standing of the journal, and the corps of writers selected for the subject, the railroad men expected to find eminently interesting and absolutely correct information. The first article is excellent, yet we believe the author has allowed an inaccuracy or two to creep in.

On page 654 he says: "Now that the Westinghouse system of power-brakes on freight trains does away with the necessity of allowing head room for brakesmen on tops of the cars, two roads can cross each other with a vertical distance apart of but 13 or 14 feet, instead of 20 feet, and there is now no excuse for not adopting crossings at different levels."

If the advice given above were followed, our roads would become veritable man traps, even after the automatic coupler was adopted. There is never a freight train when it is not desirable or necessary that men should be on top of cars to give or receive signals, to use hand brakes when accident befalls the automatic, to go from engine to caboose, or to go to or from way cars, and a hundred other reasons.

Unless all freight cars have ways provided to go through them or along their sides, men must go over them—and it is the best place, especially for signaling. The day when low bridges can be used or should be tolerated has not come yet, and it will not in many years.

Again, in speaking of the practice of placing stone or gravel ballast on top of small bridges and culverts, Mr. Clarke says:

"By this means the usual shock felt in passing from the elastic embankment to the comparatively solid bridge will be done away."

It looks to a locomotive engineer as if this was the reverse of true. Is not the ground the comparatively solid, and the bridge the elastic part of the way? All enginemen know that an engine trembles and sways much more while on any ordinary wood, iron or steel bridge than they do on the other parts of the track. We have never built any bridge, or any railways, but we have rode an engine for years over a railroad having more bridges per mile than any other road in Christendom, and we cannot remember where a bridge ever felt "comparatively solid."

There has also been used a cut of Veta Pass, on the D & R. G. Ry., that is taken from a sketch with all the inaccuracies of a sketch, instead of from a photograph. Veta Pass is a low spot between two very high mountains, one of them, Sierra Blanca, being the highest in the range. This low pass is occupied by Dump Mountain, a small mountain that probably once sat as high as either of the two peaks, but slid down, hence its name. The cut leaves out the range, showing only Dump Mountain, and makes the road look out of all proportion, and as if they had built up to see if they could get on top. The cut also shows a double-header coming down the hill, 217 foot per mile, a rather unusual occurrence, although it is sometimes done.

ASKED & ANSWERED.

(37) T. L., Alexandria, Va., asks: What is good to prevent or stop foaming in the boiler when there is not time on the road to blow out or wash the tank? *A.*—We can offer little advice about feed water, not knowing the nature of the impurities. Lime might deposit some of it, but we should not use it under any circumstances, as it will deposit itself on the heating surface, making a very hard scale. If the water carries magnesia, soda might deposit some of it, but it would be necessary to blow out often. We do not

believe, on general principles, in putting one foreign, scale-making substance into a boiler to ren ove another. A good surface blow-off cock, properly located and intelligently used, would likely be of most service in your case.

(38) Rivet, Portland, Me., writes.

Have read of use of the Adamson joint in Strong locomotive boiler. What is it like? *A*.—The first boiler for Strong engine had joint like *a* between the fire-boxes and the combustion chamber; the rivets were in the water space, the object being to keep all rivets from the fire. The trouble was that when the joint leaked it could not be calked; the Adamson joint is like *b*, and similar to the other joint, except that it has a welt or strip between the lap of sheets, and allows the joint to be calked.

(39) F. H., N. Y. City, writes:

I have an engraving of a locomotive built many years ago by Hinkley & Drury. Can you inform me when that firm existed? *A*.—To the above question, F. D. Child, manager of the Hinkley Locomotive Co., Boston kindly replies: The first locomotive built by the firm of Hinkley & Drury, Boston, was delivered July 27th, 1841, to the Portland, Saco & Portsmouth R. R. She was called the "Cumberland." The concern was in existence and engaged in building boilers, etc., a number of years previous to above date.

(40) Pony, Leadville, Colo., asks:

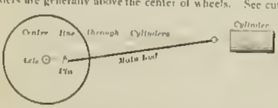
Why does the middle of a beam guide wear more than the ends? *A*.—Because the angularity of the rod is greatest when crosshead is in center of guide, and the greatest amount of work done then, and because the entire length of crosshead gibs rub the center of guide, while at the ends only a small part is touched.

(41) Reader, Gallion, O., asks.

What advantage had the old fashioned half stroke pumps? *A*.—They were behind the back driver, and not in the way of other machinery, and being operated by an independent crank on the back pin, would work when that side of engine was disconnected. Mishaps to valve motion piston or crossheads did not cripple the pump.

(42) Dead Center, Danville, Va., writes

What is the use of all the pinch bar business in getting crosshead on exact dead center? Can't a good mechanic tell by the side rod, as it stands over the axle, whether engine is on center or not by his eye. *A*.—"By the eye" is hardly close enough measurement for locomotive work. The reason that the dead center has to be found by pinching engine past center and back, measuring as they do, is that the center lines of cylinders are generally above the center of wheels. See cut



in which center line of cylinders is placed considerably above center of wheel to make it plain. As the main rod now stands, a line drawn from center of axle to center of main pin would be horizontal, but the engine would not be on her extreme dead center, the centre being about the point marked *X*.

(43) H. E. M., Monson, Me., asks:

Are locomotive driving wheels ever cast hollow, and if so, why? 2. Is a piece of pipe (iron) as strong or stronger than a bar of iron the same size? *A*—1. Driving wheels are generally cast hollow, to save metal, and because metal in the interior of heavy castings is not so strong as that near the outside, also to allow lead to be inserted to counterbalance, as it is heavier than iron. 2. No pipe is as strong as a solid bar of the same size; a pipe is much stronger for some uses than a solid bar of its own weight.

(44) J. D., Kamloops, B. C., writes:

On page 8 of your last paper you show cut of Rue Non-Lifter Injector. I want to ask the use or object of the button or valve held over the delivery tube by the spring, as shown. *A*.—It is the line check, there being none outside the injector casting.

IN THE ROUNDHOUSE AND REPAIR SHOP.

The new triple valve on improved air brake has no means of changing to straight air. It is automatic or nothing.

* * *

The Sterling Emery Wheel Co., 17 Dey street, New York, have favored us with their new catalogue of emery grinders and similar devices.

* * *

The secret of time is to keep moving. Delays, however short, if often repeated, kill the average mileage record easily. Be quick to oil, take water, clean fires, etc.—get away from stations.

* * *

The Master Mechanics decided that a step on the pilot of all engines was a needed appliance for the safety of the lives of trainmen. Good.

* * *

Angus Sinclair becomes editor in-chief of the *National Car and Locomotive Builder*, vice James Gillett, deceased. Mr. Sinclair will remove his office from Chicago to New York.

* * *

It is said that the inspectors of wheels on the passenger cars of the Delaware, Lackawanna & Western, at Hoboken, are paid a day's wages for each defective wheel discovered by them.

* * *

Many of the L engines have check valves that have a taper plug cock in the same casting with check, and between it and the boiler; this plug can be shut off and the check ground in with a full head of steam.

* * *

In nearly every instance where our correspondents report cuts in salaries of employes, the same communications also record the resignations of at least some of the best and most valuable employes on the line. In the face of this fact, who shall say that a reduction of salaries does not lower the grade of the service?—*Ry. Service Gazette.*

* * *

The American Train Dispatchers' Association are making laudable efforts to raise the pay of their members. Train dispatchers, as a rule, do not receive pay in proportion to the responsibilities they assume; they claim more pay on their merits, and have not declared that some other class of employes were receiving pay that belonged to them. We hope they will succeed.

* * *

The Deoxidized Metal Co., of Bridgeport, Conn., had an exhibition of their ware at the M. M's. convention, and remembered THE LOCOMOTIVE ENGINEER to the extent of enough desk jewelry to turn the head of a Pawnee squaw. Car brasses of this metal are now running on the Fitchburg road, that have been in use since Oct., '84, on the L. & N. since Jan., '85, and on the N. Y., N. H. & H. since Jan., '87, without change.

* * *

The surface blow-off has disappeared on a good many roads where they were once in use. There are two reasons for this; one is that the makers put about half of them from one to four inches below the upper gauge cock, and, of course, they were of no use; the other reason is that men don't believe in them and are too lazy to use them. Where they are properly located and used so that they blow water and steam alternately, they are a good thing, and rid the boiler of a great deal of impure matter.

* * *

Chas. Ellis, who has been connected with the Rue Injector Co., Philadelphia, for over 15 years, as secretary, has resigned that position, to go into the hardware business for himself. He carries with him the good will and best wishes of the company. H. F. Colvin has had the duties of secretary added to his office of general manager, with a proportionate raise of salary and a private secretary; his full title being now secretary and general manger. Their works are very busy.

* * *

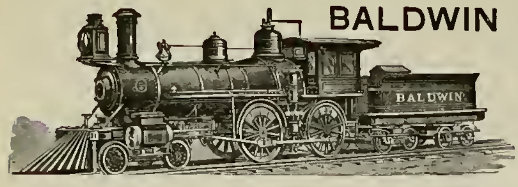
The writer recently had the pleasure of testing one of the new re-starting injectors made by William Sellers & Co. The instrument works admirably, and started itself repeatedly, after being broken, by admitting air to suction pipe, shutting off water, shutting off cock in feed pipe, and after heating injector and suction pipe as hot as steam would make it, by using heater. Since the instrument was shown in our April number, they have been put on over 60 different roads. Two or three years of road service only will disclose any weak points, if it has any.

* * *

We are in almost daily receipt of letters from all over the country, commenting on the excellence and usefulness of the air brake articles appearing in the paper; many subscriptions reading, "Commence with first paper on Air Brake Practice." The air brake has been adopted on many roads, and reliable instructions concerning it have never been furnished the men who use and keep it in repair. The articles are timely and able, and written in simple language, by an engineer having experience with the brake.

* * *

Soft plugs get about as little attention as any attachment to the locomotive; they are screwed into the crown sheet, and that is all, unless something happens to them. They should be taken out and scraped, at least once a month. On some roads a common iron plug is put in place of soft plug, and is, of course, no protection, but it is thick, and burns, and leaks, and will soon need new threads, or rather the sheet will need new threads and plug will need to be born again.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

BOILER TUBES.

ROSS REGULATOR VALVE

FOR CAR HEATING.

Low in price and always reliable. No complicated parts. Easily understood. Durable. Has no equal.

ROSS VALVE CO.,
TROY, N. Y.

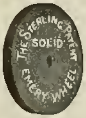
THE RICHARDSON & THE ALLEN-RICHARDSON

BALANCED SLIDE-VALVES.

Used by 140 Railroads. 3,500 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

Estate of F. W. RICHARDSON, Troy, N. Y.

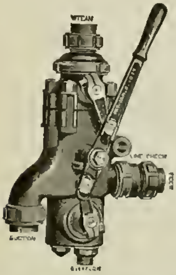


Sterling Emery Wheel Co.,

L. BEST, Manager,
MANUFACTURERS,
17 Dey Street, New York.

Our Wheels for Machine Shop Work and Tool Grinding superior to all others.

Over 115,000 Inspirators Sold.



THE "NEW IMPROVED"

Hancock Locomotive Inspirator.

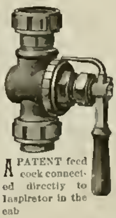
Awarded the FIRST PRIZE, A GOLD MEDAL, at New Orleans Exposition, 1885.

The Most Perfect Locomotive Boiler Feed.

Most Durable.

Most Economical.

Most Convenient.



A PATENT feed cock connected directly to Inspirator in the cab

Send for descriptive circulars to

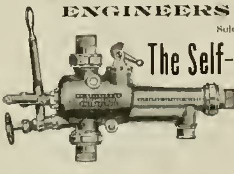
ENGINEERS & MACHINISTS.

Sole Patentees and Manufacturers of



The Self-Acting Injector of 1887.

Range of Capacity over 60 per cent., and can be regulated, therefore, to work continuously for light or heavy trains. Never fails to promptly lift hot or cold water.

No service on a locomotive sufficiently severe to permanently stop its working

IT WILL RE-START ITSELF

should the Jet break from interruption of the steam or water supply, as soon as the supply is resumed

ADJUSTS ITSELF

to varying steam pressures without waste of water. Increases quantity of water with increase of steam, and vice versa.

Very easily operated—Started by pulling out the lever, and stopped by pushing the lever in. Descriptive Circular & Price List sent on application to Office & Works,

PHILADELPHIA, PA.

BAILEY'S PATENT

COPPER CAP FUSIBLE PLUG.

A Cheap Means for Preventing Accidents to Steam Boilers through Low Water.

The fusible metal is kept from contact with the water, thereby avoiding the chemical and mechanical action, which would otherwise prevent it from melting. Cap is readily removable, permitting free inspection.

Highly recommended by American Railway Master Mechanics and others. Over [illegible] sold in Europe since first introduced, with increasing sales. Highly recommended also by the U. S. Board of Supervising Inspectors of Vessels at Washington, D. C.; by Prof. R. H. Thurston, and many other eminent expert engineers, as superior to any now in use, and filling all requirements.

GEO. VAN WAGENEN, 233 West St., N. Y. City,

Sole American Licensee and Manufacturer.

The Locomotive Engineer.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. VIII. NEW YORK, AUGUST, 1888. $1.00 per Year or 10c. a copy.

Historical Locomotives.

FIRST SKETCH.

We present on this page the picture of a locomotive that has had her name indelibly written in the history of our country.

The cut represents the locomotive "General," on the Western & Atlantic Railroad, substantially as she appears now and did on April 12, 1862, when she was captured at Big Shanty, Ga., by 22 daring Union soldiers and brought North; the object being to burn the bridges, cut the telegraph lines, etc., thus cutting off the supplies of the Confederate army at Chattanooga, Tenn.

The party of Federal soldiers were in command of J. J. Andrews, a Kentuckian; their daring feat of going many miles into the enemy's country, stealing the "General" and three cars while the crew were at breakfast, in plain sight of 3,000 Confederate soldiers, and their race North, their attempts to burn bridges, etc., that were frustrated by the close pursuit by Conductor Fuller and some of his men, their final break for the woods and their capture by mounted militia, their trial by court martial and the execution of eight of their number as spies is well known. In case they succeeded they were to receive $60,000. The survivors were granted a gold medal by Congress.

The "General" is a Roger engine—as old railroaders would know by the top of her sand-box;—she is in active service yet, pulling a light train, as she is rather small cylinder and light weight, but has 5 foot 10 inch wheels; she is a wood-burner, and has very recently made some fast time, but certainly made as good time as there was in her on that memorable day in 1862.

The "General" was also under fire at the battle of Kennesaw Mountain, June 27, 1864; having taken a train load of ammunition to the front, she was detained there during the fight, and took the wounded men from Featherstone's division to Marietta and Atlanta.

She was also the last locomotive to leave Atlanta when Hood evacuated, and her last service to the Confederacy was to take a big load of refugees and war material to the South.

The Danforth & Cook locomotive "Texas," that finally overhauled the "General," when her fuel was exhausted and her brave crew had burned the roof of a car, her tank-boxes and oil-cans, is still doing service on the same road. We are indebted to Jas. M. Brown, G. F. & P. A. of the Western & Atlanta road, for copy of illustration and other data used in this sketch.

Extension Fronts.

In many of the plans of extension fronts the netting is placed above the line of the flues. It is evident, from a very slight examination of the matter, that you want as much area of netting as is possible, and the netting, therefore, should extend from the deflector plate ahead in the center of the boiler, giving the full width of boiler to netting. What is considered an excellent arrangement for discharging cinders in one place will not do at all in another; the roadmaster that has stone ballast won't listen to the idea of blowing out on the road and between the rails. Another company object to the side shute because it dirties up the sides of cuts and makes the road look bad. Some companies don't care what you do, so you don't pile them onto the cars, and get in on time. Probably the best all-around arrangement is to use netting coarse enough to let out all but the big cinders and dump these in pits at stated places on the road where stops are made for water or other causes calling for a stop of several minutes. The extension front has come to stay along with the brick arch and the smooth-bore stack.

Burning Caking Coal.

On some of the roads in the Mississippi Valley a very poor quality of coal is burned; it melts and runs through the grates, and if allowed to stand so, will become one solid mass of melted grates and slag. To burn it with success it is necessary to carry a thin fire, keep the coal dancing on grates, when engine is temporarily shut off use blower enough to keep fire burning brightly, use a slice bar occasionally, never permit the fire to get thick or die out in the corners. Intelligent care alone makes it possible to use such fuel, and that it is used so successfully is a credit to the enginemen who handle it.

Breaking in Locomotives.

The intelligence, care and experience displayed by the man who "breaks in" locomotives just out of the repair shop, determines to a considerable extent the good running and length of service of the locomotive.

If the "tamer" is a careless, reckless or ignorant man, and gets any part of the engine hot and cutting, it will very likely give more or less trouble as long as the engine runs.

It is the usual practice to put an engine together just as she is expected to run, set her valves and turn her over to the "tamer," and we never saw one go out that way that did not have to go back more than once for finishing touches; rods bind, driving boxes heat, and valves get a little "out" when the engine is under steam that were all right when she was cold in the shop.

Frank C. Smith, Master Mechanic of the Peoria, Decatur & Evansville road, seems to pursue a reasonable and sensible course in "breaking in" his engines. He sends the engine out of the shop with only the main rods up, and runs her that way until there is nothing that gives trouble, all driving boxes are running cool, etc., then he has the solid rods put on, so that they are just right when the engine is hot and ready for work; the valves are set while the engine is moving under steam.

It is safe to say that engines got ready for work in this way will give less trouble than those adjusted in the shop by any rule. For instance, solid-ended side rods should be put up at the right length for the work, and the right length can only be proven when the engine is doing or in condition to do that work.

Setting Slide Valves.

We are in receipt of many letters like the two given below:

"Will you give rule for setting valves after engine comes out of shop? Suppose eccentrics are keyed on, but blades have slipped on eccentric straps, or some similar mishap, how are the marks made on the valve stem, and how do they use them to re-set valves?"

"Will you give the general method of setting valves on a locomotive, and the position the reverse lever should be in on the different centers?"

One writer says he has been studying the subject up, but got all tangled up in formulas about eccentrics, rocker arms and link suspension, before he got to the rule for running over valves, and, when he got there, there were so many references to

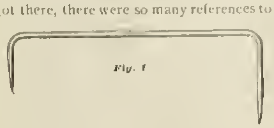

Fig. 1

those points that he never learned just what to do and why he did it, to run over valves in the roundhouse.

We will suppose that the eccentrics are properly set on the shaft and keyed there, that the suspension studs and the rocker arms are properly located, etc.; in fact, we will suppose that the engine has just been rebuilt, her eccentrics are known to be all right, but the blades have been put up any way, and it falls to the lot of our reader to "run her valves over."

In the first place, before the steam chest covers are put on, get your "port marks." To do this, secure a piece of tin or Russia iron about the length of the port, and a tram. Most roads use a standard tram. The best for this purpose is one made like Fig. 1, made of ½ inch steel, with finely ground and hardened points, of such length that, when the long point is inserted in a prick-punch hole on the top of cylinder, outside of chest, and the short point touching the valve rod, the long part of tram will be parallel with the top of rod, it should be of such length as to carry its point entirely beyond the coupling of the valve stem to the rod in any part of its travel. With a sharp scriber, scratch a line on the valve rod in the direction of its length *A B* in Fig. 2. If you are to set valves regular, it will pay you to buy or make a key seat rule for this purpose, the end section appearing like Fig 3; this will always bring this line straight with rod.

Now move your reverse lever (no matter where the engine stands) until one of the ports is uncovered, then insert your tin and hold it in the port, and let your helper move the lever slowly, until the valve pinches the tin just enough so that it is a little hard to move; hold lever in this position, place the tram in the center mark on cylinder casting, and bring the other point down on the line on the valve rod, and scratch *across* the line, then with a fine prick-punch make a mark where the lines cross, enlarging and changing its position

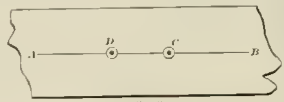

Fig. 2

until when about $\frac{1}{16}$ deep the tram comes fairly into its center; change your reverse lever and get the port mark for the other port in the same way, then you will have the two marks *C* and *D* (Fig. 2); do the same on the other side. These marks show the lap of the valve; if these two marks are an inch and a half apart, the valve is that much wider than the ports, and is said to have ¾th lap—¾th over each port when the valve is in the center. Now, by using a tram of the same length, it will not be necessary to get these marks again while the engine has the same valves.

Some shops set the valves while the main

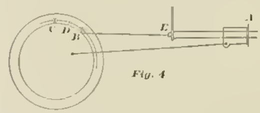

Fig. 4

drivers are on rollers, but we believe that the proper way is to make the final adjustments while the engine is moving herself under steam; by this means all the expansion and all the lost motion is taken up just as it is in every-day practice.

See that the main wedges are set up snugly and both ends of the main rod properly keyed. You will now have to get the dead centers, to prove the proper location of the eccentrics and ensure an equal lead at all points. To do this, another tram must be made that will reach from the guide yoke, frame, or wheel cover, to the upper part of main driving wheel. (See Fig. 4.) We will suppose in this case it reaches from guide yoke. Pinch the engine ahead—for

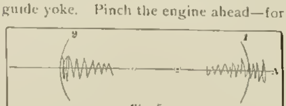

Fig. 5

forward centers, and back for back centers—until the crosshead approaches the end of stroke, say an inch or inch and a half, chalk the guide and make a mark on it as at *A*, using edge of crosshead or a point on it, and a pair of dividers to get this mark; put one end of your tram in point on yoke marked *E*, the other point against tire of wheel, and on a line drawn an inch or so from *inside* of tire by a pair of dividers, and make the punch mark *B*, take out your tram, pinch your engine ahead until the crosshead has passed the center and *passed* the mark on guide, then pinch back carefully until crosshead is exactly to mark *A*, then tram to wheel again, making mark *C*, bisect the distance between *B* and *C*, making the mark *D*, pinch the engine back until the tram comes into this mark, and the engine will be on the extreme dead center, regardless of lost motion. Now, with the lever in any notch, the distance the tram point is from the mark *C*, Fig. 2, is the amount of lead the valve has for that port and that point of cut-off. You will have to get all four dead centers in the same way.

Now all the setting there is to do, is to get the valve to travel in the center of its seat. With a little lampblack and oil on your finger, smear the valve rod just enough to show a scratch easily.

With the tram in the mark on cylinder casting, have the engine moved ahead slowly, under steam, with the lever at full stroke, and, as the stem approaches the ends of travel, scratch it across with the point of tram; it is well to do this through several revolutions, to be sure of your marks. This will give you a stem marked something like Fig. 5. Supposing *X* to be the end of stem toward chest, it would be plain, by putting on a divider and drawing the lines 1 and 2, that the stem was traveling too far ahead, by say ¼ of an inch, and, if the rocker arms are of the same length, mark on the running board, L. G. H., ⅛, which means in English, "lengthen the go ahead eccentric blade ⅛ of an

Fig. 3

Fig. 6

inch," which will make the valve travel in the center. For the back-up motion, run the engine backward, lever in back notch, proceed in the same way. It is needless to say that the other side must be done the same. When the valves travel in the center, when being actuated by each eccentric, the "setting" is done. It is well to run over the forward motion with the lever in the notch generally used, to see that the lead is the same on both sides, and the travel all right, which it will be if the engine is well designed.

To increase the lead, move the eccentric ahead on shaft; this will increase the lead, hasten the point of cut-off, exhaust and compression. Where eccentrics are keyed on they can be set forward or back, by using an off-set key, like Fig. 6.

We hope to make the sketches on "Historical Locomotives" of interest to all our readers. Anyone knowing of the whereabouts of engines, or reliable data concerning them, that have taken a prominent part in any events of moment to our country or the development of the science of railroading, we shall be under obligations if they will acquaint us with the facts.

It is claimed that the engine pulling Jay Gould's special car between Chattanooga and Knoxville, on the East Tennessee, Virginia and Georgia Railroad, a few weeks ago, made the 112 miles between these two cities in 107 minutes. For a long run, this, if true, is indeed remarkable time.

Usefulness on the Retired List.

At the Jersey City shops of the Erie road there is an old-time locomotive of the six-foot gauge, the only one the company has left. The engine is an old-fashioned and light weight machine with a single pair of drivers; her tank has been discarded and a couple of light tanks placed under her cab, and a small coal bunker inside it; she is rigidly coupled to the transfer table and has about 200 feet of track that she may call her own; she moves the entire table, thus doing away with the usual crank and gear system; being quicker than such schemes, she saves lots of time. These shops are so arranged that the table must be moved oftener than transfer tables usually are; barrows, trucks, etc., are transferred from one shop and one yard to several others. Where much material is handled, would it not be a paying investment to couple an old, light weight engine to the table and put a man in charge of her and use the tables more than they are now?

A Fast Run for a Narrow Gauge.

On June 21st, an excursion train left Ouray, Col., for Salt Lake City, over the Denver & Rio Grande road, 3-foot gauge, and went to Salt Lake, 416 miles, in 16 hours and 30 minutes, including two stops for meals and several to change engines, etc. The road is partly mountain and very crooked, and some of it is desert. Between Dallas and Montrose, 48 miles were made in an hour, and on the level, desert division, west of Montrose, the speed reached 55 miles per hour. We are in receipt of Salt Lake and Ouray papers, giving accounts of the run, and also letters from several railroad men there confirming the reports. It is the best narrow gauge record we know of, and, if true, is fast enough for anybody.

In Case of Wreck.

Don't make out a report that you were running ten miles per hour, when it is plain to anybody that you were going thirty or more. We once knew an engineer that went into the ditch with a stock train. The road held the men down to fifteen miles per hour, but on this occasion had given orders allowing eighteen miles per hour. After the wreck the crew did not meet, as the conductor walked back to a station to telegraph. The telegram was answered by the wrecking car, with several officials on board. The conductor told his story to them, but at the wreck the engineer was not seen, having gone home slightly hurt.

In a few days he was called to the superintendent's office, and asked how fast he was running when the wreck occurred. "Just about as fast as the forty-seven could turn a wheel," was the answer.

"No mistake about this?" asked the superintendent.

"Why, you don't think I was running faster do you?"

"No, but someone is a liar. Here is the conductor's report, that says speed did not exceed seventeen miles per hour. Now we wanted that stock got over the road just as bad as you men wanted to get over. All this inquiry is for, is to learn how the accident happened. When your engine is ready, you take her out. That conductor either lied or else he is no judge of speed; in either case, we don't want him. If you had sung the same song I should have discharged you."

What is true of one thing is true of another; tell the truth and shame the division superintendent.

A Feast To-Day—Famine To-Morrow.

"Orders have been issued by the Philadelphia & Reading management, directing engineers and firemen all over the system to report to the superintendents of their respective divisions, instead of to the superintendent of motive power at Reading. This change in the organization of the transportation department will tend, it is claimed, to a greater economy in operating expenses, by concentrating authority in the hands of the division superintendent. No material reduction in the force of locomotive men will be made, but the superintendent is expected to get more work out of the locomotives by this arrangement than was possible under the old plan.—*Ry. Age.*

The division superintendents will probably make a big showing of more work for a few months, then the rolling stock will be about paralyzed, and a master mechanic will be appointed to get it in shape. The interference of the transportation department with the motive power is one of the most prolific causes of dilapidation, disaster and receivership.

Outlandish Names.

The tendency of trainmen to invent odd names for rolling stock and their attachments is often amusing. All railroad men are familiar with the odd appellations bestowed upon locomotives, from the days of the "grasshoppers," "crabs" and "camel backs" to the modern genus of "hogs." The Wisconsin Central officers have been annoyed of late by a disrespectful name given by their trainmen to an artistic effort to put a distinguishing mark upon the rolling stock belonging to the company. The mark consists of a neat red shield placed on each locomotive and car, with the number painted in the middle. The trainmen have dubbed the shield the "liver pad."—*National Car and Locomotive Builder.*

Really the men name everything introduced on the road. George Richardson, although a locomotive engineer himself, had no idea of calling his safety-valve a "pop" until the road men forced that name onto the device. The Mason-Farlie locomotives with Walschaert valve gear on the Denver & South Park and the Denver & New Orleans were at once dubbed "jim-crows," and they never got rid of the name. The old locomotives with sloping fire boxes were known as "fan tails," and now Cushing's modification of the Wooten dust burner is a "mother hubbard." On half the roads in the country an injector is called a "refrigerator," a "cooler" or a "squirt." The vacuum brake is known as the "wind jamb," the caboose as the "dog house," the "monkey box" or the "ark," while the speed recorder has always been the "Dutch clock," but the worst we have heard of yet is the long equalizer from driving spring system to pony truck, on consolidation engines, that the Missouri Pacific boys have named the "Aleck."

Air Brake Practice.

BY J. E. PHELAN.

FOURTH PAPER.

The most important principle to study and practice in handling automatic air brakes is economy of air supply; that is, to do the best possible work with the least amount in pressure or volume of compressed air.

The point for study now is how to accomplish effective work with economy of air supply. To accomplish such effective work requires accurate judgment, constant watchfulness, and careful handling of air brake appliances.

The aim should be to make a stop with but one application of the brakes; that is, after once applying the brakes they should not be released and then re-set in order to stop at desired point. By this it must not be inferred that trains should approach stations or stopping places at a reckless rate of speed, and have brakes suddenly applied to make a sudden stop. This would not show good judgment.

It can be noticed in all Westinghouse illustrations or sectional views of triple valves, the position of the main slide valve that works in connection with the piston of triple valve. Within this slide valve is a small valve that acts automatically and independent in action, in response to slight reduction of air pressure in train pipe. This small valve acts as a medium for light application of brakes, opening a small passage for air to flow from auxiliary to brake cylinder without forcing triple valve to act in opening full passage through slide valve, as for full application of brakes. For illustration, let the engineer apply brakes lightly by moving engineer's valve so as to reduce 3 to 5 pounds' pressure from train pipe. In response to this reduction, triple valve acts, but does not move down far enough to open main passage from auxiliary reservoir to brake cylinder. But it moves down far enough to bring this small valve within slide valve into action, allowing a limited amount of air to flow into brake cylinder. To accomplish this the triple valve has moved down until it rests on the graduating spring in drain cup of triple valve. After making reduction for this purpose, engineer's valve is blanked so air stops escaping, and communication is shut off from main reservoir to train pipe and auxiliaries. Under such conditions the graduating spring forces triple valve up to limit of spring. This does not go far enough up to allow brakes to release, but stops flow of air into brake cylinder, and, as a matter of course, the air that has reached brake cylinder acts expansively in keeping up light application of brakes.

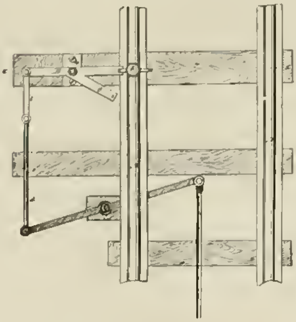
The point to be guarded against is not to trust this condition too long; for action of rods, etc., may draw pistons past limit of leakage grooves and brakes release in this way. It should be the aim of engineers to use this medium for setting brakes as much as possible. It is economical on air supply, places less strain on brake levers, brake shoes and wheels, and is always desirable in making smooth stops, so that passengers may not know that brakes are applied except as indicated by gradual slacking of speed.

The rule to govern this practice for slight application and gradual stop lies in handling engineer's valve to obtain results; first applying the brakes by slight reductions from train pipe and keeping up application by repeated light reductions, as circumstances may require. In making stops, engineers should always take into consideration the grade of roadbed, condition of brakes, and all circumstances bearing on the service in hand. A train can be stopped with very little air on ascending grade, while a stopping place on a descending grade requires cautious work, more time, and increased care.

In early air brake practice, it was taught that a reduction of 10 or 12 pounds' air pressure from train pipe would be necessary to insure application of brakes It was given as a reason that such a reduction was necessary to insure piston in brake cylinder traveling past leakage groove, which usually terminates three inches from end of cylinder. It is to be hoped that this idea is exploded. It is also hoped that the practice of applying brakes so hard that engineers can feel them forcibly taking hold in a sudden manner, while passengers brace themselves for the final stop, may be short lived. It should be settled beyond doubt that those who apply brakes suddenly and as suddenly check speed, release brakes for a short distance and then suddenly reset them for a jerking stop, don't understand their business, and are not good air brake men

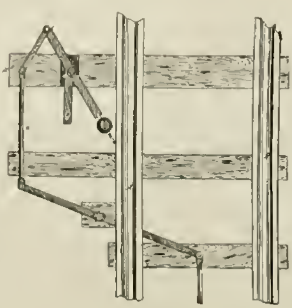
Ordinarily, with brakes in good order, a reduction of 3, 5 or 8 lbs.' air pressure, according to number of cars in train, rate of speed running, and kind of grade approaching stopping place, will give good results. Follow the rule of light application, with repeated light reductions by engineer's valve at safe distance, so that speed will gradually slacken—almost inperceptibly at first, and the approach may be made and final stop accomplished with but one application of brakes. Releasing and resetting brakes uses up reserve pressure in main reservoir, so that final application and release is roughly made at best. It is a mistaken practice to crowd brakes to stop at water tanks or other points, in attempting to be flip. A gradual approach should be made to all stopping places. Another matter, approaching stopping place at high rate of speed; engineers check speed sometimes too soon, and imagining they will stop short, release brakes, and when coming to make the stop, find it necessary to crowd brakes and waste a great deal of air to do so. In such matters it will be found that if engineer's valve is left blanked, instead of releasing brakes, train will keep moving until point of stopping is reached. When it is positively necessary to release in order to avoid stopping short, it is good practice to allow train to come fully under control down to six or eight miles per hour, then the final application to stop will be a light one.

Engineers should never take chances on running by any stopping point. In air brake practice, the engineer's judgement should always take counsel from prudence and cautious self-reliance.



Williams' Torpedo Placer.

The device here shown is designed as an attachment to any switch, signal or drawbridge mechanism, as an extra safety precaution. If used in connection with a distance signal in bad weather there is not the chance for accident there is without it. In use the strap of the torpedo is placed in a slot that fits it in the arm, and is held away from rail, except when signal is turned against the train, when it is brought directly over rail; there is an extra arm to use in case it is attached to a



3-throw switch, being arranged to place a torpedo either way it is turned. The cuts show the placer attached directly to the lock bolt of a drawbridge, and it is intended, when used for this purpose, that when a train passes over it, and comes to a standstill, the train crew will replace the torpedo exploded. There is no machine work on the device, being all plain castings, the estimated cost for arm, bed block and bolt being but 55 cents. Further information can be obtained by addressing the inventor, M. D. Williams, High Bridge, N. Y. Mr. Williams is a conductor on the Northern R'y.

The Largest Yet.

The new engines of the Reading road, designed by Mr. Cushing, have cylinders 22x28 inches, boiler shells 72 inches diameter. These consolidations take the glory all out of the Northern Pacific "Decapods," 22x26, with boiler 68 inches. Recent tests have shown that the big boiler is an improvement, and already the Central of N. J. and the N. P. have ordered engines of this size, showing how soon others will follow an advance step, if that advance is proven to be well taken. Mr. Cushing calls his new engines "Octapods."

The Modernized Wootten.

J. Snowden Bell, of Pittsburgh, Pa., takes the editor of this paper to task for remarks made about the Wootten fire-box engines in the last issue, and writes to the *R'y Gazette* to that effect, and, among other remarks asks:

"Are the new express engines to be discarded because of their great weight, because 'they look like locomotives,' or because they are 'modern;' and in the latter case, in what particular does their objectionable *modernness* consist? Is a 'Wootten fire-box mill' (first built in 1877) more or less *modern* than the new express engines of the ordinary type, with Milholland fire-boxes (first built in 1860), and have the new express engines proven themselves capable of equaling the performance of the 'Wootten fire-box mill'?

"I submit the above inquiries in the hope of obtaining some definite information as to the new engines referred to, in which, from a cursory inspection, I have been unable to discern any feature of novelty, or any peculiarity beyond their excessive weight."

The writer is unduly "soon" in his remarks, as perhaps we were in ours The item that stirred up Mr. Bell was written when a report was published in the *R'y Gazette*, stating that a test had been made with engines with the Wootten boiler and of the wagon top, and giving the Wootten a big record over the later, stating that no more of them would be built. But the engineer of tests of this road has now come forward and corrected these statements. Now we will say what we believe to be the truth.

The Wootten fire-box does just what its inventor intended it should—burns very fine coal (buckwheat size)—it does not and cannot burn culm or dirt. We claimed that the fire-box was too big, because no man could keep the grates covered as they should be; this is proven by Mr. Cushing's experiments. He uses the Wootten box, remember, not the Milholland, but has made it very much narrower, and the tests just completed show that it does better than the extra big box. We believe that the new shape of box will be easier to stay and keep in shape than the old boxes—their weakest point. The Wootten fire-box engines on express do not burn buckwheat coal, because with this fuel it is necessary to clean fires very often—they use lump coal.

The new Cushing engines are heavy, but they have *modernized* Wootten fire-boxes, their superiority and economy have been established, and we venture the assertion that the Wootten Locomotive Co. will, in the future, sell more of this style than of the old style.

Correspondence

Expansible Crosshead Pins.

Editor The Locomotive Engineer:

We have been testing the open or English crosshead, so extensively used on some of our leading roads, and considered by many mechanics to be first-class for locomotive and stationary use, owing to less winding wear on guides, and the use of solid end main rods; but the principal objection has been in the difficulty in putting in a suitable keying arrangement. Some roads use a transverse key in main rod, but in this method the movement of the key is very limited. Other roads use no key at all, and work with this disadvantage because of the many good qualities in this crosshead. The expansible pin, we have found, however, to have completely overcome these obstacles. We have given these pins a test of 27 months on one engine alone, and are satisfied that the design of this crosshead is complete with the expansible pins. The accompanying drawing represents a pin just as it was applied to one of our engines 27 months ago, and since then we have equipped 5 more engines. The first engine is a 16x24, 8-wheel, American type, local passenger engine, making about 3,200 miles per month. This engine went out of the shop in March, 1886, and from that time to date the front ends of the main rods have not been down or removed from the crosshead. The actual mileage to date for this engine is 74,977. You will note on examination of the drawing that the general make-up of this pin is that of the style used in the Laird or Mogul crosshead, excepting here is a short split bushing outside of all, *abutting against, but not entering, the walls* of crosshead. This is the expansion bushing, and is held from turning in rod brass, by having square ends, which engage in slots, allowing bushing to open or close forward and back, the direction of expansion and wear of brasses.

Should you wish to take up the lost motion, slack off nuts *A*, Fig. 1, which frees the center bolt *B*, allowing hollow bolt *C* to be moved. Set up nuts *D*; this draws hollow bolt *C* through, which expands bushing *E* forward and aft; nuts *A* are set up again, which hold hollow bolt *C* firmly in walls of crosshead, as shown in Fig. 4, the key on end of bolt *B* preventing the pin from turning, and its taper expands pin firmly in crosshead. We find that the engineer sets up nuts *D* a little each week, amounting to $\frac{1}{8}$th of a turn of

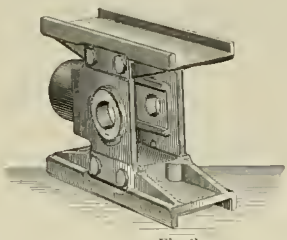


Fig. 2

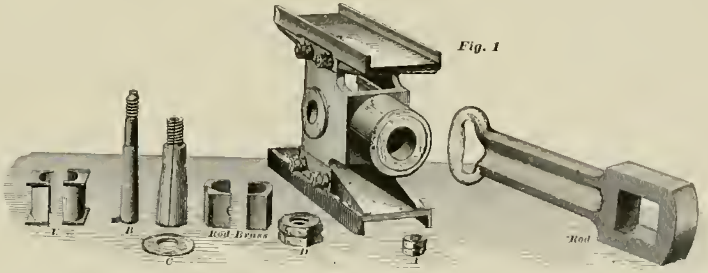
them per month, or $\frac{1}{100}$th of an inch expansion or wear of brasses. Now, as there are $\frac{31}{100}$ths of an inch limited expansion of bushing, and as for the past 27 months there has been about $\frac{27}{100}$ths of an inch wear of brass, it is safe to estimate that the engine in question will run nearly 31 months before the limit of expansion is reached, and before it is necessary to take down the rods to close the brasses; so, as the engines of this class and service go in for repairs every 24 to 30 months, the rods may remain untouched until engine is shopped. This pin can be applied to any style of crosshead where a loose pin is used. The second engine supplied with these pins is a 17x24, 8 wheel, American type, through passenger service, making the first six months 6,100 miles a month and afterward 3,200 miles a month. At the end of four months the foreman of shops examined the pins and considered them to be in better condition for the service rendered than any he had ever seen; from that time to date the rods have not been down. The total mileage is 64,248. We have this pin on four other engines in different service, with equally good results for mileage made. These engines have been run by different men who have kept up the wear, and have had no trouble from pounding and heating; so we have seen that it requires no practice for engineers to learn how much to expand bushing. Practice has shown that the pin is firmer and stronger than the ordinary one, and will not get loose in the walls of crosshead, and, furthermore, brasses can be worn much thinner than by the common keying arrangement. It is quite noticeable that the side rods on all these engines run longer without keying, because of the fine adjustment at the front end, the whole train of connections is kept up in better shape. I am pleased to say that I am entirely satisfied with the workings of these pins, for we have a good crosshead complete with pin; we have less and longer wear of brasses, a solid end main rod of simple construction, length of main rod more nearly preserved and less labor in lining and closing brasses. This Expansible Connecting Pin was invented by H M. Montgomery, of Boston, Massachusetts who has secured it by letters patent both, in the United States and Canada. It is the intention of this company to apply these pins as fast as is practicable to our locomotives.

Fig. 1



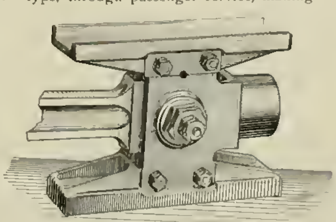


Fig. 3

J. B HENNEY,
Supt. M. P., N. Y. & N. E. R'y.
Norwood, Mass.

[The crosshead pin described above was brought before the Master Mechanics' Convention by their committee on crossheads and guides, and called out so much favorable comment that we consider it of interest to all enginemen on the road and in the shop. The tests made by Mr. Henney seem to be very complete and conclusive. The first cost is probably three times the cost of a common pin, but not more than the cost of loose rod-strap, bolts and key ends.]

Brass Eagles.

Editor The Locomotive Engineer:

Talking about brass eagles reminds me that some twenty years ago I had a fireman who had a mania for ornamental brass work. He had extra flag staffs, waste cups and torches; he had a whirligig on the headlight and a flumadiddle on the sand box, and one day he found a couple of fancy brass ornaments representing a brass squirrel in the act of eating a brass acorn—came off an old pair of andirons, I believe. Well, he polished them up and fastened them to a ball on the front end of hand rails, and they looked real nice—to him. I had not seen them and did not know they were there. We went out on the night express, and as long as I kept my head out of the window they did not show. when we were well out on the road I shut the side window and lit my pipe, and as I raised my eyes to the track, after putting away my tobacco, that squirrel loomed up in direct line with the rails, and looked for all the world just like a human form ten or fifteen yards from the pilot. I shut my eyes to keep out the horrid sight, jammed the throttle shut and squaked for brakes—that was before the days of air. We stopped, backed up and hunted for the mangled remains. The train men guyed me a good deal, but I felt sure the victim had had a miraculous escape. We went on, but before we had got a mile I saw that same tramp on the track, and began to think the engine or myself were being haunted. I went out to turn up the headlight, and found my tramp, and I brained him with a monkey-wrench. And to the day he died that fireman believed that we struck something that time, for it carried away his squirrel.

Elmira, N. Y. ELMIRA.

Slipping in Starting a Train.

Editor The Locomotive Engineer:

We have a grade here where all trains are obliged to stop, and unless they get a heavy train far enough over the grade it is almost impossible to start it. A train was recently stuck here, and one engineer in a crowd who were watching it said the train could be started if the engineer would slip the engine; all hands laughed at him, and told him to go and start the train by slipping, and he did.

Now the man who was running the engine had her on sand, and would take the slack, but could not start the train or get the slack of half of it. Some of the engineers said it was because the engine was "blind," and when one side was at the quarter the other side was on the center, and the valve did not uncover the port and give her any steam; it has since been proven that the engine had 1/8 of an inch lead and was all right. If you will let a little light in on the subject, it will help out a fireman who wants to know.

Denver, Colo. XXX.

[In the first instance the engine had but the pressure on one piston to do the work, which was not enough; the piston that stopped on the center had no power, even with the port wide open, because the crank-pin was on the center. By getting the engine off the sand and letting her slip the momentum of her own moving parts helped her over the centers, and allowed her to develop the power of both cylinders, which exerted a steady pull on the train and slowly brought it into motion; this done, the momentum of train will carry engines over the dead centers, and any amount of sand can be used, as no slip is necessary or of use.]

How to Stall on the Hill.

Editor The Locomotive Engineer:

I had about come to the conclusion that I might make a good fireman, or possibly a fair to middling engineer, but had better stop letting my ink bottle slop over so often, just because I was interested in a subject; but I see that several railroad papers have copied all or part of my article in your July number (and part of them without credit) that I thought perhaps you and the reading enginemen and railroad mechanics of the country would tolerate another dose or two from me. The kid has been giving me some pointers again, and I want to show them off.

We have got a "hole" on our division, and the new engineer usually hangs up there—so do lots of the old ones. The kid don't hang up, and he gets over or out so easy I remarked that he was the only man I had fired for who did, and asked him to explain, as I couldn't see but that other men got their trains to going faster before they struck "the hole" and worked the engines harder to get out.

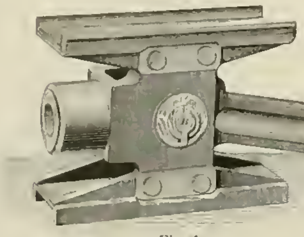

Fig. 1

SEE PAGE 5.

"That's the trouble," said the kid, "they work them too hard. Now they take a long run for the 'hole,' and just as soon as they pitch into it they pull the throttle wide open, drop the lever down among the oil cans and—stall. What stops 'em? Why, steam stops 'em, and nothing else. You take an engine and start out of a station and try to run fast without hooking the lever up, and you can't work your train up to any kind of speed at all. Why? Just because the steam follows the piston nearly its full stroke, it is admitted at chest pressure almost until it is released to the exhaust, and it takes time for it to get out of itself, and if you want it out in a hurry it takes power to get it out, until the power required to draw your train and to overcome that back pressure has used up all the power in the locomotive, and you are done; she will go so fast, but no faster; she has got her steam brake on. If you want to increase your speed your must use all the steam you can, and get rid of it. Now when those fellows strike the hole at 30 miles per hour with a big train and drop the lever into the corner they are simply choking their engine down and using up the reserve power stored in the momentum of the train.

"I just keep her hooked up and let her hit the other side of the 'hole,' going as fast as she will, and commence to drop her lever a notch at a time only as she commences to slow down. The slower she goes the further down I work her and the harder she will pull."

It may seem wrong to men who think it is a mere matter of how hard you work an engine; but, come to think of it, is not the kid's idea the correct one? Wouldn't a little judgment and thought placed over on the right-hand among the levers be as productive of good results as if mixed with the coal on Michael O'Toole's leadless shovel?

Galveston, Texas. TEXAS.

A Conundrum.

Editor The Locomotive Engineer:

Here is a question for my fellow readers of THE LOCOMOTIVE ENGINEER. A few years since I was firing an engine that was setting cars for a steam shovel. The engine was in use night and day. One night she refused to move, regardless of the night crew's efforts to make her. Three or four engineers who examined her case pronounced her dry pipe bursted, and they had all left her where she was standing. When we arrived on the scene my plug puller asked what was the matter, and was told. He ordered the night man to get up and open the cylinder cocks and move her if she would move. It was tried, but she did not go. Then he called them all to him and says: "You fellows don't know anything; that engine is all right and will go right off." Then he got up opened the throttle, and she did go. There was a foolish-looking set of men around there, and they don't know yet where the trouble was. Who can tell where it was?

McArthur, Ohio. WM. R. CLINE.

Two Wipers.

Editor The Locomotive Engineer:

I have been watching the difference in the way two young men on one of the prominent roads in New York State wipe engines.

They both work together, and Jim Poor always takes the right side of engine, while Jack Good is satisfied with the left. Of course there is nothing in that, but the right side is nearest the throttle, and that is why Jim Poor wants it. The said Poor will stroll up to an engine with a half important, lazy look, and make an effort to push a piece of waste along the end and top of steam chest, then drop down to guide, wipe it with waste filled with cinders and dust, when all of a sudden he discovers a little dirt along the front wheel guard, gives it a rub, his hand will then drop—of its own weight—down on side rods, and so along to the cab. Then comes the inspection, here a rub and there a rub, and then he decides "good enough," sit down to wait for Jack, who comes up as though he meant business, wipes all uppermost parts first, and carefully getting in each nook and corner down to the rail, wipes all of one piece before starting on another, goes over each part second time with clean waste, and when *he* reaches the cab, leaves it for some one else to inspect, if they wish.

It is needless to say what a contrast exists on engines wiped by these young men.

On opening up conversation with Jim Poor, he will strive to show how important a man he is about the roundhouse and tell you all the gossip about the engineers and firemen, but when asked if he expected to go firing soon, it was:

"Naw, a fellow don't get a show here unless you have a pull with the 'M. M.;' been wiping about two years, and it's time I had a better job, but they won't give it to me."

A few days later we managed to get in conversation with Jack, and found he had only been employed as wiper for a year and has made several trips as extra fireman; he feels quite hopeful of a chance of firing.

No preaching is necessary. The above facts ought to suggest what is expected of a young man who wants to get above drudgery. Systematic industry and faithfulness makes a good lubrication, and will have to be used abundantly before you can take hold ofthe throttle.

Troy, N. Y. TROJAN.

A Red Reminder.

Editor The Locomotive Engineer.

I am one of those runners who are foolish enough to spend $27.00 for a fine locomotive clock, and if I could not get another, no man could buy mine for four times $27.00.

Not only does it keep the best of time, but it stands there in front of me all the time with its case open, fairly begging to be looked at; if I am making a close run I always look at my watch, too, and as this gives me two times to compare, there is little room for mistakes.

On our road we use the "do not" order yet, and I am always afraid of it, and anything that will remind me of it is welcome. I always read the order to the fireman, and hang it on a hook where I can see it, and yet I have several times come within half a finger length (Mrs. A.'s measurement) of going by the "do not" station. One day, after one of these close calls, I conceived the idea of gluing a small block of wood onto the glass of my clock face, and screwing to it a long, red, dumb hand, and then dividing off the circle of the dial case and putting on it the numbers of each telegraph station, so that when I got a "do not" I could just move the red hand around to the proper station number, but I never got as far as the numbers on the case. I use the time figures—clock has a 24 hour dial—and when I get a "do not," I set the red hand at or about the time I should arrive at my "do not" station.

When I start out on a run I look to my first meeting point for a superior class train, and set the red hand to that time, and I find it a great help. It takes but a second to set it, it does not interfere with the clock, and is a simple safeguard against cases of doubt; and the way I look at these things, locomotive engineers can't have too many safeguards.

Do you think some of the makers of fine locomotive clocks would lose anything if they would fix up some neat little scheme of this kind and let the boys know of it? I should also suggest that locomotive clocks have the glass circle screw on against a felt ring and that they be arranged to wind, set and regulate from the outside of the case while the engine is running, if necessary, and by the use of keys, the holes or plugs being so arranged that no one without the key could meddle with the adjustment, and that would not be in the way of cleaning the case.

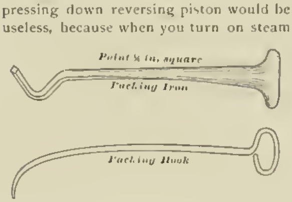
A fifty cent license has saved the pelt of a $400.00 dog; a $2.00 lightning rod has saved a big house from paralyzation, and a 30 cent telltale with a red pointer might save a train load of umbrella frames or straw hats.

JOHN ALEXANDER.

Packing Tools for Air Pumps—That Pump that Would Not Go.

Editor The Locomotive Engineer

F. E. R., Laramie City, Wyo. Ter., in reply to my question in June number, is way off, because if, as he says, the lower nut on main steam valve was loose the cylinder would take steam at both ends, on account of pistons on end of main steam valve separating; therefore, taking off cap and pressing down reversing piston would be useless, because when you turn on steam



the pistons on main steam valve separate as before. Guess again, Mr. F. E. R., L. C. W. T.

C. S. B., of Bennington, Vt., is wrong also. Although, as he says, if the button on end of valve stem was off, the pump would act as I have described it, but that was not the cause of my trouble. I hope C. S. B. will try again.

Bent Wire to hold up Nut and Gland.

As the question has not been answered correctly, I will tell you what I found; it was this: A rubber gasket from steam pipe had been drawn into the main steam valve chamber, and up into the steam port that runs from main steam valve chamber to the reversing valve bush, thereby stopping up the cylinder end of the port. As I always use copper gaskets for steam pipe joints I did not think of looking for rubber in such a place as that, and as I only examined that part of the port that runs through the cylinder head I had to work about four hours, where I could have done the whole in fifteen minutes if I had known what the trouble was.

John Reynolds, Kansas City, Mo., says a Westinghouse air pump is a mean thing to pack; and so they are, unless you have tools the right shape; here is a sketch of the tools I use. Try them, John; they save burning your fingers

I have just overhauled an air pump and put it in as good shape as it can be put in. The steam cylinder has been bored out, new bushes put in, new rings all around, new reversing valve and stem, and new reversing piston, and still it don't work. This is the way it acts: The piston will go up about half way and then reverse its motion, once in a while making a full stroke. Who will tell me what ails the pump?

Syracuse, N. Y. W. F. R.

Convention Thoughts.

Editor The Locomotive Engineer

"'Rah" for the glorious Fourth of July, but remember the poor railroader don't get much of a holiday. As a general thing, when everybody else is out for a day of pleasure, the railroad men conduce greatly to the world's enjoyment by putting in double time, and yet how few of the thousands who ride so safely from one end of this land to the other ever think of the two men on the engine, and while many speak a kind word of and to the gentlemanly conductor, how few ever go forward to give a word of praise or a cigar to the men of the oil can or shovel.

The conventions have met, transacted some very important business, given us some good data from which to work, but yet we find that many men have many minds; and yet it may be that the different locations and circumstances have much to do with the difference of opinion. With regard to boilers, fire-boxes, smoke-boxes, nozzles, etc., there will always be room for improvement. If we are to carry 160 pounds' pressure of steam (and I don't think that will be the limit), there must be a larger heating surface, according to weight, than we had when carrying 120 pounds. To get this increase means more boiler; in fact, I never saw one too large, and very few fire-boxes large enough; and if the walls of the fire-box evaporate six to ten times as much water per square foot as the tubes, it would seem to be good policy to give us all the fire-box and grate surface possible.

By the way, I am glad to see some tests have been made on the Philadelphia and Reading. One recorded in several papers shows the value of the large fire-box for burning inferior fuel. Of course the P. & R. have the advantage of cheap fuel, there being thousands of tons of the screenings of anthracite coal that can only be used by the Wooton fire-box and a fine grate. It may be that the Wooton box may be wider than necessary, as they claim to have gained some advantages with them made 18" narrower by Mr. G. W. Cushing's order, which would leave them 75" to 80" wide by 108" long. Four feet of the grate at the back end is covered with fire brick 4" or 6" thick, which, becoming red or white hot, makes a good gas or smoke burner for bituminous coal.

But the strangest thing of all was the idea of making openings in the smoke-box to improve the steaming qualities. Some of us old fellows have been working with might and main to keep out every particle of air except what came through the flues. If air gets into an extension box it don't take long to have a fire-box on both ends of the boiler, and lots of fun getting out burnt bolts and making steam pipe joints.

I see a sketch in *R. R. Gazette*, June 29th, of Mr. Lander's plan of putting in pipes to support brick arch which is very good, but if the water should be in any way bad, a brass plug in the outside sheet, opposite the end of the pipe, would be valuable, as the plug could be taken out and a rod run through the arch pipe, cleaning it out every time the boiler was washed.

Among the many exhibits at the M. M Convention were some drawings of an improvement to the link, by H. G. Manning, late of the B. & A. R. R. While there have been many trying to do away with the link, and none have succeeded very well, I think Mr. Manning has got on the right track in improving the present link motion. According to the cards taken from this motion, it would seem to be a valuable improvement. I hope some railroad company will give him a chance to prove its value.

I have been amused sometimes watching an engineer trying to oil the lower side of a top guide, pour it on the lower guide and then oil the top bar with his fingers. If he had only turned the crooked end of the spout up and raised the can, the oil would flow up against it and what fell down would oil the lower one

Watertown, N. Y. J. J. BINGLEY.

Another View of Hospitals.

Editor The Locomotive Engineer.

Considerable has been said pro and con about the railroad hospital, and I should like to present one argument in favor of the hospital. I am sure they are a good thing, even under poor management, as men are apt to be improvident, and in case of sickness or accident many of them would become objects of charity, were it not for a system compelling them to provide for themselves. And we no doubt would pay more to assist destitute cases appealing to our sympathies than we now do as hospital dues, and that, too, without a chance of sharing in the benefits of such a system.

A railroad company should not be expected to pay for all sickness, for a great deal of it is not contracted from the effects of any service required. Therefore we must provide for ourselves in the form of insurance. Hospital dues should be looked at in the same light as insurance. It is worth what it costs to carry it, and if we don't get sick or hurt, we are only out our premium.

A man may at any time draw out more than the value of a year's dues; when he does not, some one else does. When he leaves the employ of the company his insurance expires. Having been worth what it cost, he should not expect to acquire stock in the company, to draw a pension, or to have a life lease on a berth in a home for the friendless, although of course, if maimed in the discharge of his duty, he naturally expects some consideration; but railroad companies are not remarkable for even justice, to say nothing of charity

Those of us who can afford better attention than fifty cents per month calls for, can easily pay our dues, for the benefit of those less favored.

Of course those who think they know enough to take care of themselves, do not fancy the idea of having money taken from them, and used without their consent. They would rather pay a dollar of their own free will than a nickel by force.

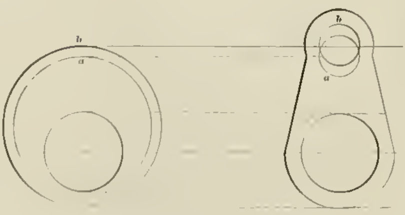
There may be objections to the company hospital as commonly run, but in a new country, where accommodations are scarce, they are all right, especially to single men. There are bad features in the system, but the good ones more than equal the bad.

Pueblo, Colo. WM. H. HUBBARD.

Turning Off Eccentrics.

Editor The Locomotive Engineer:

I have been into a discussion for six months about turning off an eccentric without changing the throw. I send a cut that my engineer says is all right, and that if you turn off a quarter of an inch you decrease the throw; he says it is the same as if you set the crank pin nearer



the center of wheel. If it was not so why do they have to make new straps when eccentric is turned? I claim it makes no difference—who is right? Give an easy way to tell the throw of an eccentric.

Galesburg, Ill. FIREMAN.

[You are right. The turning off of eccentric makes no difference; the distance from center of axle to center of eccentric determines its throw; in turning off outside you have not disturbed this. The crank example is wrong—turning off outside of eccentric would be equivalent to reducing the size of crank pin, which would not decrease its throw. The *difference* between the short side and the long side of an eccentric is equal to its throw. The diameter may be ten inches or ten feet.]

Air Pump Repairs.

Editor The Locomotive Engineer:

The cigar forwarded by W. F. R., in answer to his Air Pump Conundrum, in your April issue, was duly received by me. I did not get your June edition until a few days ago, and then had not time to read it through, but noticed the conundrum again put in by W. F. R. In answer to it I think the trouble was in the steam port, for communication of steam between the two pistons of the main valve, and to the valve chamber in the top head (which regulates the pressure on the reversing piston) getting stopped by some means (probably by the joint on cylinder head), thus making the reversing piston of no use and consequently stopping the pump from working. F. J.

Sault Ste. Marie, Ont., Canada.

A Box that Never Gets Hot.

Editor The Locomotive Engineer:

A specimen copy of your paper is before me, with which I am very much pleased. Yesterday, while running along, a friend pointed towards the left-hand trail wheel of the back truck. I told my fireman (*pro tem.*), an ebony-hued son of Ham, to see if that box was smoking; he looked into the tool box and replied in the negative. I, like Mr. John Alexander, looked at him in a fatherly sort of way, but as it was 20 miles to a stop, I couldn't get even by using the finger beam. My fireman said I needn't worry about that box—it never got hot. Send me the L. E. regular. E. C. S.

Chumuckla, Florida.

Why Won't They Slip?

Editor The Locomotive Engineer:

On our road here we have a number of sags and hills, as I suppose most roads have, and the way all our engines act on these hills has been a matter that has got me all tangled up.

It is a fact well known to all locomotive enginemen that locomotives have much larger cylinders than they need, to *pull* their trains, but they do need the big cylinders to *start* trains One beauty of the link motion is that it virtually reduces the size of the cylinder when hooked up.

Now we all know that it is little or no trouble to slip an engine under ordinary circumstances; they are enough over-cylindered to slip; if you are working your train into speed, and do so slowly, you need not slip, but if you try to hurry you will slip.

Now what worries me is this: Take one of our sags, we have 50 loads, which is, say, twice as much as the engine will pull out of the sag if she stalls; we "take a run for it" and get up to, say, 25 miles per hour; now when we are working up this speed we can slip the engines any time by hurrying them a little; if we stop in the sag and try to start they will slip, but if we run at the hill, and after striking it at a good speed, and the train commences to lose speed you cannot make those engines "fly up" if you try—I have tried. This is what sticks me. Now the same engines will slip on the same hill with four cars if you crowd them. This is not once, it is all the time, and I know engineers and firemen who could tell the same experience if they took particular notice of similar cases. Now there is some reason for this; can you tell me what in the name of common sense it is?

Trinidad, Col. SLIPPER.

[As long as you are trying to store up work in the train it is possible to make an engine slip; the momentum of the train is a reservoir into which you can store energy or work. If you supply more work than can be converted into speed in a given time it will run to waste in slipping, just as you can pour a gallon of water into a small-mouthed jug, if you take time enough; hurry, supply more water than will go in on the instant, and it runs over. Now in running for the hill you are converting work into motion and storing up power to help you over the hill; as soon as you strike the grade and commence to lose speed you are drawing on your reserve. The locomotive is pulling, but not 50 cars, the momentum is pushing. Suppose on your grade you suddenly cut off your engine, the train will follow until all its stored-up power is given out in overcoming friction, the resistance of the atmosphere, and carrying itself forward. Now when on this grade say you have slowed down to 15 miles per hour, your engine won't slip perceptibly, because the first inclination she has to slip reduces her own speed, and the momentum of the train instantly reduces the load on her draw bar, thus relieving her to that extent from the work of pulling the train, thereby enabling her to use more power in moving herself instead of the train.]

Standard Sizes for Locomotive Repairs.

Editor The Locomotive Engineer.

The modern plan of building locomotives and other machinery on the interchangeable system renders it a comparatively easy matter to maintain standard lengths and sizes in making repairs in the roundhouse and machine shop.

In the olden time, when no two engines were alike, even from the same builder, and when contracts were given to several different firms for locomotives, there was some excuse for an irregular system, or no system, in making repairs, but those days are gone, and roads now, or, at least, new roads, are equipped with engines from one builder.

It is a bad practice to alter the length of a spring hanger in order to equalize an engine. The spring is at fault, and not the hanger. The spring is changeable, its "set" is sometimes more, sometimes less. The hanger is rigid, and does not change. Make up for the weakness of the spring by putting liners, or "Dutchmen," under the gib in hanger, and when you get a spring that has full set, take liners out. When hangers are repaired, bring them back to the original length. Find out from a new engine what that length should be, and make a drawing or templet of the same, and keep it as a standard for the men to work by. If this plan were adopted, it would save a vast amount of "cutting and trying." As an example, suppose that an engine has one weak spring. The foreman or machinist gives it a squint, and reasons, very properly, that if those two hangers were shortened just a little, or that spring saddle lengthened a trifle, she would sit all right; suiting the action to the word, the work is done. After a few trips that particular spring breaks, and a new one must take its place. What is the result? Another man puts it in, he sees that something is wrong; just what, he does not know; but one thing is quite evident, that spring gear is all out of whack, and so he tinkers at this or that hanger, puts a different shape to equalizer, saddle or something, he don't care much what—anything, so as to make her set level.

The standard set of each spring should be known, and the spring compared with that standard before being put in, and, if weak, pick out the liners to make it up to "correct pitch" before you put it in. It will save lots of jacking and sweat this hot weather.

After a few years, if a haphazard style of repairing is carried on, there will be no standards, and it will be impossible, without a great amount of study, to tell what the original size was.

The same may be said of the other parts of a locomotive, set screws, nuts, keys, etc. Keep them to standard. By so doing, a supply can be kept on hand, and not a great variety either, always ready for an emergency, and sure to fit. 'Twill save many extra jobs at night and on Sunday. The expense of keeping up engines will be greatly reduced and their life prolonged.

It will save much wear and tear on the foreman. Every repair shop on the road should be furnished from the general shop with a complete set of blue prints of all parts of the engines, or at least of those pieces that will have to be repaired. From these prints patterns or templets can be made for the use of blacksmith or machinist. Jigs can be made for drilling holes, so that the labor of laying out can in a large measure be done away with.

See that the men are thoroughly informed on these points. The foreman's labor should be to think them out, and instruct the men in their use, and see that they are taken care of, and kept to standard.

Pueblo, Col. Hiram R. Jones.

Stone, Pinkerton and Dynamite.

Early in this month the country was startled with the announcement that the C., B. & Q. officials had unearthed a plot to use dynamite to destroy their property, and arrested several ex-employes of the road. It now seems as if part of the dynamiters own up to being Pinkerton detectives, and others have become conscience-stricken and "informed."

A large portion of the press of the country have turned themselves loose, and are howling about the debauched Brotherhoods, etc. We do not believe for an instant that the road can prove its charges; it looks like a Pinkerton plot all the way through. If anyone has been guilty of inciting riot and teaching the use of explosives, it has been the detectives who were into the scheme. We believe the rank and file of the B. L. E., far and near, would like to see all who can be convicted of any part in the plots punished for their crimes, be they engineers, informers or detectives.

The Engineers' and Firemen's Brotherhoods at large will be as blameless, should all charges be proven, as are the present members of Christian churches for the burning of witches at Salem 200 years ago.

Not as Bad as if it was Twice as Bad.

Hereafter the watches of the Pennsylvania railroad trainmen must be examined by a jeweler. If a watch is in good running order the owner is given a certificate, which he must present before he is permitted to take a train out. The owner of any watch that does not pass muster is compelled to purchase another or leave the company's employ. All watches must be inspected once a month, for which the company pays. There is a great deal of dissatisfaction among the men over the new rule.—*Daily Paper.*

The company are liberal compared with some of the roads that want the men to pay for their own examinations and patronize the company watchmaker too. The companies should own and issue the watches.

Same Here.

The best mining experts usually wear overalls and a blue shirt, and are pretty well spattered with candle grease. It may take them a month, or six months, to examine a mine, but the report will be short. "She's a dandy," or "she ain't worth a cuss," will be the report, and it will be practically correct. The professional expert, with his name parted in the middle and a mystical handle attachment, may, after a few hours' examination, write a long winded report with high-sounding phrases, but it will not be as reliable as the judgment of the intelligent miner who has worked for months in the mine.—*Red Cliff* (Col.) *Times.*

The above remarks are true of all trades. The technical school graduate knows all about the proper proportions of machinery, but in nine cases out of ten he can't take a lathe or drill press and make anything but repair bills. The devices used on locomotives can be best tested by locomotive engineers and firemen, and the goggle-eyed expert don't successfully run locomotives to any great extent.

The car couplers were out in force at the M. C. B. and M. M's Associations; after the decision of the former adopting the vertical plane hook, many of the link and pin men went home disgusted.

The Brotherhood of Locomotive Engineers will celebrate their 25th birthday at the city of their nativity, Detroit, on August 17. A big crowd is expected to take part. Their regular convention will be held at Richmond, Va., in October.

Some roads are building locomotives with no brace between boiler and frame at all, except the cylinder saddles and the connections at fire box. On the other hand, D. Clark, M. M. at Hazelton, Pa., on the L. V. R'y, is putting two extra heavy braces between the saddles and the tumbling shaft, and believes they are an improvement over the single brace. Who is right?

CONTENTS.

Ridiculous Claims.

At the Master Mechanics' meeting, the Westinghouse people displayed sections of their new, quick-acting triple valve, and the new engineer's brake-valve, and we heard the man in charge say to a mechanic who was examining the devices: "You see, from here to here is the movement for all ordinary stops, but when you throw the handle around here it opens these large ports and allows the air to escape, by this large passage, around the piston-valve, and is the position for emergency stops; the idea is this: *It makes the blockhead just as good a man with the air as the best engineer you have got!*" This remark opened the throttle of our thinker, and she was making 74 miles per hour from Alexandria Bay until she collided with a Jersey City ferry; we got her stopped here and were feeling around for hot boxes, when a couple of young bloods stopped side of us and one commenced to tell the other what a great time he had the night before. He had taken a party of girls out for an airing in his new-fangled naphtha launch, and launch, naphtha and girls had all got on fire and the girls jumped overboard. It so happened that they were on a mud bank, and in only two or three feet of water, or the girls would doubtless have been drowned.

"What did the engineer do?" asked his friend.

"Oh, you don't need no engineer; I was running her myself, you know; something was wrong or out of kilter, that's all!"

Then we got a paper and read an advertisement of a "No"—engine, no engineer, no expense, no explosion, no insurance, no repairs.

They ought to add: No sense, no work, no safety, no good.

There are too many devices being manufactured that people have to risk their lives on, that require no skill, intelligence or attention (?). In the case of the air-brake, there is little fear that its new valve will induce master mechanics to let it try to make their poorest engineers as reliable as the carefulest and best. The new valve is better than the old one, but it requires as much or more skill to handle it with safety and certainty; it requires judgment to use it. Any machine or device of that kind that will not do better work, more work, and do it safer and surer in the hands of a skilled engineer or mechanic than it will in the hands of the best blockhead on earth, is a bad device; claims to the contrary are ridiculous claims. You cannot make skill of brass or brains of babbitt metal.

Some Figures of the Strike.

A great many newspapers are just now very busy presenting to the laboring men of the country, "some figures of the strike," wherein they show how the Brotherhood of Locomotive Engineers and Firemen, by assessing themselves $5 per month, are expending the sum of $132,000 per month to support the strikers. There are always two sides to a story, and we herewith present "some figures of the strike" from the other side—their own figures.

The Chicago, Burlington & Quincy Railroad's statement for May shows: Decrease in gross earnings, $402,885; increase in operating expenses, $400,545, and decrease in net earnings, $803,430. January 1st to May 31st: Decrease in gross earnings, $3,113,240; increase in operating expenses, $1,081,362, and decrease in net earnings, $4,194,602.

Thus it would seem that, in addition to having an immense property on its hands doing but 30 per cent. of its original business, and losing in the above ratio all the time, it has cost the company something to sustain the struggle and pay advertising rates for articles on "figures of the strike," and in announcements that the strike was over. The strike commenced the latter part of February, and the statement dates back to January 1st, to make the loss appear less per month. As a matter of fact, the strike has cost the road just about $1,500,000 per month—their own figures. How long would this sum have paid the engineers the little extra to bring their wages up to standard pay?

The strike may have been won by the company, but we venture to say that there are few other companies that care to win one in the same way. Verily, "some figures of the strike" are not all on one side of the ledger.

To Hog or Not to Hog, that is the Question.

Engines on many roads are now "chain-ganged" or run the rounds. "Hogging it" the Pennsylvania boys call it. There are no regular engines; a man runs one engine to-day and don't expect to see her again for a week or a month. On some passenger runs two men run one engine or three men run two engines, but on freight it is first in first out, engines and men alike, and as there are more men than engines the latter are kept hot and busy. By this system less money is invested in power, engines are worn out sooner and new ones are modern; men running or firing engines do no work on them; a man is kept at shops to wipe off engines, clean flues, etc., another packs, cleans headlights and draws supplies. On some of the roads a blank form is furnished the engineers, to report their work, and a number of questions have to be checked yes or no. Men report valve stem glands screwed up, or a wick put in gauge lamp, rather than do it themselves.

This system of running has its advantages, and perhaps some disadvantages. As a rule, the engineers like their own engines, but we believe the "hogging" principle a good one if the work is done on the engines. It relieves men of lots of roundhouse work, especially the firemen, and it keeps men with notions from doing damage in the front end. It may make an engineer a machine who cares nothing for his engine, and may in time produce a set of men more helpless in case of a breakdown than the present but we do not believe it will.

After all, the engineer is the brains of a locomotive; he does the thinking and she does the work, and he is expected to direct his energies to the work of transporting passengers and merchandise, and not to repairs. Should the practice come into general use, many of the boys would have to hunt up some other excuse for staying down town four hours every trip "to pack." We would like to hear from some of the men on the chain gang, as to its advantages and disadvantages, from their point of view.

Radial Stays in Wagon Top Boilers.

Heretofore the use of radial stays has been confined to straight boilers, owing to the impossibility of staying crown sheet, under the dome. N. W. Sample, Supt. of M. P. & M. of the D. & R. G. Railway, rebuilt a number of 10-wheelers that had small, straight boilers; a very large wagon top was put onto them, extending far enough ahead of the crown sheet to carry the dome. The engines did remarkably well with the improvement, and, we understand it has been patented, the patent being now owned by the Baldwin Locomotive Works, Philadelphia. These works have been the most enthusiastic believers in the safety, durability, and cheapness of repairs, as well as first cost of this method of staying, and time and experience are showing the correctness of these views.

There is little doubt that, in a few years, crown bars will be the exception, rather than the rule, in American locomotive practice

Another Toothpick Bridge.

On the 12th of last month a heavily laden passenger train broke through a trestle 48 feet high, on the Virginia Midland road, near Orange station. Six persons were killed outright, and 25 or more injured. The trestle was old, rotten and weak, and was being filled in; the train was running but 6 miles per hour, under slow orders. The engine was nearly across the trestle when it broke down in the center, yet the reports state that one of the cars *ran off the track and tore the bridge down.*

Such talk is all bosh; all the bridges that break down are not caused by cars jumping the track. They are running trains and engines of double the weight they were ten years ago, and the old, rotten bridges have been kept in service to help out on the dividends A few wholesome verdicts by coroners' juries would be a great protection to the lives of enginemen as well as the public.

A Long Run and Fast Time.

Engineering, London, states that the highest speed any train is timed at, from start to stop, is the Great Northern Manchester up express, which is 54 miles per hour. This probably beats any card time in the United States, but the statement that this is also the longest regular run in the world without a stop, being 108 miles 26 chains, seems broad. Cannot some of our roads show a train that makes this distance without stopping? We don't expect to hear of its being done in their time, however—1 hour, 57 minutes.

Avoidable Butcheries.

On the night of July 17th there was a collision on the L. & N., near Birmingham, Alabama, in which an engineer and a fireman were instantly killed and another fireman received fatal injuries, another engineer is severely wounded. It is said the cause of the accident was that the watch of the surviving engineer was 25 minutes slow. This will be ground enough for many roads to declare that watches of engineers and conductors shall be examined periodically, and compared with the standard clock daily. This ruling will not prevent accidents of this kind; men are too hard run to always compare with the clock, and engineers will compare watches with the conductor. All kinds of watches will be used. Let the companies own the watches or clocks, keep them in repair, and issue them to the engineer and conductors with their running orders, including in the order the numbers of the watches received. By this system no watch will be out long enough to run down; it will be set to the second every trip; standard time will be maintained and correct watches carried. The cost of an accident like the one cited would buy watches for a dozen roads.

At the M M 's convention last month there was a short discussion on the proper place for blind or bald tires on 10-wheeled engines, and whether or no it was desirable to use swing trucks One man stated that he had a large number of this class of engines, and found that where the engines had rigid trucks they did not curve so well or save their tires. He said he had one engine with rigid truck that had cut her flanges until she had ¾ of an inch of lateral motion, and this in but eight months, while a similar engine with swing trucks had run two years and worn her ties but ⅜ of an inch.

M. N. Forney's article, American Locomotives and Cars, in the August *Century*, is by far the best and most interesting of the series of railroad articles now appearing in that publication.

Among other things concerning the fraternity, he says:

"Locomotive engineers and firemen read with avidity everything which is explanatory of the construction or working of locomotives, but generally have a contempt for things which have no practical bearing. They demand 'lucidity' in what they read with as much vehemence as Matthew Arnold did, and some editors and college professors, whose writing and thinking is foggy, would be greatly benefited by the criticisms of the Locomotive Brotherhood."

Mr. Forney also pays a tribute to, and gives a reason for the success of "firemen runners." As enginemen cannot pull cars with "foggy theories," why should they not demand practical reading?

The general crops of the country are better than they have been for years. Railroading will be lively this fall and winter. No one objects.

ASKED & ANSWERED

(46) T. T. Stratford, Ont., asks.

What is the longest road in Great Britain? *A.*—The Great Northern Railway operates the most miles of any corporation in the kingdom, having 2,455 miles in its system.

(47) Shake Bar, Mandan, D. T., asks:

Where do the big engines on the Northern Pacific get their name of "Decapod"? *A.*—Decapod means ten-legged, as a lobster or crab. The first decapods built were for the Railway of Brazil, by the Baldwin Works, and had ten drivers coupled; from this fact they took their name.

(48) 3-Way, Raton, N M., asks.

How does the new Westinghouse engineer's brake valve differ from the old one? *A.*—It has a loose piston below it, that opens and closes the passages to main air pipe very slightly, thus making the application of brakes smoother, when handle is operated between certain stops on valve, but has a large free opening around this piston for emergency stops. Not being obliged to compress a heavy spring, the cock handles easier than the old one.

(49) Fireman, East Tennessee, asks:

Does the crosshead of an engine move both ways when the engine is in front gear, and to what extent? *A.*—When the engine is running forward, the crosshead travels the length of the stroke both ways as far as it relates to the engine, but with its relation to the ground it travels faster going ahead and then stands still, or nearly so, while the engine runs past it as far as the stroke. Should the engine slip, the crosshead will travel back. When your engine is starting hold a stick on the ground even with crosshead when on front center, and you will find that it does not go back past it. Practically the crosshead travels full stroke both ways.

(50) R. T., Nat. City, Cal., writes:

Please give rule for finding the length of the link, the radius being given. *A.*—The radius has nothing to do with the length of links, except as the length of blades indirectly require more length if they are so short as to cause excessive slip. There is no hard and fast rule governing link length, but the almost universal practice in this country is to place the eccentric blade pins in link a distance apart equal to 2¼ to 2½ times the throw of the eccentrics, then the link has to be enough longer to clear the die or link-block and its slip when engine is working in the corner If your upper and lower rocker arms are of the same length, the travel of the valve equals the throw of your eccentric; if this is 5 inches, about 18 inches, inside measure, is usual practice for length of link.

(51) No. 14, Savannah, Ga., asks.

Would you kindly give me a receipt for cleaning engine brasses so as to retain their color? I am a fireman on the C. & S. Railway, in Savannah. *A*—No. 14 has asked a hard question, a good deal like the one requesting the size of a piece of chalk. Cab fittings that get hot will turn color, no matter what cleaning compound is used. The best known way to clean these brasses is to use flour emery, and let them turn color. Tripoli cleans very well; use water with it, and polish with dry tripoli. Rottenstone is one of the best powders to polish with after scouring brass. Oxalic acid, diluted with about six times its own weight of water and applied with waste, cleans tarnished brass very nicely. It must be washed off at once and the brass polished with some dry powder. Muriatic acid used the same way will make the brass a gold color. Bands, wheel covers and hand rails that do not get hot are easily cleaned with any of the above, and will keep clean much longer than cab brasses. A good deal depends upon the quality of the brass itself. Very white brass keeps clean easier than hard, red brass, especially if it does not get very hot. Some of the compounds sold for that purpose are good brass cleaners.

IN THE ROUNDHOUSE AND REPAIR SHOP.

The standard railway gauge of Spain is 5 foot 3 inches.

⁂

The members of Swannanoa, Div 267, B. of L. E., at Asheville, N. C., are establishing a lodge room, library and reading room. This is an investment that will always pay 1,000 per cent.

⁂

Master Mechanic Vreeland, of the Erie, Jersey City shops, has found that engines with extension fronts steam better and throw fewer cinders when the sheet that extends from the flue sheet, above the flues, to the deflecting plate, is replaced by a strip of netting.

⁂

The overhead ventilators on the "L" roads in this city are all handled by one lever placed near the door. Why would not this method be better for surface roads than the present grab-hook system that never gets any two alike, and is a nuisance to passengers as well as extra exertion for the cranker?

⁂

We notice that on some of the roads running into this city, where they use the big driving brakes regularly, that engines having moderately thin tires often have loose ones. There were shims sticking out on several wheels we noticed. Reminds you of the days of wrought iron tire and the tri-weekly setting bees.

⁂

Locomotive building at Paterson is lively, excepting at the Grant works, where most of the men have been laid off and only a few engines for the elevated road are building. Rogers' works are crowded with orders, and the erecting shop is full of men and locomotives. Cooke's works are also very busy.

⁂

The Richmond & Danville road finds it easier to lift the stacks to clean out nozzles than to open the front end and lower netting. A place to hang a light lifting tackle over each stack in the roundhouses, and the man who inspects and cleans out fronts provided with a lift, is all that is necessary to secure good results from this plan.

⁂

Several master mechanics, in private conversation at the recent convention, related experiences with different kinds of ash pans having window-shutter arrangements in the bottom, and the verdict seemed to be that they warped out of shape easily by the heat, and in winter were easily clogged up and rendered inoperative.

⁂

A person not familiar with the facts in the case, would think, to read some of the orders posted by railroad officials, or read some of the papers of the day, that men who sit at the desks of superintendents and managers are altogether different beings than the "employes." The general manager is as much of a "hired hand" as a track walker.

One of our engineering exchanges takes up the master mechanics' discussion of extension front ends and open stacks, and, in talking of locomotives, clearly gets beyond its depth; continually speaking of *expansion* smoke arches and *extension* smoke stacks, and calling the midfeather arch or water table a midfeather tube. And yet the editor of this paper used to be a locomotive engineer—probably on a horse boat.

⁂

Master Mechanic Gentry, of the Richmond and Danville road, believes that if a thing is worth using it is worth using right. He has success with brick arches, etc., and keeps a man at each roundhouse whose duty is to inspect grates, bore out the flues and pick all clinkers, etc., off each arch every trip. Requiring the fireman to do all this is putting too much work on him, and it is not always done when it should be.

⁂

Two English inventors have gotten up a locomotive feed-water heater that goes into the fire box, in place of the brick arch, and, it is claimed, absorbs heat now wasted in heating the arch. The brick arch gets white hot and aids combustion by having the gases passed over it, and it also keeps flues from leaking when the door is opened or when the fires are drawn.

The new design may heat the feed-water, but, if it does, it loses its value as an arch.

⁂

The O. R. & N. Co. have ordered some new engines that were designed by master mechanic H. N. Webber. The engines are for heavy mountain service, consolidation, and will have cylinders 20x24, driving wheels 46 inches diameter, and the smallest ring in barrel of boiler will be 63 inches in diameter. The boiler is 21 feet 9 inches in length, has 2,160 square feet of heating surface and 25 square feet of grate surface. Engine complete will weigh 126,000 pounds.

⁂

The locomotives of many Eastern roads have small cocks tapped into sides of water tanks over each truck box, and a hose arranged to drip into a hole drilled in box covers. There must be some good cause for so many hot truck boxes; insufficient bearing surface, rough or poor material. Many locomotives are running in the West that carry almost twice the weight of water and coal that ordinary engines do, and yet their truck boxes receive little attention, and only get hot from lack of ordinary care.

⁂

All the newspapers in the world have now had their slap at the mother-in-law, and she has come out on top a loved and loving institution. The brakesman who can't call the station names in English has got about half way through the line of quills. The tramp editor kept track of the vocal ability of six different brakesmen on a jaunt, last month, and five of them called with distinctness and regularity only equaled by a bill collector. The gafter is all right; these newspaper chestnuts want to sweep down the cobwebs and fish the cotton out of their ears.

⁂

M. N. Forney, in speaking of the use of some rule to determine size of boiler, at the M. M.'s convention, said that as good a rule as he knew of was to proportion the size of cylinders and driving wheels to the work and then make the boiler as large as possible for the weight allowed and the wheel base would stand. No doubt this is the right idea. There is no use in following some set rule of grate surface to size of cylinders, and then weighing the engine down with cast-iron lagging. Weight in the boiler kills two birds with one stone—weight for adhesion and abundance of steam room.

⁂

The new engines on the Caledonia Ry., Scotland, have fire doors that open inward. This class of door is well liked in Europe, and we believe will come into use here, as, when open, it deflects the air down onto the fire and makes it possible to see just how the fuel is being burned, and also prevents smoke; it takes up no room in the cab, and pieces of coal on deck, etc., do not prevent its being closed promptly when fire is in. Mr. Rufus Hill, M. M. of the Camden & Atlantic, designed and used a door of this kind, and the only one we know of in the United States.

⁂

The general agents for Pocahontas coal, Castner & Curran, 308 Walnut street, Philadelphia, have issued a neat poster in colors, to tack up in the cab. It has, in neat, large type, full directions how to fire their coal, telling its peculiarities, and a lot of useful hints on firing in general. All coal companies would do well to furnish cards of this kind to roads using their fuel. They are a great help to men not used to the peculiarities of different kinds of fuel. Directions how to make steam with some of the lignite that is used on some sections of the Mo. P. road, and not make pig iron of grates, would be doubly welcome.

⁂

At the Rogers Locomotive Works we noticed they were lagging the cylinders with asbestos mortar as well as the boiler. This is a point that is neglected more than it should be; if, in addition to the mortar around the cylinder, the sides and top of the steam chest, as well as both cylinder heads, were lined with hair felt, we believe it would result in enough economy to pay for the extra cost many times over. This company are also putting a strong iron hoop across under the eccentric blades, just back of the links, to keep them from striking the ground and doing additional damage should they become separated from the link—a simple little precaution that will pay for itself.

⁂

The writer recently stumbled onto a mechanic who was chipping and filing a locomotive slide valve and complaining because the shop had no planer or shaper to save him the work. He was delighted, and surprised to think he had not thought of it himself, when we told him of the old scheme of making a wooden frame the shape of the valve yoke and deep enough to hold the valve, and then placing this against the face-plate of a lathe, and centering the point of tail-stock in exhaust cavity of valve, to keep the rig in place, and driving it with a bolt or stud in plate. By this simple rig a valve can be faced off in very good shape for the scraper; all of which goes to prove that there are lots of simple little kinks that are old in one locality, but novelties in another. Let's trade kinks.

HAWKINS' PATENT JACK,

Lever and Toggle Joint Combined.

The Best Lifting Jack in the World for all purposes.

We also manufacture

A SPECIAL JACK
—FOR—
TRACK USE.

We expect to introduce these jacks on their merits, and on application will furnish one or more pair of any size to any responsible company on trial, billed subject to approval.

Communications by mail will receive prompt attention.

Manufactured only by the

RAILWAY SPEED RECORDER CO., Kent, Ohio.

THE

Curtis Pressure Regulator.

Reducing and Regulating Locomotive Pressure down to any desirable low pressure for Car Heating.

This Valve contains a novel combination of old and established principles; is *made entirely of metal;* occupies the same space as a globe valve, for the same size pipe, is a lock valve, is very simple and sensitive.

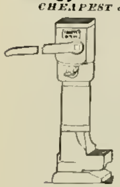
These Regulators have been in use on the Martin System of Car Heating for three years, giving excellent satisfaction, as our sales to them of more than 250 will attest. They are also in use on the Boston and Providence, Providence and Bristol, East Tennessee, Virginia and Georgia R. R., Boston and Albany, New York Central, etc., and on the Williames System, the Sewall System, and several others. Perfect satisfaction guaranteed.

All goods sent on trial and guaranteed as represented.

CURTIS REGULATOR COMPANY,
59 & 63 BEVERLY STREET, BOSTON, MASS.

Tangye's Hydraulic Jacks.

CHEAPEST and EASIEST to WORK.



No Valves or Springs to Stick in Lowering.

Lowering done by Key in the Side of Head.

REDUCED PRICES.

VOL. I. NO IX. NEW YORK, SEPTEMBER, 1888. $1.00 per Year, or 10c. a copy.

A New Piston Valve.

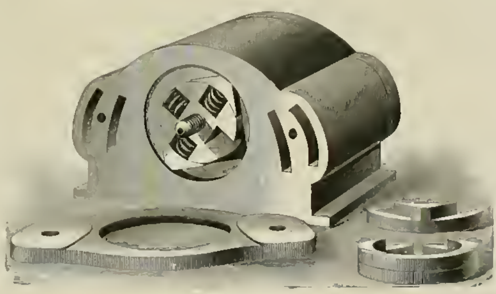
The piston valve has always been the subject of more or less thought by inventors. The perfect balance and ease of handling the engine has always been an incentive to the successful solving of the piston valve problem, but when they got into the business deeply enough they have always found practical obstacles that have made their inventions of no practical value. The chief obstacle has been that, to keep the packing rings of the valve from catching in the port and breaking, it was found necessary to make multiple ports—a row of holes instead of an open port. This, at best, is a bad device, and was alone enough to kill the piston valve for locomotives; another trouble was the proper relief of the valve and cylinder pistons, when running with steam shut off they became pumps that were constantly drawing dust and cinders into the steam chest and cutting the valves to pieces. An ordinary D valve will lift off its seat and relieve the pressure of air in the cylinder if the engine is shut off and the lever left hooked up, but the ordinary piston valve would not lift, and terrible pounding and consequent strains on entire gear were the result.

Thos. Tripp, of Boston, has recently patented and placed upon the locomotive "Onward," of the Boston & Maine road, a piston valve that seems to have successfully dodged all the difficulties on which former efforts in this line have struck.

In the first place, Mr. Tripp makes his valve and its chest go inside of the ordinary locomotive steam chest, and its stem can be attached to the present valve motion, the lead and lap of valve remaining just as it is now; the bottom of his valve case has ports that fit exactly the present steam and exhaust ports.

The large engraving on this page represents this valve case with relief plate off, with follower and one ring out of piston.

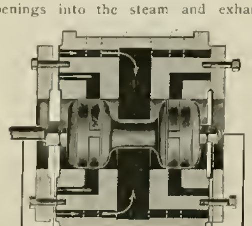
In the peculiar construction of the rings is one of the main features; there are several rings or sections of rings, but they are so made that each piece reaches across the space occupied by them all, which is wider than the open port, so that the valve with its rings travels clear across the port, giving a full opening. The construction



Tripp Piston Valve.

of the rings is shown on the right of the engraving; they interlock, and the four springs shown press outward on the wedge-shaped part of the segments, and it is plain to see that to push out one of these is to force out the entire ring; by breaking joints with these segments a perfect joint is secured.

The four long slots shown on the end of the cut are the relief passages, simply openings into the steam and exhaust



Tripp Piston Valve, Plan.

ports; these are covered by the large plate shown in front of the valve case, which is loosely supported by two bolts in the ends. While steam is in chest these are firmly pressed over these openings, as shown on right of sectional cut, but as soon as the pressure is taken off the plate drops away, as shown on the left, so that all pressure is avoided on any side of valve. These plates do not have to be removed to examine or repair valve, as it can be drawn through the large opening in the center.

The valve for a 17 x 24 inch cylinder is 5½ inches in diameter.

A moment's study of the plan view will make the construction plain. The steam pressure is on each end of the piston valve and the exhaust on both sides of the two inside heads, so that the valve is in perfect balance.

With the throttle wide open, steam pressure at 160 pounds, the reverse lever of the "Onward" can be thrown forward and back as easily as when the pressure is off. In running with steam shut off it makes no difference if the reverse lever is left hooked up.

These valves are made by the Tripp Anti-Friction Journal Bearing Co., 33 India Wharf, Boston, Mass.

An Awful Strike.

We are in receipt of a letter from a nervous gentleman, who asks us to let up and not try to have Colvin's plan of a twenty-four-hour clock adopted. He asks: "What in the name of the sufferin' Cyrus will we do when the old clock on the stairs wakes us up with its fire alarm of twenty four beats at midnight, only to be obliged to hear the bells and chimes of forty churches hammering twenty-four big welts each on a brazen monster that don't care a Continental cuss whether you sleep or not?" Maybe our correspondent can get the clock to call off its strike and arbitrate.

Many locomotives are running, especially in the East, with no provision for taking up slack between the engine and tank. The engines would ride better, and the crews last much longer, if they were provided with a good wedge arrangement.

90 Miles an Hour.

The crank with the square boiler and the ninety-mile-an-hour locomotive, built on a mathematical proportion to the gauge of the track, is still making 80 or 90 miles an hour with his scheme—in the newspapers. If it works half as well on the track as it does in the brains of the reporters, it will be a howling success.

The Boiler Explosion on the Reading.

On the first of August a Reading locomotive boiler "let go" at the 9th St. depot, killing the engineer and fireman and injuring several passengers. The engine was one of the new Baldwins, with standard fire box; and old railroad men, who have examined the wreck, inform us that it was a plain case of low water, and one of the worst on record.

The First Decapods.

We are in receipt of reliable information that even the meek and lowly editor of this journal is liable to err, the last instance being the statement that the Baldwin works built the first "Decapod" locomotive for Brazil. Our informant says that J. A Durgin, of Scranton, Pa., built two "Decapods" for the Lehigh Valley road in 1867; they were named the "Ant" and the "Bee," numbers 81 and 82. One pair of driving wheels have since been taken out of these engines and a pony truck placed at each end.

Ingenious Front Door.

Master Mechanic Thompson, of the Long Island, has many different makes of engines and many odd sized boilers, so that, to keep front end castings for all, required great expense and care. To avoid all this, he adopted a door that would go onto any boiler, and then fitted up a narrow casting for the door to swing on and fasten to. This is used for all sized boilers, and the odd sizes are fitted by the outside ring, which is made of wrought-iron. Only one sized door is carried in stock. The door and ring off any engine will fit any other engine; all that is necessary to fit to the odd sized boiler is the narrow circle of wrought-iron that any boiler maker can supply in an hour or two.

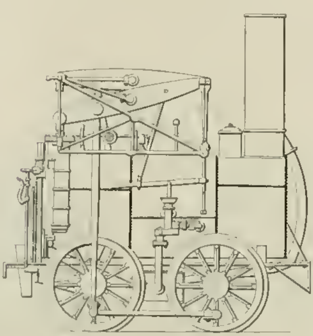
Cost of a Bridge Accident.

A couple of years ago the country was shocked by the awful calamity at the Bussey Bridge, on the Boston & Providence Railroad, in which many people lost their lives. The last claim against the company for death or maiming has been settled, all without a suit, and the Boston & Providence Co. are out on this item alone over one million dollars. This does not include cost of new bridge or rolling stock. But with all this waste of money they cannot buy back the lives sacrificed. The railroads have increased the weight of engines and cars more than double, doubled the length of trains, doubled the weight of rails, doubled the number of passengers, doubled the amount of stock, and placed them all on top of the old wooden bridges—because these bridges have not broke down before. Our railroads need more stone arches, steel bridges and stone ballast. American railway rolling stock is the heaviest and finest on earth, and we have the poorest road beds to support it. Less watered stock and more permanent ways are in demand.

Disconnectors.

When there is a break-down on the road, the way things are fixed up, and the delay caused, generally show what kind of timber there is in the engineer.

Some men seem to know just what to do to get their engine into running order, and to avoid delays both to themselves and others, while the man on the opposite run goes crazy if he gets off the track and is helpless and at sea if he breaks an eccentric strap, a piston, or a pin. A very good plan for firemen and engineers is to study every break-down that occurs on the road If Hogskin Thompson was running wild ahead of the cannon-ball and broke the left crosshead, knocked out a cylinder head, and bent the rocker-arm, put yourself in Hogskin's place and figure out how you could protect yourself and everybody else, get your engine into running order, and out of the way of the cannon-ball and opposing trains, in the least possible time, and with safety to all. If there is a class of engines on the road whose eccentrics are not on the main driver, if there is one with radial valve gear, or hook motion, look her over, talk about her, and *think;* you may have to run her some day, and she may lay down and "put you in the hole" because you did not know your business



STOURBRIDGE LION. (FROM AN OLD PRINT.)

The writer knew a youthful runner, who got to running several years before he ought to, that disconnected both sides of his engine because she would not move either way while off the track with her forward draw-head fast under a 50,000 pound car of steel rails, not a bolt broken or out of place.

We saw an old engineer walk up to a Mason-Farlie engine one day, and look long and earnestly at the Walschaert gear, when, turning to his fireman, he said:

"Bill, supposen you was running this side-wheeler, and you struck a car that didn't clear, and knocked off about half of this riggin'—what would you do?"

"Disconnect her," said Bill, promptly.

"All right, what would you take off?"

"Everything on this side but the side rod," said Bill, "or I would ask the fireman to move her and take off everything that moved. Couldn't miss it that way, could I?"

"Now, I'll tell you what I'd do," said the engineer; "I'd just telegraph in to that master mechanic and tell him to send me a general assortment of wiggle-rods and wimble-bars for his duplex side-wheelers, then I'd pick out what I wanted in place of broken ones and go on. I wouldn't let no 'ornery, dog-oned scrap like that stick me. That's the point, boy; never get stuck, never—how much wealth did you say you had? Fifty? That's the skedual boy, that's her—less eat."

Historical Locomotives.

SECOND SKETCH.

We present to our readers, with this article, illustrations of the remains of one of the most interesting pieces of old machinery in America The boiler and one cylinder of the "Stourbridge Lion"—the first locomotive that ever turned a wheel on the American continent.

There has been so much written about this engine, and so little of it was in any way reliable, that the editor of this paper decided to investigate in person, and get views of the remains of the engine, and not sketches from memory of how it looked when in running order.

It has been stated in mechanical and in railway papers that the cylinders were in use in a coal mine and the boiler in a foundry at Carbondale, but we find these statements not true

Let us begin at the beginning In the first place, it was necessary to be certain that the relics shown were really the remains of the first engine. At Carbondale, Penn., we saw the signature of Horatio Allen, the man who ran the engine on her trial trip, stating that the boiler there shown was that of the "Stourbridge Lion." Mr Allen is still alive, and has several times told the story of his first ride

Mr. Allen was a civil engineer, employed by the Delaware & Hudson Canal Co., and was much interested in newspaper accounts of trials of locomotives on the Stockton & Darlington railroad in England, and in 1828 he decided to cross the Atlantic at his own expense and see what was going on Just before sailing he was entrusted by the Delaware & Hudson Canal Co. with the selection and purchase of three locomotives.

He visited England, witnessed the trials of the yet unsuccessful locomotives, and ordered his machines, confident that locomotives would be, in a short time, the prime movers of land travel.

The Stephensons had not yet made a

success on the Liverpool & Manchester road, as the "Rocket" had not yet been built. Mr. Allen bought the "Stourbridge Lion" of Foster, Rastrick & Co., Stourbridge, and two other locomotives of the Stephensons that were the prototypes of the "Rocket," and they were shipped to New York, arriving in May, 1829, were set up, and one, the "Stourbridge Lion," was sent by canal to Honesdale, Pa., and there placed on the track—wooden sleepers with iron straps on top.

On the 8th of August, 1829, the engine was fired up, and the crowd present declared that it would not go around the curves of the road, although it had a rigid wheel base of not over eight feet. Mr. Allen had never handled any kind of a steam engine before, but he took the levers of the "Stourbridge Lion" in hand and ran her three miles into the country and returned in safety.

The engine was found to weigh seven tons, instead of four, and was considered too heavy for the track. This was the only mileage she ever made as a locomotive.

Mr. Allen says that, had one of the Stephenson locomotives been sent, he is satisfied that America would have had the glory of a first successful trial instead of England.

After this trip, the engine was placed in a shed at Honesdale, and laid there for several years, then she was brought over the gravity road to Carbondale, and side-tracked for a long time.

At Carbondale we met Mr. David Smith, a man upwards of seventy years of age, who remembers when "us boys" used to play on the old engine and admire the lion's head painted on the boiler front.

About 1834, the Canal Co. sold the old engine to John Simpson, a founder. He dismantled her and set her boiler in a brick arch, firing under the shell, and using the old fire-box flue as a smoke flue; one cylinder he converted into an upright stationary. This boiler and cylinder remained at work in this shop until 1871.

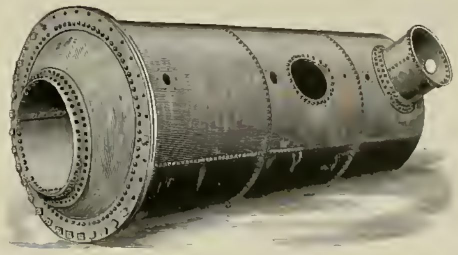
Patrick Early served his time in this foundry, and in 1869 bought out his employers, and he is now the senior partner in the firm of Lindsay & Early, stove founders, and the owners of the boiler and cylinder. In 1871 Mr. Early found that the old boiler would not make steam enough by using one ton of coal per day, and replaced the boiler and engine with modern devices, using one ton in five days.

In 1883, S Dottier, then M. M of the D. & H C Co., borrowed this boiler and sent it to the Exposition of Railway Appliances, Chicago, and there, or in transit, every flange that could be broken off with sledges and chisels was carried off by relic hunters.

The large cut shows the boiler as it now is. It is 4 feet in diameter, 10 feet 6 inches in length, the large flue shown in the back end is the fire flue, and is 2 feet 4 inches in diameter and 4 feet 2 inches long, branching out into two flues laying side by side, each 19 inches in diameter; these come together again near the front head, and a single smoke flue comes from their union up through top of boiler for the stack.

There was never any repairs made to this boiler, and it is seamed and pitted badly; it has no stays of any kind; all seams are single-riveted, nine rivets to the foot; all the sheets were of half-inch iron.

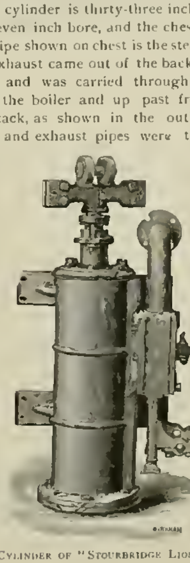
Mr. Early says that when he was a boy in the shop the safety valve often lifted with three and four times as much weight on the lever as the ball. The front head is oval, bulging out six or eight inches. There were two gauge cocks on back head, and a lead safety plug in the top of fire flue.



Boiler of "Stourbridge Lion," as it is now.

The boiler was never lagged, and will weigh about 4,500 as it now stands.

The cylinder is thirty-three inch stroke and seven inch bore, and the chest 11x11 The pipe shown on chest is the steam pipe The exhaust came out of the back side of chest, and was carried through a pipe under the boiler and up past front end into stack, as shown in the outline cut. Steam and exhaust pipes were the same size. The engine was of the walking-beam type, afterward called "grasshoppers." The wheels were of wood, shod with iron. Of the valve motion little is known—it was probably stolen off before the engine was sold for a stationary; the crosshead shown was not used on the locomotive The cylinders were bolted to the side of the boiler, not the head. All the pipe connections to boiler were made by flanged joints, and the bolt holes punched in the boiler are square; there is a large manhole on top, but no dome.



Cylinder of "Stourbridge Lion."

One peculiarity of the boiler is that it had no flanged sheets; there is an angle iron flange used at all joints, as can be seen at the joint around smoke flue, and also around the fire flue; the front head has a ring inside, and the back head has a heavy wrought ring riveted to it, and there is an angle iron flange riveted to the shell. These two are held together by bolts. These bolts were all out but four or five under the fire-box, and in 1883 Mr. Dottier put in new bolts to keep the boiler in shape. On the trip these were most all stolen out, and are, no doubt, now preserved as relics of the "first locomotive."

As might be expected, Mr. Early has had many offers for this interesting relic, but he says that he does not like to see it buried in some museum, where only a few wealthy can see it, and hopes some opportunity will present itself whereby it can be exhibited throughout the country before it goes into a national museum.

It is wonderful, when we come to think of it, that this old boiler furnished the power to propel itself before any of the 30,000 locomotives now running here were even invented, let alone being built

It is wonderful to think that the vast railroad interests of America have grown from this old hulk, and the little strap road in Pennsylvania to their present magnitude, within the life and memory of the present generation.

It is still more wonderful to think that the man who declared to the directors of the South Carolina Railroad, before even this engine was bought, that "there was not much hope of very much improving the present breed of horses, but that no man was alive who would live to see the end of improvement in the steam locomotive," and who afterward opened the first throttle-valve in America, should be alive and well to-day, and able to contemplate the vast growth of the age of railroads that sprang from the germ he furnished when he turned the steam onto the "Stourbridge Lion," August 8th, 1829.

The Westinghouse Company have "absorbed" the American Brake Company of St. Louis This puts the new air brake into the hands of the Westinghouse people; there has been considerable hope expressed that the new brake would be a lively rival of the automatic, but it seems that we have heard the last of it. The American Brake Company will still manufacture their steam driving brake, the Westinghouse Company guaranteeing a certain percentage in dividends on their capital stock.

The Dean Guide.

We are in receipt of a letter from Mr J. W. Dean, of Cambridgeport, Mass., inventor of the Dean guide, confirming the statement made by Mr. Lauder, before the Master Mechanics' Association, that an engine equipped with this guide had been in active service for over five years without any perceptible wear Mr. Dean also says that, to all appearances, the guide will run ten years more without lining up.

If some company would manufacture this guide and guarantee a service of five years without lining up, it seems to us they could do a land office business, and get big figures for their work.

On the Right Track.

The engineers of Truckee Div., No. 158, at Wadsworth, Nev., have invested $250 in a fine, Richardson valve motion for their lodge-room. There will be more of this in the next five years than there has been in the past twenty, and it is well that there should be Some day the officials of the roads will decide to hire or promote men on competitive examinations only, and they will find the men ready. Other States may take a notion to follow the lead of Alabama, and require locomotive engineers to pass an examination and carry licenses—if they do, they won't have to import engineers.

The Tootophone.

An inventor has patented a device to which he has given the above name; it is to register the number and length of all steam whistle signals blown, and is expected to settle all disputes as to whether proper whistle signals were given in case of accident. On locomotives, tugs, and river and harbor crafts, it is expected to do considerable good. This may seem to be another foolish invention, but it is much better than the average, and if in use would do away with many disputes as to whether proper signals were blown or not, and where the officials must take one man's word and not the other's; the tootophone will only tell the truth, and the truth won't hurt anybody. We would rather have a pair of toot registers on our smokingine than a spotter that lies about the toots, or a spark arrester that prevents raising steam enough to toot with.

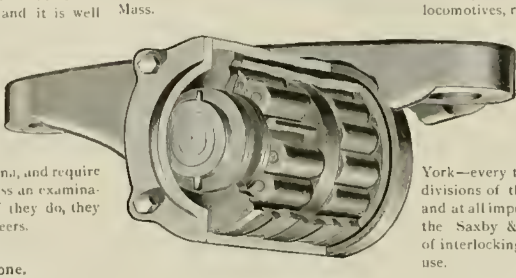
The Tripp Roller Car Journal.

We illustrate herewith a new form of roller bearing, designed for car service that seems to have overcome some of the difficulties encountered by other bearings.

The main trouble with roller bearings has been that, as soon as the outer case was worn away at the top, the loose rollers did not crowd up so that they were in line with the axle. In the Tripp journal bearing the rollers are short sections of steel tubes, and are all mounted on pins inserted on each side of a ring; the rollers at the top keep the ring in motion, and it brings up the rollers from below always in time and in line with the journal. These rollers run on a sleeve on the shaft, and not on the shaft itself, and on a ring in the box, and not on the box itself. It will be seen that, by this arrangement, those details, and not the expensive parts of a journal bearing, like a box or shaft, will be worn out. The collars on outside of shaft that holds the friction rings in place are provided with pressed paper gaskets, and the method of packing to prevent oil from escaping from box is fully shown in the engraving.

These bearings are designed for any kind of a car, and have been tried on one of the street car lines of Boston, showing a very light draft. The makers guarantee that they will run, in any service, one year without oiling.

For further information, address Tripp Anti-Friction Journal Bearing Co., Boston, Mass.



The Swinerton Locomotive.

When the Swinerton Locomotive came tip-tapping along with 105 flat spots and 41,000 pounds on her single pair of drivers, this paper was taken to task by some of the Boston stockholders for condemning a "new departure in locomotive practice before it could be tried." So we agreed to keep still for six months, which we have done.

We have watched this engine's performance, and find that she has spent as much time on the jacks as on the road, that her flat spots have got their corners knocked off, and that she has never made twenty-five miles at a stretch without getting her driving boxes too hot for safety. She has had some of her weight transferred from the drivers to other wheels, and new axle and driving boxes.

The engine was built in direct defiance of two well known laws of mechanics—the inventor claiming that increasing the area of the surfaces in contact increased the adhesion, and that he could carry much more weight on a single pair of driving wheels than exhaustive experiments had shown could be carried. In both of these attempts he has failed. For long runs, or fast runs, when there is more than 15,000 pounds on each driving box, it will be found a tender spot.

Much interesting correspondence is crowded out of this issue.

The Bazoo Car Heater.

An escaped lunatic, or his equivalent, has patented a car heater that goes at the problem in a new way. This inventor extends out in front of the locomotive a pipe having a large bell mouth; this pipe extends through the boiler in a zigzag line, and it is expected to thus heat the air that passes through this pipe, and warm the cars by hot air. As quick as the merits of this device are thoroughly known, it is more than likely that steam car heating devices will be for sale cheap, and stoves can be had for hauling them away.

Novel Features of the New Long Island Locomotives.

To the majority of railroad men the Long Island Railroad is an unknown quantity, and generally considered small, yet it does an important business.

The Long Island is a standard gauge road, 356½ miles in length, and using 120 locomotives, running over 800 trains daily; of these less than a dozen are freight trains, the rest being passenger trains During the busy hours, from 6 to 10 A M. and from 3 to 7 P. M, trains arrive and leave Long Island City—opposite New York—every three minutes. Most of the divisions of the road are double tracked and at all important stations and junctions the Saxby & Farmer (English) system of interlocking switches and signals are in use.

To successfully handle so many passenger trains the system of orders and signals must be good, the motive power must be kept up, and the locomotives must be manned by first-class men. The Long Island seems to have all these requisites.

The road is an old one, and of course has some old engines, but these are mostly used for switching purposes and light runs.

Master Mechanic C. A. Thompson has been in charge of the motive power for more than 21 years; he was formerly an engineer, and the handy devices found on his engines show that he knows what is needed. The Long Island is one of the pioneers in the use of extension fronts, having used them 14 years.

The Rogers Locomotive Works, Paterson, N. J., have recently built a number of locomotives to Mr. Thompson's designs that have some novel features, especially to engineers. On page 5 will be found a cut of the cab of these locomotives, and the Long Island engineers think they are as good as the best

The engines are 8-wheelers, and the engineer's seat is about midway between the driver's, and higher up than on ordinary 8-wheeled engines; the cab proper is made of wood, and has no projecting roof behind, and sets far enough ahead on the boiler to let the latter project out behind it about three feet; this brings the dome up through the cab, and behind the engineer; he is up on the wagon-top, and can see across the boiler much better than of old; it has been found that the engines ride much better at this point than at end of boiler.

Bolted on behind the cab is a hood of iron, covering up boiler head and extending over gangway, to protect the fireman from storms; its roof slopes toward the other cab, and at the apex has a ventilator that carries off all smoke and gas. Immediately under the dome there is a water glass, with self-closing cocks; in front of the engineer there are three gauge cocks, and there are also three on the back head, for the fireman's benefit, and to keep night men, watchmen, etc., from going into cab to try water and smoking up everything with their torches. The throttle is convenient, and the lever that handles the Luttgens damper, in the base of the stack, is immediately under the throttle. Of this damper Mr. Thompson speaks very highly.

There is a steam gauge on the boiler head for firemen, as well as one for the engineer. Two Hancock inspirators are used, and are placed in convenient positions.

They use the Westinghouse or Smith vacuum brake on cars, using the regular Westinghouse air couplings on hose, and have two lines of pipe and hose running through trains, and two accordion cylinders, attached to alternate trucks. On the engine are used two Eames ejectors to produce a vacuum; they are in front part of cab and connected by levers, so that in applying or releasing one both are operated; they can be handled from either side of the cab. With this arrangement one-half the brakes can fail, and yet the train be under full control, and by using two ejectors they get a very quick application and a quick release.

As will be seen, the windows on either side of the cab are very large and roomy, the sash sliding both ways and fastening together in the center—by this plan the runner can make the size of the window fit the weather.

All steam connections in cab come out of a turret located on top of boiler and between the brake ejectors; this fountain has a main valve that shuts off steam, or in case it is broken off closes automatically.

Another novel feature of these engines is the manner of hanging the driving springs to the box. Fig. 2 shows the plan adopted; it consists of four heavy flat hooks, that hook into pockets cast on top of the box and are joined together at bottom as shown; over the pocket formed at the bottom by the four hooks is fitted a cast-steel shoe that supports the driving springs. This arrangement does away with the bolts in bottom of box, admits of a larger cellar, and is easier to repair than the old style.

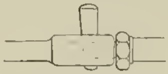


FIG. 3.

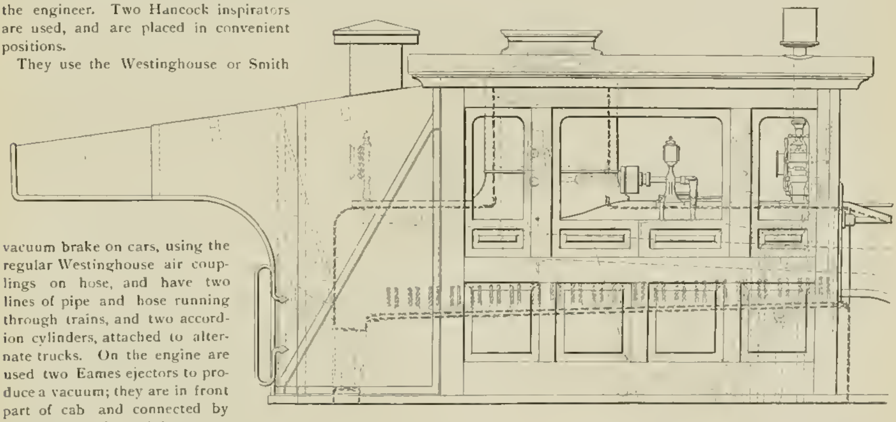
Another nice little trick is shown in Fig. 3. Every engineer who has had to disconnect a valve rod from the stem knows that in about nine cases out of ten the fit has rusted fast—there are coal-pick marks on 11,000 valve stems in this country attesting to this fact. Mr. Thompson puts a nut ahead of the union, and abutting against the rod sleeve; a single turn of this nut will force the connection apart. This is one of those little things that some people call "traps," but they save delays and dollars, even if they are made "especially for engineers."

The engines have cylinders 17x24, using a solid head and three rings, Richardson balanced valves, Laird guides, and solid-ended side-rods of I section.



CAB ON LONG ISLAND LOCOMOTIVES.

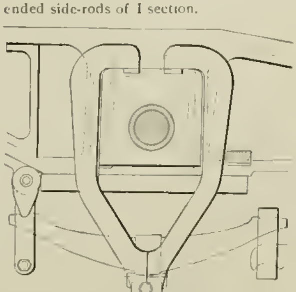


FIG. 2.

The crank-pins are hollow, having a brass plug screwed into the outside end and small holes drilled through to face of pin; these hollow pins are filled with cold tallow, and on the least inclination to heat they get tallowed automatically from the rear.

The engines have light iron pilots and are finished with brass, notably the cylinders, wheel covers, hand rails and running boards; the paint is all black except a light stripe on wheel centers and bumpers. They present a fine appearance. On the older engines the jackets are painted black; they look as well as the Russia iron, do not rust and require less cleaning.

The ash pans have three pockets, slides are connected together. The tender has no brake beam behind it, in the way of coupling to other engines, etc.; the top of the tank slopes to the center, so that the coal on back end of tank comes to the fireman and not the fireman to the coal.

These engines have iron-clad running boards, to prevent broken rods, etc., from reaching the men. They have good seats, good arm-rests, and ample room for men's dinner pails and store clothes. Mr. Thompson is very proud of his enginemen, and says they are contented, careful, competent engineers and firemen, and that it is impossible to successfully handle an important traffic with any other kind.

A Crew of Honor.

The Pennsylvania Railway officials did a neat and appropriate thing when they selected the train crew that were to take the remains of General Sheridan from Jersey City to Washington. The entire crew served under General Sheridan in the civil war. The engine, the 705, was in charge of engineer Jos. Kelly and fired by Jos. Rude; Wm Branson acted as conductor, Samuel Craig as brakeman, and H. Heberton as baggage master. It was indeed appropriate that men who once rode in Sheridan's historic cavalry should be selected as the pall-bearers in the long railway march of their commander's funeral train.

We welcome to our columns Clinton B. Conger, Mechanical Engineer, Board of R'y Commissioners of Mich.

Correspondence

Travel of the Crosshead.

Editor The Locomotive Engineer

In the August number of your paper, on page 11, is an answer to "Fireman" of East Tennessee, who asked, "Does the crosshead of an engine move both ways when the engine is in front gear, and to what extent?" This answer, while in the main correct, yet is in error when it says, "and then stands still, or nearly so, while the engine runs past it as far as the stroke." This could be true only if it were possible to have a wheel whose circumference was no greater than the full stroke of the piston. By full stroke I mean the forward and backward motion added. Thus, for instance, if a wheel had four feet circumference and two feet stroke, making four feet full stroke, back and forth, when the piston left the back center in forward motion it would move ahead (as related to an object on the ground) four feet, till it reached the forward center. Two feet of it would be the stroke, and two feet of it the result of the rolling wheel. From this point (forward center) till the back center was passed, the piston would stand still, to take another four feet jump in going over the top, and so on. But it is evident that a wheel having two feet stroke must be more than 4 feet in circumference, and therefore, in ordinary practice, no crosshead or piston "stands still or nearly so," but they will move ahead with different rates of speed. Take a wheel say twelve feet in circumference, which would be a trifle less than four feet in diameter. For every half revolution of the wheel the engine will move six feet ahead, and twelve feet for each whole revolution, but the piston and crosshead do not move with the same uniform speed, for in passing from back center to forward center the piston and crosshead move six feet with the engine, and also the length of stroke ahead of the engine, and with a two foot stroke the crosshead would move eight feet in this half of the revolution, but in going from forward to back center, the engine travels ahead on the piston and crosshead two feet, and while the wheel rolls six feet the two feet which the engine has gained leaves but four feet of movement for the crosshead, but, as eight and four make twelve just as surely as six and six, we find all parts in the same position as at first. In the case referred to, therefore, the piston does not stand still, but advances continually with greatly differing rate of speed, it being twice as fast in passing over the upper half of the wheel as it is while the pin is passing under the axle.

VULCAN.

[Correct, Vulcan; have su'thin.']

Feed-Water Heaters.

Editor The Locomotive Engineer

Are you not a little hard on new inventions? Sometime ago you done up feed-water heaters in a way that, to say the least, was rather convincing; but have you examined into the merits of the new device that simply forces the feed water through a system of pipes surrounded by the exhaust? Is this taking necessary heat out of the front end?

St. Albans, Vt. G. M. BOY.

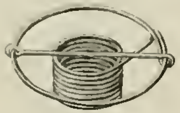
[We know of no new invention such as you speak of; the idea of forcing the feed water through a system of pipes enclosed in a box open to the exhaust was invented in 1859 by Wm. S. Hudson, of the Rogers Locomotive Works; it was given a long trial and abandoned. A feed-water heater on a locomotive doing less work than she was capable of might save a little fuel, but numerous experiments have satisfied many able researchers that they would not pay for maintenance, let alone first cost.]

Wool Holder for Link Blocks.

Editor The Locomotive Engineer

When I read that article on Link Blocks, by J. Alexander, I concluded that I had just the thing he was looking for to hold the waste in the block and lubricate the sides of the link.

I make a coil of spring wire like the sketch, and spring the smaller coil into the counterbore or oil hole in the link, and allow the larger ring to hold enough under it to lubricate sides of link. I have



made many sets of them, and they are in use here on the Alabama Great Southern road, and if the boys don't let up I will have to quit firing and start a factory. They will remain in place all right, but can be instantly removed by the fingers. I send you a pair, which please forward to John Alexander, with the best wishes of

Chattanooga, Tenn. J. R. DOWD.

They Help Themselves.

Editor The Locomotive Engineer

I have been a constant reader of THE LOCOMOTIVE ENGINEER. On its start I felt very doubtful of its future success, thinking that the field was already more than filled. But I cheerfully admit (although I take and have access to eight different mechanical and railroad periodicals) that I have already learned to take a deep interest in reading it, and feel that it comes nearer home to the real needs of locomotive men than any publication that I know of. And I predict for it, if carried on on the same practical, common sense principles, success unbounded.

At Como, the district terminal of our road, is located the Union Pacific Employes' Library Association, No. 1, of Colorado. It is supplied and maintained by the company. Employes who desire membership pay 50 cents per quarter dues.

It affords the boys spacious rooms, well warmed and lighted; a large collection of the most desirable books for railroad men; quite a list of daily, weekly and monthly periodicals, games, writing material, etc. It is just such a place as railroad companies ought to encourage more, and men ought to patronize more than they do. Some of the boys conceived the idea of building a model, showing the workings of the locomotive valve gearing, showing the effect of displacement of parts, or distortions of construction. Our librarian, Mr. C. C. Moritz, who is an expert mechanic, and skilled in the use of drawing tools, made the drawings on a scale of three inches to the foot of a standard American engine. I was to do the iron work, and the boys were to chip in to pay for material. We had the work fairly begun, when Mr. M. F. Egan, our Div. M. M., found out what we were at, offered to complete it at the company's shops, after our drawings. I think if railroad officials would follow Mr. Egan's example by encouraging such things among their men, that it would be money well invested by the company. The men would be more valuable, contented and skilled in their business, and the company receive better service.

I may, if you desire, in the future, tell you more in detail of our model.

W. W. HALL.

Denver, Col.

[Come again, Bro. Hall; this is the kind of work we like to see and encourage. Can't you send us a blue print of that model?]

Air Brake Abuses.

Editor The Locomotive Engineer.

Have been reading with interest the article on air brake practice in August number. We can't just agree with one statement we find in it. that the reduction of air pressure necessary to make a stop depended on number of cars in train, rate of speed running, and kind of grade approaching stopping place. This is all right, except that part relating to number of cars.

We would like to know what difference the number of cars makes as to the reduction of air pressure in train pipe to make a stop. On a train of twenty cars it is necessary to exhaust more air than with five or ten, but the amount of pressure need not vary. We claim this on the ground that in each case all things outside the number of cars are equal.

We recently took a few lessons in an air brake school car, and there learned several things we were not aware of before. If all engineers who have the handling of the automatic could have access to these cars, and would profit from what they learn there, we are sure there would be less complaint about the rough handling of this, one of the best appliances ever placed on rolling stock.

Some other time we want to write of some things we saw in the school car. If all who read the articles in the ENGINEER would follow the suggestions there they would be greatly benefited. There are too many men to whom it makes no difference how they do a thing, just so they get there at last; and in the use of the air brake we can find plenty of illustrations. Not long since we were deadheading over the road, and a gentleman whom we were conversing with remarked that there was a great deal of difference in engineers handling trains. He said this when the engineer, in stopping, made everyone bow to the ones in front, and in starting would start the rear coach first. There is no necessity for this. The brakes are so made that, with a little care on the part of the ones handling them, there need be no complaint. H. S. H.

Denver, Col.

A Leaky Throttle.

Editor The Locomotive Engineer.

It is astonishing what little things on an engine will sometimes make no end of trouble. I remember we got a new engine and she was troubled with the diabetes or gravel. If she stood ten minutes or more there was a pool of water under the cylinder cocks, and if she stood long the engineer would shut them to save the water, but the cylinders, steam chests and pipes got full. We decided there was a leak in the throttle, so the boys took the dome off and hauled her out and scraped and ground for half a day, and we decided it was tight, and put it in again, but still the leak was there. So we decided there was a leak in the dry pipe, either in joints or rivets. So the first chance out came the dry pipe, but no sign of a leak could be found. To make sure, we made a long ⅞ rod, put a nut on each end, and put it through the dry pipe. A 2-inch piece of pine board with a hole in the center was put on each end and the nuts drawn tight. A piece of ¾-inch pipe was screwed in one end and the test pump attached, and 100 lbs. pressure put on, but no leak. The joints were re-ground and all put in with the greatest care, but when steam was up the leak was still there. What to do next was what got the boys, until some one suggested that perhaps the bolting of the throttle pipe to the inside of the dome might draw the throttle seat out of round. So the next chance we got the dome was taken off and some red lead put on the valve and tried in; and "there lay the divil," as the boy said, pointing to the bottle as his father lay dead on the roadside. It was scraped and ground in its place and that ended that trouble. It was badly fitted to the dome, and the bolts sprung it out of round.

Another trouble with many of the heavy engines is, the steam pipes or passages have a low place, where, if there is any leak, the water settles, and will get full up to the valve face, and as soon as the throttle is opened the rush of water often starts the joints, knocks down packing, throws water out of the stack and all over the jacket and cab. We tried to cure one of these sick kittens once. We tapped a 1-inch pipe into the lowest part, above the pilot truck on each side, and led the pipes to a reservoir 12x6 inches at the back of the cylinder saddles. A 1-inch cock was put in the bottom of this reservoir and piped through the frame to near the back cylinder cock. The handle of this 1-inch cock was connected with the cylinder cock rod, and when they were opened this drain cock also opened, and the reservoir being the lowest, drained the pipes.

The sense of touch is very important to the engineer as well as to the blind man. At night he may often, by his feet on the foot-board, detect a broken wedge-bolt and wedge down, or a loose key in a connecting-rod. When locomotive inspector I often found cracks in connecting-rods on the lower side that I could not see, and no doubt saved many a poor fellow from being elevated. If there is a crack, the constant vibration will raise a small ridge on each side of the crack. I would advise engineers to make it a rule, firemen, too, as they oil round, to run the hand over the rods. Valve stems and the spokes of driving wheels ought to be run over every week. "A stitch in time saves nine."

Watertown, N. Y. J. J. Bingley.

Valve Motion Stickers.

Editor The Locomotive Engineer:

Referring to your August issue, your article on setting slide valves stops just where I hoped to gain some information. You say, "If the engine is well designed" the travel of valve will be right at an early cut-off, the same as at full stroke. I have found many engines that could not be made to show equal travel over each part with lever at different points of quadrant, by changing lengths of eccentric rods; that is, if the valve was divided right at full stroke, it would not be right when the lever was cut back, the error increasing as the center of quadrant was approached.

Please give me information on this point, and oblige

Wilmington, Del. "A Reader."

[The radius of the link and the point of suspension being wrong are the most common reasons for the trouble noted. We would like to hear from correspondents on the best remedy.]

Breaking In Engines—Modern Shop Practice—Lead Bearings.

Editor The Locomotive Engineer:

I notice in your interesting August issue an item referring to our practice in "turning out" engines which require little "breaking in." In this matter you will undoubtedly recall that it is but a few years since when a regular course had to be gone through to reduce an overhauled engine to a proper sense of duty. Today it is no uncommon thing with many, and the regular practice with us, to put the engine *at once* into regular service, without any preliminary trial trips or switching in the yard, the engines starting off and giving absolutely no trouble in any way. The reasons for this are to be found in the difference in the manner of doing work now and a few years back, and principally to the abolishment of the "scraper."

A scraper fit means a close, accurate fit, and such fits mean excessive friction until the bearing faces have obtained elbow room by the "breaking in" process. Now it seems rational *not to* inoculate the engine with disease and force it to go through a preliminary bout with the same to reach a state of good health. The first step is to do away with the "scraper" and to put up all work with sufficient original freedom. You may just as well give the engine this freedom at first, because she will help herself to it any way. On side rods having keys and main rods, we bore out the brasses two thicknesses of Russia iron larger than the pins. One thickness of this iron is placed between the joints of the brasses before they are bored out in the strap. When "put up" this leaves the horizontal diameter of brasses one thickness larger than the pin, and the perpendicular diameter two thicknesses larger. This latter enlargement prevents the brasses closing or nipping on the pin, and the rod runs cool from the start. The brasses "go up" just as they come from the lathe. The driving brasses have a little fitting done with file only.

Eccentric straps are bored out similarly to rod brasses, using heavy tin in place of Russia iron. The slight "oblonging" of brasses and eccentric straps is an important element in starting them off cool. No scraping is done on eccentric straps. Rocker arms are put up so they may be given a whirl by hand, before connected, and revolve three or four times from the impulse.

When solid engine truck brasses were used and bored out they were a source of continual grief, as we all remember. The principle of using a soft metal like lead, hardened with antimony when necessary, and letting the fit be made by *pressure* in place of by a mechanical fit, is capable of wider application. As before stated, a solid *bored* out engine truck brass is certain to run hot.

But if the brass be taken as it comes from the sand, having a dove-tailed recess cast in its crown, two inches wide, running the full length of the brass, and this recess be filled (by casting) with six to eight parts lead to one of antimony, the filling projecting three-sixteenths of an inch from the brass, with generous oil holes through it, it may be set down as an assured fact that such brasses will run as cool as can be desired. The filling is soft enough to "flow" by the pressure to a perfect fit with the journal, thus getting the desired results without mechanical aid. Metallic piston and valve stem packing is generally made of hard metal, requiring to be bored out. But if an ordinary stuffing box and gland be used a metallic packing, having all the virtues of the several patented devices, and at a cost of 50 cents for the engine, lasting eight to ten months, may be had, if the principle of "fits by pressure" be taken advantage of. The writer has used with greatest success coned lead rings, a piece of rubber hose being first placed in the stuffing-box, like a sleeve, the rings coming inside of this. The rubber gives the slight spring necessary. A swab or oil cup must of course be used on the gland, as all metallic packings require constant lubrication.

Engineers, as a class, are a "set" class of men. There are exceptions, of course. New ideas are not taken to kindly An engineer who has been used to making 10 to 15 miles to the pint of oil will at once say it is impossible to make a greater mileage. Why? Simply because he believes what he says. But fit his engine with needle cups, set them before putting on, so that they will drop two to three drops per minute; give him cans with spouts having but one-sixteenth inch holes, insist that he run ten miles beyond his usual station for oiling before he takes a can in his hand; ten miles further the next trip, and so on till he is running his engine 50 to 60 miles without the smell of an oil can, and that engineer will go on and improve his oil record till he shows 35 to 45 miles to the pint of oil. It requires an effort to get the man out of his rut, but once out, and he will in nine cases out of ten say he never could understand how he once believed 15 miles to the pint was all that could be done on *that road*, when he is now running twice that, etc., etc. If the tender trucks be packed with wool, from one to two quarts of oil a month will suffice for the whole tank, *provided* the dust guards are good and the packing be stirred up every two or three days and kept in contact with the journal by new packing placed *under* the old. Hot tank boxes are then the exception. Wool is undoubtedly the best material to pack tank, driving box and engine truck-boxes with, because its natural spring keeps it in contact with the journal. Where a railroad allows nothing but cotton waste for this purpose, the engineer should, for his own comfort, buy a pound of wool and have a little of it under the journal. Cotton waste soon becomes soggy and lies as flat as a gob of mud in the bottom of the oil box.

FRANK C. SMITH, M. M.

Mattoon, Ill.

Gentry's Oil Mover.

There are few railroad shops in the country, especially on roads using air brakes, where there is not now a system of pipes and a pressure of air. It is used to fan fires in cold engines, run drills on boiler work, test brakes, etc., and the longer the air is around, the more uses it is put to, and the more money it saves.

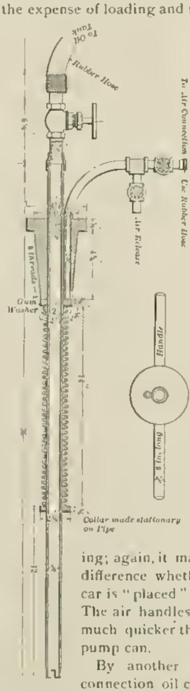
T. W. Gentry, master mechanic of the R. & D. division of the Richmond & Danville road, uses it for many purposes, and is the inventor of the tire heater that uses gas from crude oil forced through a system of pipes by an air blast—the device was shown up in these columns.

It was the custom at Mr. Gentry's shops to buy engine, signal and coal oil in barrels and pump them into large tanks at the oil house. The old plan was to pump, or elevate the barrels above the tanks and let the oil run into them by gravity—either plan is common practice, but requires lots of strong and ignorant labor.

Mr. Gentry now handles all the oil by air pressure. He drew up a plan of a barrel attachment and had one made, and the device is herewith illustrated.

As will be seen, there is a taper plug threaded to screw into the bung of any barrel; this plug carries beneath it the extension pipe that is made to go to within ¼ of an inch of the bottom by the coil spring; on the right is the air opening to the barrel, and above the plug the air hose connection. The plate above the plug carries two handles, as shown in small figure, to enable the manipulator to screw it into the barrel.

By using long lines of hose it is no inconvenience to handle oil from any out-of-the-way place, the cellar to second story or vice versa; indeed, it is the practice at this shop to empty the barrels of oil without removing them from the car, thus saving the expense of loading and unloading; again, it makes no difference whether the car is "placed" or not The air handles the oil much quicker than any pump can.



By another special connection oil cars can be loaded and unloaded in the same way.

Pressure can be applied to the large tanks in oil house, and the man in charge won't have to pump, dip or swear.

The cleanliness, efficiency and economy of Mr. Gentry's plan is enough to recommend it to any railroad master mechanic.

The sizes are all given on the drawings here shown, and any mechanic that can get to the scrap heap and a lathe can make one in a day. Mr. Gentry finds that, with any oil that will not move with 40 or 50 pounds of air, it is perfectly safe to knock the hoops off the barrel and send for a man with a shovel.

Some of the Wabash engines are "Black Marias" in the fullest sense—even the bell is painted black.

A Poor Steam Gauge, a Poorer Engineer, and a Progressive Fireman.

Editor The Locomotive Engineer

August number here and very interesting. I desire to ask you two questions. I have fired this locomotive three years and four months, and when I tell you it is the only locomotive I have ever had any experience with I trust you will attribute my ignorance to that fact.

1st What is the cause of a steam gauge getting light, *i. e.*, showing less pressure? The gauge on my engine (an Ashcroft) has been in use about one year. About a month after it was put on I noticed, when starting my fire, that the pointer stood at 5 lbs., and it has been growing lighter (if that is the proper term) all the time, and now (Aug. 5) the pointer indicates 95 lbs (the engine is cold). To-morrow the pointer will get around to 200 lbs. and then not blow off, as the pop is set at 110. Will running a boiler over frequently affect the gauge? My engineer runs her over daily, frequently three and four times, sometimes so much so that he lets the water out at the blow-off cock.

2d. This engine is supplied with a Hancock inspirator. Do you think it right to leave the throttle open when not working water into the boiler? My engineer leaves the pressure of steam on the inspirator all the time, and there is a cloud of steam coming out of the waste-pipe continuously, and grows worse daily.

E. C. SEVERSON, Fireman.

Chumuckla, Fla.

[The usual reason for a Bourdon (bent tube) gauge getting weak is because the tube gets hot, generally because there is no coil or trap in the steam pipe below it; when there is such a pipe, water, and not dry steam, comes in contact with the spring tube. If you take the hand off your gauge when the engine is cold, and place it back to 0, it will not be far from right The proper way would be to test it by a good test gauge. Perhaps the pop might be wrong.

If your engineer is in the habit of flooding the boiler three or four times a day and filling up until he is obliged to blow off, he is unworthy the title of engineer. We doubt if such work injures the gauge, but it strains and cuts and ruins a locomotive, and gives a fireman plenty of hard work cleaning. 2d. It is customary to leave globe valve open on inspirators. If the slide valve under the top cap (next to steam pipe) is tight, it is your check that is blowing at overflow; if it is the check instead of main valve, the instrument will be slow to start. From the observing and inquiring tendencies shown by this young fireman, we are inclined to think he will eventually make a sensible engineer. He is certainly entitled to a better pattern than the high-tide gentleman on his right.]

Geo. L. Perkins, treasurer of the Norwich & Worcester Railroad, celebrated his 100th birthday on Aug 5th. Mr. Perkins has been in his present position continuously since 1838. Some people think railroading is unhealthy. We should like to see a freight brakeman 100 years old ourselves.

Hot Axles.

Editor The Locomotive Engineer:

Hot axles, next to a poor steaming engine that can't be cured, give an engineer more annoyance than any other difficulty of a fast trip.

For the engine trucks, if a piece of old carpet or blanket—either is good enough if it is all wool—is cut off as wide as the inside of the truck cellar is long, and long enough so that when rolled up in a tight roll two rolls will just fill the cellar, and lay one each side of the journal, it will save lots of trouble and packing on the road. The advantage of this way is that the woolen carpet will soak up full of oil and keep the journal well oiled all the time. Then, as it is elastic, as fast as one thickness of carpet is worn through a fresh surface comes up against the journal. If the cellar is down from the journal, as they are certain to be after the brasses are worn, the packing cannot come out, as the whole roll will not string out a little at a time, as waste does, and when it wears down so the packing is not snugly against the journal, put a small roll in between the other ones and it is all right for a long time. If the holes for the bolts through the truck-box and cellar are worn large, get new bolts made that will fill the holes tight and make a good job of it in the shop, so you won't have to do anything to it on the road. Take a small bucket of slacked lime along with you and use that freely in packing hot journals.

While hot truck axles are scarce on roads where the ballast is good, steel smooth, and money enough is paid for brasses to get good ones, yet lots of runners who whale away over muddy roads, poor track, poorer brasses, and no brains at the head of the department to manage affairs, smell something hot every trip.

There have been several very good items about defects in air pumps, and the last one hits the fact about the trouble with most of them, viz.: the steam passages somewhere are stopped up. On one road they follow the practice of reducing the size of the exhaust pipe so the steam cannot get away from the pump freely "so it won't pound," and then they turn on the steam full head to keep the air pressure up to sixty pounds, when half of the live steam is used to force the other half out into the smoke arch. Their pumps last about as long as anybody else's, but they don't pump half as much air. There are a great many air pumps that won't go very well, but never a one of them but what had a good excuse for its poor work. Where every Tom, Dick or Harry is allowed to monkey with the air pumps the trouble is on hand all the time, but where one intelligent thinking man has charge of them all, he can "get onto" the disorders of the air pumps in a much shorter time, and fix them so they will work O. K.

In the August number you notice the fact that on some of the engines running into New York city, where the driver brake is used on thin tires, that the tires show signs of stretching and getting loose, but you do not say whether it is on account of the brake or thin tire. There are a great many steel tired wheels running under coaches and tenders whose tires are much thinner than is safe under a locomotive, and subjected to very heavy braking service at every stop, and they don't get loose. Why is it?

C. B. CONGER.

Lansing, Mich.

[Most coach wheels that have come to our notice having thin tires, had a flange on the inside that was bolted to the web of wheel.]

Metallic Packing for Air Pumps.

The packing here shown is the invention of Peter Dufresne, a machinist in the Connecticut River Railway shops at Springfield, Mass. It is placed in the present stuffing box in place of the fibrous packing and loose gland, the present nut holding it in place; the coned lead rings only come in contact with the rod; it is not touched by hard metals. The packing is simple, and saves lots of trouble on the road, and the scoring of rods by hard, dry packing. Its construction is easily understood from the cuts. The device is in use on a number of engines on the Connecticut River Railway, and giving entire satisfaction. It can be seen there, or further information had by addressing the inventor.

Air Brake Practice.

BY J. E. PHELAN.

In treating of air brakes and general practice it should be remembered that one kind of service should not find a place in the reader's mind, but general practice be considered at all times. General practice includes bob-tailed passenger trains of two or three cars; heavy passenger trains of nine to fifteen cars; freight trains with old style triple valves, ten to twenty-five cars; old style triple valves, and new style quick-acting triple valves, mixed in working freight trains, and the full train of fifty cars, more or less, equipped with quick-acting triple valves. The principle of practice most successful with all will be found in aiming to secure the best results with the least amount of air, excepting for emergency stops or to avoid accident. The lighter the reduction to apply brakes the better the results in even work.

A serious fault in applying brakes in general practice comes from engineers lacking confidence in their brakes, and not knowing what to expect when a certain reduction in pressure has been made from train pipe.

Engineers should allow sufficient time and distance to insure safe and gradual stops. Those who reduce pressure in quantity to force brakes to apply abruptly, so that a sudden slackening of speed is felt, are always having trouble and using more air than the ordinary pump can supply.

If the engineer reduces a certain amount of pressure from train pipe, allowing it to flow out evenly and gradually until three to five or eight pounds have been reduced, he should then blank his engineer's valve and wait with confidence the gradual slackening of speed that must follow if brakes are in good order. Care in this particular should be especially exercised in handling a mixed lot of air equipment, where old style and quick-acting triple valves are in use with old style engineer's brake valve. Where an engineer is careful and very cautious about reducing pressure from main pipe to apply brakes of both kinds, good results follow. But if the engineer's brake valve is tackled suddenly, and a large quantity of air let out to apply brakes of quick-acting and old style triple valves mixed, the train comes up standing; air has gone from train pipe, air gauge indicator dropping 15 to 25 pounds in addition to that escaping through engineer's valve, and the uninformed for the moment don't know where air has gone.

In this particular it should be understood that the quick-acting triple valve and old style triple valves act exactly the same in response to light reduction of air in train pipe, but when an unusual or heavy reduction of air pressure (10 or 12 lbs.) is made from train pipe, with the old style triple valve, it simply opens a larger passage for air to flow from auxiliary reservoir to brake cylinder; while with the quick-acting triple valves it allows air to flow from *train pipe* to brake cylinder, at same time opening larger passage for air to flow from auxiliary reservoir to brake cylinder in addition thereto.

Where the two equipments are working together, setting new brakes strong enough for air to flow from train pipe to brake cylinder, in reducing pressure in train pipe, so much more adds to sudden and hard application of old style brakes. The new brakes utilizing air from train pipes in setting brakes is cause of sudden reduction of train pipe pressure on air gauge, without a corresponding amount passing through engineer's valve. Except for emergency stops or to avoid accidents, the sudden application of brakes is a wasteful practice, and should be avoided. When properly and economically handled, old style and new style automatic brakes work well together. For emergency stops they are reliable, but for effective and economical work skill is necessary in handling, especially with old style engineer's brake valve.

It is reported that the Government of Chili will build 700 miles of road at once.

Photography in the Repair Shop.

The general foreman of a large railroad repair shop in the West has written this office, asking where he can purchase a cheap, easily handled photograph apparatus, and says that it is his belief that in ordering repairs, especially for foreign cars, such a rig would save a great deal of correspondence, and the expense of many drawings.

There is the germ here of a labor-saving, time-saving and mistake-preventing device. We hope to soon see it brought into general use. There is many a tool, or jig, or crane rigged up in one shop on a road that the other shops want; there are no drawings of it, and it would cost more to make drawing than the rig was worth, but if there was a photograph rig handy—and as many "views" of the concern as was wanted would cost but a few cents each and require no time or skill to make them—"kinks" would be more common than they are, and THE LOCOMOTIVE ENGINEER would find it easier to get hold of them.

When odd sized forgings or castings are made, a photo with sizes marked on would be a useful help if it was desired to duplicate them, and save expense of drawings.

The photograph outfit would be a reliable and truthful witness if it could be got to testify at wrecks; it would keep a record of damage done by fire, and keep the boys from lying about the depth of snow on turn-table during "the blizzard."

Fast Time.

There has been a trial of speed between the two principal roads running between London and Edinburgh, resulting in a victory for the London & Northwestern, "West Coast Line," over the Great Northern.

The distance via the West Coast Line is 400 miles, and by the opposition line 392 miles.

The winning engine was a single driver machine of 27 tons weight, and a 7 foot 6 inch wheel; she hauled a tender of 25 tons weight, and four coaches, weighing altogether 80 tons; 24 pounds of coal were burned for every mile run. The train stopped 20 minutes for lunch, and made the run, exclusive of stops, in 7 hours and 25 minutes, beating the noted "Flying Scotchman," of the opposition line, 8 miles in distance, and 7 minutes in time.

There were bursts of speed of over 72 miles per hour, and the average running was 52.6 per hour.

This is announced as the regular summer schedule, and not a fair day exhibition.

In this country we have no trains making any such time regularly. Many runs have been made, for the one time, that were about equal to, and some better than this one, but the public get no benefit of such speed. The best performance we know of in this line was that made on the West Shore road on July 9, 1885, when the run from Buffalo to Jersey City was made in 7 hours and 27 minutes, a distance of 426 miles, and spurts of speed as high as 83 miles per hour were made. This run brings the average running up to 54 miles per hour, so that the English claim of the fastest run in the world falls short. There is an undoubted record of every mile made on the Buffalo & West Shore run.

What will particularly strike the American engineer, is the light weight of the locomotive and cars, and the heavy tender; we are inclined to think the locomotive must have weighed more than 54,000 pounds. English roads run very light cars on their fast trains, while the faster the train in America, the more the average passenger will kick for the luxurious sleeper and parlor car.

The cars hauled by this fast train in England were 20 tons each, 80 tons for the entire train, while in this country the ordinary 52-foot passenger coach (8-wheeled) weighs upward of 52,000 pounds; a 12-wheeled Pullman sleeper weighs 86,300 pounds, while a parlor car weighs 80,600. It will be seen that the weight of three ordinary American coaches would almost equal the English four, while two Pullmans would be heavier than their train.

The Buffalo & West Shore engine was of our well-known 8-wheeled, or American class, weighing 83,000 pounds and having driving wheels only 66 inches in diameter. English engines "get there" in good shape, but give us the same road bed and weight of train, and the "loose-jointed American bogie" will lick them every day in the week, Sunday included.

A Birthday Party.

On the 17th of last month the Brotherhood of Locomotive Engineers celebrated the twenty-fifth anniversary of the birth of the organization, in the city of their nativity—Detroit.

In the morning there was a secret session, at which Grand Chief Arthur explained the present situation on the Q. In the afternoon there was a crowd at White's Opera House, and speeches were made by Acting Mayor John Considine, Governor C. G. Luce, Grand Chief Arthur, Rev. Chas. Reilley, Genl. R. A. Alger, Hon. J. W. McGrath, Col. J. Atkinson, the Brotherhood poet, P. Fennel (Shandy Maguire), and the founder and father of the order, W. D. Robinson.

There were several jolly old plug pullers there who were there at the "bornnin'" twenty-five years ago, and they smiled and looked as happy could be.

In the evening two pleasure steamers were lashed together, and 1,500 engineers, with their wives, mothers, sisters and ownest owns, danced away the hours from 7 till 12 on the Detroit river.

On the 18th the two steamers were again lashed together and the entire party taken up the Detroit, through Lake St. Clair and the river by that name, and landed at Oakland, fifty miles away, where a splendid dinner was served in a pavilion in the park; an ox had been "barbecued," and was now carved.

On the down trip the upper decks were cleared, and dancing was indulged in till the twin steamers touched again at the Detroit wharf.

John McMinn, chief of division No. 1, and his committee, were untiring in their efforts to make everybody happy, and in all the party we heard nothing but praise for the way the whole plan was carried out. There was not a single hitch.

In twenty-five years the Brotherhood has increased from 12 to over 30,000 members, it has raised the grade of temperance and morality of engineers, it has raised wages from $60 per month to from $100 to $150, it has established an insurance that has paid out to widows and orphans alone in 11 years, $2,582,169.61 They have also procured a side saddle for the goat, and there are now many lodges of Lady Engineers, Auxiliaries, they call themselves, and there were lots of them at the party.

It is our sincere hope that the coming quarter century will bring with it as much good and as much improvement as has the past, and that all who celebrated in 1888 may be spared to dance in the head set at the birthday party in 1913, that will surely meet at the portal city of the unsalted seas.

The Pennsylvania's Compound.

It is announced that the Webb compound locomotive, built in England for the Pennsylvania Co., has been completed and will soon be at work on that line. Some of our railroad exchanges have expressed their conviction that it was a shame and a disgrace that this engine was imported instead of being built at home The English roads are the only ones that have made very many experiments with compound locomotives, and they claim great saving in fuel for them, and we are of the opinion that the Penna. Co. did just right in ordering one of the best they had, to try on our hilly roads, and with our fuel, instead of building it themselves.

If a man should attempt to sell you a patent washing machine and made certain claims for it, you would in no way be testing the merits of his machine by having one built as near like it as you could, just because the machine was built in an opposition town.

Let them send their 3-barreled locomotive over here, and send the best engine driver in the Queendom to run it; we will give them a fair show, and if they can prove that the compound is any better than the ordinary high-pressure engine, we will speedily find American mechanics to build and American engineers to run, anything better than we have got. When the compound tackles the Pennsylvania "K" on her own dung-hill, and with her own fuel, she has got no walk-away.

A Heavy Guarantee.

As a rule, when a man claims too much for a device, we are inclined to feel as if it were a frantic effort to sell his contrivance. But when a man offers to do a certain percentage better with his device than you can possibly do without it, or no sale, there is no argument against his proposition but to let him try.

Pedrick & Ayer, of Philadelphia, are the makers of the St. John patent piston packing—the invention of a Maryland mechanic—and they have given it a number of very long and severe tests in different service, and have recently submitted the following proposition to Mr. Alexander Mitchell, M. M. of the Lehigh Valley R'y, at Wilkesbarre, Pa., which, so far as we know, is the strongest guarantee on piston packing outstanding, or any other locomotive device—barring traction increasers and feed-water heaters:

They agree to let the railroad select an engine and give her all the load she can pull up the mountain from Wilkesbarre to Glen Summit with her present packing, then change to St. John packing and add two loads to train, and if she don't make the same time as she did with lighter train, the packing or the experiment to cost the Lehigh Co. nothing.

Pedrick & Ayer are not in the habit of making failures, and if they can back up this offer with results, no railroad could afford to be without the packing, if it had to be made of sterling silver.

One Hundred Pound Rails.

The Belgian state railways commenced experiments some three years ago, in the use of rails weighing 100 pounds per yard, when they laid 300 tons of this heavy steel. Results have been so satisfactory, that last year 10,000 tons were laid, and this will be the standard rail of that country

There has long been a belief in America that there was a happy medium in rail weight, somewhere. The believers in this idea mentioned as one of their arguments that the first strap rail wore out only where they crossed the stone blocks, and that the ends of heavy rails are pounded out of shape as easily as lighter rails; they claim that all heavy rails are, to a more or less degree, anvils, on which the locomotive wheels can beat with disastrous results. There is no doubt that the weight of rails should bear some proportion to the loads they are required to carry. Sixty-pound rails are not heavy enough for locomotives weighing upwards of 100,000 pounds.

We hardly think the 100-pounders would look out of proportion under some of the late build of locomotives with a six-foot boiler.

The Brotherhood of Locomotive Firemen hold their 14th annual—or rather first biennial—convention on September 10th, at Atlanta, Ga. The B L. F. has at its head able men, the rank and file are the flower of the land, physically and mentally, and we always hear something good of their conventions. Without forgetting the other grand officers, who seem to have been born for their places, the order rejoices in and is especially proud of the Grand Secretary and Treasurer, Eugene V. Debs. Mr Debs has had for years the money affairs of the entire order in his hands, and has handled hundreds of thousands of dollars that belonged to the widows and orphans of deceased brothers, and not a single penny has there gone astray; he has been City Treasurer of Terre Haute, and not had to go to Canada; he has represented his district in the legislature, and his voice was always raised in defense of the right and in denunciation of the wrong. Mr. Debs is also the editor of the *Magazine*, the official organ of the order, and his editorials are the ablest and more widely read than those of any labor organ in America The firemen are the first to meet, and will be the first to act in regard to the proposed federation of railroad orders, and, while older orders ought to lead in these matters, we feel confident that the B. L. F. will acquit itself with wisdom, dignity and honor.

N. W. Sample, Supt M. P. & R. S, Denver & Rio Grande R. R., called at this office a few days ago. Mr. Sample is the railroad father of the editor of this paper, and, no doubt, feels much like a hen that has hatched out a duck—dislikes to see it drown because it don't know enough to keep out of the water.

Geo. W. Cushing also called on us; the last time any calls were made we called on Mr. Cushing—to ask for a raise of pay for the firemen on a road under his management We had a clear case of justice, and got the raise.

ASKED & ANSWERED.

(52) Penn., Philadelphia, asks:

How is it that the exhaust injector can be used on locomotives? You said in an article some time since that they would not work where boiler pressure was above 70 pounds *A.*—Where the exhaust injector is used on locomotives there is a supplementary jet of live steam used.

(53) 75° Phillipsburg, Pa, asks:

Where does the 60° or inter-colonial time commence to be used? I see some of the time cards of roads running into New Brunswick and Nova Scotia say "Eastern time." *A.*—Inter-colonial time is not in use. Eastern time is used from the western boundary of Pennsylvania (or above the 82d degree of longitude) to the Atlantic seaboard.

(54) D. E., Troy, N. Y, asks:

What are the principal difficulties in the steam heating problem, aside from the locomotive? As far as the cars are concerned, are there any problems yet unsolved? *A.*—So far as we can see, there is yet to be invented some successful and sure means of getting rid of the water of condensation. Steam heating will not be universally successful until a standard hose coupling is adopted, so that cars of different roads will be interchangeable.

(55) Fireman, Boston, Mass., writes:

Does the term "enginemen" include the firemen? Our superintendent has pasted the following order: The term "enginemen" does not include firemen. Firemen riding on the road without a pass will be expected to have a ticket or pay their fare. *A.*—The fireman is as much of an engineman as the engineer, and if the engineers ride without passes, tickets, or money, the firemen should. We know of no other road where the firemen are not considered enginemen.

(56) Subscriber, Fabyan House, N. H, asks:

Will you explain through your paper what is meant by "mogul engine," what is there different from the rest, and how it derives its name? *A.*—A "mogul" has six wheels connected, and a single or pony truck distinguishing them from a ten-wheeler, having six wheels connected, and a double truck, four wheels. We do not know where the name originated; perhaps some reader with more gray hair can inform us.

IN THE ROUNDHOUSE AND REPAIR SHOP.

If you are pumping oil by main strength and ignorance, read the description of the dumb pumper on another page.

***

Last month we gave the credit of Forney's article on Locomotives and Cars to the *Century*, when it should have been given to *Scribner's Magazine*.

***

There are over 9,000 stuffing boxes on the Pennsylvania Railroad packed with the U. S. metallic packing. Think of this, John Alexander and the rest of you who are picking sticks and braiding hemp every other trip.

***

On the D., L. & W. R'y passenger trains are hauled by hard coal burners, having short front ends and diamond stacks. There is more trouble from dirt and cinders in the cars than on many roads using soft coal and using the extension front and straight stack.

***

Pedrick & Ayer, of Philadelphia, Pa., makers of special tools for railway repair shops, have favored us with a work of art in their new catalogue, illustrating and describing every tool made by the firm. It is a 75 page typographical and mechanical beauty, and with no dance-house fringe on it

***

At the Long Island City shops of the L. I. R'y they have a "balancing pole" on the turn-table, a slim, brightly painted pole on each side, and in the center of table they tell the engineer where he is, no matter how dark or foggy the night. The old way of waiting till she "teeters" is not always safe.

***

In the patent office there quietly slumber several patents for preventing locomotive driving wheels from slipping. Most of them have some kind of a sifter arrangement to carry dust, ashes or cinders from the smoke-box to the rail. Dust is a good thing to slip on; fine charcoal dust will make a locomotive slip about as bad as grease.

***

The management of the estate of F. W. Richardson, Troy, N. Y., are very busy and have been for a year past. They have recently built a large brick addition to the works, that will give them much needed room for machinery on lower floors, and a large, airy drafting room above. They manufacture balanced valves, valve gear models and safety valve springs.

***

The new engines on the Erie have the hand rails extended through the cab. Men who have run locomotives whose boilers come through the cab will appreciate the new grip, if it will keep brakesmen and others from resting their hands on injector throttles, and often shutting off a fine opening the runner has set for a heater—this is awful weather to talk about heaters.

***

The car builder who invented the new style of window that will only raise about eight inches, leaving the lower part of sash directly in line with the eyes, ought to be cremated in one of his own sweat boxes. Companies that have cars varnished with a sprinkling pot, thus gluing the windows fast, should furnish crowbars to enable passengers to raise them.

In stationary practice, corn meal, bran, sawdust, or some similar stuff, is often put in a leaky boiler to close up small leaks, and sometimes does so. Once in a while an engineer will try the bran mash cure on a locomotive, but it seldom does any good; more of it finds its way to the throttle than to the leak. Next to calking the flues, a hot wood fire is the best remedy for leaking flues.

***

We are under obligations to Angus Sinclair, secretary, for a report of the proceedings of the twenty-first annual convention of the American Railway Master Mechanics' Association, held in June. The book contains 221 pages of reading matter with many engravings, and the able way it has been gotten out in such a remarkably short time reflects great credit on the ability of Secretary Sinclair.

***

The military railroad men who served the government during the war are talking of organizing. They think that "the part performed by them was of as much importance as that of those who did the fighting." They ask, "What would the armies have done without railroads and railroad men?" Well, it is the high privilege of the military railroad men to organize, for manifestly they helped to save the Union.—*Locomotive Fireman's Magazine*.

***

The Wooton fire box engines on the Delaware & Hudson Canal Co.'s road have one fire-door opening, three feet or more long, in the center of the box, instead of two doors side and side. This long opening is covered by two doors swinging to each side. There is no doubt this large opening is better than the two doors when it comes to the hard work of cleaning fires—something that has to be done pretty often with fine anthracite coal.

***

J. & J. B Milholland, of Pittsburgh, Pa., have begun the building of light locomotives for the general market, and will hereafter make it an important department of their business. One locomotive built by them eighteen years ago is still in active service. About seventy-five of their wire rope haulage plants for mines are now in successful operation, the latest improvement being, by means of one large sheave, to haul a line of 60 to 80 cars around a right angle, without need of the series of sheaves formerly used, and the consequent need of cutting away the ground for a curve of long radius.

***

The Canadian railways have doubled in length in ten years, being now over 12,300 miles. The number of passengers carried has increased by 66 per cent, and the number per inhabitant by 40 per cent.; the number of tons of freight carried increased by 107 per cent., the number per inhabitant by 97 per cent.; the receipts by freights increased by 87 per cent., and from passengers by 86 per cent, while the total receipts from all sources increased by nearly 90 per cent. and the expenses by nearly 72 per cent. The tons of freight carried last year amounted to 16,368,000, and the number of passengers to 10,686,000.—*Ironmongery*, (Eng.)

The Northwestern Railroader has changed the color of its overcoat from yellow to lavender of delicate paleness—that's right; when you wear clothes, wear stylish ones. THE LOCOMOTIVE ENGINEER prefers to just tackle this weather robed only in a smile. It all depends on how you were brought up.

***

Our correspondent, Jos. Wormald, has been returned to the charge of the N. P. shops at Sprague, Wash. T. He has been m. m. at Missoula, Mont. T., for some time, and in leaving there was presented by the motive power employes with a fine gold watch. This is an improvement on being hung in effigy.

***

We are in receipt of a copy of the fourth edition of Grimshaw's Pump Catechism, a book containing much valuable information for all who have anything to do with steam pumps. It is written entirely for practical men, and we know of no other book in the same field. That it has reached a fourth edition is evidence that it is appreciated.

***

The Cumberland Valley Railroad has a special car for furnishing electric light at picnics and camp meetings, and for removing wrecks after dark. *Engineering News* says: "It is a common box car, strongly built, in which is an 8½ h. p. boiler and engine, which runs a 15 arc lamp dynamo. Each lamp is 2,000 candle-power. There is a globe rack, a reel containing three miles of insulated wire, and all appliances necessary, including a coal box of three tons capacity, and water tank of 1,000 gallons capacity. The car has air-braking apparatus, and has been very useful. In one year it paid for itself in the increased sale of tickets to picnics and camp meetings. The Pennsylvania Railroad also hired it to light up the removal of a bad wreck at Duncannon. Such a car would be useful on almost any railway.

***

During a trip of over a week in which we traveled over more than twenty divisions of eight different roads, we took especial pains to note the way the automatic brake was handled, and found that there was a vast difference in men. On the Central of N. J., and the Reading, the brake was handled particularly rough In all the trip there was but one man, on the Pennsylvania, N. Y., division, who invariably applied the brake with release till stop was made and had air releasing while train came to a stand-still. Most of the others jammed on the brake on approaching a station, released it while everybody held their breath, ran into stations fast and threw brake on full while passengers changed seats and were thrown down by back lurch at final stop. Most of this is want of proper instruction, the rest is habit and carelessness. Many of these men would be benefited by a perusal of the air-brake papers now running in this paper by an expert engineer J. E. Phelan.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. X. NEW YORK, OCTOBER, 1888. $1.00 per Year or 10c. a copy.

Packer's Roller Truck for Locomotives.

The object of this device is to aid locomotives in going round sharp curves, and with an easy motion. Where only the ordinary trucks are used, the front end of locomotive has a tendency to be lifted up in passing a curve, thereby throwing a severe strain on frames, and also causing excessive friction on wheels and track.

The device here described consists of a traveling carriage composed of four steel rollers for each truck, together with the necessary shafts and side connecting links. Suspended from the shafts are four hangers, the lower end of each being attached to the springs which carry the center casting of the locomotive or motor. The traveling carriage thus formed runs on side rails of truck frame, the travel being limited by adjustable blocks, as shown in cut. (See Fig. 2.)

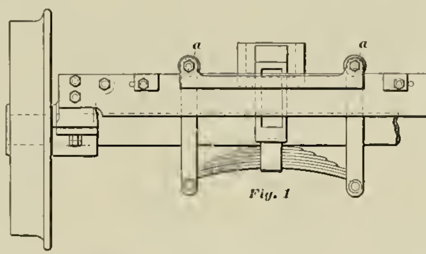

Fig. 1

When a locomotive equipped with this device is passing a curve, the front end of locomotive swings toward outside of track, causing the carriage to travel until the side links strike the blocks or stops, these blocks being adjusted to suit the curves on road where it is to be used.

If, however, in any case, in passing a specially sharp curve, further travel is required than may have been provided for by this adjustment of blocks, this further travel is supplied by the swing of links.

The patentee of this device is A. C. Packer, No. 118 Forty-fifth St., Pittsburgh, Pa., who is a practical locomotive mechanic. Several locomotives equipped with it by H. K. Porter & Co. are successfully running on curves of 35 feet radius.

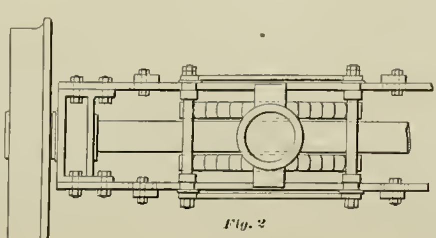

Fig. 2

The Pennsylvania standard sand box is located in the wheel cover and below the running board, being filled through a hole in the latter. It is noted for wet sand and profanity.

Worked Before They Were "Broke In."

The Central R'y of N. J. have erected two large switch towers at Elizabethport, at the junction of the Newark and Long Branch divisions with the main line. One of the towers contains 33 levers, and the other 23, the pair costing over $30,000. On Saturday, the 22d of Sept., the company issued their rules, governing the code of signals to be used, and proposed to put the system into use the following day; to this the engineers objected, saying it was not time enough to become familiar with the signals. The officers then asked all engineers and firemen not on duty, to assemble at Elizabethport on Sunday, and witness a practical trial—they did. One of the split switches failed to answer the lever, and an engine and several loads of coal turned their toes up to the daisies in the ditch.

As it will take one week to repair the damage, the men will have time to study the rules.

The accident is no fault of the system or invention, but the result of haste in putting a complicated device into actual service before it was properly "broke in."

The convention of the Brotherhood of Locomotive Firemen, just adjourned at Atlanta, Ga., declared in favor of the federation of the members of all orders of railway employes, and appointed a committee (with full power to act) to confer with any committees that the other orders may appoint. The committee are: P. F. Sargent, Grand Master; J. J. Hannahan, Vice Grand Master, and E. V. Debs, Grand Secretary and Treasurer. No other order can appoint any abler men.

Editor Wheaton, of the *Conductors' Monthly*, was away last month, and that craft was commanded by the second mate, who very ably poured a couple of volleys into the pirate craft of the Pinkertons. This is one loaf of bread among the many stones in the conductor's pantry.

It would be a blessed thing for the order if Editor Wheaton never came back.

Fatal Changes.

It is now believed by many engineers that the explosion at the Reading depot in Philadelphia was caused principally by a change of injectors and the method of placing them. The man had never handled the engine before—she was new. He had been used to a Sellers injector—the new engine had a Monitor outside the cab, with the overflow pipe turned into the ash pan. The engineers think that he started the injector and throttled it down to work fine, then getting the sound of steam in top gauge cock for water, and knowing that the injector was on, he felt safe, if the steam pressure goes down considerable an injector will often break by shooting the water out of overflow very fast, showing no steam, and if the drain pipe would carry it to the ash pan it could easily fool a man. Where injectors are located outside of cab, we believe the overflow pipe should discharge where engineer can see it; if it is inside and the overflow open, then the drip can safely go into the ash pan. Many a good man has been lured to disaster and death by changed conditions far slighter than the engineer on this engine had to deal with.

An Exhaustive Test.

"Engine 146 on the Erie experimented with Luttgens patent stack on Wednesday. The engine was attached to the milk train, and lost 23 minutes' time in the run from Jersey City to Paterson, proving a failure. —*Bergen County Democrat.*

Mr. Luttgen sends us the above item, and says it is not true in any particular. We are glad to know this, not so much on account of the inventor, as for the record for horse sense of engineers. The Luttgens damper consists of a series of openings at the base of the stack, and they are opened or closed by the engineer from his seat in the cab. If any man lost 23 minutes on account of the damper opening, when he could close it by the exercise of one grain of sense and two ounces of muscle, he must be a dandy.

Air Brake Practice.

BY J. F. PHELAN.

SIXTH PAPER.

The same general rules should apply in air brake service on both ordinary track and mountain grades, modified on mountain grades by use of the retaining valve that holds 10 lbs. pressure, more or less, in brake cylinder, and prevents that amount from escaping into atmosphere when brakes are released. This retaining valve is connected by small pipe to exhaust port of triple valve. The location of this retaining valve is under car, attached to cross-beam, or at end of car, near roof, within easy reach of train men. When retaining valves are part of brake apparatus, air always exhausts through them when brakes are released. When not in use they give free passage for air to release and empty brake cylinder. When descending mountain grades these valves are turned on by train men, and instead of leaving a free passage for all air to exhaust from cylinder when brakes are released, about 10 lbs. of amount that has been in use is retained within brake cylinder, and usually acts in keeping brake shoes well up against wheels, and greatly lessens amount of air required for applying brakes when needed. This amount of air held on brake cylinders descending mountain grades causes brakes to act promptly in response to light reductions of pressure; amount required depending on rate of speed and kind of grade descending.

Engineers who are most successful in air brake practice on mountain grades are those who study the grade and know where a "let up" commences and the steep places begin. A study of the grade is the secret of success in mountain practice.

Double-heading is a rule in mountain service, and it is always desirable to have either of the two engines in condition to use the brakes at any time while in service.

In directing such service the following rules were produced and enforced by G. W. Cushing, when Supt. M. P. & M. on Northern Pacific R. R., and are now in force on same road.

"When two air brake engines are coupled to a train the *forward engine must control the air brake*, but both engines should be coupled up to air pipes, and may be used to pump air into train auxiliary reservoirs, in case it is desired to do so, *when train is not in motion.*

"When train is in motion the rear engine must 'blank the air' by turning the valve to the right, nearly to the point of application, and let the leading engineer do all the braking.

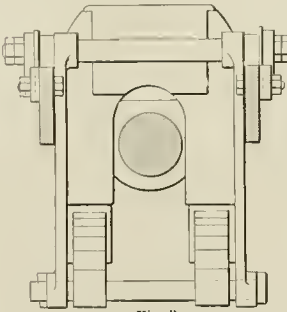

Fig. 3

"Otherwise the brakes may all be pumped off by the rear engineer, very soon after the brakes are applied by the first engineer, and this will render the brakes useless. Hence the leading engine must control the train brakes entirely and absolutely, except in case of accident to air of leading engine, and until a proper signal is given by the first engineer for the second engineer to assume control of the air brakes on train, for which contingency the second engineer must at every moment be prepared to act instantly on a mountain grade."

This "double-header" rule is not only enforced on mountain grades, but all engines have air pipe run through to pilot, where air hose is attached ready for use at any time, and in freight or passenger service, when double-headers are run, the leading engine controls the brakes.

Something to show the advantage to the country of railways can be seen in the rates of coal haulage in Pennsylvania. Anthracite coal is hauled from the Wyoming region to Philadelphia, 229 miles, for $1.90 per ton, which is but 8.2 mills per ton per mile. What it would cost to get a ton of coal from the Wyoming mines to Philadelphia by mule team can be imagined.

Safe Train Orders.

A Canadian correspondent of the *Locomotive Fireman's Magazine* says that the Grand Trunk road use a very plain system of train orders. He gives a specimen:

"A special train would get an order like this: 'All due in. Run to A, avoiding regulars.' If any regular train was late the special would get a straight meeting order: 'Meet No. 1 (one) at B.' Or else a time order: 'You can have till 9:15 (nine fifteen) to make B. for No. 1 (one).' No. 1 would get an order: 'No. 126 has till 9:15 to make B for you,' and No. 1 must not pass B. if the special is not there until 9:20, allowing five minutes for variation of watches. Nothing could be clearer than this—very unlike the complicated orders sometimes given on many roads."

The "all due in" is a good idea; on many of our roads it is customary for conductors and engineers to have to "check up the register," losing time to do so, very often, and we have heard more than one embryo dispatcher make the "crack," "if it hadn't a been for me, so-and-so would have pulled out against No. 49." And perhaps 49 was overdue ten hours. The idea seemed to be to see if the crew were "slick" enough to *ask* for orders, instead of having them ready.

With all the complication of orders, the duplexes and compounds, and their ilk, there may be more security for the dispatcher, but when a man is allowed to change time card meeting points at all, he should be competent to give single, direct orders. Any engineer or conductor would rather get an order to meet No. 1 at Smithville, than to get a closely written order telling them what half the trains on the road would do, where only one line concerned them. The complications tend to confuse men—the orders are often read on running engines and in the dead of night. It is no concern of the through express where O'Brien's work train will side-track and let Jordan's extra stock train by—both have got to keep off the time of the express. It is also no concern of O'Brien or Jordan where No. 1 and No. 2 are going to meet—they have no authority to use time on them.

Simplicity in train orders is the price of safety.

Murderous Designs.

We ran across a fireman the other day who was carrying his hand in a sling. Had to support himself while on running board by a hand rail that also served the purpose of a blower pipe—cooking meat half off the palm. Such devices as these have killed more than one man, and the parties who keep in use such designs should be held just as responsible for the murders as if they had killed the men with an axe.

The Frog (Salida, Col.), a semi-monthly, "devoted to the railway interests of the West," is out with No. 1, Vol. 1. Our old friend Cy. Warman, a stove-up engineer, is editor. We hope *The Frog* will hop into popularity and never croak.

Historical Locomotives.

THIRD SKETCH.

We have been favored with a photo. of engine 210, D & H. C. Co., the engine that drew General Grant's funeral train from Saratoga to Albany, on Aug. 4, 1885. The engine is a modern 8-wheeler, made by the Dickson Locomotive Works, Scranton, Pa.; she weighs 45 tons, has driving wheels 66 inches in diameter and cylinders 19x24.

The picture shows her as she appeared draped for the trip. There were used 350 yards of black cashmere on the engine, and 2,700 on the cars.

We hardly think the occasion calls for an expensive engraving, as there is nothing odd, or liable to soon pass away, to be shown. The draping was excellently done, and looks well in the picture.

On the funeral trip the whistle was not blown nor the bell rung, the run was made on a special time card printed with a mourning border, and the engine carried black flags—the only instance of the kind we have heard of.

Willis G Fisher was the engineer, and he runs the same engine yet on a regular passenger run between Troy and Whitehall.

Crowds of people lined the road on that day to get a sight of the train, and probably no locomotive has drawn the remains of mortal man more widely or sincerely mourned since Abraham Lincoln's cortege from the White House to the tomb at Springfield.

Peculiar Narrow Gauge Engines.

The Baldwin Locomotive Works are building a number of heavy consolidation locomotives for a narrow gauge road in Mexico, that have their drivers inside the frame; there are heavy wrought-iron cranks on the axles outside the boxes. This arrangement makes it very easy to get at, oil, clean or repair the boxes, frames, etc., and, as the frame is much wider, it admits of a wide, short fire-box, with all the drivers ahead of it. The engines in question have very large boilers. We do not see why this plan would not be an excellent one for roads to follow that expect to change to standard gauge; the right proportions could be followed, and then the change made by simply removing the cranks and shoving the drivers out into their places.

While outside frames are commonly built in European shops, locomotives are rarely made that way in this country.

A Pitless Turntable.

The Greenleaf Turntable Co., of Indianapolis, Ind., have put on the market a table of 100 tons capacity, that requires no pit. There are no end bearings or circular track. The table is supported on 16 conical rollers, and held steady against a large central pivot by 27 other rollers set vertical.

Some More Air Pump Tools.

BY H. R. JONES.

Every machinist or engineer knows the value of a "set," or "persuader"—as I call it—to loosen a stubborn nut in a bad

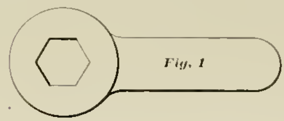

Fig. 1

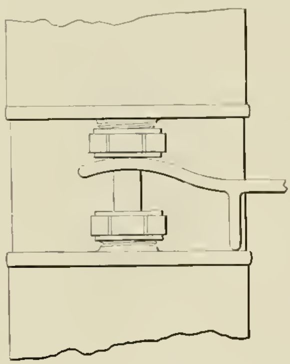
place. It is a mighty handy tool sometimes, but is used a great deal more than it ought to be, especially on finished nuts and brass work in cabs. I have seen injector throttles and cocks ruined by its use, but that it will start a rusty nut when a wrench will not is true, nevertheless; you have doubtless seen the hexagon



sides of the caps to reversing valves and pistons to air pumps all cut up by their use, but the wrench furnished by the Westinghouse Co. for that purpose is entirely too short and light to take off one of these caps when they have become corroded.

Now I have used what might be called a cross between a persuader and a wrench for this purpose. It has the advantage

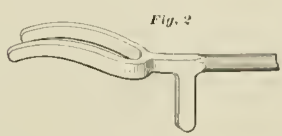


Fig. 2

of being short, light, and easily stowed away in the tool box. It will start any nut or reversing valve cap that will start

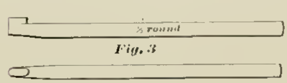

Fig. 3

with a wrench two feet long, and more than that, it will not mar the corners any more than will a box wrench. It is nothing more or less than a short, strong, box wrench like Fig. 1, used with a hammer Make one and try it and you will never be without one either in the shop or on the road. The handle should not be over six inches long.

To screw on the packing nut to the steam piston when it is hot and burns a fellow's fingers is something that makes him hot, and say bad words sometimes. Fig. 2 shows a pair of iron fingers that will effectually hold the nut up with any desired pressure till you get the thread caught, and will not make a fuss about being burned, either. By turning it upside down it will work equally well for the lower nut. Hold it in one hand and the spanner wrench in the other.

For pressing rings of packing into the stuffing box, I have found a tool like Fig. 3, to be very handy By using it on both sides of the rod you can get all around it, and by prying down over the edge of the packing nut as a fulcrum, the short finger will force the packing up into its place nicely, so that the gland nut may be easily screwed on.

There has been considerable said about mysterious pounds in air pumps I have had some trouble in that direction myself I had a pump once that bothered a good while before I found the trouble

The air piston head had worn quite loose in the cylinder, and as it reversed at the down stroke it would make a pound that would jar the whole engine. I reasoned like this, that in reversing the motion the piston head was suddenly and violently thrown against the side of the cylinder. A re-bored cylinder and new piston head cured that pound, but as the causes for pounds in air pumps are so numerous and varied, this remedy may reach only a few of the many cases. It was not a heavy thud, as when the main piston strikes the bottom head, but was of a rebounding nature, as if you should strike a bell with its clapper, and try to hold it for an instant on the vibrating metal.

In Early Days.

In the office of Pedrick & Ayer, Philadelphia, we found several old bound volumes of the *London Mechanics' Register* of 1827 28, and in them much of the experience of the earliest railroading. In an editorial, in which the editor takes other journals to task for condemning the use of steam locomotives so early in their career, and in which he claims they will pull more than horses, he says:

"We repeat that we do not wish to be whirled along at the rate of twenty miles per hour, but if we can go at the rate of ten, without danger of having our neck broken—or the insolence of coachmen, or the annoyance of dust or mud, and what is more than all, the distress of the noblest of the brute creation, the horse, we shall bless the labors of steam carriage projectors"

This was written but 61 years ago, but it was before the Rocket, or the Puffing Billy, or the John Bull, before the Stourbridge Lion was built or a mile of track laid in America. We hope the writer lived to be "whirled along" at his coveted ten miles per hour, and fifty besides.

Magnetism in Watches.

It is now a recognized and acknowledged fact that magnetism plays an important part in the destruction of watches and in making them run unevenly.

We all know that an ordinary watch can be ruined by bringing it in contact with a powerful dynamo; if this is true a less powerful magnetic current is well able to do damage in proportion to its force.

There are few intelligent railroad men who do not know that locomotives and cars produce currents of electricity, and that ordinary watches run faster or slower when the person carrying them is on or off duty.

Railroad men are so used to changing their watches to the standard clock, that they do not observe these deviations from the straight and narrow path—let alone following out the causes. Means of overcoming these difficulties have been sought by able watchmakers and electricians, but without success until the very recent inventions of C. K. Giles, of Chicago, Ill., and C. A. Paillard, of Geneva, Switzerland.

Experience has shown that main springs of watches break more easily and oftener when the watch is unprotected and subject to any magnetic influence, and that the balance and hair spring vary in their movements more or less, as the influence increases or diminishes.

Shortening or lengthening the hair spring is the means provided to delicately regulate the watch; now, when this slender spring becomes magnetized—the same as a knife blade is—the sides of the close coil stick together, and make any attempt to adjust the spring to proper length of no avail.

A very ordinary amount of electricity can easily magnetize this spring, and until it is removed the watch is in no degree reliable.

Mr. Giles encloses the entire works in a soft iron shield, that prevents any magnetic influence from reaching the works of the timepiece. The device is simple and is easily applied to watches now in use, and is already meeting with a great demand.

Mons. Paillard's invention accomplishes the same object by making the balance and spring of a non-magnetic material.

The balance and springs of the Paillard watch are composed of from sixty to seventy-five parts of palladium, fifteen to twenty parts of copper, and from one to five parts of iron.

This makes a metal that is non-magnetic and unoxidizable, and having the required elasticity, hardness and ductility for this important work. Watches provided with this invention have run accurately for months in actual contact with dynamos. The invention has made a great name for the inventor, as the alloy is of use in other arts than watchmaking. We would advise all railroad men, in purchasing timepieces, to see that they are in some way protected against magnetic influence, as it costs nothing extra; men who are inclined to think there is no magnetic influence at work on their engines now, and who only call electricity by that name when the current is strong enough to kill, are reminded that the engines and trains are liable to be lighted very soon by electricity, and there may be a dynamo on the foot-board to balance the air pump.

To Clean Strainer While Running.

H. D. Medrick, an engineer of Port Jervis, N. Y., has invented a foot cock, or lazy cock, for pump and injector feed pipes. It is placed where they ordinarily are, next the hose coupling; the taper plug is larger than ordinarily made, and contains the strainer; one side of the casing has an opening to the atmosphere. By turning the cab handle to one position the strainer is on and the feed can be varied; at another the side of strainer next to tank is open to the outside hole, and cinders and other obstructions can be washed out. It can also be used as a frost

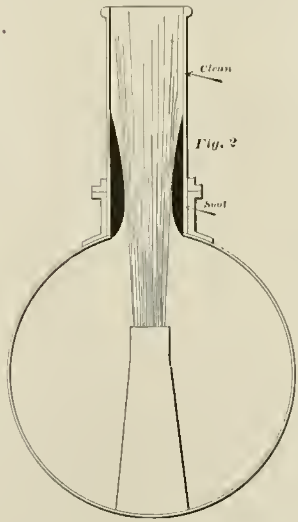

Fig. 2

plug to prevent freezing, and has an advantage in the fact that any of these results may be accomplished without stopping the engine or the engineer leaving his seat.

From Old Mexico.

Lewis S. L. Champlin, an engineer on the Mexican National R'y, called upon THE LOCOMOTIVE ENGINEER a few days since and gave us some pointers about railroading in the Republic of Cactus and Dobie dollars. Native firemen are employed almost exclusively, and natives are running most of the switch engines, and, on some roads, those on short branches; as yet Americans are employed on all main-line engines, and good pay—Mexican money—is paid them; all native engineers are working for very small pay, usually for $50 to $60 per month.

The climate is not so bad, but board and lodgings are inferior in most sections.

The American engineers have a very prosperous division of the Brotherhood located at the City of Mexico—Americano Div. No. 224. Bro. Champlin is a Connecticut boy, and has come clear up here to get "the girl he left behind him;" he proposes to do the rest of his locomotive running in a land where there is no discount on silver dollars, and where an engineer does not go to prison for killing a drunken man who goes to sleep on the track.

Bro. Champlin also ran an engine for several years in Peru, S. A., but the little tiff between that country and Chili, a few years ago, sent all the engineers from the U. S. back where they could see the stars and stripes.

For Japan.

John J. English, who recently returned from South America, where he represented the Baldwin Locomotive Works, has again shaken the dust of America from his feet, with a ticket in his pocket for Japan. Mr. English stops in Nevada, California, Oregon and British Columbia on his way. The Baldwin Works already have four locomotives at work in the Mikado's empire, and they are giving such satisfaction that specifications and guarantees for a heavier class of locomotives are now desired for the imperial highways of the realm.

The railroads of Japan, like those of Australia, are being built more like the roads in the United States than those in Europe, and in consequence the American locomotive is better adapted to their needs.

Pitless Shops.

The P. & R. shops at Reading, Pa., have no pits sunk into the floor, but have a clean floor throughout the shop. In lieu of pits they have movable tracks on iron pedestals that set up from floor. When engines are out the tracks can be removed and a clean floor left. In case but few engines are in shops, no unsightly and dangerous pits are left open, and in case the shops are crowded the pits can be arranged closer together. There are many advantages about this system that will present themselves on a little thought. On standard gauge engines having large wheels, no very extensive pit is necessary, but in narrow gauge shops, where pits need to be from three to four feet in depth, putting heavy engines up on high and narrow legs would be dangerous.

On September 9, an excursion train stopped on a curve near Pittman, O., on account of a broken connecting rod, and a flag was sent back—but not far enough. A freight train ran into the passenger, killing the engineer and several passengers, and injuring 25 more. The poorest kind of a power brake would have stopped the train. Thirty freight cars running at thirty miles per hour on a down grade, and depending on hand brakes, is a fearful thing to turn loose on a single track road.

Some Smoke Stack Experiments.

BY FRANK C. SMITH.

You are making your paper a very interesting one, and I prefer it to others in the same line. Now that you have demonstrated the want of such a paper it seems odd that a similar one was never before published. It fills a niche never before occupied. I am quite confident, however, that you are wrong in your estimation of a good heater. I have eight of my own design. (Fig. 1.)

This lies under belly of boiler, and is 15 inches diameter and 8 feet long. The water goes through the flues—the steam around them. If the drip cock be left *wide* open the engine will not steam, as the exhaust escapes too freely and no pull on fire results. But as it is only necessary to provide an escape for the condensation, which is very little, no difference in pull on the fire can be detected, whether the heater is in use or not. I use a pump with the heater, because the colder the water is introduced to the heater, the greater the absorption of heat units and the greater the economy. I find we put the water into the boiler at from 180 to 200 degrees. Now take an engine taking five tanks of water in, say, 130 miles—the tank holding 3,000 gallons, and the normal temperature being 60 degrees. The economy is the amount of coal required to heat 15,000 gallons of water from 60° to 180°. You will readily see that a very considerable quantity of steam may be taken from the nozzles without detriment, if the stack is of right size and shape.

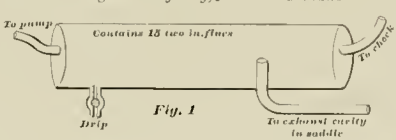

Fig. 1

The "rule" is to use a stack the size of the cylinder. Now I find a 17" stack on a 17" engine is wrong, because when I let a light down into the stack I find only a short distance of the top of the stack to be clean, the stack having a coating of soot as in Fig. 2, page 4, because the exhaust does not touch it. The outline of the soot in fact gives the proper shape and size of stack. Well, I make such a stack and find engine steams much more freely. This shows that by using the right stack I can get the same effect on the fire with larger nozzle or retaining same nozzle with less steam, using the surplus in a heater with the better economy. Now I was not satisfied with mere theory on the stack question. I therefore drilled holes 6" apart on a straight, 17" stack, as at (*a*, *a*, *a*, *a*,) in Fig. 3, and find smoke escapes *forcibly* only at the top holes. Then I change the diameter for a less diameter, until smoke escapes equally at *all* the holes, showing the stack to be filled completely its whole length.

I make another test with a vacuum gauge, as shown in Fig 4. The bend of the pipe and glass are filled with red ink up to dotted line. The pulsations of the exhaust are clearly shown when engine is working slow, by the rise of the ink in the glass. I find with the *smaller* stack that the ink rises in unison with the exhaust, as if tied to it with a string, and stays raised *much longer* comparatively than with the *larger stack*, showing a greater and longer pull on the fire. But against this, Johann, Lauder and other big M. M.'s., are on record to the effect that there is nothing in the smaller stack. Their statements will carry weight and they believe they are right. The difference is simply that any device, unless adapted in all its details, may not be a success.

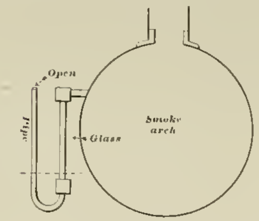

Fig. 4.

The height of the nozzle, the size, shape and length of stack, must be right. Lauder may have tried smaller stacks, but evidently not the *right sized* stack. *Facts* are *facts*, regardless of the findings of Lauder or Johann, or anybody else. As to results, I find the heater makes 1½ tons of coal difference in a run of 130 miles. In other words, with the heater the engine uses 5 to 5½ tons in a round trip—260 miles. When heater is shut off the consumption is 8 to 8½ tons.

Delaware, O.

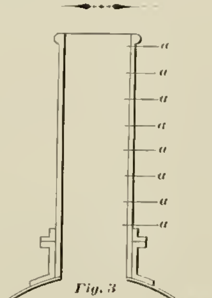

Fig. 3

Hard Tests of Chilled Wheels.

Probably no recent invention in railroad equipment has been of so much importance, or contributed so much to the life and safety of rolling stock as the Whitney contracting chill for cast-iron wheels. The chill on tread of cast wheels is produced by casting the tread against an iron ring instead of in the sand; this ring suddenly cools the iron, making it very hard, but owing to the fact that the ring of iron soon heats and expands away from the wheel, has made the chill very uneven in depth, as well as affecting the shape of the wheel. The Whitney chill is made of cast-iron with a solid outer ring with spoke-like projections to the inner ring that comes in contact with the tread of wheel; between each of these spokes is a cut entirely separating each spoke and its segment. These cuts are made by inserting pieces of asbestos paper in the mould, so that in a 26-inch wheel there are about 100 sections with openings between of about one-hundredth of an inch; this ring or segments of ring heat first, and must expand, but, as they are held in by the cold ring behind, they must go in, and in doing so compress the metal of the wheel and deepen the chill.

Last week at the Whitney Wheel Works, Philadelphia, the inspector of the Reading road made some tests of wheels for that company, using the Penna. R'y test, and the test of strength was as follows:

Average number of blows to start the first crack = 15 for 26" wheels, 53 for 30".

Average *additional* blows to break wheel in two = 50 for 26" wheels, and 30 for 30."

The least depth of chill in these wheels at the throat of the flange was $\frac{7}{16}$".

The greatest depth of chill in these wheels at the throat of the flange was ⅝".

As regards uniformity of size, or circumference:

In 133 out of 150 26" wheels, and 253 out of 350 30", there was no variation.

In 148 out of 150 26" wheels, and 349 out of 350 30", the extreme variation was only ⅛ of an inch.

This is remarkable accuracy for cast-iron work.

These works make about 200 wheels per day, all made in this chill; there are nearly 600 contracting chills in use in the works.

The Lodge Room Book-Case.

Don't have cheerless lodge rooms. Brussels carpets and pictures don't always make them enjoyable. Have a book-case with something in it; if nothing more, the bound catalogues of the different locomotive works, power brake, injector and lubricator companies, will be of intense interest and convey valuable information. Vote surplus money for books, papers, valve gear models, etc. Division headquarters and lodge rooms ought to be schools of locomotive engineering on the co-operative plan. For a few hours once a week talk over what you have seen and heard during the week at your work. Thought and discussion can have but one result, and that is the good of all who take part, from the oldest bald head that sits upon the right hand, to the youngest cub who stands pigeon-toed before the M. M for having got left.

The new passenger engines on the Reading road have been lightened up 11,000 pounds, by having their wagon-top boilers replaced by straight ones with radial stays. Their original boilers will be used on consolidation engines for the same line. It is claimed that the engines were found a little too heavy to run cool.

Fibrous Packing vs. Metallic Packing.

Prior to the invention of the double-acting engine by James Watt in 1782, all engines being single-acting, that is, taking the steam upon one side of the piston only, no stuffing-box or rod packing was required; but Watt and 90 per cent. of the steam engine builders, from his day to this, have used fibrous packing, and many enginemen of the present time suppose that metallic packings are modern improvements, but in reality, a patent on metallic packing was taken out as early as 1797 by Edward Cartwright. With these two as starters, there has since been patented enough devices on the same general principles to make, when the specifications are bound into books, eight volumes of about two inches in thickness, with a total of about 5,000 patents. But despite all the research and money represented by these many devices, no metallic packing was fully successful until 1876, and even at that date the success was limited to certain types and classes of engines.

Commencing in 1876, and making their first public exhibit at the "Centennial" exhibition, the United States Metallic Packing Co., Philadelphia, Pa., have probably done more to develop and make metallic packings successful than all other parties combined; and they are now the owners of 36 patents for metallic packings, and devices connected therewith, covering improvements which are essential, and upon which they have established a large and rapidly increasing business. They have made a special study of the requirements of marine, stationary, locomotive, and various other types of engines, refrigerating machines, etc., and while taking advantage of the good devices found in some of the earlier patents and inventions, they have learned how to avoid the errors which have caused so many failures of eminent mechanics in the past. The company did not jump into success and wealth, being extremely cautious not to undertake any important work until they had studied its requirements and fully tested the several devices to be used.

Their piston-rod packings were a success beyond question, three or four years before they were satisfied, in its application to valve stems and other rods of varying stroke, on account of the greater wear of the stem within the line of cut-off or shortest travel, and this was especially the case on packings applied to locomotive valve stems. But all of the difficulties have been overcome by the invention of the several devices which the company have since protected by letters patent in the United States, England, France, Belgium, Germany, etc.

Their packings for locomotives consist of three babbitt rings placed in a cone, the cone resting against a socket ring, which forms a ball-and-socket joint, the whole being kept in place by a follower and spring, the latter pressing the socket ring against the head of the case, and forming there a steam-tight joint, while at the same time it holds the babbitt rings within the conical cavity, and prevents their being displaced by the movement of the rod or stem, when the locomotive is running down grade or at any other time when the steam is shut off. It is essentially a steam packing, as the steam forces the babbitt rings into the conical cavity, and thus causes the rings to close steam tight around the rod, the babbitt being the only metal that touches the rod. The rod may vibrate up and down a quarter of an inch, and at the same time it may be up at one end and down at the other, and yet the rod is not touched by any hard metal, and consequently cannot be cut and grooved. This result is due to the use of the ball-and-socket ring, which is the "key of success" of metallic packings, the patent for which is the property of this company, and all packings manufactured by them, for any class or type of engine, have this essential device.

As evidence of the value of their locomotive packings, any one traveling on the Pennsylvania Railroad from New York to Chicago, or any of their branches or leased lines, can see the perfect working of these packings on most of their engines, as on these roads alone they have upwards of 9,000 packings in use. More than 200 other roads in this and foreign countries having these packings in use, bear further evidence of their merit and established success.

The Canadian Pacific, the Northern railway of this continent, is quite fully equipped. The Jacksonville, Tampa & Keywest, in Southern Florida, the Intercolonial in the East, and several lines to the Pacific coast in the far West, as well as the far-off countries of Australia and Brazil, send frequent orders for these packings.

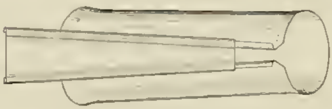
Mr. J. S. Cook, Master Mechanic of the Georgia Railroad, reported at the meeting of the Master Mechanics' Association in St. Paul, Minn., that one of his locomotives had run 160,000 miles without repairs to the packing, but the Metallic Packing Co. do not claim that they will make but about 75,000 miles on an average without renewal of the babbitt rings, which is the only part subject to wear.

That the success of this company is not confined to railways, is evident from the fact that the new steamship "City of New York," recently built for the Inman line, is fully equipped, and has 20 of these packings on her main engines alone.

Emergency Hose Clamp.

Every railroad man employed where there are air brakes has been annoyed or delayed by a slight rupture in the rubber hose; a very small leak is enough to "bleed" the life out of straight air brakes, and the same rupture will set the automatic, making it an element of danger. The leaks are caused in various ways; poor hose, jerks by not uncoupling hose, but principally by chafing against brake beams or other parts of the car or engine. The hose between the locomotive and tender are especially liable to rupture; the air is hot this close to pump—it rots the hose; the oil used in the air cylinder reaches these connections; in fact, they are a trap for most of the oil; this rots and weakens hose also. How many of you have had to stop on the road and replace a ruptured hose, or, in the absence of the "extra," have wrapped the broken one with a piece of sheet rubber and a cord? We have been there.

W. F. Relyea, our correspondent who has charge of the air brakes on the N. Y. C. road, at Syracuse, has devised a neat, cheap, easily applied and effective patch for all such trouble. As will be seen by the engraving, it is a band of sheet-metal generally Russia iron, with both edges turned over to form a groove or flange. The piece is wider at one end than the other, but is turned up straight, so that the opening is slightly tapered, a key piece suitably flanged and of the same taper fits over the opening, and by forcing this key piece up the clamp is tightened.



HOSE CLAMP.

By releasing the pressure and then applying this clamp as tightly as possible, with the fingers, the pressure can be returned to the hose, and will of itself force out the edges of the hole and make a joint. One of these clamps placed over a hole over an inch in diameter has stood a pressure of seventy pounds without a simmer. By using a piece of rubber under it, iron pipes can be temporarily repaired in the same way. They are as effective on water hose as they are on air.

One or two of these clamps would be a good thing to have in every seat box, and in every caboose and baggage car. The clamp is much neater to apply to hose for a chafing iron than the cumbersome clamps held together by bolts, we so often see.

Correspondence

Home-Made Dope for Brass.

Editor The Locomotive Engineer:

I see there are many brother firemen inquiring how to clean cab brasses. I use sperm candles, so called, rubbing them on the brass while it is hot, and allowing it to remain an hour or two, then wipe off and polish.

My brother, who is engineer of a steam fire engine, cleans cold brass with equal parts of salt and vinegar, but I could never make it work on a locomotive.

I make a dope as follows: one ounce camphor gum, two ounces alcohol, two ounces spirits ammonia, four ounces spirits of turpentine, one pound of sperm (star or miner's candles will do), one pound clean tallow and one pound of tripoli. I first dissolve the camphor in the alcohol, then melt the tallow and sperm and stir in the liquids and tripoli, and let the whole cool. Keep in a tin pail with good cover. This will give you a big dose of good dope in the shape of a stiff paste—it should be about as stiff as shoe blacking. To make harder use less tallow or more sperm; to make softer use more tallow.

Omaha, Neb. JAMES ARCHIBALD.

Been There Before.

Editor The Locomotive Engineer:

In the ENGINEER for April you have cut and description of a planer bar, patented by C. F. Geyer, Aurora, Ill. My object in writing you is that honor may be given where it is due. I have known of this device for the past six years. I believe it to be the invention of J. J. Daglish, late M. M. K. & G. S. R'y, Tyler, Tex. I took charge of the St. L., A. & T., at Tyler, in 1885, and found the tool there; it had been in use several years. Mr. Daglish is now in the hardware business at Tyler; would like to hear from him about this *new tool.*

Yours respectfully,

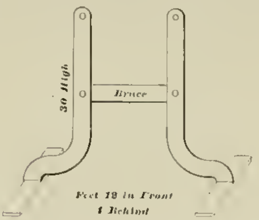
Dennison, Texas. E. S. MARSHALL.

An Unusual Air Pump Failure.—Rebuilding Pumps.

Editor The Locomotive Engineer:

As there is no answer in last month's paper to my question in August issue, I will tell what I found in the pump. There is a small hole drilled and tapped in top of reversing piston for the purpose of receiving a threaded rod to draw out the piston; the hole in the reversing piston of this pump was drilled so deep that the point of the drill just went through, leaving a $\frac{1}{16}$" hole, that being enough to allow steam to pass through to the under side of reversing piston, thereby relieving pressure on top of it and allowing main steam valve to raise, which caused the pump to act as I stated.

Believing that there is always something to be learned by an exchange of ideas and methods of doing work, I thought perhaps I might draw out something new from some source by giving my way of repairing air pumps. The first thing I do is to take the "donkey" all apart, put it in potash and let it soak for three or four days; then I take the parts out, turn the hose on them and wash them off clean, and the castings are like new ones. To erect the pump I bolt the air cylinder on a frame made of 2" x $\frac{5}{8}$" iron, with feet on the bottom to prevent tipping over (see drawing). I then ream air valve seats and fit valves to them, then put on the center piece, using copper gaskets for joints; next I tackle the steam cylinder; I drive out the lower main steam valve bush and draw out the upper one. After putting in new bushings, I put on the cylinder, put in the piston and main steam valve, and, before putting on the cylinder head, test the main piston and steam valve to see if they blow; in order to do this I fasten down the main steam valve, stop up the port that leads to the reversing valve, then pack upper stuffing box and put a piece of pipe about nine inches long on the lower end of piston-rod, with piston-rod nut and washer. Now for the test; I do this by connecting air hose on steam pipe connection of cylinder, and from there to the tender of an engine in the engine house, which is next to my shop. I start the pump on the engine and get anywhere from 80 to 100 pounds' air pressure, open stop cock on the tender and send the air to the pump in the shop, having a stop cock next to the cylinder of pump I am working on. I can use the pressure as I want it. I now put on pressure enough to raise the piston as far as



the pipe on the lower end will allow it to go, then I give it the full pressure, and if there is any blow I can find it. I leave hose connected until I get the pump all built up and ready to work, and use the same pressure to work the pump, and find leaky joints.

This is about the way I do it. Who is "next"? W. F. RELYEA.

Syracuse, N. Y.

The "Standard" 24-Hour Dial.

Editor The Locomotive Engineer

I noticed your article on the "twenty-four o'clock" system in your issue of July. As that is a subject I am interested in, I have taken the liberty to send you this communication. I surely agree with you that the double-system dial is crude, and think the fewer that get in use the better. I also think Mr Colvin's idea of putting the 1 and 24 at the bottom of the dial is correct. This idea struck me some time ago, but I never thought it had been put in practice until I read your article. I think one of the greatest drawbacks with

twenty-four hour watches is that the modern dials that have been used are confusing to most people. I send you with this letter a dial that I think you will say is both simple and artistic. I have received a patent for it.

You will see that much is gained by putting the twenty-four figures on the outside of the minute scale, as it gives the largest possible circle for them, allowing them to be made larger and put further apart than on the old arrangement. The little red figures that mark the minutes in multiples of five, serve their purpose much better on the inside of the scale, as they can be more readily seen. The little points that project from the inside of the scale help one to quickly determine whether the hour hand is pointing directly at the center of a figure or at either side, especially the *odd* numbers. One thing that helps the appearance of this dial is that the second circle does not cut out any of the hour figures, where, on the old arrangement, it cuts out the 12, and almost all of 11 and 13. I have not had any of these dials made with the 1 and 24 at the bottom, as I thought it would not be a good idea to make too much of a change at one time, so I followed the old custom of completing the hour when the minute hand reached the top. I call this dial the "Standard."

JACK SINGLETON,

St. Louis, Mo. Pullman Conductor.

A Dinner Pail Sermon.

Editor The Locomotive Engineer

Ever since railroads got to be over 40 miles long, or locomotives were in use, the men who have had to fire them and run them have been breeding dyspepsia, gout, and the holy horrors, by eating sundry cooked and uncooked decoctions from the mysterious and uncertain depths of 900 different kinds of dinner pails. What the victim eats—on a night run, 30 miles from a habitation and with the appetite of an ostrich playing hide-and seek from his spinal column to the front button on his pants—depends upon what kind of a woman he has married, or how he stands at the hash foundry. If he has an indifferent foundry he can change, but if he has an indifferent wife the victim can only wait patiently for the glad summons that calls him from hence unto that fabled Utopia where petrified biscuits do not break through and steal, or sour bread crawl into his stomach and chew the lining off.

Let us hope that he is happily married to a good woman—all are good, but some are better than others—and that she takes pains to fill his bucket with tasty food, that she studies to surprise him, that she does not give him the same old boughten drop cakes and the same old prune sauce over 489 days in the year, we will forget what is in the pail—we want to see the pail.

I have been hoping for over eleven years that some engineer would go into the tinsmith business or some tinsmith would ride on an engine regular for two months, and one or both of them go off into some vast solitude and invent a dinner pail that would make every engineer from Nova Scotia to the Sandwich Islands so proud that he would wear a plug hat on Sunday.

When I first commenced railroading, we had lots of time to eat at farm houses or village hotels, or if none happened in at the right time, we would stop and eat out of our baskets, pails, or paper sacks, each according to the dictates of his own conscience. But now-a days you have to eat on the fly, catch-as-catch-can, the fireman between fires, the bullgineer between stops or on long stretches, with one hand on the throttle, the other in his dinner pail, and his eagle eye on the rail.

When you could stop as long as you wanted to, and when you felt like it, wash up, take your dinner pail and get under a tree and eat till you were ashamed of yourself, it didn't amount to much whether your grub was in a basket, a haversack or a ten-pound lard pail. When you have to eat in dust and cinders, with the lily white on your hands not so lily as it used to be, it is of some importance how the dinner pail is built. The first dinner pail I bought was a deep round pail, with a sort of a canteen cover, with a screw top that carried the coffee in prosperity and smelt sour in adversity.

It would do for a careful man in the shop, but when Mrs. A. commenced at the bottom and laid the foundation of a lunch with a pair of ham sandwiches, laid up a few courses of rubble in the shape of stall-fed fried cakes, then underlaid the superstructure with three pillars of hard boiled eggs, erected a lamp-post of a long, slim cucumber pickle, finished the second story in fig cake, and surmounted the whole with a gorgeous, mansard roof of cream pie, it did look, feel, and smell "way up;" but bless you, after the old 71 got to dancing the racket for fifty miles, with that lunch in any box on the craft, it was a sight to behold—scrambled lunch, the fire-boy called it.

Then I got mad and squandered 75 cents for a "railroad pail," ventilated, to keep the lunch cool—and make your lemon pie look like it had been the bull's-eye in a fly-specking match—it had a tin coffee can in the shape of a brandy bottle, with a screw top; you could not get anything inside to wash it out, and after a few trips in hot weather, when the can was empty half the time, it got to smell like a hot-box; then if you took it out of the pail to warm it on the boiler head, the rest of the lunch slid into its hole, the pie tray would slide off its scaffolding and knock the pie into a cocked hat, and shove a pickled cauliflower into the tea-cup of strawberry preserves; if you took it in your lap and tried to eat, it was a jumbled mess. I had a grudge against one of the other engineers, and I gave him that pail and paid $1.25 for a copper one with a cup on top and a nickel-plated handle. This had a glass jar for coffee, and a tray that went over full size of pail; under the cup, on top of cover, was a sauce dish, and about once in six weeks Mrs. A would put something in this; as I always turned the cover upside down in my lap and fished out and assorted my lunch, strained honey or apple sauce often ran down my legs. I would have kept this one and said nothing, but the 71 laid down one day and rammed her starting bar through the copper bucket, and its precious contents, turned over the second time, and waved the wrecked pail aloft, and seemed to say: "Ah, there, John Henry! why didn't you eat at noon?"

Then Mrs. A. and I foraged the hardware stores, and marched home in triumph with a pail that had more good points than one, and some bad ones that we forgot about. It was made like the new cannon—on the built-up principle. It was made of sections of pressed tin pans, the bottom one being covered, and having a large screw top; this was for coffee. Then on top were three dishes that looked like pieces of pie, three-cornered—they were for vegetables—and when on top of coffee can made a circle; on top of these was a deeper dish for bread, etc., and on top of that another for pie, etc. A tin cup sat jauntily on top, like the gilded dome on the fabled temple of fame. The bail was eared to the bottom story, and ran up past the others and sprung into the sides of the cover. I could set it on the top of the boiler head, and when the coffee was hot the whole dinner was nice and warm. It kept out the dirt, but it looked like a tin store when all apart, and you had to get it all apart to eat. It would be great for the shop, but was too unhandy for the road. Some one stole it off the engine, and Mrs. A. discharged her hired girl because she had so much less tin to wash. Now I want a new dinner pail, and I want it made like this: A pressed tin dish, 8 inches across and 3 inches deep at bottom, with a top soldered on, and a 2 inch screw top to clean it by. On one side of this can I want another ½-inch screw top and a ½-inch tin pipe coming up outside as high as the handle, and extending down to within ⅛ of an inch of the bottom of can; it will have a cap on top. Then I want three sections of pressed tin dishes with the bottoms ¾ inch above bottom of ring, and bottom of each ring fitting over top of each dish. On one side I want tin hoops to fit over the pipe I spoke of, a cover with a loop on the inside of top for a spoon, and a bail coming from the bottom on side opposite pipe, and carrying handle at top and snapping onto pipe. With this, each kind of food will be by itself—let it shake; I can warm the whole lunch; I can pull off cap to pipe and drink coffee without disturbing rest of lunch, getting cinders in pail, using a cup or unscrewing a cap with dirty hands—my eye on the next town. I can take the whole pail in my lap, unsnap the bail and open any or all the sections by swinging them on the pipe to one side or the other. I can set the pail in the rain, the cinders or the dust, and it won't paralyze the lunch; it will be easy to clean, it wouldn't cost much, and while it might not be a conspicuous figure on dress parade, it would have about two weeks lap, and the right of the road for business.

JOHN ALEXANDER.

Handling Long or Short Trains with Air.

Editor The Locomotive Engineer:

In September issue, correspondent H. S. H., of Denver, Col, takes exceptions to statement in article on Air Brake Practice in August LOCOMOTIVE ENGINEER.

H. S. H says: "We can't just agree with one statement we find in it, that the reduction of air pressure necessary to make a stop depended on number of cars in train, rate of speed running, and kind of grade approaching stopping place. This is all right, excepting that part relating to number of cars. We would like to know what difference the number of cars makes as to reduction of air pressure in train pipe to make a stop. On a train of twenty cars it is necessary to exhaust more air than with five or ten, but the amount of pressure need not vary. We claim this on the ground that in each case, all things outside the number of cars are equal."

Now, referring to August LOCOMOTIVE ENGINEER, the matter reads: "Ordinarily with brakes in good order, a reduction of 3, 5 or 8 pounds air pressure, *according to number of cars in train*, rate of speed running, and kind of grade approaching stopping place, will give good results."

If H. S. H. pretends to say that the engineer should not take into consideration the number of cars in train, in handling air brakes, life is too short to say anything further on the subject.

The "Air Brake School Car" is a very good institution, but the theory set forth and knowledge gained therein must be modified and strengthened by practice on the road.

The problem of stopping a passenger train of six coaches, in comparison to stopping 15 coaches, descending a 40 ft. grade, would soon be solved in practice by the engineer watching effect of application on air gauge. Likewise stopping a train of 18 to 30 freight cars under similar conditions—economy of air supply, weight of train, etc., all taken into consideration.

If H S. H. would use *more* air without proportionate indicated reduction on air gauge, he would accomplish a novel feat, to say the least.

The reader will please bear in mind that general practice is treated of in my writing, and not the model in a school car or the perfect working train of quick-acting brakes with all recent appliances and improvements.

In direct answer to H. S. H., I would say, on a recent trial the difference in pressure needed to stop a train of 29 cars, compared to 10 cars, was several pounds more for the greater number. Again, on a train of 24 freight cars a reduction of 5 lbs of air did not set a brake, but a reduction of 8 lbs. set all brakes. Cutting the train to 10 cars, the 5 lb. reduction set the ten brakes.

The cause is clear enough; in handling the greater volume of air—as pressure is reduced by engineer's valve, it starts from forward cars first, and the space is filled on forward cars by air flowing from rear cars, and before triple valves will act it is necessary to have an even flow, and reduction started uniformly the entire length of cars or brakes in use. This naturally requires *more* air, more time in flowing from engineer's valve, and a consequent and proportionate reduction in pressure on air gauge.

This relates particularly to old style brakes.

We would repeat to those interested, always take into consideration the number of cars in train; in using air brakes with a heavy train, especially on a descending grade, add slightly to reduction to make sure of effective work; heavy tonnage, notwithstanding increased brakes in proportion, will need accurate management at a high rate of speed on a descending grade, where one cannot afford to experiment in releasing and resetting brakes, and ordinarily cannot afford any number of brakes not setting in proper manner.

To H. S. H. we would say, please don't graduate after taking a few lessons in an "Air Brake School Car." We endeavor to know and fully understand what we are writing about, and always stand ready to gain knowledge and take pointers that point toward correcting error. But always be sure you are right before shedding printer's ink.

J. E. PHELAN.

Brainard, Minn.

Novel Exhaust Nozzle.

John Y. Smith, the inventor of the ejector for vacuum brakes, has spent considerable time of late over an exhaust stand that works on the same principle as does his ejector, the exhaust steam issuing from openings surrounding a pipe open at the base to the smoke and gases in the front end.

There is no petticoat or draft pipe used, all the functions of this appliance being a part of the nozzle casting. There are several of these in use on a New England road, having done good work for the past four months with an exhaust nozzle opening larger in area than the steam ports in the cylinder. We will illustrate this device in our next issue.

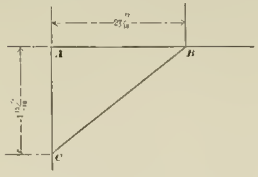
Combined Capacities.

To ordinary people twice two are four, but to mechanics twice two is often about $2\frac{3}{16}$. Some years ago a very successful M. M. received an order to "double the capacity" of a line of pipe that supplied a water tank, and, on finding that the pipe in use was two-inch, he ordered several hundred feet of four-inch piping to replace it. The superintendent of machinery o.k.ed the order, too, but a draftsman had to stumble onto the blunder, and "had the laugh on the old man."

There are a good many young mechanics and railroad men who do not know that to double the diameter of a circle increases its area four times, and there are a lot of other and older mechanics who do not know how to figure out the combined capacities of different sized pipe, cylinders or shafting, especially if the sizes end in fractions of an inch.

C. L. Redfield, a correspondent in the *American Machinist*, gives a graphic rule that is simple and easily remembered, and one that should be "pasted in the hat" of all young mechanics. Mr. Redfield says:

"Let us suppose that we have two pieces of shafting, any definite length, one piece $1\frac{5}{16}$" diameter, and the other $2\frac{7}{16}$" diameter; required the diameter of another piece of shafting, same length, which shall have a weight (or tensile or compressive strength) equal to the combined weight of the first two pieces. How many persons, draftsmen or others, are able to give this answer in one-half a minute, without the use of any tables? It is, nevertheless, the simplest kind of a problem. The whole question is simmered down to finding a diameter which has an area equal to the combined areas due to the diameters $1\frac{5}{16}$" and $2\frac{7}{16}$". We know that areas are to each other as the squares of their diameters, but the squaring of such numbers as $1\frac{5}{16}$ and $2\frac{7}{16}$ makes the ordinary draftsman inexpressibly weary. The graphic solution is shown in cut. Draw the lines *A B* and *A C* at right angles, and lay off on them



the distances $1\frac{5}{16}$ and $2\frac{7}{16}$ at *C* and *B* respectively, then will the distance between these points be the required diameter. * * It is not necessary to have paper and pencil to work this solution, as the square corner of a board and a two foot rule will answer every purpose."

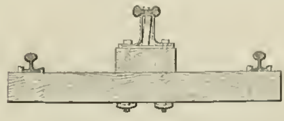
Brazilian Mountain Engines.

Probably the steepest and crookedest road operated by traction locomotives is the Cantagallo Railroad running from the city of Rio Janeiro to the coffee plantations on the elevated plateaus of the coast range.

This road has a grade of 8.3 per cent. (438 feet per mile), and curves of 131 feet, or 43.8° radius; there is no straight track on the mountain section, the line being a succession of reverse curves—there being ninety-one curves of over 40 degrees radius in a little over two miles.

Prior to 1883 this road was operated by the Fell system, a central rack rail, and the locomotives were of Swiss or English build, and were in all shapes, using from one to four cylinders; the trips were made with no regularity, repairs were heavy, and operating expenses burdensome.

In 1883 the Imperial Government made inquiries of the Baldwin Locomotive Works about engines for this line, requiring that they draw up this grade a train



of 40 gross tons. These works proposed to build and guarantee locomotives for this work that worked by traction alone, but used side bearing wheels on the center rail to help curve, and that used a steam brake gripping the central rail. Three engines were accordingly built, and were of the following dimensions: Cylinders, 18"x 20"; six driving wheels connected, 39" in diameter; wheel base, 9' 6"; boiler, 54" in diameter, with 190 flues, 2" diameter, 10' 9" long; and with side tanks, carried on the locomotive.

It will be seen that this calls for a very heavy engine with large cylinders on small wheels, and with a very short wheel base.

These engines have had several years trial and proven a complete success, so much so that these works are now building more of the same class for them

On this page will be found a diagram of the rail arrangement; the gauge of road is 3' $7\frac{1}{3}$", and the side faces of the center bearing rail are about five inches.

The curves on this road are so short that when three cars stand on them the two end ones are at right angles to each other.

Railroaders in Politics.

Committees from the five great organizations of railroad men—engineers, firemen, conductors, brakemen and switchmen—have met in Chicago and organized for political action. They propose to all railroad men in the State to cut loose from all old party affiliations and elect to office only men who will pledge themselves to help to repeal all conspiracy laws that menace constitutional rights of citizens; the repeal of the co-employe act, under the provisions of which, if one employe is injured through the carelessness of a co-employe, he cannot recover damages; the abolition of all private armed bodies under the direction of so called detective agencies. They also wish to have laws enacted that will benefit wage workers in general.

There can be no question as to the justice of the reforms asked, of the necessity of action or of the right of railroad men to move for better laws, or against bad ones.

Inhuman Practices.

On the 14th of August there was a wreck on the A & P., near East Siberia, in the California desert, all the cars of a passenger train being thrown down a 30-foot embankment, injuring many people. The mail clerk telegraphed for assistance, but the company owning the only wire, it refused to send a single dispatch for the passengers—even to tell their friends that they were all right. The passengers were picked up by the superintendent's train twelve hours after the wreck. They got up a series of resolutions, signed by every one on the train, condemning the officials who run cars unfit for service, and for inhuman treatment in refusing use of wire to allow them to relieve their friends of anxiety

It has long been the custom to treat passengers in this way, and if the A & P. can get any satisfaction out of the wholesale publication of such resolutions as those passed they are welcome to it.

This kind of work will only result in a national law compelling companies to furnish such reports as they themselves receive, to anxious friends of passengers and employes.

What did the wife or mother of that engineer or fireman suffer, knowing that he was twelve hours late, and that there was a wreck about which she could get no news?

Hasty Judgment.

There was a strike of ten hours' duration on the Peoria, Decatur and Evansville road the last of August, the cause being the alleged hard treatment of the men by Master Mechanic Smith. Mr. Smith was himself a brotherhood engineer, and took hold of the road less than one year ago.

In reply to a letter one of the officials of the road says: "Mr. Smith succeeded in running our engines 38 miles to the ton of coal, as against 26 miles, the best we had done before. He got 24 miles on the same amount of oil we formerly made 15 on, and reduced our shop expenses at least 25 per cent. He discharged several men for drunkenness, and otherwise improved the service. Charges against him were preferred, and a reinstatement of the men discharged demanded, while he was at home attending a sick child which died before he got back to Mattoon. Mr. Smith resigned because his former employers, Schoenberger & Co., Pittsburgh, offered him a much higher salary than railroads usually pay for the service he performed. So far as we know, he was strictly temperate while here."

On the other hand, the enginemen declare that Smith was a habitual drunkard, and abused the authority invested in him.

Whether Mr. Smith, or the engineers, or both, are at fault we shall not presume to say, but we do know that there is lots of unfair, underhanded, and unmanly work generally done on both sides in a case like this.

If Mr. Smith got drunk he had no right to ask his men to keep sober, and the engineers had no right to get drunk because Mr. Smith did.

Any road that employs a drunkard as an engineer is a dangerous road to ride over; any engineer who demands that a drunkard shall be kept in road service displays poor judgment, a disregard for the good name of his own calling, and criminal carelessness of life and limb.

There are a whole lot of engineers in this country who would rather go on a committee to the general officers, than to just try to see if they could run on less oil or less coal. When engineers find that they have a master mechanic who wants to reduce the consumption of coal, makes improvements in the engines, with that result in view, and asks the engineers to help him, how is it going to hurt them to enter into the spirit of the thing, and try to run on less fuel?

The engineers should put themselves in the master mechanic's place and look at the matter as he is obliged to see it, and, on the other hand the master mechanic should know under what circumstances and disadvantages the engineers work, and not ask for impossible service.

We are sorry to record such trouble as this, as we hope to see more engineers promoted to positions of trust, but when the engineers themselves, instead of helping up those of their order who get a chance, strive to keep all on a common level—the best only equal to the poorest—there is little hope for the promotion of merit or ability from the ranks.

We only use this instance as one case in a thousand. Mr. Smith may be wrong; the engineers may be wrong. Such actions on the part of the men only tend to hasten the day already talked of, when engineers will run for so much per mile paying for their own coal and oil—then the man who is a "good enough" engineer will get paid in proportion to what he really earns the company, while the man who is a careful, painstaking man will get paid for his care and his pains.

No man ever did wrong in defending himself or his fellows against despotism or oppression, but are we always just and fair in deciding that we are right and the other fellow wrong? Do we do as we would be done by? Do we put ourselves in his place? Think about this.

Educating Scabs.

In the *Locomotive Engineers' Journal* for both August and September there were correspondents who objected to the system of asking questions and giving answers in the Road Department, for fear that answers might "educate the scabs" on the Q.

Such a policy would be like stopping all the lines of travel from New York to Chicago, to prevent anarchists of the Johann Most type from reaching that city. To be sure such a policy would be a great injury to 10,000,000 people, but it would keep back the anarchists.

The trade, or art, or profession of running a locomotive cannot be learned from questions and answers; actual experience on the footboard is necessary. Questions and answers, if practical, will help any man to a better understanding of his business—you can't teach a scab, or any other person, how to set eccentrics if he don't know where they are, or what they are for. Engineers, as a rule, don't ask where the smoke-stack is or which way you point the lever to go ahead or back.

There are many men now scabbing on the "Q" who are good men with an engine; those who are sober know as much about the business as average engineers, and questions and answers will do them as much good as others with more principle.

The conductors, and brakemen, and roundhouse and cornfield chaps that are stopping and starting Q. scraps for the time being, have not had the experience and do not know enough of the rudiments of the business to profit by any questions an intelligent engineer would ask—an engineer who thinks so acknowledges that he is a numbskull at the business.

The Engineers' Brotherhood has done good work in the past in purging the order of drunkards and incompetents; it has also purged itself of many first-class engineers who did not think as the majority did. There has been lots of spite work in the past that has set adrift many able engineers with a grievance against the order. Look at the expulsions every month. Can any of us claim that men expelled for non-payment of dues are not good men with locomotives? They may have been in the order for years

We must not choke off sources of benefit and information to the tens of thousands in the ranks, to prevent a few men from "getting posted" who are fast bankrupting their employers, and will soon put the eternal kibosh on themselves.

We might as well talk of closing the public schools for fear they would put information into the hands and heads of rising youth, who would be enabled thereby to eventually become painters who desecrate nature with advertisements of the best soap, or forgers of school scrip or bank checks.

Creating Locomotives.

We see the item about the building of a locomotive in 16 hours 50 minutes, at the Altoona shops, still being copied far and wide. No locomotive was ever built in as many days. The Altoona engine was merely partially assembled; the frame was all together, the cylinders fitted, valves in chest, tumbling and rock shafts up, spring hangers and boiler braces on frame, guides up and crossheads lined, before the 17 hours' work commenced. It may be of interest to real railroad men to know the practice at the Baldwin Locomotive Works, the largest locomotive shops in the world. In usual practice it is six weeks at the least from the time an order with all specifications is received before an engine is ready to ship.

It takes from three to four weeks to make an ordinary locomotive boiler, but they have made them in two weeks—can't get men enough around one to finish them any sooner; it takes from three to four days to do the flanging alone. It takes from one to three days to properly fit a pair of cylinders to the boiler. The idea of *building* a locomotive in 17 hours is just as absurd as the idea of making a three-year-old colt in a minute. The Pennsylvania record was a good one for fast work, and they got the engine together in 17 hours by having more than half the assembling before they commenced to count time.

Poor's Manual of Railroads.

Poor's Manual of Railroads is out for 1888, and one has been placed at the disposal of THE LOCOMOTIVE ENGINEER. This is the 21st annual number, and is replete with information about our railroads. It contains a statement of all dividends paid from 1880 to 1887; a table giving the range of stock values for two years; the State debts; and a complete list of officials.

The road statements state name, location, length of lines operated, length of sidings, gauge of track, weight of rail, number of engines, number of each kind of cars, and a complete history of the road—debts, earnings, operating expenses, list and addresses of directors, time of their meeting, and anything else you want to know, except when the trains leave. The book contains upward of 1,400 pages, containing many maps, and is invaluable to anybody hunting for railroad statistics.

A Well-Earned Vacation.

A Pinkerton detective was hired, so says the *Conductors' Monthly*, by the general superintendent of the Mexican Central R'y, to act as a spotter, and, disguised as a brakeman, proposed to a couple of conductors to rob cars. They acquainted the Jefe Politico (Chief of Police) of Silao of the offer, and he directed them to go ahead and do the robbing, which they did, and the trio were roped in by the alert Jefe, and the Pinkerton man got a well-deserved sentence of 13 years in a penal settlement in Yucatan.

Supt. Mackenzie gave his evidence before the court to get his spotter out of the scrape, and the astute Judge is credited with replying: "No; if all that you tell me is true, this man has been guilty of a heinous conspiracy, trying to encompass the ruin of two innocent men, and I can perceive no mitigating circumstance in anything you say. He will have to go to Yucatan. If I were to do my whole duty I would arrest you on the spot, and have you tried for participating in the conspiracy. I shall most certainly do so the next time you try anything of the kind."

If this be true, the Mexican Judge is entitled to a monument of bronze at the hands of American workmen.

The *Conductors' Monthly* is highly pleased over this case, because the men whom the crime breeder tried to ruin were conductors.

The same paper has been for months aiding, abetting, and giving moral encouragement to the C., B. & Q. management in its employment of a young army of Pinkertons, to plot against the life and liberty of engineers, firemen and switchmen. It makes a world of difference whose ox is gored.

Protection Needed.

When the Brotherhoods of railroad men federate—which they soon will—it will not be long before organized labor, from the rock-bound coast of Maine to the shining sands of the Golden Gate, will have a common grand council. Processes of enlightenment will then be inaugurated, that will relegate strikes to the scrap-heap of oblivion, and battles of right and wrong will be fought with the ballot.

When that time comes—and pray God it come soon—the first duty of American workmen will be to elect men to office who will pledge themselves to purge this fair country of that species of venomous reptile known in Ireland as informers, in France as secret servants, in Russia as messengers of the Imperial Tzar, and in America as spotters, or Pinkertons.

That one man, or number of men, can hire at fixed rates, perjurers, liars, or assassins, to prey upon the life, liberty or happiness of other men, is a blot upon our boasted freedom that sorely needs the attention of every honest voter.

If there is any protection needed in America, it is protection from the thousand lurking vipers from within, rather than the few crazy anarchists from without.

It is the opinion of many of the ablest engineers in the country that the strike should be declared off on the C., B. & Q. road, and a chance given to many of the old men to get their places back, and the rest to seek and find employment before the winter. There is little hope for success, and the longer they wait the more experience the scabs are getting. We are in full sympathy with the men, and have hoped that the whole trouble would hinge upon rates of pay, and that they should win; but they cannot win, and the next best thing is to stop the strike and get work if possible.

We believe that if there had been less of this "follow the leader" and "hurrah boys" business, and every ballot taken was a secret one, the strike would have been off long ago, and most of the men at work again.

The "Q" is a wreck, and no manager, fair or unfair, wants any of the medicine Stone has taken, but it is doing the brotherhoods no good to stand idly by holding the empty bottle.

Alexander's Ready Reference is a little pocket book, telling engineers and firemen what to do in 101 emergencies that arise in the shop and on the road; this work has been on the market several years, and has met with a large sale. Mr. Alexander has now published a key to the Ready Reference, or The Reason Why, as he calls it. It is bound like the former book and will be of great help to those who want to know the "why."

***

While the editors of *The Railway Service Gazette* and the *National Labor Tribune* were on their respective vacations, the editors *pro tem* copied articles from THE LOCOMOTIVE ENGINEER without credit. We hope the real editors will soon return.

***

Light, Heat and Power, the ablest gas journal in the country, has become a weekly. We hope she will meter success.

ASKED & ANSWERED.

(57) Pop, North Platte, Neb., asks:

How many coils should there be in a safety valve spring? *A.*—Rose says a good spring for marine safety valve should contain 14 coils. We have never noticed any valves made for locomotives having more than eight coils.

(58) M. B. O., Sheldon, Ia., writes:

In your July number you explained that center of cylinders was above the center of drivers. What is this done for, and has it any effect on valve motion? *A.*—See question 16, in April number.

(59) Y. M. C. A., N. Y. City, writes:

My engineer claims that steam is steam, and that after water reaches the boiling point (212°) and commences to give off steam, its temperature does not increase with the pressure. I claim that the degrees of heat increase directly with the pressure and that steam at 100 pounds' pressure is 312° heat. Who is right? *A.*—Neither one of you. Steam at atmospheric pressure is about 213 Fahr., at 50 pounds' pressure the heat has increased to 298, at 100 pounds' pressure to 338, and at 140 pounds' pressure—usual locomotive practice—360° Fahr.

(60) J. T., Chicago, writes:

Some time ago you described or mentioned the steam reversing gear in use on the Pennsylvania and on the Reading roads. Do you think that, with the increased size of cylinders and valves, the steam reverse gear will come into, or should come into, general use? *A.* No. The invention of a successful balancing device for locomotive valves has done away with the necessity of a steam gear. They are expensive and have many parts liable to derangement. The simpler all locomotives are, and still made to meet all requirements of standard service, the better it is for the locomotive, the engineman and the railroad company.

(61) H K ——.

Send description of your three-cylinder engine; also your full address.

IN THE ROUNDHOUSE AND REPAIR SHOP.

The Old Colony road have adopted the Dean guide.

* * *

The Pennsylvania Railroad uses about 8,000 tons of coal per day.

* * *

Over 2,500,000 passengers per month are carried over the Brooklyn bridge.

* * *

The Central Railway of New Jersey are receiving a number of new freight locomotives with the Wooton fire-box.

* * *

The Inloes safety turn-table lock has been adopted by several Southern roads, and appears to be giving satisfaction. Mr. Inloes will exhibit his lock at the Paris exposition next year.

* * *

At the Wyoming shops of the Vulcan Iron Works, Wilkesbarre, Pa., the yearly output, aside from mining machinery, is about thirty narrow gauge locomotives. One is just now being shipped to Brazil.

* * *

Engineering, London, states that there are boilers on locomotives in the United States with 5' 4" boilers. Since this news has got over there and back we have a number of locomotives with boilers whose smallest ring is even 6 feet.

* * *

Engineer Herman E. Willis, of Clinton, Ia., has been nominated for a place on the Railroad Commission of Iowa. We hope brother Willis will get there. Iowa is just now in need of a railroad commissioner that possesses ordinary horse sense.

* * *

The Cooke Locomotive Works, of Paterson, N. J., will build new shops in a portion of the city where they can have all the room they want. They are crowded for room in their present quarters, and the new ones will have every modern convenience for the work in hand.

* * *

At the P. & B. C. roundhouse in Philadelphia they are removing the heavy iron columns between the doors and replacing them with small wooden ones—the old openings were too narrow for the big Pennsylvania engines that are now used on the line. This seems to be a better plan than flattening the sides of cylinders, as the Reading did some time ago.

* * *

The old locomotive "General," illustrated in our August number, was off on a vacation at the soldiers' re-union last month, at Columbus, O. She was accompanied by her engineer, Jeff. Cain, from whom she was stolen, and Captain Fuller, who recaptured her. She met the survivors of the raid that captured her, and—we hope—had a good time with the boys from North and South.

During last year 988 miles of road were completed and opened in India, making a total of 14,388 miles open. At the end of March the total sanctioned mileage of railways open and in course of construction was 16,870 miles.—*Ex.*

* * *

The Hartford & New Haven R'y have no hand rails or running boards on any of their engines. If you want to go out in front, you stop and walk around on the ground. We don't just understand how the boys get around to clean their engines.

* * *

The train ticket agent seems to have come to stay, and is being introduced on many roads. That they are a safeguard there can be no doubt. Let the conductor look out for his time card and orders, and be sure that the brakeman gets back far enough when he flags.

* * *

This office is in receipt of a letter stating that a gentleman recently counted the mile posts from an Erie train, and that the train made 96 miles an hour for 90 minutes. Guess the gentleman in question was counting whistling posts, road crossing posts and mile posts all together.

* * *

The Philadelphia and Baltimore Central folks hold their solid-ended side rods on by using a large-headed bolt that goes through pin and is held by check nuts from the inside of wheel; the bolt head looks for all the world like the collar of an ordinary pin, and it has bothered many railroad men who were not "on," to see how they ever got the solid rod over the solid collar.

* * *

When the Locomotive Firemen's Brotherhood undertake anything, they generally strike out for something new, original and good. Their "souvenir," or programme, of the 14th convention, held this month at Atlanta, Ga., is not only a work of art and tastefully gotten up, but contains illustrations and reading matter of interest to any railroad man, and, being bound and engrossed like a volume of poems, it will be preserved. This is the finest thing of the kind we have ever come across, and the committee who sent it out deserve great credit.

We are in receipt of the programme for the twenty-fifth annual convention of the Locomotive Engineers' Brotherhood, to be held at Richmond, Va., October 17th. It is the largest and handsomest programme they ever issued, and reflects credit upon the committee having it in charge. The first line on the cover reads: "Come, let us reason together." We hope the engineers will do lots of this at Richmond—there is need of it.

* * *

On the night of September 4, an express train between Dijon and Paris, France, left the rails, and another express dashed into the wreck. Forty persons were killed. Something wrong with the block signal here. Why would it not be in the line of reason and progress for European roads to adopt good automatic brakes and American roads good block signal systems?

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. I. NO. XI. NEW YORK, NOVEMBER, 1888. $1.00 per Year, or 10c. a copy.

The Elevated Accident.

A short time ago all New York had a shiver over an accident on the Ninth avenue elevated road. A train was taking a side track—something not usually done—when another train came along and ran into the side of it, derailing cars and throwing a truck into the street. The daily papers stated at the time that one of the automatic signals was broken and tied up with an old rope. Investigation does not prove this.

In every accident some one is to blame—sometimes the operatives and sometimes the management, and often both. In this instance it was plainly the engineer; he was simply not attending to his duty, and ran into the train with the signal dead against him. One of the hardest things the "L" roads have had to do is to keep their enginemen from looking into the windows along the road and keep their eyes on the track and the signals. The only way we see is to build cabs so constructed that men can see ahead and back only—this would be inconvenient, but it would keep the men from looking where they should not. Another way would be to keep shutters closed and prohibit good-looking females from using streets traversed by the "L."

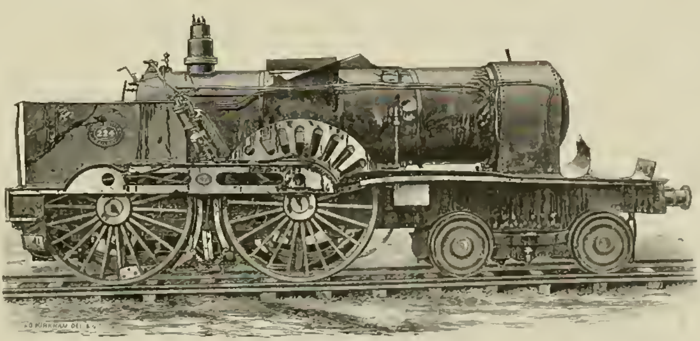
The English Board of Trade, a government institution, has asked all railroad companies in the United Kingdom to furnish a record of all railway employes who were on duty—in any instance, during the year—for 12 hours. Why should England lead in passing laws to prevent accident by reducing the hours of labor?

A Reverse Lever for Air Pumps.

"Do you see that piece of tin on the front door there?" asked a Michigan Central engineer as we sat up behind him not long ago. "Well, I'll bet you $400 you can't guess what it was for." We did not have the change, so he gave it away for nothing. "When the air brake first came out, I got one of the old-fashioned pumps with the valve tappits outside, and it used to have a habit of stopping to rest, and I had that hole bored there to punch it up with a stick in cold weather. I had an old piece of broom handle for a 'prod,' and would as soon think of going out without the smoke-stack. I kept that pump, too, until the madam went in the shop last year. I had a comical genius of a fireman, who named the stick the air pump reverse lever."

Many roads that have for years built their own locomotives are abandoning the practice, finding that they can buy better engines, built to standards, for less money and in shorter time than can be built at home.

There were 40,188,000 railway passengers who arrived or left New York between May 1st, 1887, and May 1st, 1888.



TAY ENGINE.

Historical Locomotives.

FOURTH SKETCH.

We present to our readers with this paper, some illustrations of an engine with a sad history—the one that took the plunge into the Tay, Scotland, when the great bridge that crosses that arm of the North Sea went down.

The bridge over the Firth of Tay—between Newport, on the south, and Dundee, on the north—was commenced in 1870, and the first locomotive passed over it Sept. 22d, 1877, and it was opened for traffic the following May.

The bridge was nearly two miles long—10,350 feet—and consisted of 85 openings, eleven of them being spans of 245 feet. All but one were of the form known as lattice girders.

The bridge was not straight, but built on a curve of 30 chains, 1,980 feet radius, and the tracks were 88 feet above high tide.

The bridge carried a big traffic, but being a single line of rails, was worked on what in Europe is called the "staff" system. There is a brass rod, and only one, and the engineer who proceeds over the staffed track must have the staff, and if he does he knows that no other train is on the line. At this bridge the trains slowed down to three miles per hour, to receive the staff, but it was proven that they ran as fast as 35 miles per hour over the bridge, the authorized speed being 25.

This bridge cost £350,000—over a million and a half of dollars, and was the property of the North British Railway Co.

On the night of Dec. 28, 1879, during a

fearful gale of wind, engine 224, pulling seven passenger carriages, slowed up on the south side, received the staff, and proceeded toward Dundee. Several people saw the lights of the train disappear, but neither the engineer or fireman, or one of the seventy passengers behind them, ever lived to tell how the accident happened.

Thirteen of the central and largest spans of the bridge fell—eight of them ahead of the engine—so it would seem that the storm had a hand in the disaster.

Probably no railroad wreck ever happened that was more widely known and deplored, the world over, than this. There is something appalling about the utter annihilation of a crew and train of passengers, that does not attach to wrecks where some escape to tell the tale.

The large illustration shows the general design of the engine. She is an 8-wheeler, inside connected, 17x24, driving wheels 6 feet 7 inches in diameter; the reverse lever is not common in Europe, but is employed on this road; engine had Westinghouse air brakes; as will be seen the boiler is domeless, copper fire-box, brass flues and straight stack. The rear view shows the chains and tackle used by the divers to raise her, and the pictures here shown are from photographs taken on the Dundee docks the day the wreck was raised by Messrs. Valentine & Co., of Dundee.

Keen-eyed American enginemen will notice the peculiarities of construction, though this engine is more on the general plan of locomotives in the United States than any European-built engines we have ever seen.

In the photograph furnished of the back end of engine the reverse lever is shown upon the left side. This was reversed in engraving. Mr. Angus Sinclair, author of "Locomotive Engine Running and Management," who commenced his railroad career in Scotland, tells us that locomotives are built with the reverse gear on either side, generally the left. It is the custom there to run upon the left-hand track, on double track; teams and pedestrians turn out to the left in meeting, just as they do to the right here.

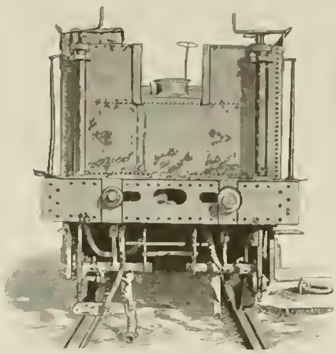
The tank view shows the heavy, double-screw brakes, and their mode of attachment, and also the peculiar construction of the coal pit, being high and small, while the water space is proportionately large.

We are under many obligations to Mr. Matthew Holmes, superintendent of locomotive and carriage department, North British Railways, Glasgow, Scotland, for data and drawings kindly furnished for this article.

"The railroads of the world are to-day worth from twenty-five to thirty thousand million dollars. This probably represents one-tenth of the total wealth of civilized nations, and one-quarter, if not one-third, of their invested capital."—Arthur T. Hadley *in Scribner's Magazine.*

An Internal Railroad.

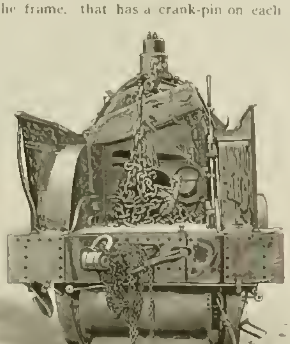
Many railroad men "from the country" have been surprised to run onto an immense freight depot in the heart of the district devoted to wholesale houses in New York city, while passengers only come in as far as 42d street, fifty blocks further north.



Tender, Tay Engine.

The N.Y Central has an immense freight depot at Beach street and West Broadway, and cars from all over the country are there switched back and forth by a number of mongrel locomotives. These locomotives are small, geared, dummy engines, on four small wheels; they are boxed up like a car, have upright boilers, and a reverse lever and throttle located at each end of the machine; the levers and throttles work together, and the runner always changes ends when he wants it to go the other way, there being a link on the reverse lever handle, that locks the latch out of gear with the quadrant on the lever not in use.

The power is transmitted to the drivers by a geared master shaft in the center of the frame, that has a crank-pin on each



Rear View Tay Engine

side, from which independent rods go to each driver.

The cars are hauled over tracks laid down Canal street to the docks, thence along the Hudson River to 30th street, where they are handled by ferry.

The streets through which these engines handle their trains are crowded with traffic, and the goats never go out of the building without a flagman ahead of them; and, in starting off to deliver cars at the end of the line, the man with the red flag rides a bay horse in front of the rushing train, that has its rush tamed down very considerably.

Steam Pipe Repairs.

In a recent conversation with two experienced roundhouse foremen, we found that, while one did a lot of work every year on steam pipes, the other rarely had to grind one in, and claimed that leaks were the direct result of abuse at hands of engineers, or too weak bolts in putting up.

Drifting into the cost of grinding in steam pipes, they differed greatly, and finally asked The Locomotive Engineer to propound the following questions to the roundhouse foremen of the country, and "average the verdict."

1. As a general rule, how often do you grind in the steam pipe joints on engines in regular service?

2. Have you any special tools for it? If so, what?

3. Do you keep a machinist and helper for this work, with tools for it, etc., or do you make the men take their turns at it?

4. How long does it take to grind in joints in front end?

5. Do you, as a rule, make the engine lose a trip for this work?

6. Do the engines on your road have relief valves on chest, to prevent overpressure in chest and pipes when engine is reversed? If so, has it cut down the work on pipes?

7. Do you note any difference between passenger and freight engines?

8. Do you use a clip or bridge over lower joints, in addition to regular bolts?

9. Do you notice any difference between pipes in extension and short front ends? Which lasts longest?

10. How much does it cost to grind in the four joints?

Our friends in the roundhouses and shops will be contributing to the knowledge of others in the same walk of life, and may call out kinks of use to themselves, by answering as many of the above questions as they can. A comparison of work can but benefit all.

It is a notable fact that the big engines being turned out for fast passenger service far and near, are, in a great many cases, keeping their driving-boxes about as hot as they do the fire-box. When we get over 15,000 pounds on a driver we are pretty close to the limits for cool boxes and fast time; if heavier mills are needed to make the time, it will pay to put another pair of wheels under them. Whether it is better to run such heavy trains and heavy engines, or to run more and lighter trains and lighter engines with but a single pair of wheels, is an open question.

A Modern Boiler Tester and Washer.

A few years ago it was a 10-hour job to get a locomotive boiler blown off, properly cooled down, washed out, filled, and steam raised again.

The demands of service have made it necessary to cut down this time, and, as it could be done in no other way, the time for cooling the hot sheets of the boiler was cut down till the limits of safety were reached, and, in many instances, passed.

At the shops of the Philadelphia & Baltimore Central R. R., at 16th street and Washington avenue, Philadelphia, engines are taken in, blown off, washed out, filled, fired, and cross the table in one hour, and without danger to the boiler.

This is accomplished by a simple arrangement of injectors on the stationary boiler, and the use of hot water instead of cold, both to wash out and re-fill the boiler.

H D. Gordon, M M of this road, now a part of the Penna. system, has designed the washer and tester shown in our engraving. The apparatus consists of two common Rue injectors—non-lifter—and the arrangement is clearly shown and all sizes given in engraving, so that any master mechanic can make one without other drawings. The large injector is used to wash out and fill up the boiler, and, as the demands upon it are not so great as if it were feeding a boiler under pressure, its delivery tube can be enlarged or its steam tube diminished, causing it to throw a larger quantity of water in a short time.

In practice the boiler is blown off and water run out, and the big injector put to work on the wash-out hose; this can be done at once, as the water is hot. As soon as the boiler is washed the plugs are inserted and the hose attached to the blow-off cock or the feed pipe of an injector, and the boiler filled with hot water.

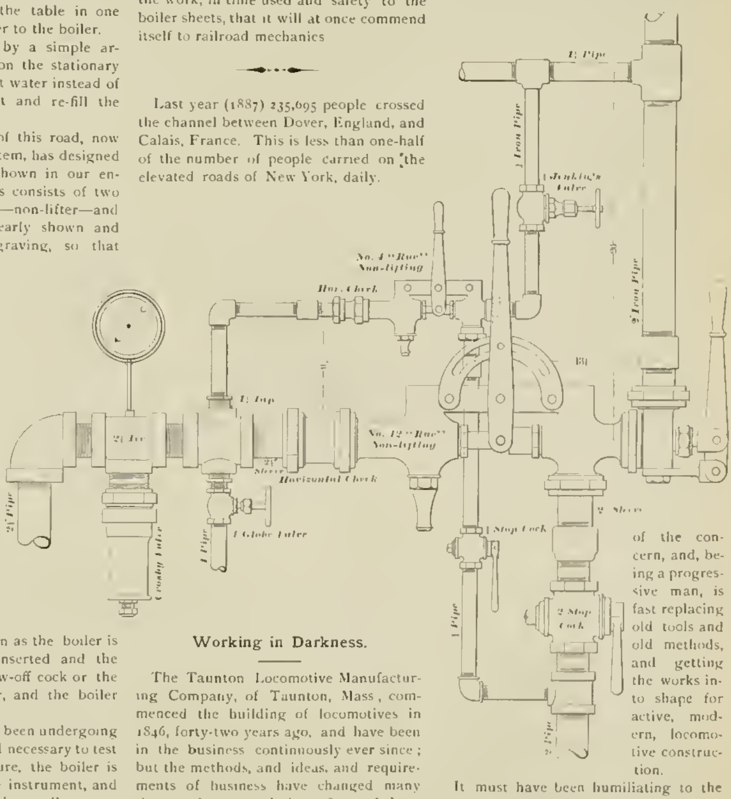
Should the boiler have been undergoing repairs, and it be deemed necessary to test it with hydraulic pressure, the boiler is filled full with the large instrument, and it is then shut off and the small one put to work; this injector is required to throw but a small amount of water, but against great pressure, and the nozzles are especially arranged to accomplish this result.

This device places the whole affair under the hand of the man who is manipulating it; the gauge tells the pressure on the boiler, and the large, inverted, Crosby pop immediately under it, prevents the pressure from reaching a dangerous point, should the tester neglect or forget his work

In testing, it is often desirable to reduce the pressure for an instant, or hold it temporarily at a given point without shutting off the feed. This is accomplished by using the small globe valve shown under the delivery connection of the tester to the main water pipe.

The Rue Injector Co. make a tester and washer, all in one casting, that accomplishes the same results as does this arrangement, but in the shop mentioned the large injector was already in use as a boiler washer, and the small instrument for some other purpose, so it was decided to utilize them.

The device costs so much less than a steam pump to wash, or a test pump to test, and is, withal, so much superior for the work, in time used and safety to the boiler sheets, that it will at once commend itself to railroad mechanics



Last year (1887) 235,695 people crossed the channel between Dover, England, and Calais, France. This is less than one-half of the number of people carried on the elevated roads of New York, daily.

Working in Darkness.

The Taunton Locomotive Manufacturing Company, of Taunton, Mass , commenced the building of locomotives in 1846, forty-two years ago, and have been in the business continuously ever since; but the methods, and ideas, and requirements of business have changed many times and very much since 1846, and those who did not keep in the current have been swept into eddies of inactivity—this has been the fate of the Taunton Locomotive Manufacturing Co. Men get old and slow, and unless they read and interpret the signs of the times correctly, they do not keep up with the march of improvement They keep old shops and old tools, not because they are as good as the best their competitors can have, but because of the good they have done in the past. A chain-feed lathe will insist on a chain-feed mechanic, and both will only turn out chain-feed work.

Twenty years ago the company cited had as good a plant, and did as good work and as much work as any other concern in the country; all was well then, they let well enough alone—there is no such thing as "well enough" in locomotive manufacturing. The old tools and old men kept at work on such business as early connections and personal solicitation would bring; time went on, letters dropped off the signs on the buildings, advertisements were withdrawn from the railroad press, and moss gathered on the reputation of the works.

Now a change has come; a new hand and a younger head directs the destinies of the concern, and, being a progressive man, is fast replacing old tools and old methods, and getting the works into shape for active, modern, locomotive construction.

It must have been humiliating to the new manager—and it certainly teaches a lesson on advertising—to be told, as he was this month, by an official of one of the Brooklyn elevated roads, that he had never heard of the Taunton Locomotive Manufacturing Co. This mechanic is not a novice in the business, but has long been connected with railroad work, and lives within 200 miles of Taunton.

The address of the president of the Master Mechanics' Association, J. H. Setchel, has been changed from Dunkirk, to Cuba, N. Y. Mr. Setchel has accepted a position with the Martin Anti-Fire Car Heating Company.

Locomotive Clock.

Locomotive clocks that will keep good time in this exacting service, and that can be bought for less than the locomotive itself costs, are a safeguard and a convenience that few engineers can afford to be without.

For some years our correspondent, W. F. Relyea, of Syracuse, N. Y., has been "fixing up" clocks for the engineers of the N Y. Central, and they have given such universal satisfaction that the firm of Becker & Lathrop, of Syracuse, have decided to put them on the market. Mr. Relyea's plan was to buy a first-class, Seth Thomas, 8-day works, with an enameled face, and put them into a steam gauge case. There are about 100 of these clocks, giving first-class satisfaction, some of them having run 12 years.

The new clock looks just like the ones sold for $20 and $25, and, the users say, are just as accurate time-keepers.

They have a six inch face, a heavy case of polished brass, with a front that screws on, dust and damp-proof They are beauties, and, being sold and guaranteed for the small sum of $10, we predict for them a welcome from the footboard.

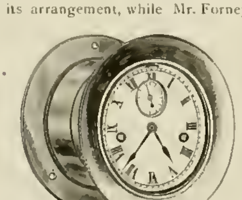
Firing Anthracite Coal.

FIRST PAPER.

Allow me to introduce myself, and show the reason why it appears that an article, or series of articles, on hard—anthracite—coal firing may not be unprofitable reading to the majority of your readers. As for myself, I am now running a locomotive, but as I have not been at it long enough to forget my trials and tribulations as a fireman, I still take a lively interest in the "boys" who handle the scoop, and hope to ever retain a fellow feeling for them, which, as the poet has it, "makes us wondrous kind." Seeing that for nearly ten years my name was on the pay-roll of our company as a fireman, six years of this ten was put in over the road, and nearly four years in the roundhouse; and I ought thus to know a little on the subject of hard-coal firing, as that is the only kind of coal used on our road.

Several years ago, a brother fireman, employed on the L. S. & M. S. R. R., in Indiana, whom I will call George Long, paid me a visit, and during that time I endeavored to show him whatever I thought might prove new and interesting; and in one instance at least I succeeded, and that was when I got on one of our hard-coal burners with him, as she was pulling a heavy train up one of our heaviest grades. The train was in motion on a nearly level section when we got on, but we soon came to a hard pull, and had a climb of sixteen miles ahead of us. I introduced Bro. Geo. Long to fireman George, whom we will call Short, and to the engineer and brakeman, and as the two firemen entered into conversation at once, I devoted a few minutes to the engineer. I soon noted that Bro. Long seemed inclined to stop talking to Bro. Short, and to get uneasy. At last he got a position where he could see the steam gauge, and found the pointer indicating 130 pounds (the maximum pressure), and still Bro. Short was ready to talk on. Bro. Long at last relieved his mind by asking me: "How long is this to keep up? When does he put in his fire?" I told him he would see pretty soon. The train moved on nearly three miles before Bro. Short shoveled any coal, and then he put in only three or four scoopsful, and with four or five more at another point, we made a run of eight miles from where we got on. At this point we stopped to take water, and while coming to the tank and laying there, Bro. Short "cleaned his fire," and then piled in the diamonds until Bro. Long thought he was never going to stop. Bro. Long had then fired some four or five years, but had never seen the like before, but still I thought his an isolated case of ignorance of "our ways," but I find that many more of the "rank and file" of firemen have no conception of hard-coal firing.

Mr. Sinclair, in his book on "Locomotive Running and Management," mentions a hard-coal burning passenger locomotive and its performance, but gives no dimensions of fire-box, and description of its arrangement, while Mr. Forney, in



LOCOMOTIVE CLOCK.

his "Catechism of the Locomotive," fails to give any cut or description of the hard-coal locomotive, or its fire-box and area. Mr. Forney, in giving the size of a "Baldwin Mogul" fire-box, gives its dimensions as $66 \times 34\frac{1}{2}$ inches. Our Baldwin Moguls measure 33 to 34 inches in width, by 8 ft. 4 inches, or just 100 inches in length, while the Cook Mogul fire-boxes are from 95 to 97 inches long; and the Dickson run as high as 9 ft. 1 inch, or 109 inches, while our Consolidation fire-boxes are 113 to 115 inches long. There is thus a great difference in the length of hard, as compared with soft-coal burning fire-boxes, as well as some difference in the construction of the grates. The grates of a hard-coal burner consist of a series of tubes called water bars, in connection with the water space in the leg of the boiler, and of two, three or four solid iron grate bars which are movable. Both series of water bars and grate bars extend lengthwise of the fire-box, and in the newly built locomotives are of a uniform level, but in some older types used to range up and down, thus giving a greater number of water bars. The water bars are of course immovable, being inserted in the water leg and fastened the same as flues; but the grate bars can be pulled out, and as the thimbles in the back leg of the boiler, through which the bars slide, are above the level of the tank floor, and the bars are provided with heads, it is an easy matter for the fireman to pull them out as far as needed in the manipulation of his fire. The number of water bars vary from six to ten, and, as stated, the grate bars range from two to four, inserted at regular intervals between the water bars, and not all in one place, as might be assumed.

The Baldwins differ from other locomotives in the fact that their grate bars do not slide, but are attached to a series of rocker arms, and these rocker arms are so connected, that the movement of a lever, having its connecting rod and handle in the left side of the cab, moves the whole set of bars out of the way by a side movement, leaving the space between the water bars and formerly occupied by the grate bars open, in the same manner as is done by pulling the bars out in other locomotives. Of course the water bars do not come so close as to touch, but have a space from ½ to ¾, and in some cases an inch, between them and their adjacent water or grate bars, forming spaces for the admission of the much-needed air. There are no fire arches, water arches or brick arches in use in our hard-coal burners, and only a few have a so-called combustion chamber at the front end of the fire-box. This combustion chamber is a recess between the line of the inside of front fire leg and the flue sheet. This varies from 6 to 12 or 15 inches, and is thought to produce a more perfect combustion of the gases before they reach the flues in their mad rush to the stack, and through it to the air. There are no dampers attached to the fire-box or ash-pan of these hard-coal burners. The only dampers the hard-coal fireman has to contend with, is the damper put on his gauge and spirits by the pump or injector, or the tongue of his engineer.

Another feature of the hard-coal burner is its ash-pan. As stated, in alluding to the grate bars, they are above the level of the floor; the front end on most of them droops a little, usually not over 4 to 6 inches. This brings the bottom of the fire high, as compared with a soft-coal fire, and leaves lots of room for the ash-pans, which are in reality small hoppers, and in the Moguls consist of two apartments, separated by the back axle. These hoppers extend downward to within 4 or 5 inches of the rail line, thus having capacity to carry a large quantity of ashes or clinkers, and they are often filled with the products of imperfect combustion of our sometimes very poor and slaty coal. These ash-pans have movable bottoms called slides, which move in suitable grooves, and are so connected to each other, and to a bell crank lever, that a pull on its connecting rod handle will allow the contents of the pan to run out on the road bed or the ash-pits. As the fire is cleaned a number of times during each trip, it is necessary to have places to dump the ashes at various points, indicated by sign-boards along the line; and this can of course be done while running, by simply actuating the slides, except in rare instances, where the mass of ashes and fire becomes baked together, and has to be broken up before it will fall out of the pan.

The door thus is the only means by which the hard-coal fireman can at all regulate his fire. In most all these locomotives the doors have one or more gas holes, fitted with slides, by means of which air can be admitted over the fire, and some doors also have ratchet latches, so that the door can be "put on the crack," accomplishing the same purpose.

Having now considered the hard-coal fire-box and its attachments, with the exception of the draft or petticoat pipe, which is, however, one of its most important helpers, and of which we may have more to say after a while, we will in our next take up the subject of putting in a fire. VULCAN.

Harpooning for Firemen.

W. De Sanno, an old-time engineer who used to run on the old State roads of Penna., has been contributing some interesting articles on early practice to the *Fireman's Magazine*, and, among other things, has the following to say of a special instrument for executing firemen:

Sand boxes had not come into general use, although sand was carried on the engines, or rather in a box on the tender. The sand pipes had a cup-shaped top, and the engineer and fireman each had a tin cup which they would fill with sand, and turn the cup to one side and let the jar of the engine shake the sand out. Cylinder cocks were not connected so they could be handled by the engineer, so it was part of the fireman's duty to jump off and run around the engine after she had started, and shut the cylinder cocks. In my first article I spoke of the front end getting red-hot. The stack mostly in use would look like the present diamond stack turned "t'other end up," placing the bulb next to the smoke-box. I think they were called the "Yankee" stack, or "pipes," as they were then called.

Petticoats were unknown; the exhaust pipes ran up to the top of the smoke-box and entered the netting, which was in the form of an inverted cone in the bottom part of the diamond of the stack. The smoke-box had nothing to help clean it out; the fuel was good wood and coal. The fireman would throw in about a dozen sticks of wood and then sprinkle a couple of shovels of coal over it; in consequence of no cleaning device in the smoke-box, the unconsumed parts of the fuel would collect there and ignite, and heat the front end to a cherry-red—the front end door was boiler iron—when they would stop for wood and water, the fireman would take water (there were no head brakemen in those days), unless some of us boys would jump up and take water for him (which water act the writer has often performed). While water was being taken, the fireman would clean out his ash pan and then go around and hoe out the front end, or there was no steam; so you see, boys, the man on the left side had no time to flirt with the girls. The fireman had another duty to perform, the neglect of which cost some of them their lives. All covered bridges were too low for the stacks; in consequence, the stacks all had a joint in them where the diamond and straight parts met. To handle the top of the stack, a long rod was connected to it, leading to the left side of the engine. On approaching a covered bridge, the fireman had to take hold of the rod and pull the stack down. It sometimes happened at night that he would not see the bridge in time, which, striking the stack, would knock it back, and drive the rod through the body of the fireman, if he happened to be on his box at the time; so you see it has been a dangerous calling ever since railroads were first worked by steam.

FIG. 2.

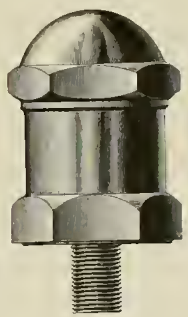


FIG. 1

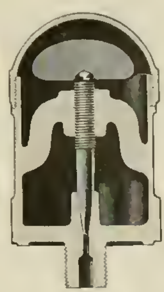

FIG. 3.

The Northern Pacific Oil Cup.

James McNaughton and Adam Beardsley, two mechanics employed by the N. P., several years ago invented the oil cups here shown, and they have since been through the test of time on that road, and have been adopted as standard. Fig. 1 is a rod cup; the top screws on, or it can be made to slip on and hold by a spring catch. Fig. 2 is a guide oiler; its cover slips over the entire cup down to the hex. for wrench. Fig. 3 is a sectional view of both cups.

As will be seen, the needle feeder is held in any position by the thread in the bridge; this bridge is cast in two pieces, and these halves are wedged apart while the thread is tapped, the wedge is then withdrawn, and the spring of the bridge binds the screw.

The feed can be adjusted by the thumb piece on top, and there are graduation marks on the cup top to regulate by, no wrench or screw-driver being necessary.

A large size of this cup is also made for engine trucks, and used on the N. P. The Reading road have also adopted this cup. Pedrick & Ayer, Philadelphia, are the makers.

A Substitute for the "Laying Off" System.

We are in receipt of a letter from a prominent railroad man, himself a brotherhood engineer, who has held many railroad positions of responsibility, saying that he has thought a good many times of some plan of punishment for breach of discipline and minor offenses, other than the common one of "laying off."

He says he knows of many instances where men have deliberately disobeyed orders and rules to get laid off when they could not get a rest by fair means, and is satisfied that in half the instances it is no real punishment unless of more than 30 days duration; he is, however, opposed to holding men off "pending investigation."

While the men would resist the fine system, it may have its advantages over the lay-off, yet we hardly see why. It would be better for the company, as it would not inconvenience them by running short of men, and for this reason would be liable to be used to excess, but whether it would be more punishment to make a man work for nothing, or not work at all, for a certain number of days, is an open question—we are inclined to think that either system is wrong and open to grave abuse, and the paying off of personal grudges.

Something beside mere reprimand is necessary for discipline, and we believe that the better way is to disgrace men by setting them back, take them off their regular runs, post a notice where all can see it that John Rogers, passenger engineer, worth $4 per day, did not answer signals given, and ran off an open switch, or had needlessly abused his fireman, and that he would run switch engine in the Agne Swamp yard for 30 days at $3.00. Or, Henry Smith, freight engineer, pay $4 40 per day, ran by red flag, causing collision; will fire freight engine 15 days, and then take his place as extra man on freight list.

This would be punishment and disgrace to men, and no one would seek to have his name on the list or go back to a subordinate position, and if he was obliged temporarily to do so, he would not be in idleness while doing penance, and his family would not be deprived of necessary support.

The Argentine Republic has a piece of straight track 211 miles long—the longest in the world. The *Railway Age* has been trying to find the longest tangent in the United States, and has settled on a stretch of track on the Carolina Central, between Marlville and Laurel Hill, North Carolina, which is 79¾ miles without a curve.

Correspondence

A Lubricator Idea from Newfoundland.

Editor The Locomotive Engineer:

In a recent issue of THE LOCOMOTIVE ENGINEER, I notice an item stating that Elijah McCoy had patented the idea of attaching lubricator's pipes to steam passages, etc., etc.

Now, during the past four years I have used lubricators on all the locomotives here in the same way, and they have given good satisfaction throughout.

ROB'T STEIN, M. M.

St. Johns, Newfoundland.

Master Mechanics Interested.

Editor The Locomotive Engineer:

Enclosed you will find order for a year's subscription, commencing with October issue. I was very much interested in your account of the Stourbridge Lion. I believe locomotive enginemen from top to bottom should read more. I have Colburn's and Sinclair's books on the locomotive, and think there is enough instruction there given to keep a man thinking for years.

I would advise all men in the business to have one or both, and in fact I now know of several who carry them in their seat boxes.

San Pedro, Los Angeles & Utah R. R.

Pasadena, Cal.

That Balky Engine.

Editor The Locomotive Engineer:

I may be a little late, but in reply to Wm. R. Cline's conundrum in August number, I would guess that his "plug puller" had taken the key out of the throttle lever's connection to the stem, and that the other fellows were only moving the lever when they thought that they were moving the valve.

Denver, Col. H. D. DOYLE.

The Golden Rule.

Editor The Locomotive Engineer:

In your article on "Hasty Judgment" I found considerable food for thought, and hope the seed will not fall on entirely barren ground.

We have had several master mechanics here in my time, some engineers and some not, and I am free to say some of them have been grumbled to death by a few chronic kickers.

I think we ought to be at least fair, and not ask unreasonable things of men who are over us, but responsible to higher officers.

We have got an old engineer here as M. M. now, as fine a man as any body of men would wish to be under, but these grumblers and growlers keep nagging at him; instead of that, we ought to be proud to see an engineer our M. M., and do all we can for his success. He has been through the mill himself, and I don't believe he would ask us to do anything but what is upright and what he would do himself. I know, for my part, he has always been very obliging, and done his best to please us.

Hoping this will help rub in your advice a little, I am a believer in the Golden Rule.

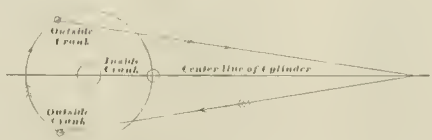
ENGINEER.

Montreal, Can.

A Triangle Engine.

Editor The Locomotive Engineer:

There are some signs of a change, or rather a necessity for a change, in locomotive construction, and I have been giving the subject considerable thought. Mr. Webb, of England, has built a number of compound locomotives, using three cylinders, and the idea struck me that the engine would be simpler and more effective using high-pressure steam in all three cylinders, and making the cylinders all the same size, and smaller than those now used. I would propose to place the cylinders in a row, and couple all three connecting rods to the main pair of drivers, and couple the back pair as usual with side rods.



I send you a plan of the cranks; the three cranks are equal distances apart, and are thus at *triangles* to each other, and not right angles.

The advantages I propose to gain by this scheme are steadier running, and you will see by the sketch that two cylinders are always at work, and the two cranks at work are more nearly opposite each other than in a quarter crank engine; by this plan the engine is in itself more nearly counter-balanced than ordinarily, and required to use less dead weight for this purpose, thus reducing the hammer-blow. Such a plan would make a more continuous application of power than the present plan of two engines coupled at right angles.

In place of the present 20 x 24 engine I should propose three cylinders of $16\frac{3}{8}$ bore. The three pistons, with their rods, crossheads, etc., could be much lighter than those now used, both because of the smaller cylinder and the self counter-balancing principles.

In Webb's compound engine it is possible to get the low-pressure and one high-pressure cylinder on the center—as the drivers are not coupled—in this case slack must be taken to start a train. In my triangle engine *two* cylinders are always in use, and no such center trouble could occur. Again, the compound engine jerks very hard when the big low-pressure cylinder takes steam—so much as to make the cars behind uncomfortable—a bad feature.

I shall not go into the details of construction or of cost; I make this show of my idea to have the mechanics of the country criticise it, and I want them to. I fancy with three smaller cylinders, a shorter cut off could be used than on two large ones; that they would wear longer, use less steam and thus less fuel; that they would apply their power more evenly around the axle, slip less, make the engine roll less, and ride easier.

We have had the celebrated Fontaine engine, the long cylinder, Roberts engine, the Strong engine, the flat-wheeled Swinerton, but we have not as yet had the *Triangle engine;* and if I do not present my humble idea, there would not be a chance for anyone to exclaim—what a fool idea!

H. KINGSLAND.

Fort Scott, Kansas.

[In 1853-54 there was a 3-cylinder locomotive built by the Phila., Wilmington & Balt. R'y. It was arranged with two sets of steam pipes, one to the outside cylinders and the other to the inside one. It was designed to start the train with the two outside cylinders and then keep it in motion with the center cylinder; she ran for several years. On the Gravity roads of Pennsylvania many of the hoisting engines are built with 3 cylinders, and when the Penna. Coal Co. started to build their road—now the Erie & Wyoming Valley—John B. Smith, now president, designed and built, at Dunsmore, Pa., about 1879, three locomotives arranged just as our correspondent has described, and possessing all the advantages he claims for them. While these engines give perfect and entire satisfaction, we notice that common, 2-cylinder locomotives have since been purchased by this company. While this style of locomotive has some advantages, it is yet—in first cost, maintenance, and liability to derangement—a locomotive and a half. Improvements in locomotives should tend to efficiency and simplification.]

Another Case.

Editor The Locomotive Engineer:

I see in the September number you have cut and description of Tripp patent piston valve. My object in writing you is that honor may be given where it is due. I have in my house a small engine that has been in good working order for over one year, that I made myself, that has the same valve; you could not tell them apart, only my relief valve is in four pieces; it has two end plates, which makes it very heavy. I can put this balance valve on any engine that has ports.

Greenville, Pa. J. P. SHAW.

[This invention seems to have been applied about the same time Tripp's valve was, but the inventor forfeited both the honor of the invention and the profits, by keeping still about it.—ED.]

Glycerine on your front windows will prevent them from retaining moisture and frost.

That Balky Engine.

Editor The Locomotive Engineer

I suppose some of the boys are wondering about that engine that wouldn't go; so here is the reason.

Her cylinder oil cups were tapped down on the sides of the boiler head, as you often see on different roads.

Some one had been fooling with the steam valve of oil cup in the absence of the engineer, and through ignorance or otherwise, of the meddler, it was left open. It was on the right side, and she stood some time without being moved; her cylinder cocks were shut, and of course in a few minutes the right cylinder was so full that she made a very sorry move indeed, it was strange the men could not find the trouble. A blind man could have located it when the cylinder cocks were opened.

Our night engineer wasn't the best in the world; hence the difficulty.

McArthur, O. WM. R. CLINE.

Some Roundhouse Pointers.—How To Grind Plug Cocks.

Editor The Locomotive Engineer

Chancing to be in a strange town, I strolled into the roundhouse of the only railroad in it, to see what I could learn, or steal, as we say. Well, I did not learn much, but I will tell you a secret. It would pay some railroad companies to subscribe for a few copies of THE LOCOMOTIVE ENGINEER and distribute them among their roundhouse men.

One gang of men were putting a new pair of wheels under the front truck of an engine; the journals, 5x7, were too large for the new brasses they were putting in, so they had planed a heavy cut off each side, so that the brass stood ¼" off the journal at each side. There was a strip of babbitt 1x6 on each side, but they were working that down to the circle of the journal. Between the strips of babbitt was a large recess for oil; the brass would not have more than ¼ the bearing of the surface of the brass, which was very rough. If they had cut a recess in the wood block they put in the brass to run the babbitt in ⅛ or ¼ deep, and as long as the brass, so as to leave the soft metal that much higher than the brass, all the fitting the brass would need would be to clean the sand well off it, and open the oil hole and put it in, pack the oil cotton good, with a little tallow on the top, so as to touch hard against the axle, the soft metal would fit itself, and the brass would come down slowly and no danger of heating. I have often cured a hot brass by putting a piece of sheet lead over the face of the brass, and turning the edges so it could not slip around.

Another thing I noticed which was radically wrong, and that was grinding brass cocks with emery. One man trying to grind a blow-off cock in the lathe with coarse emery, he would put on a lot of oil, then sprinkle it thick with emery, start the lathe and shove the body up on the plug and hold it for a few seconds; then renew the oil and emery; after awhile, when he cleaned it off, it was full of rings cut by the emery; he filed it off and did the same again. I think one copy of THE LOCOMOTIVE ENGINEER in that shop would pay well; I never saw a cock ground with emery

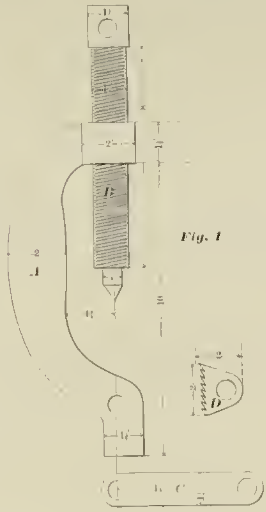


Fig. 1

Two of these links

that was worth anything. The emery will work into the brass, and commence cutting from the start. In re-grinding old work, they should be fitted first with a smooth file and a little oil, to show the high places when rubbed together. After they are well fitted, take some fine sand that is turned off the grindstone, and water, put the plug in the vise horizontally (not straight up), or the sand will work down and grind faster at the bottom than the top. In grinding, draw them apart at every turn, and they will not cut in rings. Gauge cocks often have a screw plug with the end turned to make the joint; these can only be ground by using a piece of brass without any thread on, that will go in and have the end turned the same taper as the plug. With this the seat can be ground, a slot sawed in the outer end for a screw-driver and a brace facilitates the work; then have a piece of brass with a hole in it the shape of the seat, to grind the plug with. All gauge cocks ought to have a loose plug with the stem running through the main plug, the end to come through the handle, so they can be ground without letting steam out, as the sediment and water will often answer for sand. A leaky whistle valve is a great annoyance, and the whistle is often screwed into the dome cap, and it takes ten horse-power to unscrew them; whereas if they were put on with a ground joint and three bolts, they could be easily taken off and reground; it is often these little things that could be so easily avoided, that make the worry and loss of time. An hour's thought may save a week's work.

J. J. BINGLEY.

Watertown, N. Y.

A Driving Spring Jack.

Editor The Locomotive Engineer

Having received much benefit from the "shop kinks" which I have often seen illustrated in your excellent paper, I would like to tell the boys of a handy back driving spring jack, which we find of great benefit to us in the roundhouse.

It is easily and cheaply made, and with its use we find it very easy to take out and put in back driving springs.

The enclosed rough sketch will enable you to form some idea of it, I think. *A* (Fig. 1) represents the body of jack, made of 1" x 1½" iron; the top end, through which the screw passes, we made 1½" thick, with 2" face.

The screw *B* (Fig. 1) we made of steel 1¼" x 8". These, with two steel straps *C C*, and a steel block *D* (Fig. 1), constitute the jack. The steel block *D* we fluted on the edge, which enables it to take a firm hold of the spring hanger. The fluted face of this block is 1" x 2". The two straps *C C* we made of spring steel ⅜" x 1¼", and pinned one each side of body *A* and block *D*, with ¾" x 2⅛" steel pins, allowing body and block to move freely between them. We put ⅛" spring cotters through the ends of these pins, as they can be more easily removed than nuts.

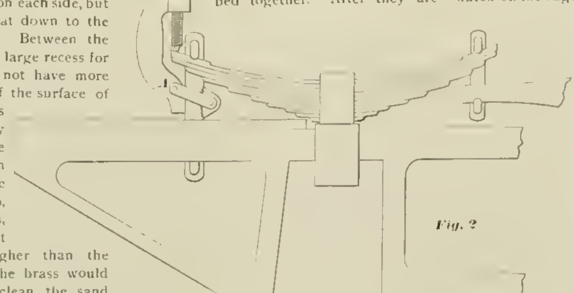

Fig. 2

To remove a spring with this jack, first raise the back end of equalizer as high as possible, and block it there. Then remove pin *A* (Fig. 2), leaving the other pin in place, pass a strap each side of spring hanger, *from the front*, and connect straps again to body *A*. When the hardened point of screw is applied to driving spring, the body *A* and block *D* are firmly clamped to spring hanger, holding it rigidly in place; at the same time the driving spring is compressed, rendering the removal of gib easy. As the screw is slacked off, after the removal of gib, the jack will roll on hanger at the point straps *C C* are connected to body *A*, and thus conform to upward and forward motion of the back end of driving spring, as the pressure is removed, thereby preventing the point of screw from slipping off the spring.

This "kink" is the idea of Mr. Seward Johnson, one of our roundhouse machinists, and has "helped us out" often when we have been in a hurry to change driving springs.

Hoping to see more of these "kinks" from the boys, I remain

L. C. HITCHCOCK,
Foreman Roundhouse.

Minneapolis, Minn.

Air Pump Repairs on the Providence and Worcester.

Editor The Locomotive Engineer:

I have been interested in the air pump articles in your paper, and thought perhaps our way of dealing with refractory pumps might help along the interest in that subject.

We came to the conclusion some time ago that it does not pay to tinker with air pumps on the engine. We keep spare pumps, which are always kept in order. When a pump is reported out of order or working bad it is immediately taken off and another put on. They being uniform, takes but little time to make the change, the engine is not delayed, and cuss words are unnecessary. When an air pump refuses to work there is something radically wrong with it, which the average engineer has not the necessary time or tools to fix. Sometimes the burnt oil and gum on the air valves can be made to work better by sucking in a little benzine or potash water. I have found the wings on some valves filled nearly full of this gum, thereby preventing proper work.

We take all pumps reported out of order all to pieces, give all parts a careful examination, and all parts fixed practically as good as new, carefully keeping the same proportions as in new pumps.

They are then tested in the shop—we have place fixed for that purpose. Every pump is tested to 75 lbs. air pressure, the pumps are started and stopped in all places and pressures, and thoroughly proved before they go out of the shop. A record is kept of the repairs on each, and the date when repaired; we know what each pump is doing.

The causes of stopping and improper work I find are many. The rings on small end of main steam valve broken—sometimes caused by the stop becoming short and allowing the ring to project below the end of cylinder—and ring springs out and prevents the valve going up, breaking the ring. Sometimes the stem on the reversing piston is broken. The reversing valve bushing sometimes needs grinding; frequently a new bushing is needed. Sometimes a bolt is found broken on the cap on main cylinder; when the reversing piston rod goes through, on the air end of pump, we find the valves badly hammered. The lift of the valves is out of proportion, and the air escapes freely. We use a reamer to true up the seats, put in new valves, and get the lift right. We frequently find the upper bush loose. This should always be examined and screwed up tight.

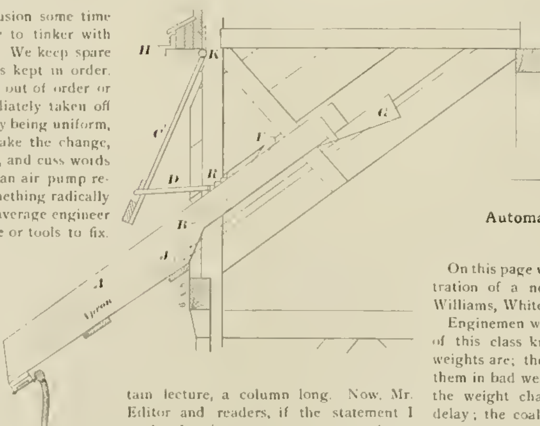
I think if these hints are followed out in air pump repairs, good results will follow. WILLIAM FOSTER.

Valley Falls, R. I.

The Long and Short Train.

Editor The Locomotive Engineer:

Judging from the manner in which J. E. Phelan came at me in the October number, he does not like any one to take exception to his writings. There I think him very inconsistent; for, after seeking to create a wrong impression of what I said, and remarking that "Life is too short to say anything further on the subject," he proceeds to deliver a curtain lecture, a column long. Now, Mr. Editor and readers, if the statement I made, that it was necessary to exhaust *more* air from a train of twenty cars than from one of five or ten, in order to reduce pressure a certain number of pounds, does not carry the idea that we take into consideration the number of cars in train in handling the automatic, I will retire and give J. E. Phelan a clear field.



He says, if we can "use *more* air without proportionate indicated reduction on air gauge, we would accomplish a novel feat."

Now I wish it borne in mind that in speaking of *more* air, I referred to twenty cars, as to five or ten.

If J. E. Phelan or any other man can reduce pressure in train pipe of twenty cars a certain number of pounds, without using *more* air than he would on a train of five or ten, he will do something outside of any known laws.

I am willing for anyone to make objections to what I say, but I don't like to have them misrepresent me.

He says he has seen a train of twenty-four cars where a reduction of five pounds did not set a brake, while eight pounds set them all. I will admit this, but go just a little farther, and ask one question: Couldn't the pressure have been reduced eight, ten or more pounds, without setting a single brake? I have seen pressure all taken from train pipe and not a brake set; but this is not saying it was done in a proper manner.

I have known engineers to start down a grade of 75 feet with a freight train equipped with air, and before going five miles to squeal for brakes. They had wasted all their air without setting a brake sufficient to do much good.

They probably handled it in a manner similar to the way it was done in the instance cited by Mr. Phelan, where a five-pound reduction wouldn't set a brake, while one of eight set all. It looks a little queer that a man couldn't get *one single brake to set* from a five-pound reduction, while with only three more he gets such good results.

For the benefit of Mr. Phelan, I will say that I have not graduated from an air brake school car, but have had a *little* experience in the use of the air brake. I am not an advocate of theory without practice. Better the practical man without any theory than *vice versa*; but I don't object to a little theory put into practice.

Denver, Col. H. S. H.

Automatic Coal Chute.

On this page will be found a detail illustration of a new coal chute, made by Williams, White & Co., Moline, Ill.

Enginemen who have used some chutes of this class know what a nuisance the weights are; the power required to move them in bad weather and the fouling of the weight chains that cause so much delay; the coal or drop door with independent latch is also a nuisance.

In this chute no weights are used, the apron being balanced and the drop door is held open automatically. By pulling on the rope the latch bolt is released from the hook *H* and the apron comes down easily, when nearly in position, arms on each side that extend back to the latches *B*, that hold the drop door *C*, on each side trip these catches and release the coal. This drop door is held open by the dog *D* dropping into the ratchet *R*. When the coal is all out the apron is given an upward push, and it returns automatically, tripping the latch *D*, and positively latching the drop door and itself. It is guaranteed that one man can always operate this chute.

Another advantage is that the trestle for cars is entirely independent of the chute building, and can be raised, lowered, repaired or removed without disturbing any timbers of the building.

This chute has been adopted on the U. P. and the C. K. & N., and each of these roads has put up over 200 pockets the past summer.

Honor to Whom Honor, Etc.

Editor The Locomotive Engineer:

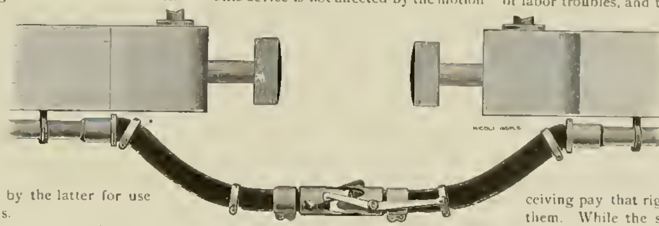
Referring to the article entitled, "Hard Tests of Chilled Wheels," in your issue for October, we beg leave to say that the honor of having invented the first contracting chill of which we have any knowledge is due to Mr. L. R. Faught, superintendent of our mechanical department. It was made in 1876.

"The Whitney Contracting Chill" was invented by the present senior member of this firm in 1885. A. WHITNEY & SONS.

Philadelphia, Pa.

Jacobs' Patent Steam Hose Coupling.

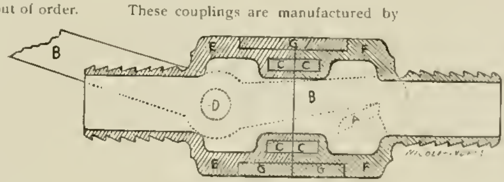
This coupling has heretofore been known as the Graydon coupling, having been successfully used by the Graydon Safety Car Heating Co., for one season, on the Vandalia R. R., and subsequently adopted by the latter for use on all their trains.



To meet the requirements for a first-class coupling for this purpose, the following conditions must be observed:

1st.—It should be constructed of few parts, all of which are strong and durable, and not liable to get out of order.

2d.—It must be easily and quickly coupled together without tools, when making up trains.

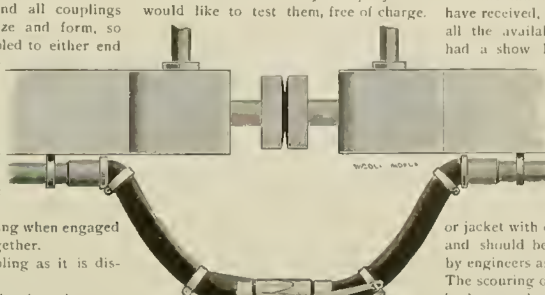


3d.—It should have a straight-through steam passage.

4th.—It must form a perfectly tight joint that will not leak.

5th.—It must disengage automatically when the cars are uncoupled and separated.

6th.—Both halves of the coupling must be exactly the same, and all couplings must be of standard size and form, so that any car can be coupled to either end of any other car and the steam couplings will match.



All of these requirements seem to be fully met by the coupling here illustrated, as will be seen on examination of the cuts.

Fig. 1 shows the coupling when engaged and the cars coupled together.

Fig. 2 shows the coupling as it is disengaging.

Fig. 3 is a section showing the construction of the device.

The coupling consists of two malleable iron castings, *E E* and *F F*, each of which has three projecting points, which overlap and project into corresponding recesses of the opposite casting. See Figs. 1 and 2.

Two levers "*B*"—one pivoted on *E E* and one on *F F*, as shown by "*D*." These levers are always on the left side of the casting to which they are attached. When the hose is coupled and depressed, as in Fig. 1, the hooks on the levers engage with the lugs "*A*," clamping the two parts of the coupling together by the combined weight of the hose and coupling, and holds them locked until the coupling is lifted or the hose straightened.

The two rubber packing rings "*C C*," "*C C*," made especially for this purpose, are of sufficient depth to insure elasticity, and made to fit the recess tightly. When the coupling is separated they project about ¼ inch. This packing has been frequently tested, and has proven all that could be required for holding steam or water.

This device is not affected by the motion of the cars or the swinging to the hose. It will hold perfectly tight until the cars are separated. There are no bolts, screws, springs or nuts to lose off, rust, or get out of order.

These couplings are manufactured by D. W. Williamson & Co., 482 E. New York st., Indianapolis, Ind., who will cheerfully furnish any further information that may be desired. A full set of these couplings will be furnished to any company that would like to test them, free of charge.

Heavy locomotives are very common nowadays. The Baldwin locomotives on the New Haven R. R. weigh 95 tons—passenger engines—and forty locomotives, weighing 157 tons each, are being built for the Canadian Pacific road, at Hochelaga, Canada.—*Engineer*.

As a matter of fact, the New Haven engines weigh about 110,000 pounds, 55 tons; on the Canadian engines Bro. Watson has probably got tons and thousand pounds mixed up. If he means tons he should have put it at even 200—if it don't make any difference to him—it is easier to remember.

Frank Eaton, an engineer on the Boston & Maine, has copyrighted a neat form of time book for engine and trainmen. It pays any man to keep his own time, whether required to by the rules of the company or not. Bro. Eaton's books cost but six cents each, or 50 cents per dozen—one might save you a trip's pay.

---

* * * Railroad conductors have, as a rule, stood faithfully by the roads in time of labor troubles, and this society and the companies may be of material aid to each other.—*Railway Register*. This, it will be remembered, is the order that claims that the enginemen are now receiving pay that rightfully belongs to them. While the society is being of material aid to the companies the latter are introducing the ticket picker—claiming that the conductors are getting pay that belongs to the company. Queer world, this.

A. W. Wright, timekeeper M. C. R'y. shops at Detroit, sends us a club of 75 names, and modestly remarks:

"The paper is exceedingly interesting, and affords a great deal of valuable information to engineers and firemen. I will send another list soon after pay day. Am sorry to say there will not be many names, as I have only about 160 men on my pay roll altogether."

While this is not the largest club we have received, it is the best percentage of all the available men. If Mr. Wright had a show he would be at the head of the class.

The practice of cleaning the outside of an engine while running—unless it may be the hasty going over of bright work or jacket with oil in case of storm—is bad, and should be condemned and stopped by engineers as well as master mechanics. The scouring of cab brass while running is almost as bad. There have been several accidents of late because signals and switch lights on the left side of an engine were not observed.

Firemen already have many duties while the engine is running—especially soft-coal firemen—but every minute not otherwise necessarily employed should be used in watching the track and signals.

CONTENTS.

What We Ought To Do.

All over the country there are being organized railroad clubs, for the discussion of railroad questions. These clubs, as we understand it, admit any person employed by a railroad company, and are being encouraged and taken part in by many railway officials. The Brotherhoods are losing ground in this very particular, when they ought to be gaining, and we hope that the proposed federation of employes will be a federation of ideas and a coöperating educational feature.

The railroad labor organizations cannot hope to offer real, lasting inducements to railroads for the exclusive employment of their members, unless some feature is introduced that will say to the companies: "We can furnish you better posted, more temperate, and more experienced men than you can get outside; our lodge rooms are furnished with books, models of valve motions and brake devices that are in themselves educational and a safeguard; we hold regular meetings to discuss operative railroad topics, in which every member must take part—invaluable advantages that can be obtained in no other way."

Do we do this? Do we offer such inducements to railroad companies to employ us instead of outsiders? Do we have the books or the models? Do we hold the discussions? Do we attempt to offer better goods, or do we seek to monopolize the goods in the market, and restrict the output, compelling employers to use us or nothing? We ought to be employed; we ought to keep up our organizations; but at the same time we ought to make it a notorious fact that a member of any of our organizations enjoyed advantages that could not be had by any other man, or set of men.

The Death Roll.

During the past month one disaster has followed another so closely that scarcely a day has passed without its list of victims.

During the month of October there were between 100 and 125 lives lost on our railroads alone. At the Mud Run wreck on the L. V. road there were 67 persons killed, and all the other wrecks in the country show a list of about as many more.

One time it is caused by men working from 24 to 36 hours without rest, the next time the old stand-by, the "lap order," then the open switch, but the flagman that don't flag has done the most work.

While the public will take great interest in the Mud Run wreck, with its sixty-seven funerals, we want to remind them there are every month about one-half this number of railroad men butchered, and they scarcely get a two-line item in the news; indeed, a prominent New York paper recently referred to a wreck where the engineer and fireman jumped for life, after doing all they could to stop, in headlines like this, "Jumped, as usual!" "The engineer and fireman desert their posts, and leave the passengers to hurt and death!" After doing all they can to stop, our advice to men in the same fix, is to save their lives if possible—dead heroes are of little use to their families.

The laws need to look after the criminally careless flagman, the low bridge, the hand coupler, the steel trap frog, and the hand brake, on one truck only operated by the hand of a frozen brakeman from an icy deck, with a rickety wheel on a wobbly rod and a rusty chain.

If as many passengers were killed daily from the same causes as there are operatives, the whole country would be organized into a vigilance committee, and some of the death traps in daily use on dividend paying roads would walk the plank.

Take Honor When Honor is Due.

Railroad men should change the reading of the old adage, "Honor to whom honor is due," to the above.

Inventions are going on all the time, and old things are constantly being invented over by men who are, so far as they are themselves concerned, perfectly entitled to credit as inventors.

If Prof. Morse had invented the electric telegraph and kept his inventions a secret while he lived and buried them when he died, and we had waited till Edison's day for the Morse instrument at his hands, Edison would have been the inventor as fully or more fully than Morse.

Every year, yes, every month there are new kinks gotten up in every shop and road in the land, to cheapen the cost, or lighten the labor, or increase the safety of locomotives or their maintenance, and the inventor is called a bully boy by shop or road mates, or is thanked by the officers, and once in a great—a very great while—is rewarded, and he blushes modestly, and there is an end of it.

Six months or six years after it, he or some of his friends pick up a mechanical paper, and lo! and behold! here is the same thing invented, patented perhaps, and the inventor making money out of it; then the first inventor or his friends write the said mechanical paper, and head their letter "Honor to Whom Honor is Due."

Write before you see the same thing somewhere else, write when you get it up; if it has been invented before, you are an inventor just the same; if it has not been heard of before, take the credit, if not the profit, of your kinks and jigs; they are the offspring of your brain and skill, they are worth being proud of—be proud of them.

Last month we published a letter from a master mechanic in Texas, about the axle box planer tool shown up some time ago. The tool invented by his predecessor may not be anywhere like the one shown, and it may be almost identical—in either case the Texas inventor has lost not only the profits, but the honor of invention, by not taking an honor when it was due him.

This month we publish another letter from the master mechanic of the New-foundland Railway—the most northern on this continent—showing that the invention of a Michigan man in the placing of cylinder lubricators is six years old to him.

This paper is the medium of the "kink breeders" in locomotive practice; it costs nothing to show up and describe your tools and kinks if they have merit; the honor is due you; take it when it is due rather than claim it after another squatter has pre-empted the claim.

The Mud Run Disaster.

On October 10th, at the little flag station of Mud Run, Pa., on the Lehigh Valley Railway, occurred one of the worst wrecks of the year.

On that day there was a celebration of a temperance society at Hazelton, and excursions were run from several places on the Wyoming division.

In returning in the evening, the trains were ordered to keep ten minutes apart and the signal boards at telegraph stations were turned against each section until the last train was gone ten minutes.

At Mud Run the sixth section was stopped by the board, and the rear of the train was pulled by the station slightly; there were over 200 people on the train, mostly boys and young people; the rear lights were lit, and on the platform of the cars, but the board was not turned against the seventh section; a red lamp was set out on the depot platform for orders.

The seventh section was a double-header with air on rear engine only; there was a brakeman stationed on each engine to watch signals, and the flagman of the sixth section claims to have been out. Despite all this, the train crashed into the sixth section and killed 67 people and wounded many others.

We all know how young men and boys on a trip like this will get off the train at every opportunity, and it is very likely that they obscured the lights on the train and platform.

One thing is certain, the flagman was not back a safe distance, and failed to attract the attention of any of the six men on the locomotives; notwithstanding the order to go far enough and get on the train, he stopped instead of trying to gain his own train.

There is no doubt that the officers of the company made every provision they could think of for the safe running of the trains—perhaps they were too safe. If the telegraph stations had had no orders to keep the trains ten minutes apart the sixth section would not have stopped at Mud Run, and no doubt the big trains would have followed one another in safety. It is dangerous to change rules temporarily for any purpose.

The engineers testified that they were running about 12 miles per hour, and were not under control; would have been it running four miles per hour; this would seem to infer that the train had very poor air brakes.

The train was coming up hill and at 12 miles per hour should have been stopped in 200 feet easily, and in 4 miles per hour less than a car length.

The engine ahead had no air, and the second engineer claims to have been unable to see, on account of steam from front engine.

The following is the verdict of the coroner's jury in full:

"We find that the engineers of locomotives 452 and 466 of the seventh section were guilty of gross negligence.—First, in failing to discover the red signal in time, the evidence showing that this signal was in full view as their train approached; and secondly, for not approaching the station under full control as required by both the general and special orders. The evidence also shows that the air brakes of the entire seventh section were under the control of the engineer of locomotive 466, and that he could have stopped the train in spite of the locomotive ahead, No. 452.

"We find that the lookout men of locomotives 452 and 466 were guilty of gross negligence in failing to report to their respective engineers the red light at the station as the train approached. These men were placed on their respective engines as an additional precaution, their special duty being to look out for signals. The lookout man on 452 failed to see the signal. The other one on 466 testified that he saw it when about fifteen hundred feet from the station, and yet he reported all right to the engineer, and claims that he did not think the red light meant anything, as nobody used it.

"We find that the rear brakeman of the sixth section was guilty of gross negligence, for when his train stopped, instead of promptly going back the proper distance to warn the approaching train, he stopped at the station. There was time enough for him to have gone back nearly half a mile, but he went less than four hundred feet.

"We find that the conductors of the two sections failed in their duty, the first in not conforming to the rule requiring each conductor to see personally that his brakeman protects the rear of his train, and the second in not requiring his train to approach the station under control."

While the company will be held responsible, and have already set aside a large sum of money to pay damages, the law has reached out for the trainmen, and both engineers of section seven, the conductors of both trains, the lookouts on both engines and the flagman of section six have been arrested and charged with gross carelessness and willful misconduct—some accounts say manslaughter. It is very evident that there were several things that helped make the accident so fatal, and no one man is entirely to blame; but no practical railroad man can help seeing that inefficient flagging, or no flagging at all, was the prime mover in that awful butchery.

The article on Firing Anthracite Coal, on another page, is the first of a series on the same subject by a man who has put in ten years at it, and who is now a freight engineer on one of our Eastern roads.

"Vulcan" is well known to a large majority of mechanical readers, having contributed for years to several railroad papers, notably the *Fireman's Magazine*. Men who wear overalls are the best and most desirable correspondents of a paper devoted to the interests of and read by men who wear, or have worn over-clothes, grease, cinders, and anxiety, upon the locomotives and in the shops of our railways.

We are in receipt of a copy of Robert Grimshaw's latest book, "Preparing for Indication," published by The Practical Publishing Co., 21 Park row, New York.

The work consists of plain instructions, profusely illustrated, how to attach an indicator to any class of steam engine, how and where to pipe, etc. It is a small book, intended to prevent practical men from having to study and experiment in a field that the author has been over a good many times. The price is one dollar.

The Illinois Railroad Record, Vol. 1, No. 1, is before us. It is a 32-page monthly, under the management of C. P. Dresser.

The first number contains the annual report of the Railroad and Warehouse Commissioners of the State. The publication office is Springfield, Ill.

ASKED & ANSWERED

(62) History, Pittsburgh, Pa., asks:

Who invented the common cast-iron steam pipe? A friend says they were first used in England, but I have always understood that they still use copper pipes. *A.*—Wm. Mason, of Taunton, Mass., was the first to use cast-iron steam pipes. This was in 1853. They are not used in Europe to any extent.

(63) S. E. M., Plainfield, Pa., asks:

Why is the locomotive reverse lever so much harder to operate backward than forward? *A.*—If the counterbalance spring is properly adjusted, the lever will handle equally well either way when the engine is standing; in motion, the slip of the block will cause the lever to pull in the direction the engine is running.

(64) West Oakland, Cal., writes:

Has a locomotive with the ordinary link motion more lead hooked up than when down in the corner? "A," who is an engineer, says it has, but "B," who is a machinist, and worked on valve setting, says it has not as much—giving as a reason, that whatever lead an engine has, it will have at full stroke, forward or back, and as the lever is brought towards the center of the quadrant, the port opening will decrease, and therefore the lead decreases; but as I have always understood that an engine had more lead at six or eight inches than when working full stroke, I am at a loss to determine which is right. *A.*—The lead increases as you hook the lever nearer the center. Consult any work on locomotives or link motion.

(65) W. R. C., Ohio, writes:

A short time since, I was running a large eight-wheeled engine, Rogers' build. In the shop one day, I was filing main rod brasses, and discovered that the left main rod was bent down in the center, a strong half inch. I had been working her very hard the preceding day in getting over the hills with a heavy train. I had a wet rail, and had to use sand pretty often. The only thing that could have caused the bend, I think, was that she did it in catching herself on the sand, as I had to put a man out on the sand-box to feed it out, as my supply was limited when the rain began, and would not run only when he scraped it out. I could not catch her, without some danger. Do you think this caused the bend? *A.*—No. The main rod could only receive the pressure of the steam on piston, and must have been bent in some other way.

(66) N. W., Baraboo, Wis., writes:

A locomotive having eccentrics of 5 in. throw, breaking one, could a 4 in. throw eccentric be used in place of the broken one, and have engine square in all points of cut off, no change being made in valve gear but that of changing a 5 in. for a 4 in. throw eccentric and its position on shaft? Have heard of its being done, but cannot see how to get a 5 in. throw from a 4 in. throw eccentric. Rocker arms are of equal length. This is a question there is a great deal of difference of opinion among a few of us engineers, and if you will answer in your paper, you will confer a favor on us all. *A.*—By using the 4 inch eccentric, that side would cut off the same at each end of the stroke and be square; but the exhaust would not occur at same point as the other side, and would be called out of square—judging by the stack. The 4 inch eccentric would have to be advanced on the shaft slightly, to give proper lead.

(67) T. H. E., Nashville, Tenn., writes:

I am familiar with the rule for setting a slipped eccentric by placing engine on center and marking the stem by using the eccentric that is not slipped, for a guide, but what I want, is a rule to set a slipped eccentric without another to go by, suppose I slip both eccentrics on the right side, what am I to do, and why should I do it? *A.*—If both eccentrics on a side slip stop at once, protect your train, and be sure the eccentrics are slipped, before you go to work on them; if they are "off" beyond a doubt, take off the chest cover and pinch the engine onto the center (no matter which center), take the eccentric next the box first, as you can get the other out of the way to work at it; if this is the go-ahead eccentric, place the reverse lever in forward notch and turn the eccentric around on the shaft *ahead* until the port opens $\frac{1}{16}$ or $\frac{1}{8}$", the amount of lead you want, and fasten it there; put the reverse lever in the back notch and turn the back-up eccentric *back* until the port is open, the same as it was with the go-ahead, and fasten eccentric. Where only one eccentric is slipped, it is best to set it by marking the stem; that plan is the quickest, as you do not have to take off the cover. You will readily see that when one side is on the center, the engine will go either way, as steam is admitted to one side or the other of the piston on the other side of locomotive, as it is in the center of cylinder, and by setting the eccentrics to give lead on the center, and by turning them the right way, you can't get them wrong. A good engineer will always save himself all this trouble and delay on the road by marking the eccentrics in their proper position, if he is running a locomotive without eccentric keys.

In the Roundhouse and Repair Shop.

The elevated roads of New York carried over 183,000,000 passengers last year.

* * *

The Siamese government has granted concessions for building two lines of railways within the realm.

* * *

Owing to delay in getting out new patterns, we are not able to show Smith's exhaust nozzle in this issue

* * *

A recently returned Penna. R'y official is credited with saying that European roads employ six men to America's one.

* * *

At the shops of the New York City & Northern R'y, at High Bridge, they are putting in the Vreeland transfer jack, illustrated in the January issue of this paper.

* * *

The "Soo" road—Minneapolis, St. Paul & Sault Ste. Marie R'y, have adopted the Wescott, Bristol & Hinsey automatic brake appliance shown up in these columns in issue of Feb. last.

* * *

Ye editor has a nice steel rule and a leather case in his hip pocket, with the compliments of the *Iron Trades Review*, Cleveland, O. We are going to stop guessing at things now, and measure.

* * *

The Taunton Locomotive Manufacturing Co., of Taunton, Mass., are showing signs of new life. Mr. Wm. R. Billings has succeeded as agent and treasurer. New tools are taking the place of old ones, and better work and more work are the sure results.

* * *

Railway Life, Toronto, Ont., comes out for October with a new dress and a new editor, Mr. A. C. Campbell. The tone of the paper has been improved, and a series of articles promised from prominent Canadian mechanics that will be of interest.

* * *

Almost every other means but actual force has been exhausted to make rear brakemen go back far enough, and be sure they are seen, to protect their trains. There is not one road in the country where it is not shown every week that men are too lazy, or indifferent of the consequences, to do their duty. On all passenger trains the rear flagman should have no other duty, and fatal disasters caused by his neglect should place him behind a prison wall. These are severe measures, but severe measures are needed and invited.

* * *

Light locomotives are coming into use in a thousand places where it was thought they could never be used. They are now used in lumber regions to log, about mines and iron works, on large farms and plantations, on docks, in warehouses, on street cars, in coal yards, in lumber yards, over coke ovens, in brick yards, and in and around sugar refineries, etc. There are over 500 locomotives in the logging and lumber trades alone. There are many firms and corporations scheming to use locomotives where animals are now used, and this trade is one that is on the increase.

Smith's Triple Expansion Exhaust.

The exhaust stand here shown is the invention of John Y Smith, of Doylestown, Pa., the inventor of the exhausting device used on vacuum brakes, and it works on the same principle.

The stand can be used in short or extension fronts, and takes the place of the present nozzle stand and the petticoat pipe.

The passages marked *S* are exhaust steam passages, and it will be seen that there are three of them. Near the bottom of stand there is an opening through from front to back, and in its center a small exhaust nozzle, 1 inch in diameter; the blast of this nozzle draws in the hot gases from the front end, and, mingled with the steam, they are discharged through the central pipe *A*. As the gases in front ends are several hundred degrees hotter than the exhaust steam, they will superheat the exhaust, make it drier and hotter, and thus produce velocity.

The outside circle is also a steam nozzle, 9 inches outside diameter, and having an opening of 5/8 inch, or an area of 16 square inches; the second circular opening is for cinders and gases only, and has an opening of one inch, and is open at the bottom to the front end through the openings *A A*, all around the largest part of the stand; the third opening is 5 5/8 inches outside diameter, and has an opening at top of 3/8 inch, containing 6 square inches of area.

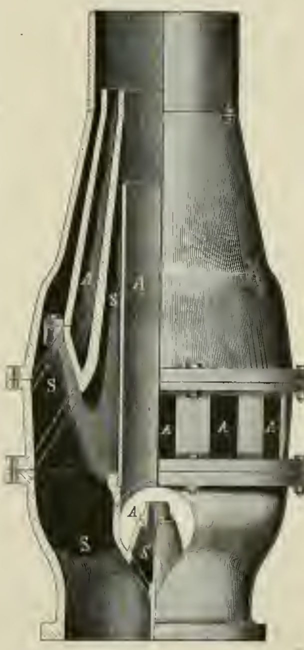
The combined area of the three openings of the exhaust are 23½ square inches, which would be equal to a single nozzle 5½ inches in diameter, or a pair of double nozzles, each 3⅞ inches in diameter.

Some of the beneficial results hoped for are: Reduction of back pressure to a minimum; prevention of ejection of sparks from smoke stack; almost complete absence of noise from exhaust, and keeping free and clean the flues and smoke arch.

Two of these stands have been in use for the past six months on the Boston & Maine, on engines with cylinders 16 x 24, and, we believe, are the largest nozzles in the country.

This road has ordered more of them, and several prominent roads have ordered trial pipes.

There is no doubt that there is merit as well as novelty in the plan, and from the success made of the exhausting instrument for vacuum brakes, we feel that it is in the right direction.



Smith's Triple Expansion Exhaust.

We know of a division of engineers who, a few years ago, were offered a valve motion model, by the master mechanic of the road where they were employed, and they refused to take it. The firemen got the model. Thomson's colt has always been considered the foolishest fool on earth, but for swell-headed ignorance that is glad of it, this beats all records.

STEAM PIPE REPAIRS.

The Experience and Practice of 150 Roundhouse Foremen.

Last month we asked for information about steam pipe repairs, and below will be found about half the replies we have received. Comments are made in another column.

HOUSTON & TEXAS CENTRAL.

About three years; time, about 8 to 10 hours; cost, including exhaust pipe joint, $4.60.
T. E. Kinney,
Hearne, Tex. R. H Foreman.

NEW BRUNSWICK.

About once a year; time, ¾ of a day; cost, $2.44.
Thos. Armstrong,
McAdam, N. B. Gen'l Foreman.

NORTHERN PACIFIC.

Have had but one case in three years; time taken ordinarily, a day of ten hours; cost, about $2.
S. L. Bean,
Fargo, D. T. Div. M M.

BALTIMORE & OHIO.

When bed-plate keeps tight on smoke-box, do not have to grind pipes, except when engine goes in for general overhauling; extension fronts seem to be a little the hardest on joints; to take down, grind and replace, costs about $3.
Zach. T. Braulner,
Highlandtown, Md. Gen'l Foreman.

CHICAGO, ST. PAUL & KANSAS CITY.

Only when in for repairs; time from 4 to 10 hours, sometimes longer; the cost, of course, depending on time.
C. J. Quimby,
Chicago, Ill. R. H. Foreman.

WISCONSIN CENTRAL

As a rule our engines run without steam pipe work, from one rebuilding to another, but the work is sometimes done. Scrape the joints first, then grind from 8 to 10 hours. Our machinist gets $2.50 per day.
Wm. Smith,
Chicago, Ill. Asst. Supt., M. P. & M.

EAST TENNESSEE, VIRGINIA & GEORGIA.

Ninety per cent. of our engines go from one overhauling to another without steam pipe work. Usual time, 18 hours, cost, $5.
A. T. Hooker,
Chattanooga, Tenn. Gen'l Foreman.

N. Y. CENTRAL & HUDSON RIVER.

Only when leak, seldom; work done by boiler maker and helper in about one day; cost, $3.75.
J. D. AVERY,
West Albany, N. Y. R. H. Foreman.

NORFOLK & WESTERN.

They run from 12 to 15 months; time, about ten hours; cost, $2.
JOHN A. HUMPHRIES,
Roanoke, Va. R. H. Foreman.

Only when overhauled. Machinist and helper will be ten hours at it. Cost, about $3.00.
ROBT. OWENS,
Crewe, Va. R. H. Foreman.

ILLINOIS CENTRAL, C. & D. DIV.

No oftener than we renew flues, or other work requiring removal of pipes; average time, ten hours; cost depends on condition; $2 to $3.
J. H. POLLARD,
Cherokee, Ia. R. H. Foreman.

RICHMOND & DANVILLE.

Have very little trouble; usually takes ten hours; costs $2.25; this includes removing and replacing, but not labor of putting netting and other appliances back.
GEO. W. O'BRIEN,
Atlanta, Ga. Gen'l Foreman.

MISSOURI PACIFIC.

Grind once in about two and a half years; time, eight hours; cost, $3.60.
EDWARD SLATER,
Lincoln, Neb. R. H. Foreman.

GRAND TRUNK.

Scarcely ever have this work to do, except when pipes are removed for flue work. It usually takes a fitter and helper two days to grind and replace.
Palmerston, Ont. THOS. MCHATHE.

DENVER & RIO GRANDE WESTERN.

About once in a year; time and cost depend entirely on how badly they are leaking.
F. W. VOLL,
R. H. Foreman.
Pleasant Valley Junc., Utah.

SHENANDOAH VALLEY.

Average run, eight months; not including T head; ten hours from time boiler maker commences to remove front casting, till engine is ready to fire up. We use a cement composed of twenty-five parts clean, sifted, cast-iron borings, two parts whiting, one part sal-ammoniac, dampened with water; we calk this between top of saddle and bottom of extension, to prevent front from getting air. Cost, $3.75 for entire job.
J. G. MASK,
Hagerstown, Md. R. H. Foreman.

CAIRO, VINCENNES & CHICAGO.

Unless some accident happens, only when they go in shop. Time, eight to ten hours. Usually $2.00 to $2.50.
W. F. GIBSON,
Cairo, Ill. R. H. Foreman.

MILWAUKEE, WEST SHORE & WESTERN.

Never, except engine is in shop for general repairs; time there about sixteen hours. Cost, $2.56.

I have been connected with this company for nearly six years as foreman, and have never seen but two engines on which the steam pipes started to leak after the engines were put in service, and this was caused by the cylinder saddle becoming loose on the smoke arch.
F. SLATER,
So. Kaukauna, Wis. Gen'l Foreman.

K. C. S. & C.

From twelve to fifteen months; time, one man about two days. Cost, $5.00.
W. S. KNAPP,
Olathe, Kas. R. H. Foreman.

BURLINGTON & MISSOURI RIVER.

Have only ground one set in two years; as near as I can figure, cost about $5.
J. C. KENNEDY,
Red Cloud, Neb. R. H. Foreman.

CUMBERLAND & PENNSYLVANIA.

All our engines are extension fronts, and run from six weeks to six months; time, ten to fifteen hours. Piece-work, and costs about $2.25.
W. H. SCHUTS,
Wellsville, O. R. H. Foreman.

CINCINNATI SOUTHEASTERN.

Once in two years; time, about twelve hours; cost, about $4.00.
J. C. KISER,
Somerset, Ky. R. H. Foreman.

CINCINNATI, NEW ORLEANS & TEXAS PACIFIC.

About every two years have taken out, gound, replaced, and had engine ready for train in thirteen hours. Cost, $1.00 per joint.
C. E. WALKER,
Ludlow, Ky. R. H. Foreman.

When engine is overhauled, or about once in two years; time, one day; cost, machinist and helper, $4.00.
THOS. WALSH,
Somerset, Ky. Div. M. M.

CHICAGO & INDIANA COAL.

Once a month; time, about four hours; cost, $2.00.
A. RUNYON,
Lacrosse, Ind. R. H. Foreman.

CINCINNATI, SANDUSKY & CLEVELAND.

Only when in shops for repairs; time, eight to ten hours; cost, $3.50.
W. B. PORTER,
Springfield, O. R. H. Foreman.

WEST SHORE.

About once a year on engines making 256 miles per day; time required to take down, ground, and replace, fifteen hours; cost, about $6.00.
V. B. LANG,
New Durham, N. J. R. H. Foreman.

ATLANTIC & PACIFIC.

Will average about eight months on extensions. Time, machinist and two helpers, ten hours; cost, about $8.00.
PERRY J. BROWN,
Albuquerque, N. M. R. H. Foreman.

MILWAUKEE, LAKE SHORE & WESTERN.

When in shops; time, two days; cost, $6.00.
ED. MURPHY,
Ashland, Wis. R. H. Foreman.

BALTIMORE & OHIO.

I have recently resigned the position of foreman at B. & O. shops here, but we seldom did such work on engines in service. I would ask brother foremen if there is found any more trouble with steam pipes in engines where the fire-boxes of boilers are supported on the vibrating hangers, placed above the frames as in the Wooten and P. R. R. (Class P.) type of engines. It appears to me to be more with them than with the eight-wheel engine, where fire-box is between frames and secured by angle plates, clamps, and braces on back head.
W. A. BROWN.
Wilmington, Del.

OHIO, INDIANA & WESTERN.

When engine is shopped or has flues removed. Keep a cheap man for such work. Time, from 5 to 7 hours. Keep no itemized account of cost.
LOUIS PFAFFLIN,
Indianapolis, Ind. Gen'l Foreman.

WABASH R'Y.

We have no general repair shop at this point. I give the practice as near as I know on the road, as a whole. We have very little trouble with steam pipes, seldom taking them down until engines go in for flues or general repairs. With so many different classes of engines as we have, I find a great difference in time to do such work. Average, 18 months between grinds; time, 18 hours; cost, $4.50. Your paper gives good satisfaction, and is doing good work; hope to see all our boys take it next year. No trouble to pick up a kink in it, and you are sound on the Q. and Frank Smith questions.
FRANK C. ROBINSON,
Danville, Ill. Gen. Foreman.

Very seldom; have taken down both pipes and nigger-head, ground and replaced in 7½ hours, two men; cost depends on work; have ground set for $2.80.
J. H. MCCLURE,
Andrews, Ind. Gen. Foreman.

FLINT & PERE MARQUETTE.

Once in from 12 to 18 months; time, 10 to 12 hours; cost, $2.00; if rings have to be scraped, $3.00.
J. CHRISTOPHER,
E. Saginaw, Mich. R. H. Foreman.

KANSAS CITY, FORT SCOTT & GULF.

Once in 2 years; time, 12 hours. $5.00 will cover all expense.
ROB'T E. WHITE,
Fort Scott, Kan. R. H. Foreman.

NEWPORT NEWS & MISSISSIPPI VALLEY.

Grind when necessary. A machinist and helper will do job in from 8 to 10 hours. Cost, about $3.00.
J. R. PEARCE,
Memphis, Tenn. R. H. Foreman.

CHICAGO, MILWAUKEE & ST. PAUL.

In modern engines very seldom do steam pipe work; one man will grind the four joints in ten hours. We let the engine lose a trip on account of heat in extension front end. For short fronts $2, and for extensions $8, is a fair estimate of cost.
JOS. ADAMS,
Milwaukee, Wis. R. H. Foreman.

CHICAGO, ST. PAUL & KANSAS CITY.

Grind steam pipe joints about once in 18 months—when setting new flues. Time, about ten hours. Freight engines are hardest on pipes—hilly division. Total cost, about $5.
G. W. ROBB,
Des Moines, Ia. R. H. Foreman.

WRIGHTSVILLE & TENNILLE R'Y.

Our steam pipes require grinding only once in from eight to ten years—they are copper; it takes about one day. We use varnish on the joints. Our engines are of one class, 14x24, wood burners, short front ends; we require them to pull both passenger and freight trains. Our steam pipes are of copper, with cast-iron joints; we have a loose joint of brass between the T pipe and steam pipe, flat on one side and a ball on the other. When joint is defective, we face the loose joint up in a lathe, and file and scrape the others, preparatory to grinding. We have no special tools or special men to do such work. Our joints never give any trouble.
B. T. COLE,
Tennille, Ga. M. M.

ROME, WATERTOWN & OGDENSBURGH.

Usually takes from eight to ten hours; have cast or boiler iron covers over lower joints; time, one day for two men.
DAVID DRAKE,
Norwood, N. Y. R. H. Foreman.

DELAWARE, LACKAWANNA & WESTERN.

Not oftener than once in two years, when cylinders are properly fastened to arch and frame, only when engine is overhauled. Time depends entirely on how long it takes to get pipes out. Ordinarily one good man will do it in two days; cost $5.00.
W. B. DAY,
Port Morris, N. J. R. H. Foreman.

CHICAGO, ROCK ISLAND AND PACIFIC.

I have seventy-five engines, and don't grind six joints a year. Time required, a day or a day and a half; cost, $3.50 to $6.
E. W. KENYON,
Chicago, Ill. R. H. Foreman.

CENTRAL IOWA DIVISION,
C. R. I. & P.

Very seldom except when pipes come down for flue work. Time and cost depends on condition of joints.
C. S. BINKLEY,
Des Moines, Ia. R. H. Foreman.

Flues are re-set every three years; steam pipe work, seldom done at any other time; time, 10 hours; cost $5.
MOSES HOBBS,
Davenport, Ia. R. H. Foreman.

Scarcely ever, except when flues are removed; time, about three hours, unless very bad; cost, about $2. A. L. SWIFT,
R. H. Foreman.
Leavenworth, Kan.

MISSOURI PACIFIC.

Out of 52 engines grind about two sets a year. Time, five to fifteen hours; cost, from $1.37 to $4.25. CHAS. HAMMOND,
Sedalia, Mo. R. H. Foreman.

ST. AUGUSTINE & PALATKA.

Have had them run five years without grinding; never do the work in the roundhouse.
E. BALLARD,
R. H. Foreman.
St. Augustine, Fla.

PENNSYLVANIA R'Y.

Only when necessary to take out flues; time, about three days, with extensions; cost, from $3 to $9.
JNO. SEXTON,
So. Amboy, N. J. R. H. Foreman.

Very seldom do this work; the time taken, as well as the cost, depends entirely on how long it takes to get the pipes out.
WM. H. VANDEGRIFT,
Kensington Shops, Phila. R. H. Foreman.

As a rule, about once in 18 months; sometimes it takes from four to six days—depends on how badly they are worn; cost, from $16 to $20. J. W. MADDEN,
Columbia, Penna. R. H. Foreman.

If smoke-box is in good order, about once a year; time according to condition, say forty five minutes to an hour per joint; cost, hard to estimate, say from $1 to $2.
J. J. W.,
Cressona, Pa. Gen'l Foreman.

Only when engines are in for flues; time, from seven to ten hours for all joints; cost, from $1.75 to $2.
J. A. BEAMER,
Altoona, Pa. R. H. Foreman.

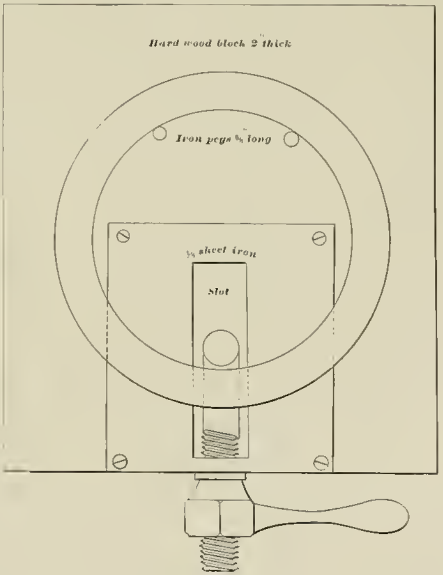
Only when flues are renewed, or they accidentally leak; time, for two men, fifteen hours; cost, $7.20. S. GARABRANT,
Jersey City, N. J. R. H. Foreman.

CANADIAN PACIFIC.

No trouble with joints; time depends on conditions; have done some in three hours, and on others it took fifteen; cost, of course, depends on condition, and what kind of men on job. M. COLLINS,
Brodview, N. W. T. R. H. Foreman.

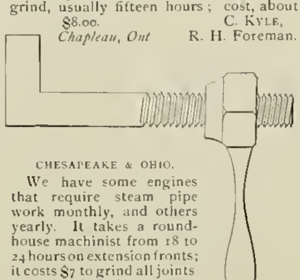
Seldom leak; have engines now running five years without a leak; average time, ten hours; cost, about $4.00.
S. PHIPPS,
Fort William, Ont. R. H. Foreman.

We seldom have trouble, except when cylinders get loose or other similar causes.



KYLE'S RING HOLDER

I send you a sketch of a block we use for holding the rings; any mechanic can see the design and use of the device. Time to grind, usually fifteen hours; cost, about $8.00. C. KYLE,
Chapleau, Ont. R. H. Foreman.



CHESAPEAKE & OHIO.

We have some engines that require steam pipe work monthly, and others yearly. It takes a roundhouse machinist from 18 to 24 hours on extension fronts; it costs $7 to grind all joints
J. T. MARLEN,
R. H. Foreman.
Newport News, Va.

RICHMOND & DANVILLE, V. M. DIV.

Only when overhauled; usually takes five hours to take down, grind and replace; costs about $2. JAS. W. SHINN,
Alexandria, Va. R. H. Foreman.

ATCHISON, TOPEKA & SANTA FE.

It takes machinist and helper ten hours; to grind alone; cost, $4 to $8, exclusive of taking down and replacing. I have lately resigned my position as foreman at Argentine, Kan., my successor being P. F. Baker. BEN JOHNSON.
Ithaca, N. Y.

About every five years; time, about ten hours; cost, grind and replace, about $6.
FRANK SINGER,
Pueblo, Col. Machinist.

Once in eight months on freight engines; time on extensions, 12 to 15 hours; short fronts, 10 to 12; cost, short fronts, $5; extensions, $7. H. GIEGALETT,
Raton, N. M. R. H. Foreman.

OHIO & MISSISSIPPI.

About once a year; time, from eight to ten hours; cost, about $3.80. A. J. ROSS,
Seymour, Ind. R. H. Foreman.

C., B. & Q.

Grind steam pipes only when engine gets a general overhauling; if they are not in bad shape, one man can grind the four joints in a day; costs about $2. G. J. CEMPESRY,
Rock Island, Ill. R. H. Foreman.

Since introduction of relief valves, very seldom; time, machinist and two helpers, about one day; cost, about $7.
GEO. L. BECKWITH,
Creston, Ia. R. H. Foreman.

CHICAGO & NORTHWESTERN.

About ten months; takes one man a day and a half. We use shields on lower joints in extension fronts; cost, $1.85 for short fronts. NOAH WARRINGTON,
R. H. Foreman.
Huron, Dak. T.

Every 15 months; time, about 16 hours; cost, $2.20.
FRED. W. COX,
Belvidere, Ill. R. H. Foreman.

Only when we take out to reset flues; time for steam pipes alone, half a day; cost, about $6.
J. W. CRYSTER,
Chicago, Ill. R. H. Foreman.

When engines go in for general repairs; time, from one to two days, depends on condition of joints; cost, from $3 to $4.
JOS. COCKFIELD,
Boone, Ia. R. H. Foreman

When they go in shop, as a rule; time, from two to five hours, depends on condition; cost, $3.85.
PETER MOTTERSHEAD,
Boone, Ia. R. H. Foreman.

When shopped for general repairs; we use a rose double bit; time, about five hours; cost, $1.25.
E. J. HAYWOOD,
Janesville, Wis. R. H. Foreman.

On the W. & St. P. Div., every 8 to 16 months, or when we put in flues; time to grind and replace, 10 to 20 hours; cost, $4 to $6. C. B. PECK,
Tracy, Minn. R. H. Foreman.

We have no rule as to time; have to grind in considerable; time, one to two days; cost, $3 to $4. GEO. ALLEN,
Des Moines, Ia. R. H. Foreman.

A Blow-Back Kink.

On some of the P. & N Y engines we notice a large 3-way cock in pipe to Ashton, blow-back safety valve, so that the fireman can send the steam to the stack to act as a blower, or to the tank. As far as our experience goes, when the water is low in the tank, and the boiler hot enough to pop, it is not only annoying, but absolutely dangerous to blow steam into the tank, especially where injectors are used.

What the blow-back wants is a valve that will make it blow into the atmosphere, except when a man holds it open to the tank.

A Pennsylvania Railway Shop.

The tramp editor started out last month to find something new, and the results of his observations are recorded below

A CHANCE TO EAT.

Having heard much about the Pennsylvania shops at Renovo, we headed for there and the first thing we hit, out of the usual run of things, was breakfast at Williamsport—not but that we eat regular—but when we got into the dining room the tables were all set; meat, potatoes, eggs, coffee, and all steaming hot and ready to be eaten, and the agile waiter stood behind the guest and replaced hot cakes as fast as they were worn out; by this arrangement 20 minutes is long enough to eat. A railroad man that is used to the old catch-as-catch-can plan, is liable to founder himself.

RENOVO SHOPS

At Renovo we found large, well-kept shops, built around a square, and everything, from the smoke-stack to the scrap heap, was clean.

Most of these shops were built in 1860, but they differ very little from those built last year.

Wm L Holman is master mechanic here, and has been for some years, having been with the Pennsylvania R'y over 20 years.

CLEANLINESS PREVENTS DIRT.

The square between the shops has wide cinder roadways, running in every direction, through grass plots and flower beds. The cinders are as level and clean as if just swept. When Mr. Holman came to the shops this square was the scrap heap and dump yard for all the shops, and any employe who had any dirt to get rid of went there with it, and men were kept constantly at work cleaning up. He had it thoroughly cleaned, and gave notice that no dirt must be thrown there; and now once a month is often enough to clean—because it is not dirtied.

FIRE APPARATUS.

Near the center of the square there is a neat engine house, and a new Le France fire engine stands within, in all the glory of nickel plate. Live steam is supplied to the boiler by connection to the stationary boilers, and the fire-box is all charged for a quick fire, an engineer is in charge of the fire apparatus, and the men are trained for fire duty.

USEFUL OLD FIRE ENGINE.

An old-style fire engine, discarded, has been rebuilt and is used to send away to pump at water tanks, while other pumps or boilers are repaired, to pump out cellars, bridge foundations, or any similar work.

THE PIECE-WORK SYSTEM

Everything at these shops is done by the piece; there are 700 mechanics employed and they are at work for themselves. Every bit of work has a price for it, and is duly recorded in books in each department and in the office It is worth so much to ream and fit a bolt, and if you have to go to the storehouse or blacksmith shop for it, it is so much more; if a car carpenter bores a hole in an end sill he knows he has earned so much, and the laborer who carries the piece to the saw or planer gets so much per stick—some of these jobs are figured down to 1-7 of a cent.

The erection and dismantling of engines is done in the same way.

THE SYSTEM OF INSPECTION

is much like that at Baldwin's; each man inspects the work of those ahead of him; if one man accepts a piece of planer work to do turning on, and finds, when done, that the planer man made a mistake, it is his funeral, not the planer man's; he must measure the piece by the drawing and know that it will finish, before he puts work upon it These shops build quite a number of engines every year in addition to their work of maintenance.

MACHINE SHOP.

The machine shop is large and well lighted—there are electric lights throughout the shops—and the machines are about as seen in any shop, except that there is not enough for the work in hand. The General Foreman, Chas. H. Potts, is a young man less than 30 years of age, who learned his trade in the shop, and seems to know the place and the work, from the ground up. The air pump repairs and the polishing of bright work is done upstairs and the heavy grinding in the cellar. The shops are wide, and the pits are on one side and the machine tools on the other—which seems to be a better plan than the usual one with the tools in one end of a long shop and the pits in the other.

THE TOOL ROOM

occupies one corner of the machine shop, and is divided from it by a wire screen. Complete sets of gauges are there carefully kept in cases, together with the thousand and one templates and distance pieces found in a shop building everything to as close a standard as the P. R'y demand. Here we saw a very simple, yet ingenious machine, for making flat split keys for car work. Commercial keys of this class cost from 10 to 12 cents per pound, the iron costs 4; by attaching an arm of this machine to the back of a shaping machine bar a boy will make a barrel full of keys a day, costing less than half the price of commercial keys. Milling cutters are used for many purposes, and all keyways are cut with them, to avoid sharp corners—we were shown several old driving axles that broke, always starting at the keyway

THE BLACKSMITH SHOP

is one of the largest, busiest, and best arranged we ever saw, and is under the care of John Green a most ingenious mechanic. There are several steam hammers of different sizes, punches, shears, and heating furnaces. There is hardly a piece of forging for locomotives or cars that he has not a die or former for—indeed, these devices occupy a large plot of ground outside the shop. His special tool for forming the standard wrought-iron draw-head for freight cars under the steam hammer, without a single weld, is a most ingenious thing. It was found that a loss of time and fuel was sustained when the heating furnaces were allowed to cool off at night so they are kept hot, and to keep the heat from going to waste, a blacksmith, heater and hammer boy will work at night on some work that is principally heating and forming under the hammer, thus keeping up stock and doing work that is in the way of the workmen in the day-time.

THE FOUNDRY

is not extra large, but is cleanly, light, and turns out good work, and lots of it. It is under the foremanship of Wm. H. Nichols, and every item of work done there is paid for by the piece.

THE CAR SHOPS

are quite extensive, well fitted with machinery, have a steam transfer table, etc.; they are under the foremanship of R. M. Messimer.

THE ROUNDHOUSE

is in charge of Jos. Spencer; is large and well kept, but, like all other roundhouses where there are shops, there is little work done there; one novel feature is a man on the turntable who oils every tank truck box that crosses it. The engines run first in first out, and are kept going, no one having a regular engine. Here, as everywhere else on the Penna. system, the master mechanic has nothing to do with the engineers and firemen—they are under the superintendent—the motive power department simply furnishes them engines to run; the

ENGINEERS

have no work to do; they have no regular engines, and when they come in they simply report anything that is wrong. Of course, with such a system there must be a connecting link between the transportation and the motive power department, and this is found in the

TRAVELING ENGINEERS.

These men are selected from the cream of the engineers, and hold responsible and important positions; they are not, as a rule, men who think injectors are a mystery, or that it is unlucky to start an air pump on Friday. John W. Sheldon holds this position here, and the men say he is so square he has got corners on him.

WAGES.

Mr. Holman became satisfied years ago that some mechanics were worth $5 per day and some 50 cents, the way he was paying them, and concluded to pay for what they did, and his plan of piece work is the result of years of study and experiment He figured to let men make 35 cents by the piece where they would get 30 cents by the day, and this is the average rule. Average pay of machinists is from 30 to 35 cents per hour, and in busy times they make from $100 to $120 per month. All the men with whom we talked said they made more money than they could by the day, and liked the system, and the fact that so many of them stay for years is proof of their preference.

APPRENTICES

are required to work 3100 hours for a year, and are paid by the hour when not on piece-work. Most of the men learned their trade in the shop; they very seldom hire or discharge a man.

THE SYSTEM

has its advantages and disadvantages, but, so far as we are able to see, it is better for the men, cheaper for the company, and prevents loafers from getting the gout by reading novels and smoking in the unwholesome closets.

The Dickson Locomotive Works.

These works, at Scranton, Pa., are reasonably busy on an order of twenty-eight engines for the Georgia Central, two for the K P., four for the D & H C. Co., and one for the Normandale Lumber Co.

The Georgia Central engines are built to the designs of Mr Blackwell, the Supt. of M. P., and are very handsome machines. He uses solid-ended side rods of I section, and the back end of main rods are of the fork, or open-end design, so much used on the Penna. He also uses an improved form of Laird guide, with a lower bar of wrought-iron, and the top one very wide and heavy, of cast-iron. The works are building many engines with this form of guide.

This firm have made a needed improvement in their designs, that could well be followed by others; instead of using two studs at lower joint of steam pipes, they use four bolts, and they are held to cylinder saddle by heads let into T slots; this makes a sure joint, and the bolts are easy to get in and out; studs burn, break, and have to be drilled.

In the machine shop there is a room devoted to small work, mostly drill presses and bolt cutters. As all the "cubs" land here when they start to learn the trade, it has got the name of Castle Garden.

The drawing room is the best kept place about the works, and the card system of drawings for shop work is here carried out very successfully; no scale is used, but every piece of work is drawn on a certain sized card as large as it can be made, and all the sizes are marked on; these cards are coated with three coats of shellac and washed after every trip to shops, and some of them are plain and clean after twelve years of service. A general plan of all engines built is drawn on a scale of two inches to the foot, and filed for future use. These works furnish repairs of all kinds, boiler frames, cylinders, etc., or do rebuilding for others.

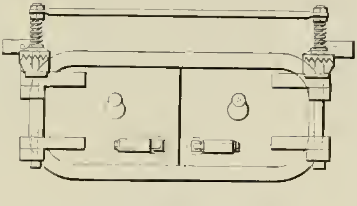
Outside the shops we noticed the Hawley screw snow plow, that they built some two or three years ago, and an old-time consolidation engine built at the Baltimore Locomotive works many years ago. There was no date on the relic, but some genius had chalked on the cylinder "1936 B. C." About the handsomest and cleanest little engines in the country are the watch charms built by this firm for the N. Y and Brooklyn bridge.

A New Fire Door.

The fire door here shown was designed by Chas. Graham, M. M. of the D. L. & W Ry. at Scranton, Pa., and is intended for culm or dirt-burning engines with a very wide fire-box, and is double the size of the ordinary door—a much handier and neater design than two independent doors.

The doors work entirely independent of each other, and are provided with wooden handles—a humane kink that firemen will appreciate.

In the center of each door is a "peep-hole" to watch hard coal fires; but the best part of the arrangement is the device to make them stay where you put them. This consists of two loose blocks of iron with ratchet faces, that are more or less



tightly pressed together by a spring above them.

The lower block is cast to fit over the hinge casting, and must turn with the door; the upper one has a wing that abuts against the boiler, and is thus prevented from turning. The rod across the top is merely to brace the spring rods

The fireman can keep the spring just tight enough to prevent the ratchet from slipping, and the door will stay in any position without any other latch. The device could be applied to single doors as well as double. It is not patented.

Manual Training Schools.

The American people, or, more properly speaking, the American press, are very much given to over-estimating the results of every new, good thing If a man invents an electric motor that propels a street car, the reporter or the editor see only the street car in motion, and they at once write glaring head-lines for glowing editorials, stating that "Locomotives are Doomed," "The Last Steam Boiler Built," "The New Power," etc., etc. It is the mechanic who goes behind the scenes and finds the big steam engine that furnishes the "current," which in this case is only a belt.

The latest chance for over-doing and promising unreasonable things for a reasonable and rational improvement is the Manual Training School.

The daily papers of this city have repeatedly represented that a professor was teaching boys to be carpenters by a few lessons with bench tools, and mechanical engineers and draftsmen were being made offhand out of whole cloth.

The manual training school is a grand, good thing; it mixes up a little practice and a little theory and gives them out to those able to receive them. They tend to lay the foundation for practical mechanics who are well grounded in the theory and history of mechanics, and of draftsmen and designers who know a meat-axe from a buzz-saw.

One of the most successful schools of this kind is the Spring Garden Institute, opposite the Baldwin Locomotive Works, Philadelphia. This school was originally founded by officers in these works to aid their apprentice boys to a better education and greater usefulness. They depended on the shop to teach the trade and the evening school to teach the theory and drawing; outsiders sought admission, and practical shop operations were taught them by supplying tools and giving them examples with the shop boys. The duller students made good mechanics, the brighter are draftsmen either in the Baldwin Works or other works in the city.

Mr. Crawford, chief inspector at the Baldwin Works, has taken a deep interest in the work, and informs us that all the young men who go through the course are engaged ahead to take positions of responsibility.

Manual training schools do not manufacture mechanics or mechanical engineers, but they do help apprentices to become well-grounded, able mechanics, and they do help draftsmen and designers to become familiar with mechanical operations.

Last month his duties as general road foreman of engines of the entire Northern Pacific system, bore so heavily on the hands of our contributor, J. E. Phelan, that he skipped his regular air brake article. He resumes the subject in this issue, which we hope will be considered an answer to the many inquiries we have had on the subject

Some of the D. L. & W. culm burners have a water column in the cab, such as is used on stationary boilers set in brick work. We do not like the idea, and see no reason why the gauge cocks and water glass should not be tapped directly into the boiler—the water column is only another connection to be broken off in case of accident.

On some L. V. engines with a crooked draw bar between engine and tank, General Foreman Ross, at the Wilkesbarre shops, has made a needed improvement. He puts an extension plate below the tail piece of the engine, and couples between the lower piece and the extension. This allows the use of a straight bar, makes the engines ride better, and saves work on the connection.

Correspondence

Pull of Reverse Lever.

Editor The Locomotive Engineer.

In your November issue you tell S. E. M (Question 63) that the reason the reverse lever pulls in the direction the engine is running is because of the slip of the block. Now, while this is the universal reason given, and is taught in locomotive books, it is not right. The angle of the link is changed from front to back in running, and if it was the block, it would tend to lift during one-half its travel and pull the other.

The real reason is, the friction of the straps on the eccentrics is tending to pull the links down in the forward motion and to lift them up in back motion. In an engine with very short eccentric rods the pull is greater, because the leverage is shorter; with very long rods you have the advantage of the long leverage, and the pull is less preceptible. While it is of no importance, so far as practice is concerned, what we *think* causes the pull, like Josh Billings, I believe it "better not to know so much than to know too much that ain't so."

What do the draftsmen think of it?

Germantown, Pa PRIMER.

Feed-Water Heater Tests.

Editor The Locomotive Engineer:

In the November number of the *National Car and Locomotive Builder* you will find an article on a test of the Rushforth heater, and I am sure you will say the test was conclusive. You rather got the best of me when I called the St. Johnsbury heater a new principle, but think there has now been a test of a heater by a man who, to say the very least, is a disinterested party. G M. BOY.

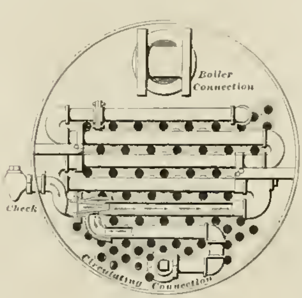
St. Albans, Vt

[Our correspondent cannot say more about the honesty and sincerity of Mr. Sinclair, of the *Car Builder*, than we will endorse; however, all flesh is liable to err, and in this instance we think Mr Sinclair did not know the exact conditions The Rushforth heater is a stand of pipes in the front end, as represented in the cut; the check is placed between the injector or pump and the heater, and the heater itself has two connections to the boiler, top and bottom.

The thermometer was applied to a nipple attached to the heater at the top connection to boiler. The thermometer stood at 353° before the train started, because it was virtually applied to the boiler. After the feed was put on, it fell 129 degrees, or to 224°, but steadily gained until it reached 260°. As an injector will feed water at from 140° to 160°, Mr. Sinclair presumed it fair to give the heater credit for 100° gain of heat.

Now, if you will look at the cut, you will see that just inside the check there is a nozzle—to promote circulation—and after the injector gets fairly to work, the water going through this nozzle draws in and mingles with itself water from the lower connection to the boiler, and the readings on the thermometer were only readings of a mixture of warm water from the injector and hot water from the boiler, and it was, of course, hotter than the injector would deliver, and colder than that in the boiler We have never disputed the claim that any of the devices made would heat the water, but the heat is taken at the expense of something else—simply stated, there is no waste heat in the front end of a locomotive.

The only real test of a heater would be to weigh the fuel for a series of trips, with a given load, both with and without the heater, and subtract from the record of the heater the cost of maintenance and interest on the first cost, and, in the case of the heater in question, the loss of the heating surface of two flues that have to be removed to get the heater in.—ED.]



The Block System.

Editor The Locomotive Engineer

Although not a railroad man at present, I take an interest in R R. matters, and take your valuable journal. Now, what is meant by "the block system"? and how is it operated? Please answer in your next issue, under the "Asked and Answered." B. F MAYWOOD,

1st Sg't. Co. "E," 3rd Infantry, U S. A

Ft. Snelling, Minn.

[Any system of running trains is a "block system," where, by the display of a signal at telegraph stations, one train is kept from going onto the track between the signal displayed and the next signal, until the preceding train has passed the station ahead. In England, and on some roads in this country—notably the Penna.—signal towers are placed beside the track, one mile apart. There is an operator in each tower, and as soon as he receives word that a train has passed the next station, he sets his white, or safety signal, and the next train can follow without even slowing down; as soon as the train enters the "block," he sets his red, or danger signal, and if a following train arrives before he receives word from the other end of the "block," it has to stop. The "block system" is the safest and surest way of handling heavy traffic. It is principally used on double-track roads, but can be, and is sometimes used on single track.—Ed.]

Ideal Overclothes.

Editor The Locomotive Engineer

When Adam was tending sheep and pruning Siberian crab trees in the garden of Eden, we are told that he loafed around in an airy suit, composed of a dwarf fig-leaf with worm-holes in it. Adam never ran a locomotive, without cone or netting—if he had, he would have looked as if he had been soaked for a generation in a tank of mustard plaster.

King Solomon's purple and fine linen, Cæsar's royal toga, and Queen Elizabeth's low-and-behold jersey were eminently fitting to the people and the time—but that was before the days of slipped eccentrics and double-headers, and history tells us that these eminent people lived so remote from the rest of us that they never saw a train of cars.

People who ride on our trains can encase themselves in linen dusters, goggles, and skull caps, and ask the conductor the same question 34 times in 24 miles, and never sweat a hair or soil the collar of their linen armor. Not so the men who are shoveling smoke and boiling water at the front.

While there are other men proud enough to wear overclothes—because they can't help it—engineers and firemen do so more regularly and more raggedly than other folks.

I believe with Henry George, that man's chief reason for living at all is to satisfy his wants with the least possible exertion—I have tried for years to get up a pattern for overalls and jacket that I could put on by simply laying down on them. The suits sold in the stores were not made for mortal man—they are a triumph of buttons, little cloth and big tags

They are too small in the leg for a man who has two wooden legs; one leg will shrink up long and thin—like an umbrella cover—the other will go wide and short—like the fatigue uniform of a bass drum.

The buttonholes are cut so that they will come unbuttoned, and the buttons so that they will come off with the minimum of tension.

They rip for fun and they bleach out for spite, and the shirt or jacket is just like the overalls, only worse. The buttons are six inches apart in front when new, and ten miles the first day out; the collar is nine sizes larger than the sleeves are long, and the cuffs are the same size of the collar. I rebelled against them ten years ago.

Some of the men on our road had clothes made by their wives that looked fairly well, and I got married, more with the idea of getting some decent overclothes than of keeping house. Mrs. A struck out the first week and borrowed a pattern, and got a receipt. I bought a bolt of blue denim, and we soaked it over-night to get the shrink out of it. Mrs. A had my written order to make the legs large enough so that I could put my foot through cross-ways, and could get into any known position and not have them tight any place—she did.

She was to double-seam everything and sew the buttons on with double-twisted and waxed silk—she did.

She was to make the front open far enough down to prevent ripping, and make the seat big enough to go on over my overcoat—she did.

But bless her dear heart, she made six pair after she lost the front pattern, and there was just as much slack in front as there was behind—I never could tell whether I was going to Boston or New York.

Those things did not bind, nor draw, nor shrink, but every wash-day the wringer chewed off a button or a huckle, and I often went around with the overalls hanging to my overshirt by the front slack and a nail.

One day I was down on the dock, and I stumbled onto an old salt with a pair of canvas pants on, and while I was sizing them up, he remarked that he was so hungry he was empty, and reaching around to his side, took a reef on a cord, and wrapped the end around a cleat.

After all these years, here was my ideal overalls, and before I left that man I knew more about his style of pants than he did, and had a pair for a pattern.

If a man has pockets in his overclothes, they will be full of old orders, matches and cinders, and he will always leave his knife and plug tobacco in them, and then go home and kick the dog—I have no pockets in mine.

I had some overalls made that had big legs, and were loose, and had slits down the outside of each leg for ten inches—you can reach through them into your pants' pockets for anything you want, and the slits prevent tearing in getting on or off.

There is not a button, a button-hole, a strap, or a buckle on my rig; buttons can't get lost, unbutton, or the holes tear out.

There is no front door to tear, keep unbuttoned, catch cinders, and make you swear.

There is a heavy cord drawn through a hem in the front and back; these are sewed fast in the center, to keep from losing them, and each end sticks out six inches beyond the cloth.

It matters not whether you have on only an undershirt in summer or are bundled up for winter, the waist of those pants always fit. They are easy to get in or out of, they catch no cinders, they are cheap, and they never lose a button at the last minute. As quick as I find a steel rope tempered in lightning to use in place of the cord—the best I can find will wear out and break—I will have a perfect thing.

Mrs. A. says a man with as big feet as mine ought to have his pants made to go on over his head—but she is prejudiced. I want something to keep the dirt off my clothes, and I would rather look like I had shrunk a little and had room to grow, than to look like a second-hand mummy swathed in blue bandages. This overclothes business is not a theory, it is a condition—a buttonless condition with a rip in it. JOHN ALEXANDER.

Get your old piece of belting out that covers the slot around the reverse lever.

Pumps That Won't Supply.

Editor The Locomotive Engineer :

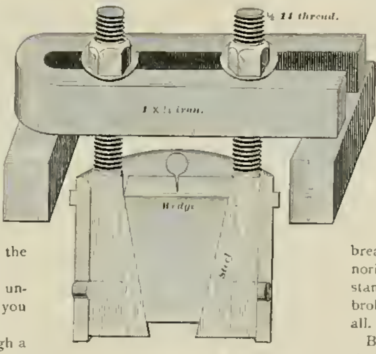
I am a young runner, and have an engine to care for, and am in a little trouble. The pump on the right side will not feed the boiler; it throws a good stream from the pet cock. I have had the pump taken down, and the machinist claims there is nothing the matter with it. The question is, why won't the pump supply the boiler? I started out of a side track the other day, and had four cocks of water, and before I had gone two miles, the last two of them were gone, using the right pump all the time.

Now, if there is nothing the matter with the pump, as the machinist claims, I can't see why it won't supply the boiler. Please answer through your journal what you think is the trouble.

JOHN F. MCCORMICK.

Hallstead, Pa.

[You do not give data enough. We cannot tell what service your engine is in, or whether the pump is large enough to supply the boiler or not. Presuming that it is, we should suggest that, if machinist has found valves in pump itself all right, you have him look at the check to see if it has lift enough, as you say pet cock throws a solid stream. If check is all right, look to the lazy cock and strainers; perhaps the pump is starved. The writer has had trouble of this kind from the lining of the water hose coming loose and partially shutting off the supply. —Ed.]



RELYEA'S BUSH REMOVER.

Tool for Removing Air Pump Bushes.

Editor The Locomotive Engineer :

I was pleased with the illustration of tools in October issue, designed by H. R. Jones, especially the iron fingers. I have made a pair of steel, and they work like a charm. I hope Mr. Jones will come again.

The air pumps on N. Y. C. & H. R. R. R. engines are hung just above the driver brake cylinder, with just room enough to get off the bottom head of air cylinder. So, in order to get the lower discharge valve out, I have heretofore used pieces of ½" gas pipe 4" long, to push the valve up. But I found that kind of rod too inconvenient, so I made a flexible rod by winding a close spiral spring, about ¾" diameter of No. 12 wire, and 18" long; this does the business nicely.

For removing upper main steam valve bushes, I use an arrangement or "combination" like the drawing; I think it will explain itself. W. F. RELYEA.

Syracuse, N. Y.

Driver Brakes.

Editor The Locomotive Engineer :

What public sentiment demands at the present time is not theory, but results, and to produce the best results in railroad operating is now largely left to the ingenuity of the railroad mechanic. Public sentiment now expects that all the available power be applied at a moment's notice by the man who first sees the danger. As we have already utilized the cars and tender for this purpose, the next step is to apply it on the engine also. In all short local trains, which run fast, make quick and numerous stops, the engine alone weighs as much as two of the coaches, and without driver brakes the coaches have to stop the engine as well as themselves.

Some of the master mechanics do not believe in their use at all, and others complain that they "can't use the driver brake on their equipment because the men shake things up so." This is all wrong, and we engineers should be glad to see all the brake power supplied that can be used. It is a puzzler why engineers should object to using the driver brake when it is on their engines, but some of them do. Some engineers keep it cut out and will not use it, because they think it breaks the driving boxes and frames, ignoring the fact that, where it is used constantly and judiciously, fewer boxes are broken than on the roads not using it at all.

Brother engineers, don't let us stand in the way of improvements which tend to protect our lives and situations. How many slight collisions could have been avoided altogether, and the force of more disastrous ones made lighter, had good brakes and more of them been where we could use them ourselves at a moment's notice?

How many good engineers now out of work would be happy in the possession of good jobs, had a driver brake been on their engines, in working order, when they wanted it worst?

When a man wants to stop, to avoid an accident, he wants to stop awful had, and every means should be at hand to make that stop.

Some of us stood out against injectors ten years ago, and declared that they were no good; that the only way to feed a locomotive with water was with a pump; but those engineers had to step one side, or get walked on by the column of improved devices that have been successfully used on the locomotive of the present day.

CLINTON B. CONGER,

Handling Air Brakes.

Editor The Locomotive Engineer

In article on Air Brake Practice, in August number of THE LOCOMOTIVE ENGINEER, occurs this observation: "Ordinarily, with air brakes in good order, a reduction of 3, 5 or 8 lbs. air pressure, according to number of cars in train, rate of speed running and kind of grade approaching stopping place, will give good results."

In September number of THE LOCOMOTIVE ENGINEER, H. S. H., of Denver, Colorado, takes exceptions to the above, as follows: "We would like to know *what difference the number of cars makes* as to reduction of pressure necessary to make a stop. On a train of 20 cars it is necessary to exhaust more air than with 5 or 10, but the amount of pressure need not vary. We claim this on the ground that, in each case, all things, outside the number of cars, are equal."

This is followed up by H. S. H., in November number of THE LOCOMOTIVE ENGINEER, as follows: "Now, Mr. Editor and readers, if the statement I made, that it was necessary to exhaust *more* air from a train of 20 cars than from one of 5 or 10, in order to reduce pressure a certain number of pounds, does not carry the idea that we take into consideration the number of cars in train in handling the automatic, I will retire, and give J. E. Phelan a clear field."

"Now, Mr. Editor and readers," it is very evident to man up a tree, that H. S. H. rushed in for September where he would not have rushed if he had taken time to consider the matter he took exceptions to. THE LOCOMOTIVE ENGINEER is a good subject for study and consideration, and its friends should not bite off more than they can chew.

Readers should bear the fact in mind that in air brake practice there is quite a margin for individual skill and intelligence, but to the engineer with a train of 20 ordinary air brake cars, more or less, I repeat, always take into consideration the number of cars in train, and know that the greater the number of cars in train, the more the quantity or volume of air required with proportionate indicated reduction in pressure on the gauge. Respecting October observation as follows, "In handling the greater volume of air, as pressure is reduced by engineer's brake valve, it starts from forward cars first, and the space is filled on forward cars by air flowing from rear cars, and, before triple valves will act uniformly, it is necessary to have an even flow and reduction started uniformly, the entire length of cars or brakes in use. This naturally requires *more* air, more time in flowing from engineer's valve, and a consequent and proportionate reduction in pressure on guage," particularly so on old style brakes.

Brainard, Minn. J. E. PHELAN.

Firing Anthracite Coal.

SECOND PAPER.

On nearly all hard-coal roads the usual "hostler" of soft-coal roads does not exist, but in his place we find the "watchman of the roundhouse." The "watchman" does not leave the roundhouse to take charge of incoming locomotives, nor does he take locomotives out to coal up and make up trains; instead of that, all locomotives are delivered up to him by the men in charge in their stalls, in the house, and also taken from there by the enginemen. Each hard-coal fireman is expected to be at the roundhouse at least thirty minutes before the engine is to leave the house, to get his fire down, and do other preliminary work. In the present instance, however, we propose to consider the treatment of a locomotive which has no fire in it, having been washed out or under repairs. When such is the case it becomes the duty of the watchman, or some of his helpers, to "fire up the locomotive," as it is a matter of some time to take a boiler filled with cold water, and bring it to the boiling point, and then to a moderate steam pressure.

A supply of wood is usually put on the tank, before the locomotive is put into the house to be "cooled off," and this being at hand, the watchman or his helpers proceed to start the fire. This is done by saturating a few bunches of waste with kerosene, lighting and throwing them into the front end of the fire-box. The smaller sticks of wood being selected, we soon have a lively fire, warming up the sheets and flues. I have found it best not to raise steam too quickly, thus avoiding too sudden and quick changes of temperature and expansion; and have also found that a fire ought not be built the full length of our long (8 to 10 ft.) fire-boxes, for wood must have a large quantity of air for free combustion, hence, by building a fire in the forward end of the fire-box, filling, say, about half the grate surface, and leaving the fire-door open, sufficient air is admitted to make a bright fire, comparatively free from smoke; but if the whole box is filled with wood, prudence compels you to close the fire-door. When the door is closed, the fire does not obtain air enough for a free combustion of the wood, for there is not sufficient draft to cause a suction at first. Feeding the fire at intervals, in about 1½ to 2 hours after starting the fire, we have a few pounds of steam, say about twenty. The blower is then put to work to draw the smoke and flame up the stack, while an even layer of wood, about 15 inches thick, is placed over the whole grate surface. After this is done, the hard coal is shoveled on top, in an even layer of, say, a foot thick. This should be broken up in size of about 5 to 8 pounds, and carefully spread so as to leave no "holes," where the air could rush through unchecked. When the locomotive is taken out with a new fire in, the fireman will have to watch the fire carefully as the wood is burned out, and fill up any holes or low spots that may have been left in the fire, and he will soon have a bed of live coal, say 33x100 inches, and one foot thick. The Baldwin fire-boxes have their grate bars about 18 inches below the fire-door, while the Dickson, Rogers and Cooke locomotives, range from 16 to 20 inches deep at the door, to about 12 to 16 at the front end.

A new fire that has settled to a foot thick all over the grates in a Baldwin, will suffice to do light work with an occasional feeding, say at intervals of one mile, or, if worked harder, at a less distance; but if real hard work is to be done, the fire should be put in about even with the fire-door, or about 18 inches thick, and running about the same depth all the way to the front end of the fire-box. The sides of the fire against the side sheets should be kept from 4 to 6 inches higher than the center, thus leaving a depression running lengthwise of the fire-box in its center, or, as the boys express it, "building it hog-trough fashion."

The Baldwins are generally sure to make steam, but not very freely; but they will also "hold their steam" while "being fed," hence in "feeding" a Baldwin on the road, three to five shovelfuls can be applied at a time, and if done quickly, the door can remain open while it is being put in. The aim of the Baldwin fireman should therefore be to carry a nearly level fire (excepting the rising sides), and keep it at that by feeding along the sides alternately, and as the parts are being worked by the exhaust.

The other classes of locomotives will have to be treated somewhat different, for they need what the boys call a "wedge shape fire." After the new fire has settled uniformly over the grates, the fireman will aim to have the front end of fire about ten inches thick, and ascending from that at a steady slope to the fire-door, where it is from 18 to 24 inches thick. As a rule, the "Cooke" will require the heaviest fire of any at the door, while a few of the Dickson and Rogers build also want at least 12 to 14 inches of fire in the front end, and somewhat heavier back. VULCAN.

Air Brake Practice.

SEVENTH PAPER.

BY J. E. PHELAN

Though automatic air brake appliances are being successfully handled on thousands of miles of railroad, few, excepting the engineers who know how to skillfully handle the brakes, and the observers, who know how the brakes should be handled, really understand the real care required to insure smooth service and good air brake practice.

With cars coupled closely with Miller or Janney, or other styles of close couplers, and but few cars in train, air supply and air brake appliances can be used, and often are used, without regard to manner or effect, so long as stops are made.

All that seems to be considered for haphazard work is to turn the handle one way to set brakes and then turn it another way to have brakes release. This apparently being all thought of, or considered by many in days past, and a few lingering specimens in the present. But air brakes are now moving into an extensive field and instead of being confined to a few engines in passenger service, they are in many instances being applied to all kinds of equipment; and knowledge of air brake practice must form part of a locomotive engineer's ability in the future.

The good air brakeman will learn and always know what every movement of the engineer's brake valve means, and what each motion leads to, in use of air supply; where that air supply comes from, and where it goes, and the part it performs in response to handling of the engineer's brake valve and the needs of the train.

So far as trains made up of a few cars are concerned, if such were mainly in hand for air brake appliances, and no increase in number of cars required, the automatic air brake could have gone along, and come along, in comparatively simple style, with the old 3-way cock for an engineer's brake valve to regulate the supply of air to the uses of the triple valve; and the triple valve to automatically utilize the supply of air (in effective work) given to it through medium of engineer's valve, without necessity of improvement.

As the number of cars in trains has increased, and having the automatic brake applied to each car in train, so have air brake appliances improved to meet the requirements of increased tax on designed action, and the cause for this improvement has been that an automatic or self-acting brake might be applied to each car and always kept in readiness for use in emergency, when running on the road. Having cars, especially in freight service, expensively equipped with air brake appliances, the service should have the benefit of every such brake in train, and each car so equipped should be connected with the engine, and have its supply of air ready for use in any emergency.

Men often make the assertion that ten cars, more or less, of air brakes next the engine is all that is needed for service intended. Men making such assertions imagine air brakes are placed on cars so that brakemen may have an easy time, or that air brakes are only to be used for stopping at stated intervals. But the principle of automatic brakes and the cause of its being on all cars should not be lost sight of. They are placed there to prevent accidents, and it should be borne in mind that broken rails, broken axles, etc., do not always commence to play havoc with a train within ten cars from the engine. A train does not always choose to break in two within these ten cars, but when only this number is in use, and train breaks in two back of such point and causes damage, it brings in some awful forms of excuse; but the boys never lie.

Increasing the number of cars in trains to an indefinite number, and requiring a brake on each car in such trains to act automatically and promptly for reliable work, has required improvements until we now have an engineer's brake valve and improved triple valve, meeting the requirements of the circumstances. These improvements in turn call for close couplings and but little slack, to make the service what it should be for all occasions.

With a full train of closely coupled cars, equipped with quick-acting triple valves, and operated by an improved engineer's brake valve, we find an outfit made up with a view of lessening the bad effect of poor handling of brakes or bad air brake practice.

But scattered about among the various equipment of railroads will be found to-day, and likely to remain in service for years to come, thousands of air brake cars equipped with link and pin couplers, and among them find the various stages of improvement in air brake appliances—the earliest good enough for fair work, and far too valuable to be thrown away.

Take a freight train of 20 to 40 freight cars, with link and pin couplers, variously equipped with old style and quick-acting brakes, with all brakes only in average condition, and it makes a combination on which the average engineer looks with dread. The engineer who handles this fruit of genius made up into an air brake train, without unusual slack, before having considerable experience, must be acknowledged a dandy, and a good student in thought and action. But trains *can be handled* fairly under such circumstances.

Automatic air brake practice now being comparatively in its early stages in many sections of the country for freight service, the object should be to throw out practical suggestions to prompt thought and study, that will in the end produce good results.

The skillful engineer must often make up for, and overcome by his good practice, defects in machinery and appliances. While an engineer may not be open to censure for doing poor work with indifferent appliances, it must stand out as greatly to his credit in doing good work under unfavorable conditions, while it must show up the man in very poor light, who cannot do fair work with the best of modern improvements.

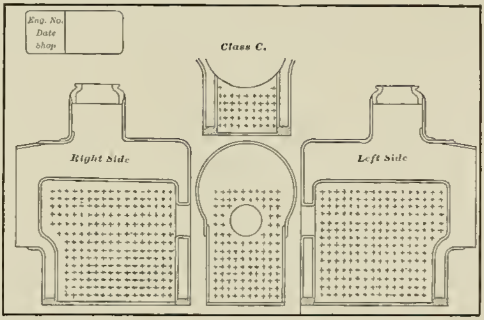
Rigid Boiler Inspection.

At the Renovo shops of the P. & E (now Penna.) they have a very safe system of boiler inspection.

Once in six months the boilers are tested by hydrostatic pressure to 25 pounds above their working pressure, and during such test a man is placed inside the fire-box and one outside, to listen for fractures. Safety valves and steam gauges are tested every month.

Every week an inspector makes a hammer test of all stay bolts, and he is furnished with a blue print card, showing location of every stay bolt in the fire-box; if he finds one broken he crosses or checks it on the card, and the engine does not go out till it is repaired.

The cut shows card for a consolidation, and is half size. Duplicates of these cards are filed in the office, and any number of years afterward the record of inspection and work on each boiler in the service can be determined



Enlarging the Wilkesbarre Shops.

The Lehigh Valley road are making some needed improvements in their Wilkesbarre shops. They have completed a two story oil and supply house, 25 x 50; a tool room and pattern shop, 25 x 50; and a carpenter shop, 60 x 110. They recently built a new boiler shop, so that the painters are nicely fixed in the old shop, and the machine shop will get all the room now occupied by the carpenter and pattern shops and the tool room. The road has also put up a coal chute of simple design, nine pockets, holding from four to six cars of coal each, and a device whereby the engines can take as much as they want; the chute is high, and under the bins there is a storehouse for odds and ends.

The track is above the chutes, so that dump cars can be unloaded into them, and one man is all that is needed in the building.

The foundation is partially down for a thirty one stall roundhouse.

The shops are quite busy on repairs, and are also building a number of new boilers to replace old ones in service. The shops are now under the charge of Mr. Fred. Ross, who succeeded the genial Mr. Drumheller, deceased.

These shops are under Mr. Alexander Mitchell, M. M., and Supt., who, in Feb., 1866, designed and built the first consolidation locomotive, and two years ago turned out, but did not design, the big Strong engine—the Duplex. One has become the most popular locomotive on the continent for freight service, the other is, as yet, a case of doubt

They are putting new boilers on several freight engines.

CONTENTS.

Close of Volume I.

With this issue closes the first year of our existence, and the index for the year will be found herewith. The index is intended to aid regular readers in finding articles as they remember them by the headings, and the matter has also, in many instances, been indexed, so that matter bearing on any one subject can be found by referring to the subject itself.

Experience has proven the correctness of our original assumption, that the great majority of mechanical papers were aimed too high for the average railroad mechanics, and treated on altogether too many subjects foreign to their occupation.

The year's experience has also shown that what is of interest to the men on the engines, and in the shops, is of interest to the master mechanics and superintendents over them—as the names of prominent master mechanics, traveling engineers and general foremen, that have appeared in our correspondence columns during the year, will attest.

We do not propose here to pat ourselves on the back, or make any rash promises of future greatness, but will simply say that, in the year to come, we shall try harder than ever before to make the paper interesting and instructive, its aim being to "raise the grade," mechanically, morally and financially, of every man in the service it represents.

An Avalanche.

Last month we made some inquiries about steam-pipe repairs, and at this writing, Nov. 20th, we have received 143 replies. To publish all these letters in full would fill three such papers as ours, and we have therefore been obliged to cut down the letters to the three most important items: How often done, how long it takes, and how much it costs. Then, by publishing about half this month and half next, we will be able to show up the practice very fully.

Twenty-one foremen have answered the questions, and say that it is against the rules of their road to publish such information, or simply marked "not for publication." To question about special tools, 105 say they have no special tools except wooden block to hold rings; 26 say they use a brace and rose bit; 4 send sketches of ring holders or rose bits, and 13 do not answer at all.

As to who does the work, 36 say men take turns, 42 that they use the first man they come to, 4 keep a regular man, and 16 that boiler-maker does the work.

Seventy-six say that engines do not lose trips for this work.

Thirteen report the use of valves to prevent over-pressure on pipes and steam chest, and 9 of these say they note no difference on pipe repairs.

Sixty-two say freight engines require the most work, 39 that passenger service is the hardest, and 16 say they note no difference. Only 7 report the use of clips or bridges over lower joint, 5 report the use of cement, and 12 the use of iron cover over lower joints on extension fronts.

The time between grinding varies from one month to ten years, and the cost from $1 to $20. A majority mention that the cost and time are about double on extension fronts over short fronts, and all but 4 who report a loss of a trip say it is on account of the heat of extension.

Taken altogether, the replies are interesting, and show what interest and care for details is taken by the roundhouse foremen of the country. Those replies crowded out of this issue will appear in the next.

What is Under Control?

Recent accidents, where it is claimed that engineers disregarded the order to approach certain places "under control" have raised the question at the head of this article.

Once upon a time in our experience, we were taken to task by our superintendent, for passing a certain point with a freight train at about 15 miles per hour; when we asked him to define "under control" he was at a loss for an example and we finally asked if he would call a train under control if it could be stopped inside of its length; he thought it was, and we got out of the scrape by assuring him that, with the excellent air we had on every car, that we could kill 15 miles per hour much short of forty cars—we were both wrong.

One very good definition is, that under control is to have your train so that it can be stopped inside the distance you can see—if you can see but 100 feet, the train should be run slow enough to be stopped in that distance; if a mile, a higher rate of speed would be under control.

This is a pretty safe rule, but circumstances alter cases; for instance, if ordered to run under control past a point within plain sight, but in bad weather, or during the prevalence of freshets, an engineer would have to use his good judgment, and no set rule should be followed.

It is always well, however, to have a perfect understanding between the engineers and the officers to whom they are responsible, and when a superintendent is found who says six miles per hour is under control under all circumstances, it is better for the men to run six miles per hour, than to argue on the green carpet about what under control really is.

Burning an Engine.

There is a disgrace attached to a runner who allows the water in his boiler to get low enough to burn the crown sheet, that he never entirely outlives. Not only does he get, as a rule, his dismissal from the service, but his reputation follows him, and, a few years back, he was lucky if his superior officer did not blackball him instanter. But this was not the end of his misfortunes; if he happened to have a few enemies in his brotherhood division, they would insist on the enforcement of a law expelling him, and publishing his name in the official organ of the order, as expelled for "burning an engine."

All these reasons combined tend to make a man sacrifice all other considerations to keep water on the crown sheet; and any runner would rather tear off both cylinders and all the link motion, than to scorch the rafter bolts even a little.

That, with all human care possible, this disaster will occasionally occur, only goes to prove that humanity is prone to slip up in its calculations.

It is seldom that a crown sheet comes down and injures anybody, and it costs much less to repair one than it does to repair wrecked cars and broken heads caused by a collision; and, no matter how much a runner is at fault in this case, his fellows do not expel and disgrace him.

When a man burns an engine through incompetency, gross carelessness or intemperance, he needs discharge, expulsion and disgrace; but if a man with a good record as a runner makes a mistake, is overworked and goes to sleep, or is deceived by changed conditions, or hampered by inferior boiler feeders or bad water, he does not deserve the lifelong punishment he receives.

When a runner, to keep from burning his boiler, carries water so high that it is constantly carried over into the cylinders, he annually costs his company more money for repairs than if he scorched a crown sheet regularly, on each and every New Year's morning

Last month an engineer on the Lehigh Valley road dropped the crown sheet of the "Bee," No. 82. The immense crown sheet came down where the ash-pan ought to be, blowing a man off the tank, and killing him. The engineer was a runner with a reputation, and an experience of nine years on the road, and he honestly said that he would have sworn, one minute before the accident, that he had three gauges of water, but since looking at the sheet, he was satisfied that he did not have any. Such a man feels his disgrace, and is punished enough, without any action on the part of his brothers. Men who cause, or may cause accidents of any kind, because they are incompetent, intemperate or ignorant, should be expelled, or, better, kept out of the orders in the first place.

Burning an engine is bad, and should receive punishment; but it is no worse than a hundred other things that men do and are excused—because they are good men—why not be a little more lenient for this offense?

The engineers should bear in mind that it is the sinner, not the saint, that needs salvation; and officials, that it is no more dangerous or expensive to scorch a crown sheet by not using water enough, than to use double the amount of oil and coal, and cut cylinders, valves and seats, and tear valve motion to pieces by using too much.

The trouble is that the burning process takes place in a few minutes and is a shock, while the drowning process takes a year or so, and we get used to it before the final collapse. Both are death—one by lightning, the other by consumption.

The Pennsylvania Coal Premiums.

The Pennsylvania R'y. Co., instead of offering a premium to the man who can run on the least coal for a month, or six months, go on the principle that when a man saves a dollar for the company he is to get half of it. Each month they post at all roundhouses on each division, a list of the trains on the road and the limits of coal they are expected to run under. The trains are allowed so much coal per car per mile, some on the New York Division as high as 24 pounds per mile, and some as low as 3.8 pounds. The company allows nothing for taking the engines over the road, except when light; this is unfair, as the man with the big train has an advantage always; if a man has one car only the coal used to run the engine is all charged to that car, and if he has a hundred cars it is divided up into a hundred pieces; they ought to allow so much for an engine under all circumstances.

When a crew run under the amount allowed by the bulletin for a month, both the engineer and the fireman receive 60 cents per ton for all coal saved, and the extra money made by some of the best men is enough to keep them in clothes. This plan is superior to the prize plan, as it gives every man a chance to profit by his care, intelligence and devotion to his business. There are many men on the Penna. R'y, however, who always burn more than the amount allowed to their trains, and they are only occasionally asked the reason.

This idea that railroad men have been pushing for years, that one is as good as another, is dead wrong. There are engineers and engineers. Let us liken a road's force of engineers to a beef carcass; now, suppose we cut up the whole beef into slices and call it steak, there will be some choice cuts of porterhouse, about twice as much fair-to-middling round steaks, and a whole mess of neck and heels. Don't be the tail.

Books Received.

ANNUAL REPORT OF COMMISSIONER OF RAILROADS OF MICHIGAN has been received; like all other reports of its kind it goes into the financial details of all the roads, and also states all the progress made during the year. Last year the legislature of that State provided for the appointment of a mechanical engineer, who should have at least ten years' practical experience. The commissioner appointed Clinton B. Conger, an engineer, and in showing up the work this man has done for the good of the employes, the safety of the public, and the profit of the companies, in language that we very much regret space forbids repeating here, he says: "I think the results of the first year's experience fully demonstrate the wisdom of the legislature in deferring to the request of the railroad employes in the employment of a mechanical engineer to be taken from their number" Many recommendations of Mr. Conger for the safety of trainmen are embodied in the report, and are worthy of the man and the time

POOR'S DIRECTORY OF RAILWAY OFFICIALS contains list of officials of all roads in United States and Canada, and Great Britain and Ireland, also street-car lines, lumber and logging roads, etc. This is the third annual number, and issued as a supplement to "Poor's Manual of Railroads." It is the most complete and reliable list of this kind as yet compiled

GRIMSHAW'S BOILER CATECHISM, Practical Publishing Co., 21 Park Row, has been received. It is elementary, and very much on the advertising line, as almost every cut and description used are of boilers or devices patented or manufactured by some firm. The work is not intended for, and would be of very little use to locomotive engineers.

DIXON'S MACHINIST'S AND ENGINEER'S CALCULATOR, D. VanNostrand, 23 Murray street. We often receive inquiries from firemen and apprentices—and often engineers and machinists—who want a book on mechanics, with tables, etc., but in plain, elementary language, and in which simple arithmetic is used in place of algebraic formulæ and technical phrases, beyond the understanding of men in possession of common school educations only. This is a book of this description, is bound in morocco, in pocket form, and contains rules and tables that would be of great service to young students. It has a chapter on locomotives, full of points and "reasons why," and has a description of an injector that is the one commonly given to firemen by their engineers; it is very brief and a little shady—if not entirely incorrect

The C. B. & Q have recently turned out some passenger engines with solid-ended rods all around, even the back end of the main rod. Their performance will be watched with interest.

ASKED & ANSWERED.

(68) Apprentice, Rome, N. Y., asks:

Who invented and first used cast-iron steam pipes, and when was it? *A.*—Wm. Mason, of Taunton, Mass., in 1853

(69) D. M., Taunton, Mass., asks:

Do you consider the braces usually placed between the boiler and the frame a necessity? *A.*—If the engine always remains on the track, no. But if she ever gets a tumble, we believe the boiler braces will save lots of broken and bent pieces.

(70) Virginian, Alexandria, asks:

Is there any known torpedo placer that will drop them from a running train, and if so, how do they work? *A.*—Yes, by employing torpedoes having a spring steel strap instead of one of lead or tin; these steel straps are sprung open and held so in slots in a forked iron head on a wooden handle long enough to reach the rails from the rear platfrom. By placing the fork over the rail, and giving a quick punch, the torpedo is jerked out of fork, and the springs firmly clasp the rail. They are in use by a number of railroads.

(71) Texas, Galveston, writes.

In a recent discussion on what constituted an "American engine," I mentioned as one of the distinguishing features the bar frame, and was at once pounced upon by several, who claimed the bar frame was first used by Compton, in France. I could not back up my statement, as I did not know. Can you enlighten me? *A.*—The Compton engines have a slab frame. The bar frame, as now universally built in America, was, so far as we know, first used by Wm. Mason, 1853-4

IN THE ROUNDHOUSE AND REPAIR SHOP.

Covering iron decks with inch boards makes them warm, and prevents accidents from slipping.

* * *

There was only one railroad accident in England last year in which passengers were killed, but that one was enough—25 killed, 92 crippled.

* * *

The *Engineers' Journal* could make us happier if they would credit items they use, that originally came from this sentiment foundry.

* * *

The Jacksonville, Tampa & Key West shops at Jacksonville, Fla., and the New Orleans, Texas & Pacific, at Ludlow, Ky., have recently equipped their shops with the Vreeland transfer jack.

* * *

Steam car heaters are scrambling for trial and adoption. If this should be a very severe winter, it would go a long way toward the correct solution of the problem.

* * *

At the Renovo (Pa.) shops, we noticed an old English slotter, too much worn to do accurate work, that was doing very good service as a punch in the blacksmith shop.

* * *

Most English locomotives with outside cylinders have the steam chest inside the smoke arch. No doubt this method prevents radiation and saves coal, but it must be very unhandy about repairs.

* * *

The *Firemen's Magazine* will be enlarged to 94 pages. The *Magazine* is a grand, good one, but we believe it would have been better to drop the resolutions on deaths, and leave the book its present size—it is already worth more than one dollar per year.

* * *

We have received word from the manufacturers that the cases of the locomotive clock, shown in our last paper, are not steam gauge cases, but special cases made for that purpose, and the dials are finely painted ones on zinc.

* * *

All boxes for locomotives, whether for tools, oil or clothes, should have a cover the full size of the box, so that, when opened, all cinders and dirt on them will be thrown away from the box, and not into it, as the hinged arrangement provides for.

* * *

The A., T. & S. F. have cut down the hours in shop service 16 per cent. They are reducing expenses in every possible way—in the shops—to make a better showing on the dividend sheets. Taking dividends out of running repairs or bridge timbers is like an exposed army withdrawing its pickets.

* * *

Some of the very best cylinder lubricators in use on marine engines are open cups, the feeding being done by a small pump operated by the moving machinery; they are simple, feed as long as the machinery moves, and stop feeding when it stops. They require no glass tubes or steam-tight joints, and we know of no good reason why they would not be a success on a locomotive.

* * *

At the Wilkesbarre shops of the L. V. R'y we saw a Wooten boiler in for repairs, that had broken nearly 150 stay bolts in the fire-box. This was one of the older designs, and had a light channel bar, instead of a solid mud ring. One year ago this same box had over a hundred new stay bolts.

* * *

On the D., L. & W., there are a number of locomotives that have been in service for five or six years, that use a solid cast-iron driving-box—no brass or babbitt at all. These boxes have given entire satisfaction. Would not a few experiments in this line pay most any road—especially those using moderately light engines?

* * *

An engineer on a D., L. & W. passenger engine, was badly hurt not long since, by being struck by a mail catcher placed near the track; it was ordinarily far enough away, but it is supposed the man was leaning far out of the side window to see the overflow pipe of his injector—one of those abominations that is turned inside the frame. The best place for an overflow pipe is where the runner can see the discharge end of it.

* * *

The Manhattan Elevated R. R. Co. is trying some experiments just now with a view of utilizing a cheaper grade of coal than they are now using. Engine No. 93, built at Rome, N. Y., cylinders 11x16, driving wheels 42 inches, grate surface 55 inches long by 44 wide, 125 1¼-inch flues 8 feet long, 4 inch nozzle, train 5 passenger coaches with Lehigh pea coal the engine did well enough to indicate that, when the men are familiar with using the fuel, it can be made a success in that class of engines. It is intended to try the buckwheat coal at an early day. E. J. Rauch, general road foreman of engines, has charge of the tests, and this fact alone insures a fair, free trial, and success, if success is to be had.

* * *

Where is the man who makes felt headlight wicks? Some makers send out felt wicks in new headlights, but the roads furnish canton flannel, and the man in the supply house will tear off a piece that looks as if it had been gathered for a doll's dress. We don't know what canton flannel is furnished for, unless it is the well-known fact that it makes the poorest kind of a wick. It is a nasty job to get one in at all, and then it is seams, and lumps, and feather edges. It would pay any company to buy good, ready-made, seamless wicks, if they cost $1 apiece; it would pay any manufacturer of headlights to put four dozen in each headlight case; it would pay any engineer to buy them instead of making excuses for wicks and swear words without excuses; and it would pay any man who makes these wicks, to advertise them.

CAST STEEL WORKS

—OF—

FRIED. KRUPP, Essen, Germany.

AMERICAN OFFICE, 15 GOLD STREET, NEW YORK.

P. O. BOX 2878.

Represented by THOMAS PROSSER & SON.

These Works cover an area of 1200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

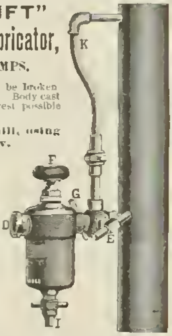
LOCOMOTIVE TIRES, CRANK PINS, PISTON RODS, SPRING STEEL, &C.

STEEL-TIRED WHEELS.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. · If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

The "SWIFT" Sight-Feed Lubricator,

FOR AIR PUMPS.



Has no glass tubes to be broken Flash Feed readily seen Body cast in one piece, and fewest possible joints.

Feed will not Chill, using the hardest Tallow.

Sight-Feed Glass is a disk, and can be instantly replaced while running.

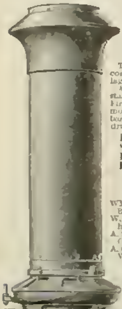
607 MARKET STREET, — — — — — — PHILADELPHIA PENNA.



LUTTGENS' PATENT

Variable Exhaust Damper.

This device provides for the inside of a Locomotive Boiler what the application of lagging and casing provides for the outside. A circular valve is opened at the base of the stack, so that the cold air does not enter the Fire-box, the Flues or the Smoke-box, but it modifies the draft by admitting air at the base of the Stack or at a point where the draft is produced.

It effects a reduction in the coal bill.
Softens the exhaust.
Is a complete Spark Arrester.
Improves the steaming of the engine, and proves a comfort to the Engineer and Fireman.

REFERS BY PERMISSION TO

Price-List furnished on application.

Address,

H. A. LUTTGENS,

P. O. Box 181, Paterson, N. J.

The Giles Anti-Magnetic Shield for Watches.

CLEVELAND, O., July 22, 1887.

Messrs. GILES, BRO. & Co.

Gentlemen:—I am acquainted with the merits of the Giles Anti-Magnetic Shield for Watches, and believe it is a very valuable invention for protection of pocket time-pieces, and very desirable for railway service. Yours truly,

(Signed) P. M. ARTHUR, G. C. E.
T. S. INGRAHAM, F. G. E.
H. C. HAYS, F. G. A. E.

The Shield can be Fitted to any Case.

Sure Protection from all Electrical and Magnetic Disturbances.

No Railroad Man should buy a Watch without it.

ANTI-MAGNETIC SHIELD CASES FOR SALE BY ALL JOBBERS.

For further information or descriptive circular, send to

GILES, BRO. & CO. DIAMOND MERCHANTS AND SILVERSMITHS, 99 & 101 STATE ST., - CHICAGO.

NEW HANDY BINDER FOR THE LOCOMOTIVE ENGINEER,

(In Stiff Covers,) 50c. at this Office, or 75c., postage paid, to any address. Will hold Two Years' Numbers.

AMERICAN MACHINIST PUB'G CO., 96 FULTON STREET, NEW YORK.

BAILEY'S PATENT

COPPER CAP FUSIBLE PLUG.

A Cheap Means for Preventing Accidents to Steam Boilers through Low Water.

The fusible metal is kept from contact with the water, thereby avoiding the chemical and mechanical action, which would otherwise prevent it from melting Cap is readily removable, permitting free inspection.

Highly recommended by American Railway Master Mechanics and others. Over 150,000 sold in Europe since first introduced, with increasing sales Highly recommended also by the U. S. Board of Supervising Inspectors of Vessels at Washington, D. C.; by Prof. R. H. Thurston, and many other eminent expert engineers, as superior to any now in use, and filling all requirements

GEO. VAN WAGENEN, 233 West St., N. Y. City.

Sole American Licensee and Manufacturer.

THE LOCOMOTIVE ENGINEER.
DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO. I. NEW YORK, JANUARY, 1889. 1.00 per Year. or 10c. a copy.

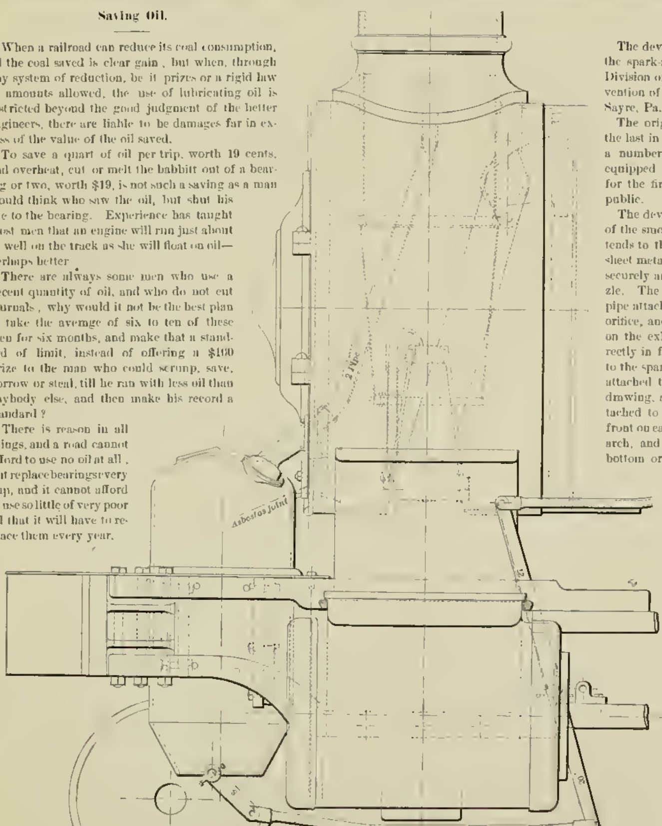
Saving Oil.

When a railroad can reduce its coal consumption, all the coal saved is clear gain, but when, through any system of reduction, be it prizes or a rigid law of amounts allowed, the use of lubricating oil is restricted beyond the good judgment of the better engineers, there are liable to be damages far in excess of the value of the oil saved.

To save a quart of oil per trip, worth 19 cents, and overheat, cut or melt the babbitt out of a bearing or two, worth $19, is not such a saving as a man would think who saw the oil, but shut his eye to the bearing. Experience has taught most men that an engine will run just about as well on the track as she will float on oil—perhaps better.

There are always some men who use a decent quantity of oil, and who do not cut journals, why would it not be the best plan to take the average of six to ten of these men for six months, and make that a standard of limit, instead of offering a $100 prize to the man who could scrimp, save, borrow or steal, till he ran with less oil than anybody else, and then make his record a standard?

There is reason in all things, and a road cannot afford to use no oil at all, but replace bearings every trip, and it cannot afford to use so little of very poor oil that it will have to replace them every year.



Weaver's Spark Arrester.

The device shown on this and the third page is the spark-arresting arrangement of the Northern Division of the Lehigh Valley Railroad, and the invention of Mr. J. N. Weaver, master mechanic, at Sayre, Pa.

The original patents were granted in 1876, and the last in 1884, and the device has been in use for a number of years, there being 130 locomotives equipped with it. It is now, however, shown up for the first time, as we believe, to the railroad public.

The device consists of an extension to the bottom of the smoke-stack, made of sheet metal, which extends to the top of an inverted cone of perforated sheet metal, the bottom of the cone being clamped securely around a flange cast upon the exhaust nozzle. The exhaust nozzle is provided with a jet pipe attachment, which projects slightly over each orifice, and extends downward through the flange on the exhaust to an L-shaped nozzle, located directly in front of the bell-shaped opening, leading to the spark receiver. The receiver or spark-box is attached to the front of the engine, as shown by drawing, and is provided with two suction pipes attached to its top, which pass through the engine front on each side, pass around the side of the smoke-arch, and enter the bottom of smoke-stack. The bottom or lower opening of each of these suction pipes is protected by a perforated metal screen, to prevent sparks from being drawn through them. The bottom of spark receiver is provided with double, butterfly valves, which are operated from the cab. The sparks can be readily dumped standing or running. At each exhaust of the engine, a portion of the exhaust steam is conveyed through the jet pipe, which is attached to the top of exhaust, producing, with each exhaust of the engine, a corresponding exhaust through the bell-shaped opening into the spark receiver, carrying what sparks may have been drawn into the smoke-box with it into receiver.

The action of the exhaust of the engine, in passing by the ends of the suction pipes in the stack, creates a suction through them, which not only assists in drawing the sparks from the smoke-box into the spark receiver, but carries off the steam from the jet pipe exhaust, allowing the sparks to drop to the bottom of the receiver, where they can be allowed to cool before dumping. It makes no difference in steaming of engine whether box is full or empty, as the front end is always clean.

The action of the suction pipes, in connection with the jet pipe exhaust, keeps the current through the bell-shaped opening into spark receiver almost constant, in an outward direction, thus preventing any admission of cold air into the smoke-box, so that,

Angus Sinclair is re-writing portions of his well-known book on Locomotive Engine Running. The new edition will have several chapters on combustion and other subjects, of special interest to, and for the instruction of firemen. The revision will add much to the value of a work already highly prized.

The Safety Valve copies (without credit) part of a letter from our correspondent, H. R. Jones, published in our last January number. Clippings are entitled to credit—if they are a year old.

At some of the P. R. R. shops, locomotives receive a general overhauling, including new fire-box, at a cost of $2,400. This is an exceptionally low figure.

whether the butterfly dumping valves are open or closed there can be no cold air taken into the smoke-box.

The arrangement and proportions of the apparatus are calculated to produce a uniform draft through the flues. The bottom flues remain clean and open equally with the top or middle flues.

This device takes the place of the extension front, and is in use on this road on many different styles and sizes of engine, some burning hard, others burning soft coal. It seems to be a cheaper and neater arrangement than the extension.

New Boilers on the Lehigh Valley.

Alexander Mitchell, Supt. and M. M., of the Wyoming division of the Lehigh Valley road, has recently built a number of consolidation freight engines with a new design of boiler. They have extra large grates for burning fine coal—fire-box is above the frame, like the Wootten—but the box narrows up to the width of the boiler about eighteen inches above the grate. He has built a number of these boilers, and has used the Belpaire system of direct stays, the crown bar and the radial stay, and the record of repairs and service of these boilers will do considerable to determine the relative merits of the different systems, as the boilers are exactly alike in every other respect, and the service the same. By narrowing the sides of the fire box, he gets a low running board to cab, and a full-sized door in the rear of it, so that the runner and fireman are not divorced or stand in need of speaking tubes, etc.

The arrangements of the cocks and levers in the cab were made for the comfort of the men who ride the mills—an unusual departure.

With the cab in the center of the boiler of long consolidation engines the riding is improved, and there is less demand for kidney remedies.

Rock Island Watch Inspection.

The Rock Island road have decided that all conductors, engineers, yard masters, train dispatchers, section and bridge foremen, and all officers connected with the operating department shall carry high-grade watches. They must contain fifteen jewels, patent regulators, and be adjusted to heat, cold, encased in anti-magnetic shields, and be examined by the company examiner every three months. Blanks will be furnished, to note any variations the watch may make. As long as the men own the watches these blanks will not be filled out truthfully, if filled at all. It is now considered justifiable to lie about the record of a watch, if nothing else—we have heard good, honest Christians who were running trains or engines, by an oroide case and a penitentiary escapement works, to solemnly swear that "She is just on the tick, and I ain't touched her regulator since a year ago last August."

The only safe, sure and right way for a company to keep absolutely correct and uniform time in train service, is to own the watches, and issue them every trip, the same as train orders; then, if a watch varies a sixteenth of a second a man will note it on a blank. But to report a fault with his own $150 ticker—not much!

The Rock Island folks have made one improvement—they do not make the men pay for the examination.

We can guarantee a poor return from the order to "compare time, and make note of difference on blank at least once a week."

Cleaning Work in Repair Shop.

At the Renovo shops of the Pennsylvania road they have a very neat way of cleaning the grease and dirt off the different parts of locomotives that go in to be overhauled; instead of wiping and scraping, they cook it off.

Just outside the machine shop there is an iron tank sunk into the ground so that its top is only a few inches above the level; it is wide enough to take in a truck and is perhaps four feet deep and ten feet long; one end slopes at an angle of about 30°, to facilitate the removing of pieces too heavy to lift bodily.

This tank is filled to within about a foot of the top with water, to which is added enough potash to make a very strong lye; into this is placed such pieces as it is desired to clean, and then the lye is boiled by steam from the stationary boilers.

For small pieces, such as bolts, nuts, washers, keys, etc., they have a small iron car with perforated iron box that retains them and makes the removal easy and sure. Such pieces as shoes and wedges, ordinarily so filthy, come out of this bath as clean as from a planer; one man can remove and clean all ordinary pieces from a large shop, if provided with proper truck, etc.

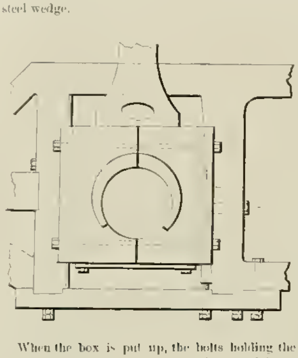
As the grease boils off it comes to the top, where it is easily skimmed off, and fresh water and potash are only required as the supply is reduced by evaporation. It would be a great scheme if some of these roads that are too stingy to wipe their freight engines would arrange a tank track near headquarters, where the engines could run through a half mile of boiling lye on the home trip; then, if they fixed up another tank of oil on the outgoing track, the engineers would not have to get off their seats to oil.

A New Axle-Box.

The axle-box shown herewith is the invention of J. Des Brisay, a machinist in the Canadian Pacific shops at Vancouver, British Columbia.

The idea is to make the box in halves and bolt them together to finish the bearing, etc.

The jaws of frame are lined with thin steel plates, and pockets in the sides of box carry small steel rollers that bear upon these plates. These rollers are made tight between the frame and box by a thin steel wedge.



When the box is put up, the bolts holding the halves together are slacked off, and the weight on the spring saddle above crowds the halves against the rollers and the frame.

The inventor hopes by this plan to do away with all devices for keeping the box lined up in the frame, prevent sticking, and keep the bearing on the journal closed up.

In the bottom of the halves is a large hole that is used to hold the cellar; this is made of any sheet metal, and is held in place by the plate shown on bottom of box. What success will be achieved remains to be seen, as the device has not yet been tried.

Read This—It Will Make You Tired.

LEBANON, Dec. 5 [SPECIAL].—Robert H. Coleman, the millionaire owner of the Cornwall ore mines, who is an expert mechanic, yesterday ran the 11 o'clock train on the Lebanon Valley Railroad from this city to Harrisburg. He did it for the purpose of making a test of a spark arrester of which he is the inventor. He handled the throttle with skill, and the sight of the millionaire engineer attracted a great deal of attention to the train.—*Daily Paper*.

[Here it is, simple enough when you see into it, the way to make all engineers handle the throttle with skill, and attract attention to their trains and their roads, is to employ millionaire engineers only. Of course, the regular engineer could not have tested that spark arrester—he did not have the million dollar skill.]

Air Brake Practice.

EIGHTH PAPER.

By J. E. PHELAN.

One of the principal causes of annoyance to be overcome in handling long and heavy freight trains, needing considerable air, is the heating of air valves and air cylinder of the air pump, and burning out packing. It is the same old cause mainly; where hurry commences, trouble begins. The air pump cannot be crowded beyond its capacity, and must have proper time to do its work. Often they are not properly cared for, and all kinds of dirty oil being used and allowed to be sucked in through air valves, dust accumulates and gum forms, until air passages become contracted, and adding to and increasing compression and friction in consequence, and pump laboring so much harder against unfavorable conditions, it has every inducement to get hot and stay hot. An air pump should work moderately and freely, and should not be crowded in its work. The pump should not be required to keep up more than 60 to 80 lbs. of air pressure in main drum for ordinary work. A pump will seldom heat working against this pressure, where it will often heat pumping against 100 lbs. pressure. Pumping against this latter pressure causes increased friction, especially when air is mingled with the ordinary amount of grit coming from a sandy road bed. The air cylinder should be shielded from such dust as much as possible.

Pumping air to supply leaking pipes, instead of the simple supply for uses of the brakes, makes a hard tax on the pump. It is poor economy to pump air and compress it to working pressure, only to have it leak from defective pipes back to the atmosphere.

An air pump ought to have daily attention of some kind. The air cylinder should be kept clean, and oiled with a small quantity of pure oil, free from gumming or corroding quality, that should be used and put in through small oil cock at top and back of air cylinder of pump for that purpose.

The duty of the present is to be skillful with appliances in use, and be ready to tackle anything the future may have in store.

To do successful work, waste of air in any form must be guarded against. All pipes and connections should be absolutely free from leaks and escaping air. The engineer who starts out, knowing that leaks in train pipe exist, cannot be depended on for good or reliable work. It should be known that brakes are in good working order before starting on a trip.

On freight trains, or any other train when brakes are in good condition, and all pipes and auxiliary reservoirs stored with air, it is a good plan to avoid application and use of brakes, except when necessary for the requirements of actual stops in service or emergency.

Aim to work the air pump as lightly as possible to supply air enough for the needs of the brakes in doing their work when skillfully handled. Don't make an air pump do in five minutes what may just as well be accomplished in twice the time with better results.

Nothing is more evident than the fact that, for successful air brake practice, the engineer must skillfully provide the amount of air necessary, by good judgment, in caring for his air pump, and keeping it in good order, and bear the fact in mind that the air pump compresses air enough, if too much is not used—similar to an engine steaming; very often a good engine's steaming qualities may be condemned because the man in charge can uselessly use more of the product than can ordinarily be supplied.

In the matter of air cylinders of air pumps getting hot, there is always a reason for it, and such reason should always be learned, and the evil remedied. If the heating does not come from the pump being run too fast, and forced into extraordinary action—and this may be relied on as the most common cause—there may be other defects needing a remedy. The matter of air passages gumming up, and cylinder becoming dirty, ought to be carefully watched.

One remedy for this is said to be gained by disconnecting discharge pipe from air cylinder. Then take a quantity of lye, and allow it to be sucked in through air valves and allowed to flow out where discharge pipe has been disconnected, where it can be caught and used over again.

Disconnecting air cylinder, taking off heads, and dropping it into a vat of hot lye, long enough to soften the gum and dirt, so that all passages and parts may be wiped clean, then putting it up again in good order, and keeping it properly oiled and cared for, and not overworking it, ought to ensure effective work without heating.

Where pump governors are in use, and no pump can be complete without it, a common fault is to start an air pump running at a rapid stroke, depending on the governor to stop the pump when required pressure is gained. Before pump governors came into use, air pumps were run at a moderate speed, and fear of excessive pressure governed the engineer's actions in controlling the pump. The knowledge of the pump governor's action, and confidence in the same stopping pump, leads to overtaxing the air pump for space of time it may work; while, maximum pressure once gained, a total stoppage of pump occurs. Doing work in such a manner, an engineer might just as well be making a 60-mile run on level track, where no stops are required, work steam for a certain distance, and then shut off steam entirely, because maximum speed had been reached, instead of keeping up an even rate of speed by working his engine uniformly over entire distance to be run without stopping.

The pump governor is a contrivance located at a point in steam pipe between the steam throttle of air pump and steam cylinder. All steam for running air pump passes through the governor, and this governor is so arranged and can be adjusted so that when maximum air pressure is reached, the pressure acts on a valve inside the governor that automatically closes steam passage to steam cylinder, and stops its working.

When air pressure falls below maximum pressure, the steam passage is automatically opened, and pump starts to work until again stopped by maximum pressure being reached.

It is good practice to run pump on same principle as though no governor were in use; simply have the governor as a vigilant, to keep pressure from going too high if forgotten.

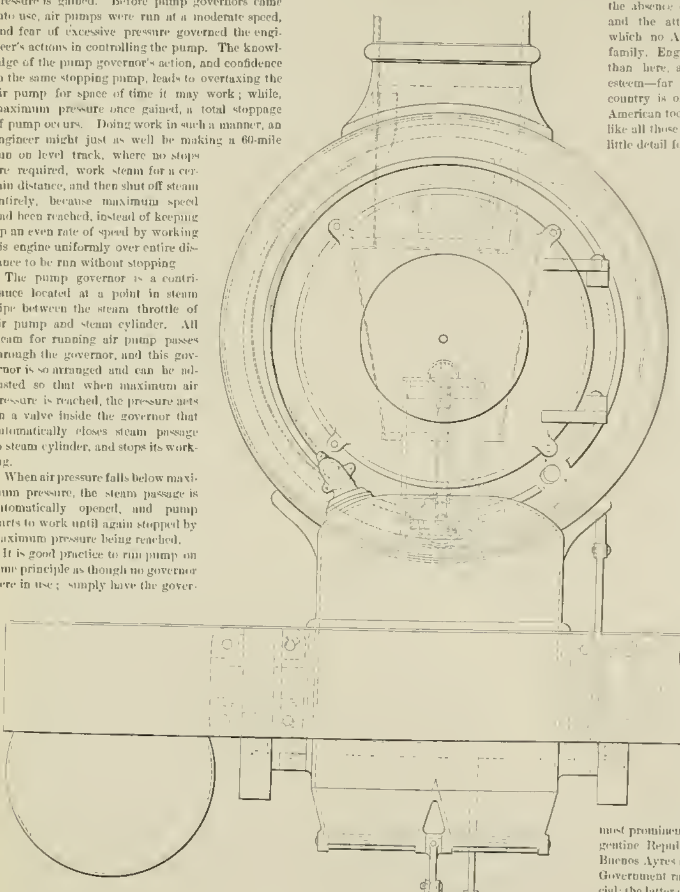
It is not only *poor*, but dangerous practice, to put blind gaskets into joint of waste pipe of governor, in order to secure excessive pressure.

The man who does the best work with the lowest amount of air pressure consistent with safety in an emergency, is the best air-brakeman, and will be a source of unseen profit to a railroad company, in not destroying and sliding wheels.

The man who slid six pairs of steel-tired wheels on one train within the United States, not long ago, making a regular station stop, and turned easy-going Pullmans into rattle-boxes, does not dream of leather medals, yet uncut, for such work. But he deserves one.

Taking the Left-Hand Track.

Several New England roads now run their trains on the left instead of the right-hand track, claiming, and rightly, that the engineers, being thus placed between the two tracks, can see all signals or obstructions better. In Great Britain it is the general practice to run upon the left-hand track, but the reason for so doing is not the same, for most of the locomotives there have the runner on the left side, and one reason given for keeping him there is that he is on the outside, and can see the station platforms better.



Notes on South American Railroads.

BY A FORMER RESIDENT.

South America can best be mechanically considered by dividing it into two distinct parts, Brazil being the first; for here all labor, other than mechanical, has been in direct competition with slaves, wages being very low. The second part consists of Argentine Republic, Uraguay and Paraguay. We will first consider Brazil, and take railroads as a basis for comparing wage rates. The trackman (called section hand in U. S.) receives 800 reis per day, large figures but little money, for it equals about 35 cents when money is not depreciated, and it often is, making the wages even smaller. No houses are provided, as is often the case here on new railroads, and out of his wages must come all the family expenses, consequently food and clothing are of the poorest quality.

Mechanics' wages are about on a par with those of Southern Europe, as everyone knows, very much lower than here, a first-class mechanic rarely receiving two dollars per day.

Comparing the living basis with our own, we first take clothing; the climate allows a light and inexpensive material, but the frequent laundrying, which the climate necessitates, makes the amount as much or more than here for the same quality. The houses are very poor, likewise the food, and the absence of schools makes education a rarity, and the attendant ignorance breeds customs to which no American would care to introduce his family. Engineers, or "drivers," receive less money than here, and are not held in the same high esteem—far from it. The shop practice of the country is on the English plan, although many American tools are to be found. The buildings are like all those erected in tropical climates, with but little detail for the comfort or health of employes.

As we consider railways great, Brazil has none, *i. e.*, no trunk lines, the main railway being owned by the Government, the smaller ones by foreign corporations, mostly English, with a few French. On the Government and French roads the American locomotives are used, the English, however, using their own make.

Passenger equipment is mostly American, modified to suit climate and Brazilian ideas, while the freight rolling stock is mostly English on all the roads.

When we consider the vast territory that composes Brazil, without mechanical means of transportation, except within a few miles of the sea coast, we may say that Brazil has no railroads.

The whole interior is without access to the coast (except to the dwellers along the Amazon and its tributaries), nor are any lines to the interior projected.

The Argentine Republic is so vastly different, and such an advance from her northern neighbor, it may not be out of place to state here that the constitution of this country is modeled after our own, being nearly a copy of it. As all have an equal standing before the law, there is no competition with slave labor, and wages are correspondingly higher, though not equal to our own country for the mechanic or railroader. The railways here are the most extensive of any in South America, and are rapidly increasing, both in numbers and length of road, the largest being built by the Government, and companies of English origin. The most prominent are: Great Southern R. R., of Argentine Republic, the Central Argentine, and the Buenos Ayres and Pacific. There are two classes of Government railways, the National and the Provincial; the latter employ only natives, if possible, while the former make no distinction. The methods of construction will be of interest, as they differ from ours in many ways. The general plan is of English design, and was used in Egypt many years ago. The grading work is similar to ours, though they are far behind in appliances and rapidity.

It is not till the laying of permanent way begins that the American gets fully interested. Wood being scarce in the southern part of the country, cast-iron ties or sleepers are used, "pot sleepers" they call them; they are cast with the top surface like a turtle's back in its oval appearance, and have two lips cast to receive each rail, a steel key with corrugations, corresponding to those in the hole of the sleeper, fastening the rail to its place. The soil of the country is used for ballast, no sand or gravel being available, and tie rods have to be used to hold the ties in position with each other. They ballast as follows, between the tracks, one inch below rail, outside for twenty inches from each rail, level. The flying dust resulting—for the flange of wheel runs in dirt—can be imagined.

In the northern section, wooden ties from a tree called kinbracha are largely used, and make an excellent tie. Spikes cannot be driven into it; a special spike is used, square, with round point. A hole is bored so that the end will just enter, they are then driven home, holding by the corners only. So firmly is this held that the head may be pulled off the spike without starting it. Though so hard, it is very inflammable; a hot coal will eat a hole through it in short order; so the road is ballasted even between the rails, as with the "pot sleeper." The bridges of the country are mostly English, being imported complete; all are of iron.

The depots, or station houses, are mostly of brick, divided for the different class of travel; for, even though a republic, they have first, second, third, and sometimes fourth class. The platforms are a curiosity. A wall is built beside the track, at a proper height from the ground to be convenient for the car steps, and the space behind is filled with earth, in most places, with cement in a few. Ales, wines and liquors are sold at all stations.

The baggage system is after the American plan—a long ways after, too, by the way—but is improving slowly. Their rate per mile is slightly in excess of ours, being about four cents per mile, while the "drivers" receive less than here; first class men receive about $96 when the greenbacks of the country are at par, similar to war times here. The conductors and brakemen are not respected as here, are less independent, and receive less money. Comparing the cost of operating railroads between here and Argentine, the Argentine seems to be less, though coal is ten and fifteen dollars per ton, in gold. But they have no wood in the southern portion, and coal must be had at any cost. In the north, however, wood abounds, and is used there.

There exists in this country a system which is a very fine thing for the men there, for most of the railroad men are natives of either Great Britain or the United States. It might be called the "good behavior and continuous service rewarding system." For every five years of continuous service, in any capacity on the railway, he receives five months' vacation, his wages being continued during the time, and his passage to and from his home, be it in Great Britain or the United States. Engineers, and all above, receive first class passage, mechanics second class, and laborers third class. This promotes a good feeling between the men and management, which is worth many dollars to the corporations. C.

We are in receipt of a note from John C. Thompson, President of the Eames Vacuum Brake Co., in which he calls attention to a suit recently entered against his company by the Westinghouse Air Brake Co., as lessees of the American Brake Co.'s business, for infringement of certain patents on driving brake apparatus. Mr. Thompson offers to furnish guarantee to any and all users to protect them against all suits or claims for damages.

On some of the dirt burners on the D., L. & W., where the engineer is in the middle of the boiler, the steam and air gauges are made to face him, and not the rear of boiler; the cocks and gauges on these engines, with the dome through the cab also, make it impossible for a man to get over the boiler in case of a wreck—a trick the writer has had occasion to perform on several occasions.

The water glass on Pennsylvania engines is protected by a guard, composed of strips of plate glass, held around the water tube by suitable brass corner strips. This arrangement allows the glass to be seen from all sides, prevents cold drafts of air from breaking the glass, and, in case of breakage, flying pieces of glass and hot water do not put their birthmarks on the crew.

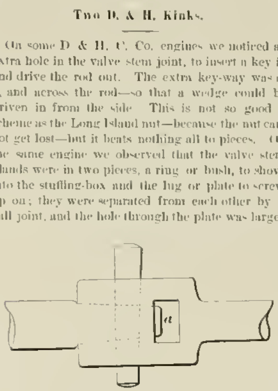
A funnel-shaped cup, of any sheet metal, with a perforated cover depressed into it, makes a clean thing for front trucks. The pipe below the cup should be long enough to bring it up where it can be reached, without drawing a map of oily lines across the frame and wheels.

Jekyll and Hyde Again.

A mechanic who has had considerable buying to do for railroad companies, and was always welcomed, wined and dined by a number of supply houses when he came to town, recently came in to sell something, instead of to buy. He reports a vast difference in his reception, and is hot about it.

Two D. & H. Kinks.

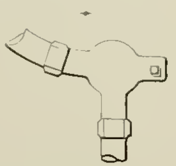
On some D. & H. C. Co. engines we noticed an extra hole in the valve stem joint, to insert a key in and drive the rod out. The extra key-way was at *a*, and across the rod—so that a wedge could be driven in from the side. This is not so good a scheme as the Long Island nut—because the nut cannot get lost—but it beats nothing all to pieces. On the same engine we observed that the valve stem glands were in two pieces, a ring or bush, to shove into the stuffing-box and the lug or plate to screw up on; they were separated from each other by a ball joint, and the hole through the plate was larger



than that in the bushing. This arrangement prevents the cramping of the gland and consequent scoring of the rod.

The new Strong engine, recently built at Hinkley's for the Santa Fe road, has been out on trial on some of the New England roads. The Strong has done some very good work, both as regards speed and weight of trains hauled, but we feel constrained to say that there is no prospect of their superseding our present style of locomotives. They cost more, are more complicated, and carry more weight on trucks than other engines—and trucks do not pull cars.

Some of the writers who give the average life of a locomotive at 30 to 40 years, should remember that the case is like that of an old New Englander who wore a pair of socks forty-two years. His wife renewed the feet one winter and the legs the next, and at the death of the owner they were found "as good as new"—same as the locomotives.



Oil Pipe Holder.

On some D., L. & W. engines they use a fitting like the sketch, to hold oil pipes on side of arch. The fitting is secured to smoke-box by the tap bolt shown, and prevents twisting the pipes in taking down or putting up, and from being cut and jammed by using alligators or pipe wrenches on them. The long oil pipe running under the jacket is a very unsatisfactory and wobbly thing to screw against.

At Renovo, Pa., the extra tenders in the roundhouse yard are protected from the weather by side and back pieces, made of matched flooring, and held on by hooks over top flange of tank. This arrangement is cheap, quickly adjusted, and preserves the paint.

The switchmen held a meeting in Chicago, on Dec. 10th, and declared the "Q" strike off, so far as the switchmen were concerned.

Firing Anthracite Coal.

THIRD PAPER.

The fireman must study the peculiarity of each engine as he is at work on her, and try to fire accordingly. The position of the draft pipe and the size of the exhaust nozzles have a great deal to do with the steaming of a locomotive, and a slight change in either or both makes a vast difference in the manner of firing, necessary to make steam. One instance, which occurred shortly after I began firing, comes to my mind, and may be instructive. I was put on a locomotive which had a bad record, being regarded as a "scrap heap," "not able to make steam," "nor haul a train even if she had steam." I worked on her for nine or ten months with very indifferent success, and did not break her bad record, for, while she would steam some days, the general rule was "no steam," and the "blower" and "injector on," all along the road. I would "clean the fire" from four to seven times in the trip of 100 miles, and shovel from five to seven tons of coal, and still have "no steam." I blamed myself and believed I had "missed my calling," and was assisted to that conclusion by occasional hints from the brakemen about not being "able to keep a cook-stove hot."

But after all these months of "torture," another engineer was put in charge of the locomotive, and on the second day declared "he would try to make her steam," which he did by simply raising the draft pipe ½ of an inch, but, not content with that, he made her do even better yet, by raising it ¾ of an inch more, or 1¼ inches from its original position. After this I could and did sometimes run my fire a round trip of 100 miles "without cleaning," and with steam enough and to spare.

The change in the draft pipe was the only change made, for after a week the former engineer again returned to work; and we thus have the same engineer and fireman on the same locomotive, and she was transformed from the worst to the best steamer on the road, by this simple act. Another fact about her was, that it did not matter how I fired her to make her steam, for if I had time, while at a tank or in a switch, I could put in coal enough for a six or eight mile run, or I could put in a "light fire," and depend upon her getting "hot" and giving me a chance to feed her on the way.

As a rule, it will, however, be found best to carry a fire sufficiently heavy to make a run of six or eight miles, even up grade, with not more than three "feedings," of say three or four scoops of coal, and the hog trough fire as described for the Baldwins, and the "wedge shape" for the others, will generally give the best results.

After a hard coal fire has been used for some time or distance, (of which the fireman in charge must be the judge, because of the different circumstances under which it is used, and the changing quality of the coal,) it becomes necessary "to clean the fire," to get rid of the ashes and clinkers, which are sure to accumulate on the grates, and which, with some kinds of coal, will be found to constitute the greater portion of the contents of the fire-box. To clean the fire, the grate bars before described are pulled out about 3 feet, or dropped aside in the Baldwins. This gives a space of about 3 to 4 inches in width, through which the fireman "knocks out," into the hopper ash-pans, about 2½ to 4 feet of the front end of the fire. If the fire has been heavy and not very much cut up, it is a good policy not to bother with the bars, but to shove them in after finishing the fire. When the fire is light and much cut up, or fine, it is best to replace the bars, after "knocking out the front end." The remainder of the fire is then worked over, to get out all ashes or clinkers, and secure a layer of 3 or 4 inches of live coal over the grates, to serve as kindling for the new coal, which is to be put on top, and furnish the heat for a continuation of the trip. The front two-thirds of the fires are worked over with pokers, averaging about 11 feet in length, while the back end is "barred up" with the corner bar or slash bar about half as long. After putting on a layer 5 or 6 inches thick, the usual practice is to warm it up by the blower, and then put on another layer, to bring it up to the required thickness for the amount of work anticipated. As "cleaning the fire" in a hard coal burner is a matter of time of from 10 to 30 minutes, much owing to the skill of the fireman, or to the improper condition of the fire-box or its adjuncts, it is a job not to be undertaken while the locomotive is using steam, except it be under very favorable circumstances, such as a very light train, or favorable grades, or while drilling or switching out cars. This process of cleaning the fire falls to the lot of the hard coal fireman, from one to six times a day, varying this much on locomotives doing the same work. Much of this (often unnecessary) work is caused by incomplete or imperfect combustion, which may be caused by the quality of the coal furnished, or the imperfect or faulty construction of the petticoat or draft pipe in the front end. The usual style of hard coal burners have been without the extension front end, using a double exhaust nozzle, with a draft pipe leading from the low nozzles to the stack, and having a cone to break up the sparks and a netting to stop the large ones located in the diamond stack. Of late years, however, many hard coal burners are built with extension fronts and straight stacks, and it is believed that they will gradually supplant the diamond stacks altogether.

VULCAN.

New York city is full of reporters, and the New York Central road is handy at 42d street. When one of these roosters wants railroad items he goes up and interviews "the boys," and the engineers invariably fill him up with ghost stories. The latest is the kick about the engine being sulky and mean —because she was tired and wanted to be laid up for a week of rest.

Clinton B. Conger, Mechanical Engineer, Michigan State Ry. Commission, recommends in his report to the commissioner the exclusion from the State of eastern freight cars with heavy dead woods, or bumpers, on each side of the draw heads. He says they are useless in the State, and annually cripple many train men. They are man traps, and should "go"—the sooner the better.

Correspondence.

Long Service.

Editor The Locomotive Engineer:

I am much pleased with your paper. I came here in August to do the repair work on the engines between here and Punta Gorda, seventy-six miles on the Florida Southern. I went an apprentice Oct. 2, 1837, under W. Duff, at Baltimore, Md., was out of my time July 26, '42. I am now sixty-seven years old, have run 1,300,000 miles that I know of, been running steadily since 1840, and still able to run or do a good day's work yet. I am not much grey, and feel young enough to think of marrying again.

Bartow, Fla. JOHN G. ECKMAN.

Like All the Rest.

Editor The Locomotive Engineer:

Enclosed is the amount for renewal of subscription to THE LOCOMOTIVE ENGINEER, which please send to same address until further advised. I am greatly interested in the paper, and think it is doing good in a direction not reached generally by other publications of its class. I wish you success, and my friends in your office a Merry Christmas.

Chicago, Ill. G. W. CUSHING.

Encouragement like the above from such able managers of motive power as G. W. Cushing, shows that the original assumption—that matter of interest to enginemen was of interest to the management—was correct. The enginemen of a railroad are the brains of the locomotives—when there is water on the brain they won't pull cars with any regularity.

About Inventions.

Editor The Locomotive Engineer:

No doubt many of your readers turn eagerly to the article headed "Kinks." We all have a love for kinks, or, as the word seems to indicate, something practical; and these valuable hints, which may have been thoroughly tested by the writers, may also, by being ventilated through your valuable paper, serve to lift some poor toiler over the hill of difficulty.

But while a man may have a large fund of this kind of knowledge, and his hands practiced to all kinds of ingenious devices, yet he may not be a thoroughly successful man; there may be a weak spot somewhere in his make-up, in his younger days he may have spent his leisure hours on the street corners, or in the saloons, when he might have been storing away a fund of useful knowledge, which in after years he could turn into capital in almost any position. I would like to impress these things on the minds of the young readers of your paper. It needs more than a knowledge of how to heave coal, pull a throttle or carry water, to make the locomotive engineers of the future. Intelligence, energy and sobriety will be a winning card every time.

Speaking of inventions, there are so many of the so-called inventions that are only discoveries, the result of certain forces in nature, which by accident arrested the attention of the observer, that may have been the most familiar things; but in a moment an idea flashed through the mind, and we have a discovery, or often mis-called invention. Men often, while seeking for something else, will by accident stumble on the very thing long needed. It is said that a ship worm, boring its way through the wood, and leaving behind it a secretion that gave a hard, smooth finish, suggested to Brunel the idea of the tunnel under the river Thames.

Many other discoveries might be mentioned to show that very trivial things will sometimes result in great and valuable discoveries. I have just been looking at a beautiful engraving of how young James Watt, holding a teaspoon over the spout of the teapot as his parents sat at tea, and seeing the water drop off the spoon, discovered the condensation of steam, which has proved to be one of the greatest discoveries of the century, having revolutionized the merchant marine of the world. So the gold or dross in men will, by some act or word, show itself, and our employers will take us for what we are worth.

Watertown, N. Y. J. J. BINGLEY.

Mistake in Initials.

Editor The Locomotive Engineer:

You are mistaken in saying our road, the D. & H. C. Co., are using two doors over a single opening in Wootten fire-boxes. We use the double-doors placed near corners of fire-box, to let fireman get coal in the corners.

JACOB EITEL,
Carbondale, Pa. R. H. Foreman.

[Item should have read D., L & W.—ED.]

A Typical Heater Test.

Editor The Locomotive Engineer:

In your December number you mention the St. Johnsbury feed-water heater, in connection with the Rushforth heater, giving a thermometer test of the latter. I enclose a thermometer test of the St. Johnsbury heater, also the figures of coal with and without heater; these figures are just as the engineer sent in on his coal tickets, with no expectation of any test.

Temperature of atmosphere, 40° above zero, water in tank, 50°; throttle half open, cutting off at 11 inches, pump $\frac{3}{8}$ open; temperature in heater, 140°; throttle $\frac{7}{8}$ open, cutting off at 17, tem. 200; throttle $\frac{3}{4}$ open; pump wide open, cutting off at 14 inches; temperature, 195°.

On engine number 21 on Boston & Maine Ry., for 10 days in October, with heater, the coal used was 45,500 pounds, ten days with heater off it was 61,500, eight days in November, heater off, used 65,000 pounds of coal, eight days with heater on used but 50,000. Engine was 16x24 cylinder on through freight.

I am a reader of THE LOCOMOTIVE ENGINEER, and agent of the St. Johnsbury Feed-Water Heater Co., and would like to see this test published.

Lyndonville, Vermont. E. C. POTTER.

[This is no test at all; engineers' coal tickets tell no more about the weight of coal than any other guess, and the loads the engine hauled are not given. It is evident that, if heat could be taken from the exhaust to heat the feed water, the engine would run with a larger nozzle, consequently with less back pressure, and save as much or more fuel in this way than by the use of a heater.

When any heater company on earth can prove that, by the use of their device, the average locomotive can save 18,000 pounds of coal every ten days, there will be an immediate demand for 30,000 of them—no road could afford to run a single day without them.

Now, "figures do not lie," but they often get us into scrapes if we quote them recklessly; our correspondent claims that, in the 8-day trial, they saved 15,000 pounds of coal—a saving of within a fraction of 23 per cent.

Now, at 130 pounds' pressure (which would be about 145 absolute) there would be (leaving out fractions) 1,222 heat units per pound, the water is already 50°, so that we want to add 1,172 heat units to the water. At its best he could get but about 212 in heater, and, as the water is 50°, it could be raised by its use but 152°; 152° imparted to the pound of water, would be a saving by use of heater, of but a fraction less than 13 per cent. So that our correspondent claims 10 per cent. of saving more than he can possibly get.]

Teaching a Fireman.

Editor The Locomotive Engineer:

When running a hard coaler a few years ago, I had a fireman who was very hard to teach. I said to him one day, "Jack, I think there is a pound in that front end on your side; you look, and I will handle her for you; when you are ready let me know." I saw him take the monkey wrench when he got down, and thought he was going to let up on the set screw and drive the key, but soon there was a stream of gas out of the fire-box door, and the sound of a voice within, saying: "All right now!" I walked out on the running board, and that man was looking in the smoke-box for the pound.

Fitchburg, Mass. PNEUMATIC.

The Father of Kinks.

Editor The Locomotive Engineer:

Your inquiry about "kinks" received; when you or your readers get to talking about kinks, I just want you to remember that I am the old, original He-kink himself.

I have tried more schemes on locomotives than any other mortal man this side of my late lamented friend Hero, of Alexandria, who passed away something like 2,000 brief summers ago.

He was a real live engineer and genius, was Hero, but when he got up a fountain, or a steam engine, or a drop-forged dart to throw at the enemies of his country, he was content to sit down on his front porch and have fun with the models—never asked for a patent, never yelled "Ereky! Ereky!" or got off his base. A cool, level-headed old runner, was Hero.

Many and many a time have I labored and brought fourth great gobs of thought, and in me thoughts methinks I see a 30-ton hog that rides well; a reverse lever that don't touch a pipe or injector when it gets down in the terminal notch among the oil cans, a door that won't swing shut on crooked track, a time-keeper who don't say "we" can't allow delayed time on account of snow-storms because they are the acts of Providence, and admits that "we" can't control Providence.

I see reachable holes, wherein to oil, and oilable oil to deposit therein, I see schemes that prevent grates from sticking and let me burn 113 per cent. of the fuel and all the smoke with an 11-inch nozzle; I see schemes to make a 42-inch boiler make steam for a pair of 48-inch cylinders, and pop every time you ease her off, but about this far in my dream that tormentor of my life, the fire-boy, roughly informs me that I have run by the tank, and yanks my wandering spirit back from sweet communion with Hero, and Watt, and Stevenson, and Baldwin, and Fontaine, and Swinerton, and Strong, and other congenial spirits.

But I am not always an idle dreamer—sometimes I have the nightmare. I have got up more checks, and gauge cocks and cylinder cocks and throttle latches and spring seats than you ever saw in your abbreviated existence, young man, many more. And where are they now? Ah, there it is, there it is, they are gone, young man, gone like the children whom you fondle on your knee to-day, they go to school to-morrow, the day after they are big enough to wear your clothes, and there is whiskers on 'em, and by Thursday they are gone, gone out into the great, bustling, anxious, itchy world. But in your old heart there is a tender place for 'em, and memories of their little capers fill the niche where they sat in their high chairs, and the ghostly memories of little feet, and soothing syrup, and dirty faces, and doctors' bills loom up before your eyes—and that is the way with my kinks, young man.

Some are here, and some are there, a great many are dead—dead as a smelt—and some have gone out into the world, and multiplied and replenished and made a grandfather of me, and not a few of the handsomest have gone out and married. Everybody wants 'em at first sight, they are captivating; but most of 'em have come home to live; nobody else seems to want 'em very long. But they did not watch 'em grow, and tend 'em, and love 'em, and cultivate 'em, and coax 'em to live, like I did.

Many a time has a new idea come to me while packing my old war-horse in the house, and I have gone off behind the tank to think it out in peace. Then I would give the fire-boy a couple of ten centers to finish my work, and go home with a light, elastic, sort of india-rubber step, and a glad light in me eyes, and call Mrs. A in from the kitchen and the smell of dish-water and stewed onion, and kiss her classic face, and tell her I had got up a patent, and we would soon be rich and I would quit the road, etc., etc. And then she would wipe away a tear with her dish apron and say, "Oh, John, if you could but leave the road." She never seemed to think of anything else, never even asked what the patent was—she was used to it—and then I would get one made, and try it, and decide not to patent it, but give it to the world, and before I hardly realized it, it would be adopted from Halifax to Arkansas, and its name changed—or else it crawled off and died.

But, Mr. Editor, I wander; I have seen your kinks from time to time, and I like to see them and hear of them, just as a proud father loves to hear of valiant deeds of his absent son, or a bang-up match by his absent daughter; for all those kinks are mine, true, some show the marks of their contact with the rude, cold world; some have lost legs, and arms, and ears, and some have gained. Young man, you never heard of a "Kincque" that won't own me as its father. Why, sir, my children have played for years with brass models of all those you have shown up, and many more, many more.

If you want me to, I will spring some of 'em on you; but, mind you, young man, if I go right down into this kink business I can harrow up your young soul, and make 9,000 patentees stand on end like quills upon the fretful porcupine. Shall I do it? Will you give me a regardless order, put out a red flag and take the consequences?

JOHN ALEXANDER.

Pointers Wanted on Driving Spring Practice.

Editor The Locomotive Engineer:

Since we have heard from quite a number regarding the manner, time and cost of handling steam pipes, would it not be a good idea to propound a set of questions regarding the manner of treating driving and engine truck springs, also a description of the various appliances used in roundhouses throughout the country in applying springs to locomotives?

Any information on the above subject would be read with interest by myself, and I am quite satisfied that others would find it equally interesting.

I trust you will give this subject your valuable consideration. E. J. BOUCHARD,

Greenville, Texas. R. H. Foreman.

What is Wrong With This Pump?

Editor The Locomotive Engineer:

I have read many questions and answers concerning air pumps, in THE LOCOMOTIVE ENGINEER, and have a question to ask; am in need of information. I am called a machinist, but do not think myself worthy of the title. Some few days ago I tackled my first air pump, to give her a general fitting up; I cleaned all the working parts and steam passages, set discharge and receiving valves $\frac{1}{16}$" lift each. The steam pump and parts seemed to be worn very little, and needed nothing that I could see. I put pump together, and in position on engine (the only testing process we have), steamed engine to 110 lbs., but the pump would only work when tapped hard on upper cylinder head, and stop at the end of down stroke, and sometimes would go up before a full stroke was made, and I am stuck fast on my first pump. Can your air pump correspondents tell me the cause, and how to remedy it, and oblige a patient subscriber?

Cuero, Texas. SNOOKS.

Feed-Water Heater Tests.

Editor The Locomotive Engineer:

In your last issue a correspondent comments on tests I made of a Rushforth feed-water heater, and you editorially assume that I was ignorant of the peculiarity in the construction of the heater, which makes the water in the boiler circulate through the coil. You are mistaken there. As part of the test, I made them dump the fire of the locomotive and ascertain the temperature of the feed water, with the smoke-box cold. With 140 pounds' steam pressure the feed-water temperature was about 160 degrees, so I concluded that the estimate made of heat saved was near enough for all practical purposes.

I very much doubt the soundness of your dictum, "there is no waste heat in the front end of a locomotive." With a smoke-box temperature of 800 degrees Fah. and upwards, which is quite common, it looks as if there was an unnecessarily high jump above the temperature, inside the boiler, of 360 degrees Fah. and under. After the gases of combustion have emerged from the flues, their heat is of no more use for steam-making purposes; when a forced draft is employed, and if it can be utilized in any way, the whole of the heat saved must be gain. That is a dictum which I think few steam engineers will question. ANGUS SINCLAIR,

Editor National Car and Locomotive Builder.

He Wants Lights—13 of Them.

Editor The Locomotive Engineer:

Will you kindly tell me the following in your valuable journal, in as plain words as possible:

(1) What position should engine be in when front end main rods are taken up? (2) What position when back end main rods are taken up? If they are taken up when they are on $\frac{1}{4}$ or $\frac{1}{8}$, is there not a great deal more danger of a green hand at the business taking them either too short or too long? Is the plainest and surest way to (for back end) caliper pin with outside calipers, and then caliper brass with inside calipers, and find out how much is to come off of brass—divide it so as to find out how much is to come off of each half? Say brass is $\frac{1}{4}$ inch more than pin on its centers, take off $\frac{1}{8}$ of each half. Then file back 1 inch on top of each half, top and bottom say about $\frac{1}{16}$ off. Put brass in strap and key it up, and if it can be turned all around freely, it is right. To shorten rod, put liners in between strap and brass, and to lengthen, put in between end of rod and brass. That is my idea—but have never had rods to take up.

(3) Will side and main rods both knock while passing dead centers and working steam, or only main rods? (4) Please give me plain directions how to always tell a piston from a valve blow, without taking off cylinder head. (5) How is best and surest way to bring engine to shops with a broken front driving-box—when it is broken clear through from top to the journal—without cutting journal? (6) How is it some engines will bear "rawhiding" or "gouging," and steam well, and others will not? (7) There is considerable talk here of one of our engineers working engine throttle wide open and hooked high. Is not that the best way to work an engine? If not, why not? Does heavy steam pressure on valves (downward), when wide open, have any bad effect? If so, please explain it. (8) If you are running an engine ahead, and back eccentric strap breaks, can you, by taking down that strap *only*, run on (forward) without further danger of breaking any more of them? (9) What is a sure plan of always telling which eccentric has slipped, and best and quickest way of setting them? Sometimes they have slipped so little it cannot well be told by examining them, and they are so tight you cannot tell by feeling them. (10) How is a valve stem clamped when putting engine on one side when metallic packing is used? (11) I was on a passenger engine recently, and when air brakes were applied, pump would not pump enough air to release brakes for several minutes—both stuffing-boxes of donkey were leaking very bad. Was that the cause? (12) Why is the steam gauge pipe always bent? (13) What will a valve model for lodge-room cost? I mean a nice one. Where can it be bought? Why don't some manufacturers of such advertise them in your largely circulated journal? It seems strange to me that publishers of machinist and locomotive engineers' books, manufacturers of engineers' torches, pipe wrenches and steel pocket graduating rules do not advertise them in your paper. J. O'CONNOR.

Birmingham, Ala.

[(1) On the down quarter—because the crosshead pin is not round after worn, the most wear being when the engine is leaving the centers, and the least from where the exhaust takes place to the next center. They should be keyed on the largest part of pin, to prevent heating, the top quarter is as good, except that front key is generally harder to get at. (2) On the engine center (when the crosshead is at end of stroke)—because the main pin is flat where it receives thrust and pull of piston, and is largest where least work is put upon it, at the center; if keyed on the quarter or eighth, you could close the brass on an old pin so that it could not pass the centers. Main rod brasses should not be worked on very much without measuring the stroke, and striking points, and dividing the clearance. In filing brasses, care should be taken to keep the outside fit, in the strap, good, and both brasses in line. Brasses should be keyed in the strap and fitted to the pin on the center, and should be free at that point. You shorten or lengthen the rod correctly. (3) It is claimed by most men that side rods (on 8 wheelers) will not pound, but they do rattle and slap very hard, and a side rod with a knuckle-joint in it, will pound, and pound hard. (4) A piston blows at intervals, as it receives steam, a valve blow is usually more constant. If you place engine you suspect on the quarter, the reverse lever in the center, and open the cylinder cocks and throttle, a blow out of either cock will come from the valve. If you block the engine at the quarter, and give her steam with reverse lever in corner, a piston leak will show at both cylinder cocks, and also blow through the nozzle. It is very easy to distinguish a blow by the way it blows. (5) Anything that will relieve the weight, or lessen the speed, will reduce the tendency to cut. The easiest way is to run the engine light and slow, and oil often. An easy way to relieve weight is to block up equalizer and relieve or remove spring over broken box. (6) Switching with road engine is what we always called rawhiding. Do not know why one engine should not steam as well as another under the same treatment. (7) A wide-open throttle, and as short a cut-off as will do the work, is the theoretically proper method; there are many cases, however, where controlling speed and work by the throttle is necessary, especially engines that have very few notches in the quadrant.

The writer is free to confess that he has tried the full throttle and hooked-up plan hundreds of times, and with all kinds of trains, but has met with more failures than the opposite; in nine cases out of ten we have found a place both for lever and throttle, where the engine did better in every way, and it "seemed right."

The load on a slide valve is enormous, but wire-drawing the steam relieves it but a little, and at the expense of the pressure on the pistons—where all the work is done. (8) No, take down both straps. (9) The best way to tell when an eccentric is slipped is to have them marked, a good way to mark them is to place the engine at some one point, say the forward center on right side, and mark across all the *straps* and eccentrics—these marks are easier seen than those on the axle, if anything is wrong with your exhaust, place engine on this center and examine your marks; if three of them are all right the one that is off is the one that needs bringing back to the mark; if they are right, look elsewhere for your trouble. (10) See answer to Question 34 in June number. (11) Probably leak prevented pump from accumulating air fast, and air pressure had been reduced unnecessarily low by improper manipulation. (12) To form a trap to retain water, direct, dry steam overheats, and destroys the tension of gauge tubes and diaphragms. (13) Extra fine valve model is worth about $200.]

From the Land of the Sacred Crocodile.

Editor The Locomotive Engineer:

Papers went all over the country before they got to me, on account of your spelling Sohagpur, S-o-h-a-l-p-u-r, and many have gone astray. I enclose my address in full.

I find American papers are far superior to English ones, and they are cheaper, and the postage less.

I shall soon send you photos of some of our engines, they were made in England and Scotland; I could also send you photos of ancient temples, etc., as I am something of an amateur photographer. I commenced work as a railway apprentice at the shops of the Great Western Ry., at Swindon, in 1856—thirty-two years ago—consequently I am not a young man; yet all work appertaining to railways is still my hobby.

I have been twenty-one years on this road, the Great Indian Peninsular Ry., seven years as an engineman and fourteen as a foreman.

FRED. W. BEDFORD.

Sohagpur, C. P., East India.

Solid Bushings in Side Rods.

Editor The Locomotive Engineer:

I have watched with considerable interest the advent of the solid bushing, and have taken some pains to find out the opinions of different engineers as to its merits. Their opinions differ widely. It reminds one of the days when the parallel driving box shoe began to displace the tapering wedge on the front jaw. It was no uncommon expression to hear an engineer say, "How can a man keep his engine in tram without adjustable wedges all around?" But the shoe has evidently come to stay, and many a man has learned that an engine once put up with driving axles square across the frame will stay so, much better with the shoe than with the wedge. He has come to learn that the less he tinkers with the lining and squaring of rods and axles, the better his engine will run. Of course there are exceptions—as in case of inferior workmanship, etc.

The rod bushing has the same prejudice to overcome, but it seems to be getting there all the same. It makes its mileage right along, and don't get hot about it very often, certainly not as often as its ancestor, the loose brass—which is well named, for it was more often loose than otherwise—and when loose we all know how fast it will file itself, the key, and the strap, also how the loose liners will cut into the strap, especially if they are a little short up and down. What can be more un-mechanical than to take down a rod, and have a half-dozen liners spill out on the floor?

In comparison, how much neater and simpler the solid end looks than the strap end.

Compare the vast difference in first cost between the two styles in favor of the former. Note the difference in cost of maintenance in favor of the bushing.

A solid bushing, if properly put up and broken in, should run from six months to a year before being renewed, and in all that time you have not had to turn a set screw, drive a key, or tighten a bolt, and when worn so as to rattle too much, they can be renewed all around, and not lose more than a trip or two, and when the job is done the side motion is also taken up, which is not the case with keyed brasses.

I understand that some roads are adopting them for main rods, as well as for side rods.

I have an engine in my charge that has bushings in front end of main rods, and the ones put in by the builders ran for four years before being renewed.

Yes, bushings are a hobby with me.

Pueblo, Col. HIRAM R. JONES.

Using Slack—A Peculiar Engineer.

Editor The Locomotive Engineer:

I was much pleased with the letter from that fireman in Florida, and thought I would tell you a little about the peculiarities of my bold engineer. We haul long, heavy trains here, and my right hand partner never can start without taking the slack, and, although the slack of 15 cars will start any train, he is never satisfied with less than all—slacks back till he sees the caboose hob. I suppose if he wanted a vent in a barrel he would make it with a two-inch auger. Often when almost stopped he will pull the engine over and take up all the slack as she stops, and always leaves lever back while he oils around, etc. He is afraid his fireman will learn to be an engineer, he never lets me handle her at all. He don't take your paper, because he says railroad papers are nothing but love stories and lies. He is a crank on manners, and objects to his fireman flirting or waving his hand to the girls along the road, and will lay down his pipe if he sees a lady on the depot platform, and won't go into an eating house without taking off his over clothes and washing his face. He makes life a burden for me by his old maid actions. He don't say much—that's one good thing about him.

Indianapolis, Ind. FIREMAN.

[We should judge that you have been firing about six months—that is about the time a fireman thinks he knows more than the master mechanic—and will venture to say don't know half as much about your own duties as you think you do of your engineer's. From your own testimony, you must have a good engineer, he knows how to start a train, at least, and we will warrant does not break it in two, as he would if he slacked a few cars and used the rest as a dead weight to jerk against, as he works it he only starts one car at a time. You will probably get a chance to switch once in a while after you know enough to fire, and the swelling in your head goes down.

Your engineer is justified in his estimate of railroad papers if he has never tried but one; that he is a gentleman, and wants you to be one, and you are not, is to his credit and to your discredit. Keep your eye on that runner, he is a good one.]

About Burning Engines—Some Notes from an Old Timer. Boilers that Split their Water.

Editor The Locomotive Engineer:

Permit a word, if you please, from a reader. It does an old 'un heaps of good to read THE LOCOMOTIVE ENGINEER, if even at intervals of a month, and especially a fellow who has not been on the foot board, except for fun, for over twenty years, but one who loves to read of the successes of the boys, and sympathizes with them in their mishaps and disasters.

I would not dare approach you with this scrawl, only to offer a suggestion to a very useful man, who, however well he may be adapted to his present calling, in our opinion, might do better, and not suffer so much as he will this winter whilst plowing snow and trying to keep his pumps open, and the old mill alive.

There is not probably as much solid science in John Alexander's communications as in some others of your correspondents, but for downright solid laugh, give us John. My friend, your subscriber, Mr. G. P. Mowry and myself look for John sure, and are seriously disappointed when he ain't on deck. But our suggestion emanates from Mr. Mowry after reading John's Ideal Overclothes, and is warmly seconded by me, I am personally acquainted with Mr. Geo. W. Peck, of *Peck's Sun*, Milwaukee, and see the necessity of an infusion of fresh blood into the *Sun*, as, since the Bad Boy left the *Sun* office, it has never shone with its wonted luster.

Now, just tell John to run in the old mill, and leave her between two good coal stoves in the roundhouse, and come up to Midway, Wis., we will give him a letter to Bro. Peck that will make him associate editor of Peck's *Sun* instanter, and we will subscribe for fifty copies.

I dare not touch the more intricate subjects treated of in THE LOCOMOTIVE ENGINEER, knowing how lightly the old fellows who love to hear the click of the pump valves, and who never handled a Westinghouse air brake, a Hancock inspirator or a Monitor injector are esteemed by their modern brethren who are so thoroughly posted on all the kinks. Yet, methinks, some of the old fellows might get over the road yet without much trouble, after learning the names of the improvements.

Your article on "Burning an Engine" is a good one, and, whilst I am not an advocate of burning an engine, nor ever did burn one, yet I do know how easily it could be done; and as I am sure that many of your readers will call your engineer of the Bee, No. 82, a fool for being ready to swear that he had three gauges of water, for your and their benefit I will relate a little incident in my own experience, corroborated by two other good men.

In the year '59 or '60, I am not sure which, I was on an extra engine for one or two trips, whilst some temporary repairs were being done on my regular engine, and was then running for the Memphis & Ohio Ry. Co., from Memphis, Tenn. to Paris, Tenn., the engine was the Rogers engine "Frazier Titus," M. M. James A. Long. Our water was a little inclined to foam in West Tenn., and we had to be very careful, but my engine showed three gauges and was running with very light pump-feed. She was steaming well and doing good work, yet her water kept up—solid water, but it kept up almost too well, so that I began to doubt her veracity, and tried the second or middle gauge cock, the water was broken, the top cock solid, the third or lower cock *blue steam*. I shut her off immediately, and when the water settled, had just a flutter in the lower cock. Well, although not a very young runner at the time, and not generally considered a fool by my fellows, yet I dare not tell of the circumstances, for fear of being considered a fool or a liar; but inside of two weeks from that time, a very intimate friend of mine, whose engine went into the shop when mine came out, was running the same engine, the F. Titus, on the same train, and as we sat in the evening, after supper, I noticed Mr. Duncan Andrews in a deep study. I asked him what was troubling him, and he tried to evade a direct answer, but, being intimate, I pressed him kindly to tell me why he was so deeply lost to his surroundings. His answer was that he did not want to tell me, lest I should think him a fool, but I still pressed him closer, when he asked me if I had ever seen an engine working well and show solid water in the top cock and blue steam in the lower one. I told him I had, he was surprised, and said that he was afraid to mention the circumstance for fear no one would believe him. He then described the trick the Titus had tried to play on him. It was just a repetition of my own experience with her, and on the same grade and same train. We kept the matter to ourselves, and did not talk it much, lest it might get out, and both of us be considered cranks.

In 1861, immediately after the fall of Fort Sumter, I quietly closed up my business at Huntsville, Ala., by putting my engine into her stall and getting my time from Mr. James Crawford, M. M., and W. A. Purse, ex-locomotive engineer, acting as head clerk in the M. M.'s office, and came up to this country, where I went to work on the 20th day of May, 1861, for what is now known as the C., M. & St. P. Ry. Co., but was then the Lacrosse & Milwaukee R. R., C. L. Rice, M. M. I think it was in 1862 or 1863 that Mr. Chas. Morse (who was on the road when I came, and afterwards went back on the C., B. & Q., where he came from) was running the Rogers engine No. 26 on the western div., from Portage City to Lacrosse, I was running No. 27, a fac-simile of 26, on the opposite run, but Charley and I got together one Sunday, and he was very much interested and looked a little worried about something, finally he told me that he would like to ask me a question, if I would promise not to laugh at him and consider him a fool. I promised, and he related what No. 26 had done for him yesterday on Round Bluff, and asked me if I had ever heard of such a thing before. I told him of my own experience and Duncan Andrews' with the Titus, another Rogers, and it relieved him.

Now, whether any of your readers have ever had a similar experience, I would like to know through THE LOCOMOTIVE ENGINEER, and therefore, I think, under similar circumstances, it would be an easy matter for even a good man to burn an engine, but I would hate the record. And whilst the hydraulic man may be the worst runner, and may as effectually produce death to the engine by consumption as the other fellow by lightning, yet two wrongs do not make a right, and I am still convinced that nature makes the engineer, and practice and education equip some of them. But all the practice and all the education a blockhead may get cannot make a first-class man, and I think there is yet room at the top.

Midway, Wis. T. B. LIVINGSTON.

LOCOMOTIVE ENGINEER.

NEW YORK JANUARY, 1889.

CONTENTS.

Our New Dress.

THE LOCOMOTIVE ENGINEER is a year old, and has been put into short clothes. As will be noted our new type is brevier instead of long-primer—two sizes smaller. This gives us more meat in the same shell. The same matter that would, with the old type, have occupied three columns, will occupy but two in the new; so that in 12 pages we gain four. We propose to give three or more of this gain to the readers, and use the other for advertising, and in some instances, as in the present number, the advertisements may come over upon the 11th page; but, as we will be giving three for one, think all will be satisfied.

We also change the editorial page from the 10th to the 8th page, which appears to us a neater arrangement typographically.

About Federation.

The Engineers' Brotherhood, at their recent convention in Richmond, declined to accept any of the plans of federation proposed. After mature deliberation we are of the opinion that this is best. The railroad orders should adopt rules of non-interference in case of trouble, but it would be a herculean feat to unite all the interests and keep them united. The Engineers' and Firemen's Brotherhoods have interests that are identical, yet the engineers have been unduly jealous, and distrustful of their juniors. The late trouble on the C., B. & Q. has proven that these fears were entirely groundless. When the engineers meet next year at Denver, we hope to see some of the men who have been talking and writing about "the twin brotherhoods" get up and offer an amendment to the constitution, abolishing that close-communion, barbarian clause requiring a young engineer to withdraw from the Firemen's Brotherhood before he can join the engineers. This might be federation and it might not—it would be right, anyway.

A Hero in Overalls.

At 4 A. M. on Dec. 18, a light engine, running ahead of the Texas Express, on the St. L. & S. F., ran into an open switch near Springfield, Mo., making a fearful wreck of itself, and disabling the engineer and breaking the fireman's leg at the ankle.

The switch rails had been moved by train wreckers, expecting to ditch the express. The fireman, disregarding the agonies he suffered from his broken leg, dragged himself back on the track for a mile, flagged and stopped the express with 200 passengers on board. If this were time of war, such deeds of sacrifice to duty and humanity would win for the man who suffered, but shirked not his duty, the love of a nation, and shoulder-straps of promotion and honor. This man saved 200 people from the horrors of a fearful wreck, and his employers from a great loss of property and damages, and if the "'Frisco" route follows the practice of other roads in similar cases, they will quibble about allowing him half pay for the time he is laid up, and refuse to pay his doctor's bill outright.

It is this very devotion to duty in small as well as great emergencies, that surrounds the American traveling public with a safeguard that money cannot produce—and it deserves recognition and remuneration something nearer its value than it gets.

We regret that we did not learn the name of this young hero of the scoop.

Putting Motive Power into the Hands of Transportation Department.

The Erie road has made a new departure in putting, not only the engineers and firemen, but the shops and all other employes of the motive power department, under the immediate charge of the division superintendents.

Such a move is obviously a last resort—a sort of death struggle.

The division superintendent can no doubt get more service out of the engines, for far less money —as long as the power lasts—then they are done.

When a road commences to drop out master mechanics, and run the power for all it is worth with no responsible mechanic to look after its maintenance, it is high time for the thoughtful public to take some other route, and stockholders would save money if they secured a receiver at once.

Managements that resort to such measures *to make a show* always point to the Pennsylvania as an example of superintendents' management of motive power. The Pennsylvania does put all the enginemen under the transportation department, but they are careful to have the best of shops and systems, under the best of mechanics, to furnish engines for their use, and no man has a regular engine; they are all of certain standard designs, and kept in the best of repair.

With the Erie's numerous classes and builds of scrap heaps, no heads to the mechanical departments, and the shops under the division superintendents, the paralyzation of its motive power will be only a matter of time—and short time at that.

Promotion of J. E. Phelan.

It is with pleasure that we record the promotion of one of the progressive young enginemen of the country, J. E. Phelan.

Mr. Phelan is well known to the readers of this paper, as the author of the series of articles on Modern Air Brake Practice, now running. These articles are the first of their kind that have appeared from a practical engineer, and have attracted attention far and near.

J. E. Phelan commenced firing in 1873, at the age of 16, and handled a scoop a little over seven years. Always a close observer and a student of his business, he passed rapidly from freight to passenger engineer, when once promoted, and then to traveling engineer, and for some time past has been general road foreman of engines of the whole Northern Pacific system, from the Father of Waters to the Pacific.

On the first of December he was appointed master mechanic at Mandan, D. T., with new shops, new offices, a fine equipment of locomotives, and a class of enginemen of his own selection—a responsible and important position for a man of 31.

J. E. Phelan does not owe his position to family or friends; he has gone steadily on through changes of administration—because he tried. Nor has he gone as far as he will, if he pursues his former habits of study, observation, and the widespread instruction of his fellow enginemen; some road will want him to write Sup't M. P. behind his name—because it would pay them to do so.

We are not given to the habit of remanding men who are hard at work that they can be president, senator, master mechanic or even engineer, if they will do as George Washington, or General Grant, or John Smith did, but every man on a locomotive in this country can cite this case and rest assured that it is always the man who fits himself for promotion who keeps it when he gets it, and the man who don't think and don't study, don't get it.

Attempt to Burn Pea Coal on the Elevated Road.

In last month's paper we called attention to the fact that there was an attempt being made to burn pea coal on the elevated road, engine 93 being used to conduct the test.

Through the courtesy of General Manager Hain, the writer was enabled to ride on this engine and see how she did with the cheap coal.

We made two trips over the road, with different engineers, both on light, 4-car runs, and saw enough to convince us that the "L" will not make a fortune by using pea coal this winter. The engineers and firemen tried hard and faithfully to get steam with it, but it was no go.

The elevated engines have to start and stop every fifth block, and the engines are, as a rule, worked pretty hard for two or three blocks and then shut off; this treatment tears the light fire of small coal all full of holes, and then lets it die. In no instance in two trips did the throttle go shut before the blower was singing its little song; the engineers favored the engines in several cases to one gauge of water, and the steam was oftener at 90 to 100 than at 135, the blowing-off point; in one case it fell to 85 pounds.

At both ends of the run, Third avenue, time 30 minutes, the grates were one solid clinker. This road has a very poor chance to clean fires, and there are strict orders against it at the City Hall station; yet this had to be done, or the engines would have died. The Manhattan had one Wootten fire-box, but it was not a success—had to clean fires too often—and there is no hope of using wide fire-boxes above the frame, as the engines are limited as to weight by the superstructure, the engines now in use weighing 46,000 pounds.

The Manhattan Elevated road carries more than half a million of people daily, and it was a mighty mean Wall street spirit that prompted the desire to burn dirt for a slight saving in fuel, to the discomfort and delay, if not actual danger, of this half million people. The end came in a few days, several engines were out with dust, and they laid down between stations. At first the passengers good-naturedly walked to the next station, but on Saturday, the 15th of December, several train loads refused to walk, and the engines that were having Wall street chills were pushed in by engines burning coal. The remarkable freedom from fatal accidents on this road, carrying, as it does, the largest passenger traffic in the world, has been due in the past to excellent management, well-maintained power, and painstaking enginemen; but if the greed for dividends is allowed to step in, the patrons of the road must look out for disasters. When burning pea coal, both men were worrying over, and working at, their fire, and, as a consequence, neglecting their outlook, signals and track.

With the lives they handle, the "L" roads should pay, if necessary, extra high prices for extra good coal, to enable the engines to get over the road without possible delay on account of steam, instead of jeopardizing 500,000 lives daily to save a few dollars per month on fuel.

A Dangerous Practice.

The Erie, following in the wake of other roads similarly mismanaged, has made a deep cut in the motive power department, to help out the management and the dividends for the hard-working gamblers who own its watery stock in Wall street.

Cutting down expense at the risk of decreasing the safety of its motive power, is the worst form of railroad suicide. It invites wreck and ruin, and it uses up all the available power, so that in better times the road is short-handed, and can only do a fair amount of business by buying new power outright.

Any man that knows anything about it knows that such relief is only temporary, and the reaction doubly severe.

If the Erie is going to do any business, the repairs to her motive power and rolling stock must be kept up.

Another thing, good men do not have to work for half-pay, while other roads want good men at full pay, so that what help they do keep is the poorest. Mr. J. H. Vreeland, M. M. at Jersey City, resigned rather than stand a reduction in his department below the safety line, although he has been with the company 23 years. Mr. Vreeland has a wide experience as a master mechanic, and is not only thoroughly up in locomotive maintenance, but has had charge of the machinery of the ferry, tug, and harbor transfer boats of the company. Some road that does not expect to run the machinery department, with the pop screwed down, and no water in the lower gauge, will want him and his experience, and the Erie will have lost an advantage, and the other road have gained.

Discussion on the Contracting Chill for Cast Wheels.

At the regular meeting of the N. Y. Ry. Club held on the evening of Dec., 20, Mr. J. N. Barr, Supt. M. P. of the C. M. & St. P., read an able paper on the improvement of cast wheels by the use of a contracting chill, and described his chill and its action.

Mr. Barr's chill is surrounded with a hollow rim, into which he introduces steam before the wheel is poured, thus expanding the chill, then, as the wheel is poured, the steam is replaced by a stream of cold water, this contracts the chill and keeps it in contact with the wheel longer—producing a deeper and more even chill.

Mr. Whitney showed photographs of the chill used in his works; this chill has internal segments like Mr Barr's, but the expansion of the metal in these segments, causing the chill to reduce its size—or contract—is brought about by the absorption of heat from the wheel itself.

There was a pretty lively criticism from wheel makers who do not use contracting chills, but we believe the greater majority of the mechanical men who attended the meeting went away convinced that there was merit in the plan. We regretted to see no one there to represent the claims of L. R. Faught, of Phila., for recognition as the inventor of this great improvment in the mechanic arts.

Mr Barr is the inventor of the chill that is expanded, before pouring, by the application of heat. Mr. Whitney has made contracting chills cheap and efficient by the invention of a process of dividing the segments of the chill in casting—making a clean cut through two inches of solid iron, but $\frac{1}{100}$ of an inch wide; in itself a great invention.

But Mr. Faught invented the contracting chill, he is the father of the idea of making the expansion of the metal in the chill go *toward* the wheel, instead of *from* it.

The inventions of any and all these gentlemen are of service to mankind in the production of cheaper, better, and safer rolling stock, but of the trio Mr. Faught is the central figure, on whose fundamental principle the others have built and improved. His invention dates back to 1876, and his patents nearly as far. Mr. Faught is to the contracting chill, what Howe was to the sewing machine, Whitney to the cotton gin, Ericsson to the screw propeller, and Jethro Wood to the common plow—the pioneer.

The discussion on standard axle for 60,000 pound cars was not discussed very freely, and the subject was held over for the January meeting. There is much to be learned in the discussion of practical questions in such meetings, and railroad men should interest themselves in the meetings—we mean real railroad men, enginemen, car hands etc.; information gained here would tend to make you able to advance from your present positions—and stay advanced.

We noticed at the Long Island shops, several Richardson balance valves that had the small relief hole in top closed up to about $\frac{1}{8}$ of an inch. The original is $\frac{1}{2}$ or $\frac{3}{4}$ of an inch in diameter, and is always provided to let any steam that might leak past the packing strips out into the exhaust. When a balance strip is broken or comes out it is hard work to get the engines to pull their trains with the big hole "bleeding" the steam away. The small hole does just as well for the relief. Accidents to the packing strip are very rare, but no device is "perfectly perfect."

L. S. Allison, manufacturer of mining machinery, Hazleton, Pa., is fitting up extensive branch works at Minersville, Pa., and will make a leading specialty of building mine locomotives.

Books Received.

THE CORNELL UNIVERSITY REGISTER, 1888–9.

This is the book issued yearly by Cornell University, which embraces Sibley College of Mechanical Engineering and Mechanic Arts.

"This college was founded and endowed by the liberal gifts of the late Hon. Hiram Sibley, of Rochester, who, in the year 1870, gave about thirty thousand dollars for the erection of a suitable building for the Department of Mechanic Arts. He also gave ten thousand dollars for increasing its equipment of tools, machines, etc., and afterward made a further gift of fifty thousand dollars for the endowment of the Sibley professorship of practical mechanics and machine construction. During the years 1883 to 1887 he gave more than seventy five thousand dollars for the purchase of models, the extension of the Sibley College buildings, and the building and equipping of a complete set of workshops. The total amount thus presented to Cornell University is nearly one hundred and fifty thousand dollars. The college is divided into three principal departments: that of Mechanical Engineering, including a laboratory, in which experimental work and investigations are conducted; a department of Mechanic Arts or shopwork, and a department of Drawing and Machine Design."

This college has an excellent reputation as an institution of learning for mechanics, and young men contemplating study and improvement in mechanical engineering should send to the University, Ithaca, N. Y., for this book, which is furnished free.

ASKED & ANSWERED.

(1) W. M. E., Leavenworth, Kan., asks:

Do you know of any kind of metallic packing that can be used in packing pistons that have the old style gland—I mean used without turning out stuffing-box or making face plate or cone to fit? *A.*—There are several makers of coned lead rings for pistons to use in common stuffing-box, but we do not know where they are.

(2) H. H., Benzinger, Pa., asks:

Will a locomotive with all its weight on four drivers pull as much as the same locomotive on eight drivers, provided she has a flexible wheel base? *A.*—Theoretically, the number of drivers will make no difference, adhesion is governed by the load, regardless of the number of points of contact. If the engine has weight enough to prevent slipping she ought to pull more with four than with eight wheels; there would be less friction.

(3) T. H. L., Toyah, Texas, asks:

How do they measure curves on railroads by degrees? What is meant by a 17° curve? *A.*—Surveyors measure curves in degrees, by assuming the curve to be a part of a circle so many feet radius, or the distance from the center to the outside of circle, and counting a 1° curve as having a radius of 5,730 feet, a 2° curve having half as much, or 2,865, a 3° curve one third as much, or 1,910, and so on, each degree representing a proportionate fraction of 5,730. A 17° curve would represent part of a circle of 337 feet radius.

(4) Ouray, Gunnison, Col., writes:

We have heavy, consolidation, narrow gauge locomotives here, with main pin on the second pair of drivers. In starting a heavy train, these engines roll or rock a great deal, and you can increase the rocking on the start by hooking them up about half way; after the train gets to going four or five miles per hour this rolling motion stops; why do they rock? *A.*—Probably the roll is caused

Fig. 1

almost entirely by the angularity of the rod; the center of cylinder is above the center of the driving wheels, and the rod is very short, when it is passing the lower quarter, as in Fig. 1, it allows a more or less direct lift against the

Fig. 2

cylinder, frame and boiler, and the fact that the center of gravity is high and the frame narrow lets it cant the weight over onto the springs of the opposite side, these are compressed, and then help the crank on that side to throw

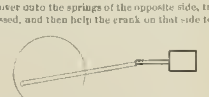

Fig. 3

the boiler back as soon as it gets into the position of Fig. 2, and the side that threw it over that way gets at or near position in Fig. 3, and lets go; over the top half of the stroke the angularity is not so great, nor in position to

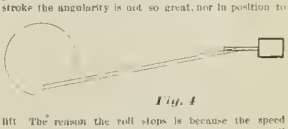

Fig. 4

lift. The reason the roll stops is because the speed increases, so that the engine does not have time to roll between the pulsations or lift. An engine with a long connecting rod, like Fig. 4, will not roll so, as it has not the angularity to the rod. A low center of gravity or a wider frame would also tend to diminish it.

(5) W. L. S., Emporium, Pa., asks:

Will a chilled tire adhere to a rail and pull as much load as a steel tire? If any difference, how much? *A.*—Assuming that the writer means tire for locomotives, we would say that chilled tires were used to a considerable extent before the introduction of steel, and they did fairly well. At that time they ran on soft iron rails, and many mechanics claim that chilled tire would slip easier on a steel rail than steel tire. The writer has seen cars alike in every other way, except the wheels, some having cast-iron wheels with chilled tire and others paper wheels with steel tire, and the brakes would slide, one as soon as the other, with same air pressure. We do not know of any chilled driving tire now running. The difference in work done would not be very much, but the safety, ease of repairing, and turning would be greatly in favor of the steel.

Locomotives and Railroads from 1800 to 1888 in America.

By William Barnet Le Van.

FIRST PAPER.

Railroads are an ancient institution, and locomotives are the outgrowth of a machine invented to run on them.

Many relations of ancient history are sufficient to prove that the principle of the railroad was not unknown at a very early period. We read of the transportation of heavy masses—stone for the pyramids of Egypt—heavy carriages, warlike machines, and baggage, across marshes and swamps which could not be passed, until artificial roads had been first contrived. In after ages, at the memorable siege of Constantinople, the genius of Mahomet conceived a plan for transporting his light vessels from the Bosphorus into the shallow water of the harbor "A leveling " says Gibbon, " was covered with a broad platform of strong and solid planks, and to render them more slippery and smooth, they were anointed with the fat of sheep and oxen. Fourscore light galleys and brigantines, of fifty and thirty oars, were disembarked on the Bosphorus shore, arranged successively on rollers, and drawn forward by the power of men and pulleys."

Railroads were probably invented by the ancient Egyptians—their origin can be traced to a period of the most remote antiquity Railroads, composed entirely of massive blocks of smooth stone, and adapted to the passage of wheeled carriages, are still in existence in the vicinity of the quarries whence the stupendous stones were extracted which were used in the construction of the pyramids These roads have been incidentally mentioned by the French and Italian *savants* who have visited that cradle of the arts; but none of them have hitherto imagined that they were, in fact, railroads. Their preservation for three thousand years, notwithstanding their exposure to the assaults of time, the havoc of wars, and ravages of barbarians, is remarkable, whilst every vestige of the numerous canals which were constructed by the Ptolemies, or Caliphs, in Egypt, has long since been obliterated from the face of the earth. In Palmyra and Balbec, similar railroads still exist; and in Cyrene, in Africa, long lines of such railroads, composed of stone blocks, may yet be traced for many leagues, connecting the ruins of the once splendid cities which the modern desert contains. (See Cerville's Travels, vol. 2, p. 20, published 1825 by the Geographical Society of Paris)

In Italy, parallel stone railroads are now used, and have been used for ages in the streets of Milan; they are worthy of imitation in every town.

Mr. Wood, in his work " On Railroads," with some probability says that Mr Beaumont, of England, was the first contriver of the railroad, or at least the first who had tested its utility. Leaving this as undecided, it is certain that, in the year 1676, we find a description which cannot be misunderstood. In the life of Lord Keeper North occurs the following passage " The manner of the carriages is by laying *rails* of timber from the colliery to the river, exactly straight and parallel, and bulky carts are made, with four rollers, fitting those rails, whereby the carriage is so easy that one horse will draw down four or five chaldrons of coal, and is an immense benefit to the coal merchant."

Wooden rails have been used from time immemorial in the mines of Germany

It was not until a century ago that the rails, which had been of wood, began to be shod with iron. These iron rails were at first merely protectors of the wood but in a short time they became of greater importance, were made heavier, and now their material is steel.

AMERICAN RAILROADS.

In this country the term *railroad* is used, in England the common term is *railway*. The term *railway* applies to the superstructure, namely, the *ways made of rails*, including their supports, ties or sleepers, fish plates, bolts, etc., and their *immediate* foundation. The term *railroad* is more comprehensive, as it includes the *railway* and the *graded road bed* on which it is placed

Railroads were first introduced in Pennsylvania. In September, 1809, the first experiment track in the United States was laid out by John Thomson, Esq. (the father of John Edgar Thomson, who was afterward the President of the Pennsylvania Railroad Company), civil engineer, of Delaware County, Pennsylvania, and constructed under his direction, by Sumerville, a Scotch millwright, for Thomas Leiper, of Philadelphia. It was sixty yards (180 feet) in length, and graded an inch and a half to the yard. The gauge was four feet, and the sleepers eight feet apart.

The experiment with a loaded car was so successful that Leiper, in the same year, caused the first practical railroad in the United States to be constructed for the transportation of stone from his quarries, on Crum Creek, to his landing on Ridley Creek, in Delaware County, Pennsylvania, a distance of about a mile It continued in use for nineteen years. Some of the original foundations, consisting of rock in which holes were drilled and afterward plugged with wood to receive the spikes for holding the sleepers in place, may be seen to this day

In 1816 the first railroad on which self acting inclined planes were erected was executed by a Mr. Boggs, on the Kiskeminetas River, in Indiana County, Pennsylvania.

The Mauch Chunk railroad was the third to be finished and put in operation. It was made entirely of wood and worked by gravity. This road commenced at the coal mines which are, in fact, in the valley of the Little Schuylkill, on Panther Creek, a short distance below the summit of "Mauch Chunk," or "Mountain of Bears." It is used for the purpose of carrying the Schuylkill coal from this valley to the top of the mountain, and thence to the Lehigh River; hence, the common, but erroneous name of this coal, in the market, is Lehigh coal. The road was commenced in the winter of 1826–1827, and was finished in four months. The extent of the main line, which is single, is nine miles, and the branches and side lines extend in the aggregate three and three-quarter miles. This was the first railroad of any considerable extent made in the United States. This road was run with mules, which were walked on the outside of the track, to protect the sleepers from wearing; and, the road having considerable descent one way, the cars ran down, themselves. A low car was provided, similar to a "gondola" car, and taken with the train; and on that part of the road where the cars ran themselves by gravity, the mules were made to mount the platform of the low car, and were *carried down with the load*; and it was astonishing how soon the mules became accustomed to, and fond of this diversion.

On one occasion, the car on which the mules rode down the plane (of about seven miles in length) broke loose, and descended without its passengers (mules), and it became necessary to send for it, the mules, however, with characteristic firmness, refused to be driven down for the purpose of bringing it back. Persuasions, threats, and even the *ultima ratio* of drivers—the logic of the cowskin—could not induce these favored quadrupeds to waive their usual privileges and to submit to the degrading employment of drawing, in lieu of their pastime of riding, which they had come to look upon as a vested right. Their drivers were actually obliged to change lots with them, and harnessing themselves to the car, to drag it up to the malcontents, who triumphantly took possession of it, and resumed their wonted cheerfulness This railroad is better known to fame as the "Switchback," which has been traveled with such rare gratification by tens of thousands.

The fourth railroad was built at Quincy, Massachusetts, by Gridley Bryant, in 1827. This road, which is known as the "Granite Railroad" was designed and built by those interested in getting material for the Bunker Hill monument from the granite quarries of Quincy.

The gauge of this road was five feet, and the rails consisted of pine twelve inches deep, covered with oak plank, and protected by flat iron bars. The wooden rails were laid upon granite sleepers 7½ feet long and spaced 8 feet apart. The road had considerable incline from the quarries towards the landing place on the Neponset River, and a single horse drew immense loads over the rails. From the wharf the granite blocks were towed around the harbor of Boston by a steam towboat, and landed at Charlestown. In 1871 this railroad ceased to exist, being purchased by the Old Colony Railroad.

In the early period of railroad history in the United States, the practice was a lighter construction of the permanent way than was adopted in England. This, no doubt, has materially aided the remarkable extension of railroad lines over so great an area of country. The rails of our early railroads were composed of flat bars (strap-rail) attached to wooden stringpieces, 6x10 inches, supported on cross-ties similar to those of our present street passenger railroads. The weight of the locomotive, concentrated upon four wheels with a narrow wheel-base, was entirely too much for such a substructure. The roadway soon became uneven, and travel over it was both uncomfortable and dangerous. Very often, the end of the rail would be turned upward and forced through the bottom of the car; in railroad parlance, these were called "snake-heads," and they were often the cause of fatal accidents. On some of the early railroads, wooden piles and trestles were first introduced as a substitute both for sleepers and embankments—notably, the South Carolina Railroad and the Carbon and Honesdale (Horatio Allen, chief engineer). The superstructure was composed of flat bars attached to wooden stringpieces (6x10 inches), supported generally on piles, the latter were secured by ties The piles were driven to a great depth in some of the marshes which the road crossed, and in other parts of the work they formed a substitute for embankments.

The checks used on the Penna. Ry. are inside the boiler—so that they cannot be knocked off in case of wreck. They are very hard to keep tight, and expensive, both in original cost and maintenance.

The D. L. & W screw a plug cock onto the overflow nipple of monitor injectors and run a rod from the handle into the cab. A man can put on the heater in an instant without burning fingers, reaching outside the cab, or diverting attention from the track.

The boys on the Brooklyn, Bath & West End R. R. presented T Dickson, M M, with a gold watch for Christmas. Our subscriber, General Supt. Heindell, made the presentation speech, in which he referred to the necessity for ability in the mechanical department of a railroad.

IN THE ROUNDHOUSE AND Repair Shop.

Steam Pipe Repairs.

We present herewith 46 additional answers to our questions on steam pipe repairs These replies cover an immense territory, and show something of the interest taken by practical railroad men in subjects near their business.

We still have on hand a number of replies, which will be published next month.

PITTSBURGH, FT. WAYNE & CHICAGO.

Seldom, except when engine gets new flues—which about every thirteen months on freight. Out of 125 locomotives running into this house, we took out but five sets last year, on account of leaking. Removing, grinding and replacing, eight or nine hours, cost, $3.68. T F. BUTLER,
Fort Wayne, Ind. R. H. Foreman.

CENTRAL IOWA

When rebuilt, once in two or three years; time, one day for machinist and helper, cost, about $4.20.
J. FREW,
Keithsburgh, Ill. R H Foreman.

EAST TENNESSEE, VIRGINIA & GEORGIA

If cylinders are not loose on arch, from 12 to 18 months, extension fronts five or six months sooner. Time, from three to four hours cost, $1.54. I have done away with the copper gasket under exhaust stand, and made a ground joint, it does much better W L TRACY,
Atlanta, Ga. R. H Foreman.

DELAWARE & HUDSON CANAL CO.

Average eight hours on the work, cost, $3, more if joints are very bad.
C. O. VEDDER,
Binghamton, N. Y. R. H. Foreman.

Only when in for general repairs; time, eight to ten hours; cost, about $8.35.
JACOB EITEL,
Carbondale, Pa. R. H. Foreman.

Grind pipes every six to eight months, time, about eight hours, cost $3.
THOS. HOWARD,
Oneonta, N. Y. M. M.

Have engines here out of shop 20 months, and steam pipes good yet, machinist and helper have taken down, ground and replaced a set in six hours.
J. HINTON,
Quaker St., N. Y. R. H. Foreman.

About once in twelve months, time two hours per joint, cost $1.10.
SAM'L BOOTH,
Schenectady, N. Y. R. H. Foreman.

About once in two years; true rings up in lathe, and steam pipes off with reamer; saves grinding; have ground a set and sent engine out in five hours, cost, about $4.50 to $5.
J. A. WISHART,
Plattsburgh, N. Y. R. H. Foreman.

DENVER & RIO GRANDE.

When they leak; takes machinist and helper eight hours, cost, about $3.75 to $4.
C. H. S.,
Denver, Col. R. H. Foreman.

ON THE WEST SHORE.

It takes us from five to eight hours, depending on the condition of joints, costs 60 cents per joint.
JOHN HOWARD,
Frankfort, N. Y. R. H. Foreman.

LOUISVILLE & NASHVILLE.

Time run, from nine months to three years, according to engine. The whole job takes ten hours for two men, cost, $5.
P. RYAN,
Russellville, Ky. R. H. Foreman.

Not done very often, takes 10 to 24 hours, costs from $4 to $10, according to condition. We have had more trouble with leaky pipes on account of the saddle being badly fitted to the smoke arch, than from any other cause.
CHAS. BEAN,
Pensacola, Fla. R. H. Foreman.

HOUSTON & TEXAS CENTRAL.

Only when putting in new flues; time, about ten hours; cost, about $4.50.
J. H. DEHN,
Walnut Springs, Tex. R. H. Foreman.

ATCHISON, TOPEKA & SANTA FE.

Depends on kind of water used; here we have good water, and joints seldom leak, but on some of our southern or desert divisions, where the water contains alkali, soda or salt, it is very hard on all steam joints, there they do not last over eight months on an average. It generally takes ten hours to do the work. Cost, about $4.05 for four joints.
W. H. TRAVER,
Denver, Col. R. H. Foreman.

When I find joints leak, we take the bolts out, oil and tighten up, thus often saving the expense of grinding. If they have to be ground, it takes a machinist and helper from 10 to 20 hours.
WM. LAWRENSON,
East Las Vegas, N. M. R. H. Foreman.

On this division (So. Kansas), we use Blood engines, and have no trouble whatever with steam pipes. Do not remember of ever having ground in a whole set at once.
J. BUSWELL,
Ex. R. H. Foreman.
Cherryvale and Wellington, Kan.

Average once in 12 months, life of a joint very uncertain in extension front. If front is air-tight they last very well, but if the accumulation of cinders ignite, it injures joints. I have taken out pipes from short fronts that no one knew how long they had run. Time, about eight hours; cost, about $4.
JOHN M. WEIGLE,
Nickerson, Kan. R. H. Foreman.

Takes us about seven hours, and costs about $1.60 to grind only.
JOHN KIRK,
Emporia, Kan. R. H. Foreman.

SOUTHERN PACIFIC.

Steam pipe repairs are governed by so many circumstances that affect the time and cost, that I doubt if there are many cases alike. Our engines run without this work about three years, time, five hours for handy man and helper, cost, about $2.75. Wages are a little higher here than in the East, but we work our men a little harder.
R. E. FRENCH,
West Oakland, Cal. R. H. Foreman.

Pipes generally last as long as the flues, unless bolts break. Time, ten hours, cost, $6.25.
C. F. HALL,
Tulare, Cal. R. H. Foreman.

TEXAS & PACIFIC.

Takes two men two days, and costs about $9.
G. F. MILLER,
Toyah, Tex. R. H. Foreman.

Diamond stacks and short fronts, 12 months, extensions, six months. Time, about 20 hours; cost, $6.
G. W. DEATS,
Ft. Worth, Tex. R. H. Foreman.

CHICAGO, MILWAUKEE & ST. PAUL.

Not often done; if not cut too badly, eight to twelve hours will do the work, cost, from $2.50 to $3.
EDWARD WILLIAMSON,
Oxford June., Iowa. R. H. Foreman.

As often as we renew flues, say from one year to 18 months; time, average, ten hours. We use a ball reamer. If the lower joints came up higher, free from accumulation of dirt and water, they would last longer. We have recently renewed six sets of pipes that were cut out by cinders.
A. J. EDMONDS,
Mason City, Ia. R. H. Foreman.

OHIO & MISSISSIPPI.

Takes from 12 to 15 hours, costs about $3.
L. DE LONG,
Louisville, Ky. R. H. Foreman.

DELAWARE, LACKAWANNA & WESTERN.

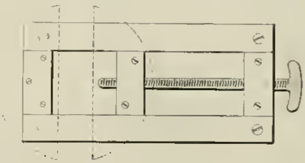
When needed; use a ball reamer. Time depends on conditions; from two hours to all day; cost, $2 to $6.
JOHN MUIR,
Kingsland, N. Y. Foreman Machine Shop.

CHICAGO & ALTON.

We find that by using a wooden plug to hold ring, and using a brace, we can do double the work we did by holding ring in the band. Have ground in pipes in eight or nine hours, but some cases are so bad it takes two days. Cost, for removing, grinding and replacing, from $4 to $5.
W. P. STRUNK,
Roodhouse, Ill. R. H. Foreman.

CHICAGO, ROCK ISLAND & PACIFIC.

Only when pipes are in the way replacing flues, a machinist and two helpers complete the job in a day; cost, about $6.
JAMES MIRFIELD,
Rock Island, Ill. R. H. Foreman.



CANADIAN PACIFIC.

Practice on this road differs very much, here we use water rank with alkali and a native coal, but do not grind pipes very often. Usually put a helper on the job if we have time; usually six to eight hours; average cost, $2.50. Herewith find sketch of a very handy ring holder, it is made of wood, except the screw; the half-rounded pieces of wood shown in dotted lines are screwed to the blocks, one of which travels on the screw. They are cheaply renewed, and do not spring the rings.
H. G. GORHAM,
Locomotive Foreman.
Swift Current, N. W. T., Canada.

Only when they give out, which is only about 1 per cent. per annum on this road. One man can do them thoroughly in ten hours. Cost, including removing and replacing, $5.
C. R. ORD,
Hochelaga, N. T., Canada. R. H. Foreman.

GRAND TRUNK.

Seldom done except engine has general repairs. It is one day's work for one man, for the style joint we are using. Labor, about $2.50.
J. N. MARTIN,
Portland, Me. M. M.

Seldom required, unless putting in tubes or other work. Take down, grind and replace in eight hours, costing $3. This is on the assumption that faces have not been cut to any great extent, and that no bolts break and have to be drilled out; in such cases, the cost runs up.
W. F. BROUGHTON,
R. H. Foreman.
Niagara Falls, Ontario, Canada.

Done very seldom; on brass ball joints, about ¼ day for a mechanic and helper.
WILLIAM BALL,
Richmond, P. Q., Canada. R. H. Foreman.

As a rule they run from one general repair to another. We can grind the joints in two hours, but to take down, grind and replace, it will take a day, cost, two men at 20 cents per hour.
S. C. MCNEILL,
R. H. Foreman.
Pt. St. Charles, Montreal, P. Q., Canada.

N. Y., NEW HAVEN & HARTFORD.

If cylinders are not loose, not over once a year, time, about ten hours, cost depends on price of labor employed, usually from $4 to $6.
EDWIN CHATTERTON,
New Haven, Conn. R. H. Foreman.

Boiler maker and helper do all this kind of work, and it generally takes two days, as all our engines have extension fronts, costs, to grind the joints, $2.25; to do the whole job, $5.
DAVID GIBSON,
Bridgeport, Conn. R. H. Foreman.

A machinist and helper generally do this work, think joints last longest in extension fronts, takes about two days for the job.
C. C. LACKY,
Hartford, Conn. R. H. Foreman.

Our engines are overhauled in from 20 to 36 months, and we do little flue work outside of what they get there; have not ground a set in three years. Time, from 8 to 15 hours, cost, from $5 to $15.
GEO. H. PLATT,
R. H. Foreman.
Harlem River, North N. Y. City.

SOUTHERN KANSAS.

No trouble with joints, can grind in all joints in five hours, cost, $1.37½.
S. ECKNAYR,
Ottawa, Kan. R. H. Foreman.

INTERCOLONIAL.

From 18 months to two years, takes two laboring men one day; cost, $2.20. We use the loose ball joint, and have no trouble with it.
N. L. RAND,
Moncton, N. B., Canada. R. H. Foreman.

CHICAGO & NORTHWESTERN.

Seldom leak, time, from one to four hours. Price depends on condition of joint and price of man on work.
WM. HUTCHINSON,
Council Bluffs, Ia. R. H. Foreman.

FLORIDA SOUTHERN.

Once in two years, have no trouble.
W. H. YOUNG,
Palatka, Fla. R. H. Foreman.

KANSAS CITY, FORT SCOTT & MEMPHIS.

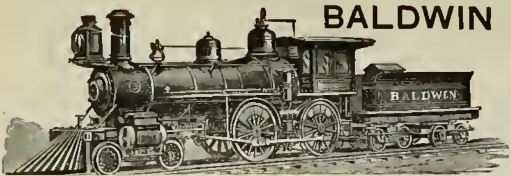
Have never ground in a joint, except when engine goes in for repairs, but most of our machinery is new.
P. T. BUTTERLY,
Springfield, Mo. R. H. Foreman.

PHILADELPHIA, WASHINGTON & BALTIMORE.

The average not one per month out of 65 engines. Use a handy man, time, about two days, cost, $6.
JOHN BREAR,
Wilmington, Del. R. H. Foreman.

LOUISVILLE & NASHVILLE.

If joints are well made when new will last till engine is shopped for flues; time, about one day. I would state that, when we have a joint leak, we invariably find a cylinder working loose. Our cylinders are double-bolted to a ring 1¼ by 6 inches wide, and joints are very low in the arch. They are all cast-iron, we use no brass or composition joints, we protect the inside of exhaust pipe joint with a small apron.
EDWARD MARRIOTT,
Louisville, Ky. R. H. Foreman.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

ANNUAL CAPACITY 650

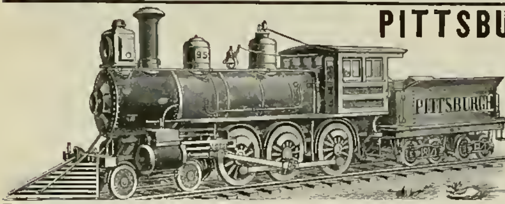
LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable.

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, Etc.

Illustrated Catalogues furnished on application of customers.

BURNHAM, PARRY, WILLIAMS & CO., Proprietors, PHILADELPHIA, Pa.



PITTSBURGH LOCOMOTIVE WORKS,

PITTSBURGH, PA.

Manufacturers of

LOCOMOTIVE ENGINES

For Broad or Narrow Gauge Roads.

From standard designs, or according to specifications, to suit purchasers.

TANKS, LOCOMOTIVE OR STATIONARY BOILERS

Furnished at Short Notice.

D. A. STEWART, Pres. D. A. WIGHTMAN, Supt. WILSON MILLER, Sec. & Treas.

WIRE ROPE HAULAGES

J. & J. B. MILHOLLAND, EXPERT ENGINEERS AND DESIGNERS,

And Builders of HAULAGES for Coal Mines and Tramways.

75 Complete WIRE ROPE HAULAGE Plants in successful operation. Plans and Estimates Given on Application.

NARROW GAUGE LOCOMOTIVES,

Steam Engines and Machinery Generally. 240 FIFTH AVE., PITTSBURGH, PA.

VULCAN IRON WORKS,

Office, Wilkes-Barre, Pa.

VULCAN SHOPS, WILKES-BARRE, PA.
WYOMING SHOPS, WILKES-BARRE, PA.
PITTSTON SHOPS, WEST PITTSTON, PA.

MANUFACTURERS OF

NARROW GAUGE LOCOMOTIVES,

For SWITCHING, LOGGING, MINING, PLANTATION, AND OTHER PURPOSES.

AND

Coal Mining Machinery,

IN GREAT VARIETY.

"LITTLE GIANT" INJECTORS

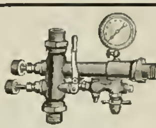
WITH ADJUSTABLE TUBE.

SUITED TO EVERY SERVICE. POSITIVE, CONVENIENT AND DURABLE.

BOILER WASHER AND TESTING DEVICE.

Uses warm water, avoiding injury, and facilitates raising of steam. *Send for Catalogue to*

RUE MFG. CO., 116 N. 9th Street, Philadelphia, Pa.



TIRES

THE STANDARD STEEL WORKS

PHILADA., PA.

THE RICHARDSON AND THE ALLEN-RICHARDSON

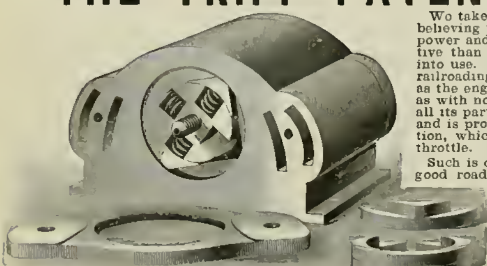
BALANCED SLIDE VALVES.

Used by 140 Railroads. 4,000 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

Estate of F. W. RICHARDSON, Troy, N. Y.

THE TRIPP PATENT PISTON VALVE.



We take pleasure in presenting this Valve to Railroad men and others, believing that its use on a Locomotive Engine will effect a greater saving of power and expense in the maintenance of the working parts of the Locomotive than has been accomplished since the Locomotive was first brought into use. We also believe that its use will add largely to the safety of railroading, and prevent the destruction of many lives and much property, as the engine can be reversed as easily with 160 lbs pressure on the Valve as with no pressure, it being a **Perfect Balance Valve.** The Valve in all its parts is as durable as any of the working parts of the Locomotive, and is provided with a relief device, simple in its construction and operation, which relieves back pressure instantly when running with closed throttle.

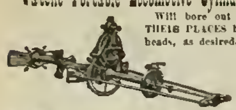
Such is our confidence in this Valve that we will furnish a pair to any good road for trial, on their furnishing following dimensions: 1st Diagram of cylinder face showing ports. 2d. Travel, inside and outside lap of valve. 3d. Distance from cylinder face to center of valve stem. 4th. Size of valve stem. 5th. Length, width and height of steam chest from cylinder face. Internal measurements.

Said Valves not to be paid for until they have demonstrated their value to the satisfaction of the road.

Prices, terms and additional information furnished on application to

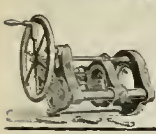
THE TRIPP ANTI-FRICTION JOURNAL BEARING CO., 33 INDIA WHARF, BOSTON, MASS.

Patent Portable Locomotive Cylinder Boring Machine.



Will bore out Locomotive Cylinders IN THEIR PLACES by removing one or both heads, as desired, and piston. THE END THRUST IS ALWAYS IN EXACT LINE WITH BAR. It is fed with constant feed of cut gears.

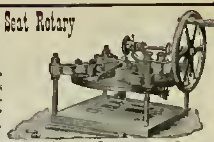
PATENT PORTABLE CRANK-PIN MACHINE.



For turning off Crank-Pins IN POSITION and while wheels are under the Engine, keeping the original centres of the Pin.

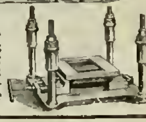
PEDRICK & AYER,
Manufacturers of
Special Tools for Railway Repair Shops.
1025 Hamilton St.
PHILADELPHIA, PA.
CIRCULARS ON APPLICATION.

Patent Portable Valve Seat Rotary Planing Machine.



Will face off the Valve Seats of Locomotives and other Engines perfectly true, without the use of files or scrapers.

PATENT PORTABLE VALVE CHUCK.

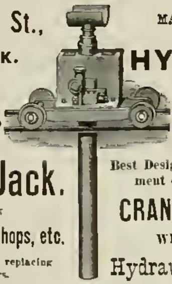


Used in combination with Valve Seat Rotary Planing Machine; quickest and easiest way of facing a valve; obviates use of planer; adapted to round-house and repair-shop work; adjusted by the four graduated columns.

WATSON & STILLMAN,

210 E. 43d St.,
NEW YORK.

MANUFACTURERS OF
HYDRAULIC JACKS.



Vreeland's Transfer Jack.

INVALUABLE IN
Roundhouses, Repair Shops, etc.
For rapidly removing and replacing Locomotive Drivers.

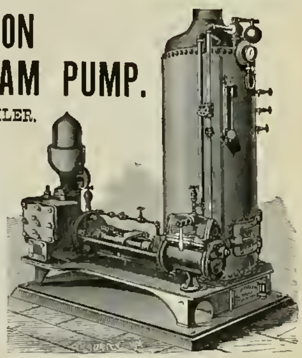
Best Design and Largest Assortment of Sizes and Styles.

CRANK PIN JACKS.
WHEEL PRESSES.
Hydraulic Punches, etc.

SEND FOR CIRCULARS.

THE CAMERON STEAM PUMP.

COMPLETE WITH BOILER.



Send for Illustrated Catalogue.
THE
A. S. CAMERON Steam Pump Works,
Foot of East 23d Street,
NEW YORK.

IMPORTANT TO USERS OF VALVES.

Owing to the popularity the JENKINS BROS. VALVES have attained, the market has been subjected to BASE IMITATIONS.
One important defect in the imitations referred to is *insufficient opening* for inlet *of steam or* Fluid, *thereby checking the flow*. Purchasers of Valves should be careful to know that they are of capacity suited to size of pipe to which the Valves are to be attached. All Valves manufactured by

Jenkins Bros. are Warranted Full Opening.

JENKINS BROS., 71 John St., N. Y.; 105 Milk St., Boston; 21 North Fifth St., Phila. 54 Dearborn St., Chicago.

SIGNAL OIL WORKS,

LIMITED,
FRANKLIN, PA.
Manufacturers of
SIBLEY'S PERFECTION VALVE OIL,
The only perfect Locomotive Valve Lubricant.
J. C. SIBLEY, Prest.

STEEL CASTINGS

From 1-4 to 15,000 lbs. Weight.

True to Pattern, sound, solid, free from blow-holes, and of unequaled strength.
Stronger and more durable than iron forgings in any position or for any service whatever.
40,000 CRANK SHAFTS and 30,000 GEAR WHEELS of this steel now running prove this.
Cross-Heads, Rockers, Piston-Heads, etc., for Locomotives.

STEEL CASTINGS OF EVERY DESCRIPTION.

Send for Circulars and Prices to **Chester Steel Castings Co.**

Works, Chester, Pa. Office, 407 Library St., PHILADELPHIA, PA.

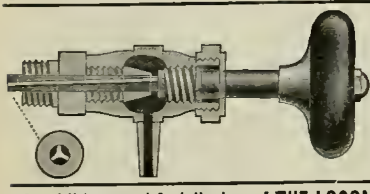
SELDEN'S PATENT PACKING.

With Rubber Core for Steam.
With Canvas Core for Water.

Try it on your Hydraulic Work.
Try it on your Westinghouse Air Pumps.

RANDOLPH BRANDT,
SOLE MANUFACTURER,
38 Cortlandt Street, New York.

SHAW & O'TOOLE'S SELF CLEANING GAUGE COCK.



Every movement of the handle cleans out the tube. A bronze valve on a brass seat. Will not leak. Valve seat readily taken out for examination or repairs. Heavy, well made and adapted for the severest locomotive service.

SHAW & O'TOOLE, MFRS.,
GIRARDVILLE, PA.

GALENA OIL WORKS,

LIMITED.
LUBRICATING OIL.

The STANDARD Lubricating Oil of America is the Galena Engine, Coach and Car Oil. Cold test 10° to 15° BELOW ZERO. It will not freeze in the coldest weather, and insures entire freedom from HOT JOURNALS at any time and under all circumstances, as its exclusive use on a majority of the leading railroads has demonstrated. It shows better results than have been shown by any other oil in the market.

GALENA OIL WORKS (Limited),
CHARLES MILLER, Prest. FRANKLIN, Pa.

Bound Volumes and Back Numbers of THE LOCOMOTIVE ENGINEER—Vol. 1, 1888.

We shall be prepared, within a few days, to furnish BOUND VOLUMES (cloth), comprising all the issues of 1888 (Vol. 1). Price, $2.00, postage paid, or $1.75 at this office. The volume complete, UNBOUND, now ready, will be sent by mail to any address in the U. S., Canada and Mexico, at the regular yearly subscription rate, $1.00. Single copies (any issue) sent by mail at 10 cents each.

AMERICAN MACHINIST PUBLISHING CO., 96 Fulton Street, New York.

TOOLS FOR LOCOMOTIVE BOILER WORK.

The Cut shows our
PATENT PLATE BENDING ROLLS,
Specially adapted to this work.
HILLES & JONES, M'frs.,
WILMINGTON, DEL.

Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast-iron bedplate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started, stopped or reversed instantly.

THE GLACE LOCOMOTIVE CHECK VALVE.

Three Separate, Distinct and Independent Valves in One Case, insuring Freedom from Sticking, and obviating difficulties experienced with old-style single valve.

POPULAR WITH ENGINEERS
Wherever Tried.

J. E. LONERGAN & CO.,
MANUFACTURERS
Locomotive Pop Safety Valves, Guide and Rod Oil Cups, Railway Brass Goods, etc.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO
THE SPECIAL INTERESTS OF
LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO. II. | NEW YORK, FEBRUARY, 1889. | 1.00 per Year. or 10c. a copy.

Danger of Recalling Flagmen by Whistle.

Another awful wreck has happened, this time at Tallmadge, O. It was a bad night, and a train broke in two, getting on to a siding. The engineer sent out his fireman to stop a passenger train, and then went back to get the rest of his own train. He blew a signal to call in the rear flagman; the fireman mistook the signal for him, and came in, letting the express crash into the freight, causing several deaths, the train taking fire from the stoves and roasting those imprisoned in the wreck.

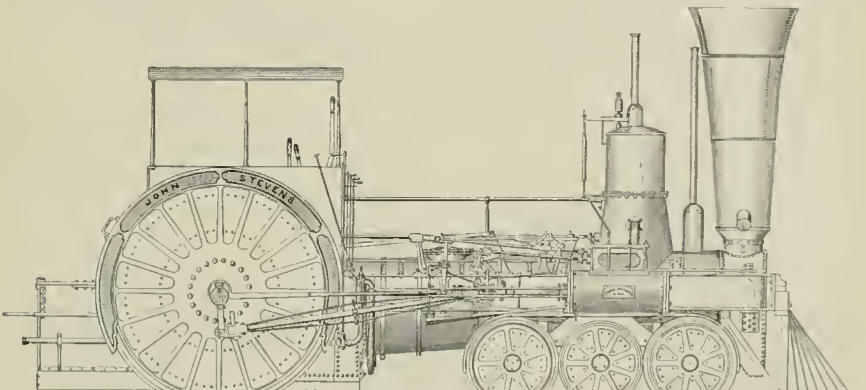
The rule that five whistles call in one flag and four another is always open to mistakes of this kind.

We believe that a whistle signal to call in a flag should not be allowed, except for the head end. If, in all cases where a flag has been out, a torpedo is placed, it would be a warning to approaching trains to run slow; but the recalling of all protection on a man's ability to detect the number of blasts of a whistle is dangerous—especially so where another line runs very close.

The recalling of one flag and not the other is sure to leave a loop-hole for wrecks.

There is not half enough flagging done in this country, and what is done is not done half well enough.

Division 400, B. of L. E., has been organized at Mount Carmel, Ill. Four hundred active lodges don't look much like "a disbanded organization," that some people expected if the "Q." strike failed.



Historical Locomotives

FIFTH SKETCH.

On our first, second and third pages will be found engravings of the "John Stevens," the first of the series of 8-foot wheeled passenger engines once famous for fast time on the old Camden & Amboy road. These engines—seven in number—were built at the Norris Locomotive Works, Philadelphia, Pa., to the order of that eminent engineer, Edwin A. Stevens, afterward well known as the founder of the Stevens Institute of Technology, Hoboken, N. J.

The picture on the first page represents the engine as she was originally built, and is taken directly from the original drawings—kindly placed at our disposal by Henry L. Norris, Jr., of Philadelphia, grandson of Richard Norris, founder of the once famous works that bore his name, and a son of Mr. H. L. Norris, then associated with his father and uncle, and who made these drawings at that time. The original order entered upon the order book of the works reads as follows

"One passenger Loco. for Camden & Amboy Ry. Gauge 4 9½'

Boiler. 38 inches diam , made with spiral seams to burn anthracite coal, the steam dome to be put on cyl. part of boiler, with steam pipes leading to steam chests.

Cylinders. 13x34 inches Horizontal.

Cut Off Worked from an eccentric on outside of shackle pin.

Guides. Of steel, with block and heads

Crossheads. Of wrought-iron, with cylindrical journals.

Wheels. 2 driving wheels, 8 feet dia.

Axles. Axle 6¾, truck wheels with tires 36 dia. Axles 4 dia.

Tubes. 98 of iron, 2 dia , 12 long.

Name, John Stevens, No. 28, tried April 17, 1849."

These engines were not to exceed 50,000 pounds, and the road furnished their own tanks. No weight is given of these 8-footers, but one, the same in every way, except that it had a 7-foot wheel, is recorded as weighing 49,253 pounds, so the 8-footer must have come very near the mark.

Both the driving and truck wheels were made of wrought-iron, and the spaces between the spokes filled with wood.

The boiler is very small—38 in. diameter—with but 98 flues. In the longitudinal section on page 3 can be seen the plan of staying, the long rods among the flues being then deemed a necessity. The fire-box was 5 feet long, no width given, but it could not have been over 48 inches; the crown bars running lengthwise were stayed to outer sheet by bolts, spaced 10 inches apart. The dome was very large, and had a flanged joint near the center of its height, the throttle was of the old slide pattern, encased in a box that was located on top of an arch pipe that went out each side of dome to the chests; there was a dry pipe above the throttle.

The fire-door was below and behind the axle, and the fireman stood in a pit, the bottom of which was on a level with bottom of ash-pan, the tank deck being about breast-high.

On top of the dome was a safety valve whose lever extended to a spring scale, shown just back of dome, this was the only means of knowing the pressure carried—as steam gauges were not then in use.

Near the stack is shown a safety-valve that was encased, to prevent the men from meddling with it.

J. W. Sanford, M. M. of the Penna. shops at the Meadows, Jersey City, fired and ran this engine and others of its class. He says they used to pull six of the old, light cars, but even this train was more than they could handle well. They were not provided with sand boxes, and were slippery and very slow to get a train under way, but, once in motion, with a light train, they would run as fast as men cared to ride. Mr. Sanford recalls the experiments made with different kinds of smoke stacks, one of which terminated in an elbow at the top, with a loose joint, and provided with handles, with which to turn it out of the wind.

The one shown had a place to clean it out, and the lower extension of smoke-box also had a cinder slide.

The exhaust pipes were carried from the chests along each side of the boiler between the frames, and entered the side of smoke-box about half-way up. This engine and its mate had a stroke of 34", but the rest of the series had 38" stroke.

The steam ports were only 8" long by 1 1/8" wide, the exhaust ports 8" by 2".

The cylinder cocks were of the old, independent kind—fireman had to run around the engine and close them up after the engine was in motion.

The pump was provided with ball valves, and the plunger received its motion from a lug, keyed to the piston rod. The feed was delivered in the front of the water leg, just above the mud ring—about the worst place it could be got. The 6-wheeled truck was pivoted to the boiler so far back that it carried most of the weight, making the engine very deficient in adhesion and prone to get off the track. The center pair of wheels were without flanges. The peculiar plan of arranging the truck springs is shown on this page, and seems to have some advantages over modern devices.

There were no seats, the men standing up to their work all the time; the gauge cocks were outside of the cab, and reached by rods, and, in order to be seen and heard, they were large—and often froze up in cold weather.

To the younger generation, the valve motion will seem complicated; the two main eccentrics were located inside the wheel and operated the large hooks, shown with the curved lifting rod, these worked the main rocker arm and the main valve, and the reversing was done by changing from one hook to the other by handling one of the levers in the cab. The independent cut-off was a small valve, riding on top of the main valve, and operated by the return crank eccentric on the main pin; this motion was transmitted to the valve through the back rocker.

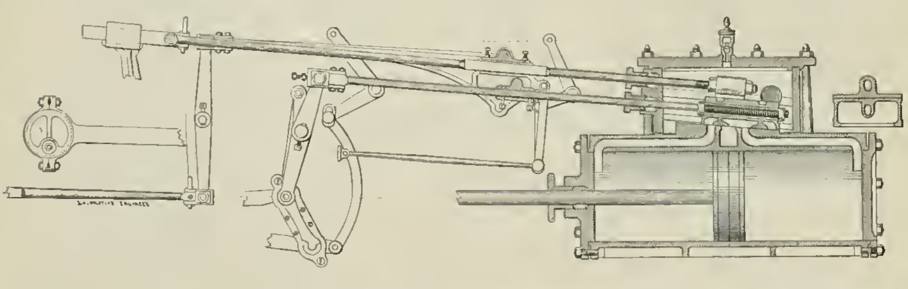
It will be seen that the back end of the upper valve stem was supported in a guide, and at the end of this square part of rod there is a joint, to which is pivoted the rod whose other end terminates in the double **V** hooks. This loose end is supported and held by the bell crank, shown just back of the cylinder. On the upper valve stem there is a loose block, running as a crosshead on a square section of the rod; this is driven by the cut-off eccentric; just below it, on the main valve stem, is another block, held rigid by set screws; this block also carries a pin that can be engaged by the lower **V** of the double hook.

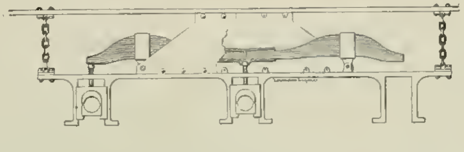
Now, in starting, the cut-off lever was moved so as to engage the lower hook. This made the cut-off valve come to the center of the main valve, and, as that always ran full stroke, it would cut its own steam off, the cut-off motion merely sliding the block on the upper rod back and forth, and doing no work. As soon as the engine was under way the engineer "threw on the cut-off," which disengaged the lower hook from the main valve stem, and engaged the upper one with the cut-off valve, which traveled on top of the main valve, cutting the steam off short, much as a link does when hooked up, except that, as the main valve controlled the exhaust, it was carried well to the end of the stroke.

The throttle lever is shown as the back lever in the cab, with rod running over top of boiler to dome. There was a handrail over top of boiler, no running boards being used.

These engines ran from 1849-50 to 1861-2, and one as late as 1865, two of them were cut up and the others were also cut up, with the exception of the cylinders and guides, these being used on some 8-wheeled engines with 6-foot wheels, that were built at that time.

Engineer Timothy Hennessey, of Moberly, Mo., has been elected Railroad Commissioner of his State, for a term of six years.





Getting an Injector Down Fine.

Engineer John McIvor, of the Rio Grande road, is an expert manipulator of the throttle and brake valve on mountain engines, and, when he figures on a thing, is nothing if not correct.

Some years since a new class of engines came onto the road, that were supplied with a different make of injectors than they had been using, and John got one of them. One of the officials, anxious to know how the new instruments were going to do, asked John about them. "Well, sah," said John, "I can put this engine on a side track, slow the air pump down to three strokes per minute and set that squirt to just supply her—if the throttle gland leaks she'll loose water! Fine, why, it works finer 'n silk."

During the year just passed, the Rhode Island Locomotive Works built 229 locomotives, divided as follows: 56 10-wheelers, 52 moguls, 44 Forneys, 40 8-wheelers, 21 6-wheeled switchers, 12 consolidation and 4 4-wheeled switchers.

The *Northwestern Mechanic*, Vol. 1, No. 1, has made its appearance at Minneapolis, Minn., in place of *Wood and Iron*, deceased. It is in much better shape than the old paper, contains more matter, and has no "overcoat."

Air Brake Practice.

NINTH PAPER.

By J. E. PHELAN.

In eighth paper on Air Brake Practice, January issue, regarding excessive pressure of air, and air cylinders of air pumps heating, the following occurs: "Often air pumps are not properly cared for, and all kinds of dirty oil being used, and allowed to be sucked in through air valves, dust accumulates and gum forms, until air passages become contracted, and adding to and increasing compression and friction in consequence." In the eighth paper we did not go into the why and wherefore, or the philosophy of increased air compression and friction in air pumps, but we are now prompted to it by a letter received from an intelligent engineer employed on the Canadian Pacific Railway, at Winnipeg, Manitoba. This letter from Chas. Pope is far too valuable to go uncared for and unseen, for it contains elements that show up to the enginemen's credit in having progressive thought and thinkers in the ranks, men who seek the why and wherefore in a philosophical and manly way. Hear an extract: "In reading the eighth paper, it has occurred to me that there may be another cause for air cylinders becoming hot when air is compressed at a rapid rate to a high pressure, say to five or six atmospheres. I refer to a natural law, viz., the friction of the air upon itself. According to some of our best American authorities, the greatest obstacle to economy and the practical working of thermodynamic engines arises from this natural law of heat generated during compression, and the low temperature caused by the release of compressed air.

"Although this law of the low temperature caused by the release of air does not, at this time, affect the friction, I have often verified it by the comparatively cold temperature of the air which escapes from the drip-cock in reservoir of engines.

"A lack of facilities has prevented me from testing the increase of temperature, which, under this law, takes place in the air cylinder during compression, and, as the friction of the air ceases as soon as it *becomes at rest*, and the heat which is generated by compression is soon lost, or absorbed by the cylinder itself and other parts, it hardly makes any perceptible difference in the outside temperature of main reservoir.

"Now, as I don't go much on theory unless it is verified in practice, I would like to ask if you do not consider that this law of heat during rapid compression is another important factor in causing the troubles referred to in your paper. If so, it is another very powerful argument in favor of running the air pump at as moderate a rate of speed as is consistent with the requirements of the service."

In this you find clear-headed reasoning that conforms with good practice, and likewise bears out natural law. Hence our assertion: "Air passages become contracted, and, adding to and increasing compression and friction in consequence," will bear further expansion and explanation.

We have often thought air pumps would be better for general and heavy work if made larger.

While air brake trains have lengthened, and air brake cars increased to an indefinite number, air pumps have increased in diameter two inches, with shorter, and consequently quicker stroke. Our reason prompts us in a desire to see an air pump that will increase largely the volume of air to be gained at each stroke, and, in consequence, make the strokes fewer in number and more moderate in speed, and better generally for maintaining an adequate air supply with slight exertion.

But our mission is not to suggest improvements in present appliances, so much as to make the best possible and most skillful use of appliances now existing.

But this principle of air heating by friction will prove interesting to many thoughtful and reasoning enginemen. We may call it the friction of air upon itself, increased compression causing increased friction, or the simple entrance of heat into the air in air chamber of the air pump, when at work.

It remains our privilege to trace the cause. We used to read Prof. Balfour Stewart on Physics, and therein learned that entrance of heat means the entrance of some kind of vibratory, or backward and forward, motion. Heat in itself is vibratory motion. A heated body has its particles in rapid motion, so that, when a body is heated, each extremely small particle of it is moving about, either forward or backward, or round and round.

Mr. Pope remarked the friction of the air ceasing as soon as at rest. Herein he found the principle. Heat enters by friction, or rapid motion, or intense compression, all centered in rapid motion of air particles. As soon as this motion modifies or becomes at rest, heat departs, unless it has in meantime become, as we may term it, stored in metallic substances surrounding air chamber.

Now, if we start an air pump, and run it rapidly until it pumps a pressure into main reservoir of 100 lbs., or to seven times atmospheric pressure, and continue running the air pump at as rapid a rate as 140 lbs. steam may drive it against such pressure, imagine what kind of a devil's dance there must be among the particles of air compressed in the air cylinder; especially if air passages are gummed up and contracted to less than usual size or required opening.

Even at 80 lbs. pressure it is contracting considerable force and energy into a small space. It is a matter of energy producing heat, and the less energy you place there the less heat you will have.

Think of the compression in this air cylinder, or the simple matter of force against some obstacle or opposing force. Or, in plain Anglo-Saxon, your pump, drawing an amount of air from the atmosphere very easily, but meeting with stout resistance when it attempts to force it against the opposing pressure, or through a too narrowly contracted passage.

You cannot help readily seeing the friction that must come from the air particles pressing hard in this limited space. It is simply a matter of friction producing heat. Rub two sticks together rapidly enough and long enough, and heat will be produced. The same principle applies to air or any other substance. Hard hammering or successive blows will produce heat, clapping your hands together, for instance. Think of the pounding an air piston must do on this compressed air, when seeking to put it somewhere, faster than it can be really accommodated.

Heated bodies also expand, and once the heat enters, and your pump keeps bringing in and adding cool air, and, in addition to its being compressed, and having to oppose this obstacle of high pressure, and contracted passage, being expanded by heat, and filling out so much more in consequence—is it to be wondered at if air cylinders get hot?

It is simply the matter of the engineer creating a little hell for himself, within the bounds of the air cylinder.

Heated bodies expand—get larger in all directions, and this heat from the air communicates to the brass air valves, and, if they are a snug fit, they expand in greater proportion than iron bushing or casing holding them, and trouble increases and pounding begins. But the remedy comes in piston rod getting hot and burning out the packing, and brings the engineer to realize the situation. Then the pump is allowed to run slower, and, while it runs at slower speed, half the air it absorbs from atmosphere is wasted through stuffing-box, and still the brakes are kept at work in a way.

When once the principles are understood, thinking enginemen will have little trouble running air pumps at proper speed, and handling engineers' brake valves and train brakes in a skillful manner.

Let us get January issue of THE LOCOMOTIVE ENGINEER, and read the eighth paper again.

Rate Cutting Remedy.

A bill has been introduced onto the Wisconsin legislature, that is intended to prevent rate cutting. It provides that rates shall never be raised, that the lowest rate reached during a cut shall become the fixed rate for that service until another cut shall be made. At first thought this looks as if it might prevent some of the ruinous cuts that do so much harm to the roads, preventing them from paying dividends, crowding the lines with traffic one month, and causing a cut in wages and a reduction of the number of men employed the next. Rate cutting is a menace to the safety of every employe on the road; cuts his pay, hurts the company, and stagnates the business of the country. If the Wisconsin legislators can scheme up any way to prevent it they will do the country a service.

A Southern Railway Shop.

For some time the tramp philosopher of this publication has contemplated a winter campaign against Richmond, and, inscribing on his mental banner the war-time motto—"On to Richmond," he struck out. Having first arranged for transportation for his baggage, and with three days' rations in his grip, he advanced, by forced marches, and reached the walls of the historic city, only encountering one charge—the Pullman porter's—this he easily repulsed, although the colored troops fought nobly to make the charge a success.

A RAILROAD CENTER.

Richmond has many railroads, some of them among the earliest in America—the Petersburg R. R. having been chartered in 1830 and opened in 1833. There is here also an extensive locomotive works, and at Manchester, just across the James river, one of the largest and best equipped railroad shops in the South—those of the Richmond & Danville Railroad.

THE MANCHESTER SHOPS.

These shops were originally built for a road 140 miles in length, but this road has absorbed many other smaller roads, until now it has 2,383 miles of track, 275 locomotives, and nearly 6,000 cars, yet these shops, with nothing like a proportionate increase in size, do the principal work of the entire system.

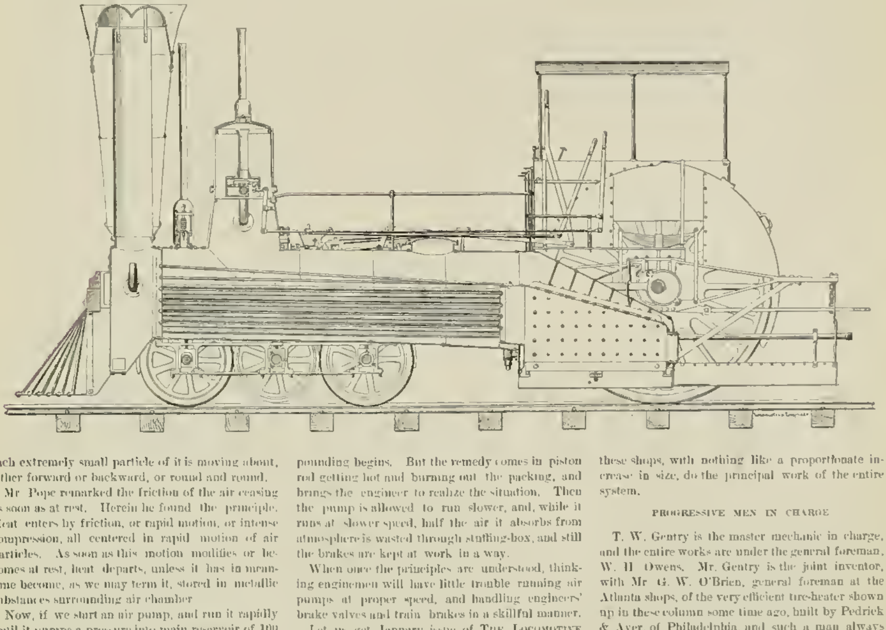
PROGRESSIVE MEN IN CHARGE.

T. W. Gentry is the master mechanic in charge, and the entire works are under the general foreman, W. H. Owens. Mr. Gentry is the joint inventor, with Mr. G. W. O'Brien, general foreman at the Atlanta shops, of the very efficient tire-heater shown up in these column some time ago, built by Pedrick & Ayer, of Philadelphia, and such a man always has a shop a little out of the general run.

The shops lay along the James river bank, and are of brick. The main shop, wood shop, and roundhouse were built before the war, and were used by the Confederate army as a hospital, one side of the roundhouse was used as a dead-house for the hospital, and it retains its ghastly name to this day.

There are extensive car shops and paint shops for passenger equipment, with all the usual attachments of upholstering, lacquering and drying departments. The passenger cars have the new, quick-acting, automatic brake, the whistle signal apparatus, are heated by the Martin system of steam heaters, and provided with Janney couplers—about as modern as any. All the new freight cars have automatic brakes and Janney couplers.

A very neat arrangement for raising water from tanks under the floor is used in some of the special cars built at these shops. Air is taken from the auxiliary drum for this purpose, but the car is sup-



plied with a hand pump, to use when there is no pressure under the car.

THE FOUNDRY.

The foundry is large, neat and light, and has the reputation of turning out some of the best and cheapest work in the country; cylinder castings are very smooth and clean, and are turned out at a very low cost, as they are finished complete for $132 per pair. This foundry does all the work for the entire system, and as all the little roads, that form the gigantic whole, had all kinds of power, the pattern storehouse is full of odd sizes of all manner of things that are gradually fading away as the old mills are scrapped.

USE OF COMPRESSED AIR.

These shops use compressed air for many purposes, one of which, the moving of oil, we illustrated some months ago. This air is found about the place everywhere, to test brakes, etc. In the roundhouse they are putting in a new drop-table, of Mr. Owens' design, that will be operated by air pressure; they also have in the shops lines of steam pipes, with which they run a small engine for cylinder boring, and have attachments in the machine shop to test valves of all kinds, and also to fill up boilers of locomotives being rebuilt, to test joints and connections, and to finally run them out of shop. In the roundhouse there are connections at every stall, to attach a hose to blower pipe, to blow engines that are being fired up, with cold water in them.

A MODERN IDEA.

In the boiler shop they are building a heavy, standard, locomotive boiler, to take the place of the one that now supplies power for the shop, instead of painting up and using a condemned one off some old locomotive.

THE ROUNDHOUSE.

The roundhouse is a complete circle, and was, when built, amply large for any engine in the country; now they have been obliged to chip out the brick each side of the doorways, to let the cabs of their new consolidation engines in, and then, as the engines were considerably longer than the pits, they took off all the doors, and headed the engines in, and the big leviathans look like the picture of the fabled camel, who asked the privilege of putting his head into some fellow's tent and then took his hump in, their tanks stick out of the house so far that they cannot use sweeps on the turntable, and are so close to the doors that a No. 10 man cannot get by them.

MAIN SHOP.

The machine shops are fairly well equipped with tools, and there are many kinks used about them that show the natural genius and ability of Mr. Owens; some of these devices we hope to be able to illustrate at no distant day; the machine shops are run by a sleepy old full-stroke engine, making about twenty-five revolutions a minute, that positively makes a fellow feel tired and lazy to look at it.

There are six pits, and they are always loaded; some of the old engines—marked, M. W. Baldwin & Co.—look real modern with new boilers, injectors, etc.; many of these old engines were overcylindered, and Mr. Gentry has been giving them a little medicine in the shape of larger boilers of heavier metal, and six-inch iron decks.

It is surprising how quickly and cheaply tires are removed and replaced here, where the men have the Gentry-O'Brien device down fine. The storehouse is very extensive, and carries a very large stock of everything in the railroad line, from a union depot to a match.

THE BONE YARD.

Out in the cemetery track—without which no railroad shop can count itself well managed—we noticed three old wood burners, ready to be cut up; they were small engines, and old style, but have done a world of work in their day, it is hard to tell just what make they are; they were, no doubt, thirty or thirty-five years ago, Norris engines, but during and since the war they have been grafted with sprouts off Mason's and Rodgers', and Baldwin's, till their own mothers would not know them.

In the shops there was one wood burner getting slight repairs, the only wood burner the corporation has left.

LOCOMOTIVES, GREAT AND SMALL.

The new engines of the company are large and modern engines, and predominate in numbers, still they own an awful lot of old engines of all classes, that seem too good to throw away, and yet there is little doubt it would pay to do so. This road, in common with all others, do not find the big engines of to-day as good, in proportion to their size, as the little engines of the '60s and '70s. The little 16-inch engines, now being crowded to the wall, were wonderful pieces of machinery for their weight—there is no rubbing that out.

THE ENGINEMEN.

The engineers on this road run by the mile, freight men getting 4 cents per mile, the firemen get $1.60 per day, 30 days every month, whether they work or not, do not have to clean the engines at all, and seem contented with their remuneration. Extra firemen are allowed to help on running repairs in the roundhouse, and the management of this department find that it pays to let them pick up all the pointers they can in this way, old firemen are thus taught to care for packing, face valves, set up wedges, grind in cocks, and do similar work, besides being where they see and understand what must be done to get an engine in when broken down, as they see all the break-downs here, instead of only those on their own engines on the road.

Opportunities of this kind develop men, and in the end it pays the company in gaining efficient, capable and *thinking* engineers. Roads that want men to throw six tons of coal over a division twice a day, and then clean $2 worth for their ride, can't expect to post their firemen, or make engineers of them—they don't give them time to think.

We must say that the enginemen of the R & D are as intelligent and gentlemanly a set of men as ever looked at the philosopher on his rounds, and wondered whether he was a life insurance agent or a brigadier-general in the Salvation Army

Richmond Locomotive and Machine Works.

On a recent visit to the South we had the pleasure of inspecting the Richmond Locomotive and Machine Works. These works occupy the shops formerly used by, and are successors to the business of, the Tanner & Delaney Engine Co., and do a large business in stationary engines, boilers, farm engines, logging locomotives, street cars, etc.

They have for years built small locomotives for many purposes, and have commenced the manufacture of standard gauge locomotives only in the last year or two.

The shops are large and roomy, well equipped with machinery and appliances; they are now building an addition to their machine shop, that will just double the floor space, and have invested $60,000 in new machinery for it.

They had in the shop three locomotives—one, a ten-wheeler for the Georgia Pacific, that was as well designed and as modern a looking piece of machinery as one would see in any place. A street car motor for the Richmond & Seven Pines road was complete, and a very handy little engine it was. They also have a gas-burning motor in course of construction, as well as several pole road locomotives.

These works built the handsome motor cars for the electric road in Richmond, better designed and better finished street cars than usually seen.

Mr W Simpkin is the superintendent in charge, and he is paying particular attention to the locomotive department of the business, it being the intention of the company to fully develop locomotive building in the South. And there is no good reason why they should not.

The new dress and size of the *Fireman's Magazine* puts it far ahead of all other labor organs. Editor Debs has a way of showing up wrong and abuse that is at once conclusive and manly. The firemen are justly indignant, that, after all they have suffered and lost in the "Q." strike, the engineers should proceed to call off that battle, without consulting the firemen. And who can justly say that they have not just cause for complaint? What has become of the "twin Bs"?

Firing Anthracite Coal.

LAST PAPER.

Very much of the proper combustion of the fuel depends upon the adjustment of the draft pipe with the low double nozzles. The draft pipe requires such adjustment as to distribute the action of the exhaust over the fire as equally as possible. It is generally admitted that the height of the draft pipe above the nozzles governs the action of the exhaust on the front end, while the space between the stack and the top of the pipe governs the exhaust on the back end of the fire. Sometimes both these conditions can be satisfactorily met with a pipe as furnished, but it is hardly to be expected that a standard draft pipe can be made, that would be suitable to all kinds of locomotives. An adjustable pipe, made so as to slip one part over the other, would seem to be requisite, for then either end could be adjusted without disturbing the other, while with a stiff pipe the proper adjustment of one end might prove just wrong for the other, and then there is no remedy, except by cutting off, or adding a piece. When I first commenced firing, I was put on a locomotive, on which I cleaned the fire from three to seven times a day, with very little steam, and the injector and blower on at every stop A proper adjustment of the draft pipe produced such a change, that I was enabled to fire the same locomotive a whole day without cleaning, and never cleaned more than once a day after this, so it is very evident that a proper adjustment of these parts is of paramount importance to the steaming qualities of a locomotive

A locomotive which has too strong a draft on front of fire will soon kill the fire there by overwork, leaving other portions unburned. The front will require constant watching, and frequent feeding, to keep it alive; but, unless great care is used, it may soon become too heavy there, and when it gets to that condition, she will not steam, through inability to work the fire.

Some locomotives also have a tendency to "haul their fires" This is caused by too heavy a draft on the back end, by which the coals from there are drawn ahead and deposited on the front end, which thus becomes heavier with every exhaust, until she fails to steam. The remedy for a too heavy fire in front is to get rid of it as soon as possible, sometimes it must be done with the packer, but often with locomotives having sliding bars, pulling them out and jumping on these ends will start the fire to running out, and when reduced to the proper thickness, shoving in the bars stops its further exit. While this is being done to the front end of the fire, a heavy layer of fine coal spread over the back end will generally stop the hauling, and, if followed by a layer of lumps, the fireman may be able to gain the victory.

Sometimes fires will be overworked along the sides and "die out"; these spots must be knocked out, and live coals shoved over the grates, and tied down with a few shovels of new coal, fresh coal, thrown into a hole, will not "catch," as in soft coal—it must have live fire under it.

On arriving at the end of the trip, the fireman "knocks out the front end" of the fire, as described for cleaning, and generally also "bars up" the back end (to insure good draft through it), and covers it over with a thin layer (4 or 5 inches) of new coal, and such a fire will last in the roundhouse, without any other attention, for 12 hours, by which time it is presumable the locomotive will go out on another trip. In getting her ready for the trip, the same operation of "shoving the fire down" and working it over, to free it from ashes and clinkers, is performed as in cleaning on the road, with the exception that more care is probably necessary to secure a good layer of kindlings from the coal which has been thus lying inactive for twelve hours. If a locomotive is in the roundhouse longer than twelve hours, with fire in her, it is "barred up," and new coal applied from time to time by those in charge of the roundhouse, who, of course, are also required to attend to the water in the boiler, and keep it at a proper height. VULCAN.

Mr. L. B. Paxon has been appointed Supt. M P. of the Reading Ry. system.

An Injector Suggestion.

While riding on an elevated locomotive a short time since, the writer could not help but notice the attention required to start and stop the injector—they used a Monitor No. 4. The runner not only shut off the ram, but the throttle valve in steam pipe as well. To start he had first to open this steam valve to get steam to the primer, then the primer, then the ram; all this takes time and attention, and it looked to us as if an improvement could be made by using injectors that operate by one lever only. The engine was trying to burn pea coal and the runner had to play with the squirt a good deal to get along at all—perhaps with decent coal a man don't have to shut off the injector every time he tries the gauge cocks. An injector that will start and stop with a single motion of a lever, does not require a man to look away from the track or his signals, and has an advantage over any one that does.

An Electric Brake.

A new electric brake was tried, some time early in January, on the Lehigh Valley road, and the usual glowing accounts given in the daily papers. As now constructed the apparatus is trappy, being on the "grab-and-wind-up" order. The daily paper description is as follows:

"The essential features of this new system consist of a composite sleeve cast onto the car axle, upon which two friction pulleys, properly geared, are thrown into action by an impulse of electric current by which a chain gear is wound and the brake applied. The electricity is stored in the engine and rear car, and carried by insulated cable along the train, with proper couplings between cars. Each car is acted upon independently and instantly, and the train stopped without bumping or any vibration."

There may be a future successful electric brake, but it must be one in which the power is applied direct—not the trigger to release a spring, that releases a dog, that releases a hammer, that descends on the charge, and finally fires off the brake.

The new automatic brake that will supplant the air brake must be a simpler, surer, quicker, safer, and cheaper device than the one we now have.

Richmond Shops of the Atlantic Coast Line.

At the shops of the Atlantic Coast Line road at Richmond, Va., we noticed an improvement in the blow-back pop—a 3-way cock that lets it blow into the air as well as the tank. Mr. O'Brien, the master mechanic in charge, has some of the best looking passenger engines in the South. They are Baldwin 8-wheelers, extension fronts and straight stacks, 18x24. It was found that the first of the series were a little heavy on their front trucks, and the later ones have the air drum on the tank and are lightened up in front as much as possible, a wrought stack base being used.

Mr. O'Brien is applying eccentrics with a 4" face to all his engines. These eccentrics are cast in two pieces that lap by each other, and are riveted together on the axle, making, to all intents and purposes, a solid eccentric.

These engines are provided with Bryant's hose and strainer cleaner, of which Mr. O'Brien speaks very highly. Sellers' '88 injectors are used, and the men like them, but say they do not throw as much water as the '76—it is a matter of record that the '76 Sellers will throw more water than any other instrument of the same size, under varying steam pressures.

This line of road use the Sewell system of steam heaters and use no reducing valves on the steam pipe, but send back 70 to 80 pounds of pressure, in order to run a small engine and dynamo in the baggage car. As might be expected, they have lots of trouble with leaky couplings and ruptured hose.

This road owns and runs the last Norris engine built, delivered in 1865; of course she has had a new boiler and a new set of wheels, but the rest is intact, and all "Norris." The engineers say that, with a train of her size, she can wag her rudder at anything on the road.

These shops resemble a saw mill more than a machine shop, and the tools are in keeping with the building, and it is to Mr. O'Brien's credit that he maintains his power as well as he does, with the facilities at hand. Modern shops, new tools, and a roundhouse are sadly needed.

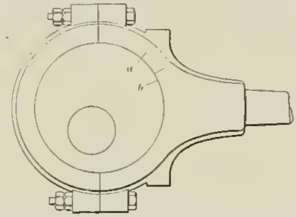
Why Lead Increases as Reverse Lever is Hooked Up.

The reason why the ordinary link motion, or shifting link, employed on locomotives, increases the lead of the valves as the reverse lever is hooked up has often been explained by eminent writers who evidently wrote for the few who were supposed to understand the subject, rather than for the many who do not.

Engineers and firemen, as a rule, are too busy to study these complex demonstrations of a simple problem, and their educations are seldom equal to the problems if they had the time.

Each and every one of them know that the lead does increase as the lever is hooked up, and that this is one of the reasons that the locomotive will run faster, etc., but you pin nine out of ten of them right down, and demand to know *why* the lead increases, and there is not one in one hundred who can give an explanation off-hand. They know they have read so-and-so, and could find the reason in some work. Yet the explanation is simple enough.

Now, if we take a locomotive with ordinary link, and want to increase the lead, we would do it by advancing each eccentric in the direction it is to run. If, for example, we take the R.-go-ahead eccentric and mark it as at *a*, and then proceed to move the eccentric ahead, to increase the lead, the mark would show a break as at *b*. Now, when we hook the reverse lever toward the center, we do not move the eccentrics ahead on the shaft, but we do move the straps back on the eccentrics—which



amounts to the same thing—the lead increasing the farther the lever is hooked toward the center, and the mark would show a break as at *b'*, the same as if the eccentric itself had been advanced on the axle. With locomotives having very long eccentric rods, the lead will not increase so much as with locomotives having very short blades, or rods,—because the short rods make it necessary to move the straps farther around, and back, on the eccentrics, while with the long rods the ends at the link could be raised from six to ten inches without moving the strap on the eccentric but a very little. This is not offered as a substitute for those explanations that describe the increase by the difference in the arcs the rods would describe if they embraced the axle instead of the eccentrics, etc., etc., but as a short, simple, easily understood explanation for practical men.

Get It Right.

The Westinghouse Air Brake Co. have had trouble in the past by the improper application of their brake apparatus to cars and locomotives. Of course, it is of the utmost importance that the best results should be got from their device, and they have followed a sensible course in issuing a circular calling attention to these facts, and end by saying:

"We will be pleased to also provide, without charge, a competent representative to co-operate with your officials in the education of your employes in matters pertaining to brakes, and to superintend their attachment wherever applied.

"In this connection, we would suggest the insertion in your engine or car contracts, when our brakes are specified, that they should be applied to such vehicles in accordance with plans provided by this company."

New Shops.

The Eames Vacuum Brake Company are very busy; they have recently moved into their new blacksmith shop, one of the best arranged in the country. They have 20 fires provided with Sturtevant blowers, and an exhausting fan to clear the shop of smoke and provide pure air. They have also completed a new foundry of modern design.

Correspondence

Setting Slipped Eccentrics.—A Rule(?)

Editor The Locomotive Engineer:

In looking over the November number, I noticed a communication from T. H. E., of Nashville, Tenn., asking for a rule to set a slipped eccentric. Now, I think that the following will be just what he wants, as an eccentric can be set by it in less time than it takes to tell it. First, place your reverse lever clear down in the corner, either forward or back, then get down under your engine, and take pin that goes through the reach and link out, and let your reach down upon the ground, then lift reach up, and you will find that holes in reach and link do not match. Right here is the place where you do your setting; have fireman turn eccentric on axle until the holes match and pin will go back in again, without *prying* or *moving* link, then fasten eccentric, and you are all right. It takes but a second to do this, and if some of your readers should happen to slip an eccentric, I would be greatly obliged if they would try it, and tell us how it works. "SQUAB."

[We are inclined to think this is one of those old rules (?) that are altogether too numerous. Can "Squab" tell us the *reason why?* What makes the link assume its correct position when released from the eccentric that has gone astray? Setting a slipped eccentric is no great feat when one understands how to go at it, and the reason certain things are to be done. Let's see you prove it, "Squab."]

Has Been There Too.

Editor The Locomotive Engineer:

I note in January number of your paper an article from T. B. Livingston, relating to engines carrying water. As I was around Wisconsin in those days, I can say I remember all about the circumstance referred to, of engines 26 and 27, and well remember Mr. Chas. Morse, and I think I can go a little further than friend Livingston has in this subject, by bringing in Mr. Geo. T. Thompson's name as having claimed just as Mr. Morse and friend Livingston has.

I only mention this to give proof that the circumstances were known to me, and if these few lines bring out any discussion on this subject, I will, at some other time, give my experience of a similar nature, on a *Gould* engine, in 1857, on the then Milwaukee & Mississippi R. R., now the Prairie du Chien division of the St. Paul Ry.

Should this come to the eye of T. B. Livingston, he may be pleased to know I am still among the living, and following about the same line of railroad life I have, for the past twenty-five years.

K. C., Ft. S. & G. R. R. H. BATES.

Revenge is Sweet.

Editor The Locomotive Engineer:

I cannot pass unnoticed your criticism of the Erie R. R., in abolishing the office of M. M. Your criticism may be all right so far as it goes, but if this move of the management upsets the pitchforking that has been in vogue on the Erie and some other roads that I have worked for, then I think it is a God-send.

You won't print this, as it's against your teaching, neither would I care a tinker's dam if you did, as I don't railroad now. HUGH CRUMLISH.

Buffalo, N. Y.

[THE LOCOMOTIVE ENGINEER does not exclude any man's opinions because they differ with our teachings or anything else. We oppose the placing of the motive power out of the hands of mechanics, and the reduction of the hours of labor and the number of men employed, and the reduction of the pay of those finally left in the ranks, simply because it is dangerous to the lives of the enginemen and the public. The engineers and firemen of this country are running enough of neglected engines over uninspected track and rotten bridges. Any railroad that deliberately lets its motive power and permanent way drop below the safety line ought to be closed up by law. We make men have their boilers inspected, to keep them from endangering the lives of the public, but we let a few gamblers send out the order that passenger trains must run over hundreds of miles of track that is not cared for and drawn by locomotives that are not kept in safe running repair. It is inviting disaster.]

Opinion of a Manufacturer on Railroad Papers.

Editor The Locomotive Engineer:

I thank you very much for your kindness in sending to me back copies of your paper. I am an old "railroader" myself, having put in twenty-five years of my life in the service, and have, during that time, read, of course, many so-called railroad papers. It was not until recently (having been for the past five years out of the service), that I have seen your paper, but I must say, and with no desire to flatter, that I consider it the best railroad newspaper I have seen.

The fault with most railroad newspapers is that they are "filled in," in great part, with extracts from railroad reports, and all the floating "flotsam and jetsam" which they clip from the daily newspapers, and from their railway exchanges (each from the other), and from every source they can lay hands on.

Your paper is largely original, and with common-sense matter from practical railroad men. It does not come too often (once a month is often enough, a large weekly railroad paper is a bore), and when it comes it is clean and clear. I enclose $1 for subscription for one year from January 1st, and will thank you to give me your lowest rates for advertising.

With best wishes for your future success,

131 *Rittenhouse St.*, J. H. BURRELL, JR.
Germantown, Philadelphia, Pa.

Good Report from the Triple Expansion Exhaust.

Editor The Locomotive Engineer:

Your favor December 13th received. In reply I will say I have been using "Smith's Triple Expansion Exhaust Pipe" in a Baldwin "Mogul" engine. We have had considerable trouble with these engines, from their not steaming well. Since applying the device we have had no trouble whatever, and the engine will haul from three to five cars more than other engines of the same class. I consider it a first-class invention, and that it accomplishes something which we have been trying to overcome for many years—back pressure, and I am satisfied that it does it effectually.

A Few Inconsistencies with a Kink.

Editor The Locomotive Engineer:

Mr Editor, in the ante bellum days, when you used to do the grand, right-hand act on a wheezy smokingine, did you ever stop at a station, say, for example, Tarryall—where you expected to meet the "howler"—with a freight train, a slow conductor and a fast speed recorder, at exactly 2.01 P. M., by the steelyards, and have the telegraph "operation" come out on the front porch and give you frantic signals to come ahead, and wave aloft a yellow order like the traditional reprieve—just in time —and then get an order, saying that by the order of the dispatcher and the grace of the train master *et al.*, you could have until 2.7½ to get to McGlory, 10.3 miles away, and up a 3 per cent. grade, regardless of the "howler."

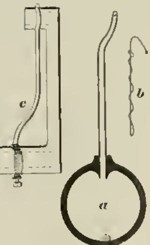
You have? Well, did it ever dawn upon your benighted intelligence that such an order made it any easier for you or your old cob-chopper to get in on the turnout at Tarryall, and wait 2 hours and 37 minutes for the howler that was trying to howl with thirteen sleepers on an engine that was built for four?

Kinder sort o' inconsistent, ain't it? Simply a reminder that the dispatcher is not so very sound asleep.

Now, that order is just as consistent as it is to put an oil-cup on a brass plug, brazed onto a copper steam pipe, to the air pump, *and not punch a hole in the pipe;* but that is just what I found on one of our scraps the other day, and she had run a year that way, *with a sight feed cup on, too!*

Once upon a time I fired an old hook motion, whose right pump wouldn't work, because the tank valve was not attached to the rod, *and never was!*

A few years ago I got 90 days leave of absence—called division superintendent a liar—and went West to grow up with the real estate, etc. Got a job on a mountain road, and was given a consolidation scrap with a driving brake rig right in front of her links; she was new, or rather just out of the shop, and the first thing I did was to get the lower end of a link hanger hot, because it did not get oil —expected one to oil a hole thirty-six inches away, with an old, free-for-all oil-can, with a fifteen-inch snoot. Another case of inconsistency.

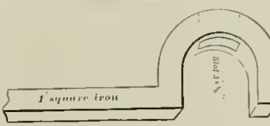


I run several of these boats, and will bet four dollars that the lower end of hangers did not get a drop of oil in a hundred miles, and couldn't have kept it if they had, and three drops was all they needed.

I went to work and made a ring like the sketch, *a*, and soldered a ¼ inch copper pipe, *c*, into the top, long enough to come up to top of hanger, and sticking through into the ring ¼ of an inch; this and the solder around it being filed down, so as to enter the countersink of oil-hole. The set screw below would hold the device in place.

I bent a wire, as shown at *b*, and put a couple of inches of woolen yarn in it, and this I shoved down in the top; the space above it would hold, say ten drops of oil, and would feed all day. If cinders got in the mouth of pipe, or I wanted to put a lot of oil directly over the bearing, I pulled the wire out. I could easily change the rig from one engine to another. It did not cost much, and was good in its place.

There ought not to be a place for such kinks, but unfortunately there is. JOHN ALEXANDER.



Keeping Air Pumps in Service—Relyea's Tool for Hose Head Repairs.

Editor The Locomotive Engineer.

The hints on air pump repairs in November paper, by William Foster, are very good, but if he has as many pumps to care for as we have here it must keep him moving to change pumps every time they "kick up." Mr. Foster says: "When a pump refuses to work there must be something radically wrong with it." I don't think so, because there are many simple causes for pumps refusing to work, for instance: the exhaust pipe in front end sometimes gets stopped up with cinders, when the pump makes one stroke and stops; again, if the oil-cup don't feed, or the engine raises her water, so that it works through the pump, it will stop it, so if a pump refuses to work it does not follow that there is something radically wrong with it. When a pump is reported to me as working bad, if the engine has steam on I start the pump, locate the difficulty, and repair it; or if the engine is dead, and the engineer tells me how the pump acts, I generally find the trouble and overcome it without taking off the pump, thereby saving time and labor.

"Keeping the same proportions" is all right in general repairs, but in ordinary repairs I think we can deviate a little without affecting the working of the pump very materially. For instance, I have had pumps that were in good shape, except that the upper and lower main steam valve bushes were worn to a shoulder; in such a case I have a fluted reamer, about two inches long and $\frac{1}{32}$ larger than lower end of main steam valve; this reamer I screw on the end of a long arbor, and with a small ratchet ream out the shoulder worn in the lower bush; the upper bush I take out and chuck it in the lathe, and bore out the shoulder. By doing this I get another year's work out of the pump, and it works just as well as if I had put in new bushes.

With a good lubricator and proper care, an air pump ought to run two or three years before it needs a general overhauling. When the rubber packing ring in hose couplings wears out I put a new one in without taking the hose off. To do this I use a tool like the drawing. If any of your readers, having any of this kind of work to do, should make one, they would soon "get on" to the manner of using it, and would like it. I put the coupling in the hook, which has a slot in the curved part to admit the projection on the end of the coupling head, this tool, or hook, is about three feet long, and by holding the coupling and hook in the left hand, and letting the lower end of it rest on the floor, I take an open wrench in the right hand and unscrew the cap very easily.

"Snooks" says he is stuck on his first air pump; I have had pumps act the same as his does. The causes were a loose reversing cylinder, or bad joint on top of reversing valve-bush. I am very much pleased with the improved appearance of THE LOCOMOTIVE ENGINEER; success to it.

W. F. RELYEA.
Syracuse, N. Y.

Cab Fixings.

Editor The Locomotive Engineer:

Of all the lamps on the engine, the gauge lamp is generally the worst. It has a glass globe on it, which is painted on the inside, and is smoked up so black, that what little light is made by the flame is absorbed by the black surface and never gets out. The oil tank is filled with lard or sperm signal oil, so the wick has to be turned or picked up about every two hours, and on a long, all-night run, the oil is burned out before daylight, so it has to be filled fresh. Some of these dandy lamps can be found with your nose before you can see them, as they make more of a smudge than a light. Some of them have fancy brass bottoms that have been in two or three smash-ups, and in the tinker's hands at least twenty times.

If the boys who have one of the above described lamps on their engine want solid comfort, let them clean the globe of all paint, pictures, and dirt on the *inside*, and paint it white on the *outside*, about two coats, and after that is dry put on one coat of green. When this is dry it will be just as smooth as the glass. The white paint next to the glass will make a reflector, and what light is made by the flame will be utilized.

After the paint gets dry set the lamp up where it belongs, scrape off the paint, so the light will shine through a hole about the size of a silver dollar, on the steam gauge, another small hole to let the light on the air gauge, one for the clock, if there is one on the engine, a big one to light back into the tender, and, if the lamp comes in the right place, a little hole in each side will light up the tallow cups for the valves. Try it, boys, and see how much better it is. Fill your lamp with kerosene oil, use a small burner and narrow wick, and you will be surprised to find that a flame no larger than an ordinary steel pen will light your cab, and not smoke, but burn all night without picking up.

Sometimes, when you get down to oil around, the torch is so big that you can't get your hand around it and the oil can both, and the torch drops to the ground. Get a smaller piece of pipe next time for a torch. The wick drops down into the torch most every time, and leaves you in the dark. When you get in, take your torch to the man who runs the little lathe, and get him to cut a fine ragged thread from one end of the wick tube to the other. This will catch the wick so it is not apt to fall down, and a much looser one can be used, which gives a better light, and don't blow out so easy.

If your dripper is so made that, when you try your gauge cocks, the dirty water splashes up on your side window, and all over the side of the boiler, get a piece of brass wire gauze, as long as the slot in the top of the dripper and wide enough to roll up and fill the dripper full, squeeze it into the dripper, and when the water strikes the brass gauze it will go through and stay there. Don't put iron gauze in, for it will rust out in a week.

Lansing, Mich. CLINTON B. CONGER.

More Proof of Water Splitting.

Editor The Locomotive Engineer:

I am a reader of your valuable paper, and I think it the boss paper, and if more of the enginemen would read it they would be better posted on a good many points. I saw an article in your last paper, about steam splitting the water in boilers. I want to put my experience alongside of those other *cranks* (at least that is what the others call us). I commenced running an engine on the old T. H., A. & St. Louis road, in 1857, and almost the first engine was a McQueen, 5½" wheel, 16 x 22" cylinder, pulling freight. I asked the man that I took her from why she was on freigh; the said, "She is a tough cuss, but don't be afraid of her, no matter if you can't find any water in her, if the pump works well." Well, sir, I run her one month, and there were times when she would have plenty of water one minute, and the next not a drop to be found in any of the cocks. Another time, plenty of water in the two first cocks and none in the third.

That engine had run on that road over a year in just that way, and she never leaked a drop of water that I ever heard of. She was given to every new man that went there to work. I was there three years, and she never played out on account of low water. There were two others there of the same class, that were all right as far as the water was concerned. I never met the man that could tell why it was thus.

I have served thirty-one years and seven months on the foot-board, and that is the only engine that I ever met that I did not know whether I had water in her or not. I have seen three minutes pass, throttle open, working hard, and not a drop of water in sight—and I never was drunk in my life.

Meadville, Pa. C. M. SPOFFORD.

Another Good Driving Spring Kink.

Editor The Locomotive Engineer:

Having given you a description of the device we use for the removal and replacing of back driving springs, which I see you have illustrated in your November issue, I wish to ask you if you will please explain to the boys an appliance we have for the removal of front driving springs. It will readily be seen that the jack used for removing back springs cannot be used for the removal of front springs, owing to the lack of space between the top of front spring and boiler.

I have removed front springs by the use of a chain and bar. Have also used a jack with chain attached to it, but I have known several cases where men have been injured by the chains breaking.

To avoid this danger, in place of chains I use iron strips ½" × 2", *A*, Fig. 1. These strips are each in two parts, the longer piece being offset to receive the shorter one, which, when they are pinned together, leave the inside faces parallel when placed in position for removing spring.

By drilling three holes in each piece these strips can be lengthened or shortened, as the different builds of engines may require.

The long and short parts of each strip are pinned together with ⅞" × 1½" steel pins, through the ends of which ¼" spring cotters pass. The lug *B*, Fig. 1, is jumped on to the face of the short piece, as shown by cut. Both the upper and lower edges of this lug should be rounded, as should be also the upper part of the slot through short piece *C*.

The crosshead, *D*, through which the screw passes, has a 2" face, as shown at *E*, Fig. 1. The wings of this head have ⅞" × ½" slots cut in them, as shown, to receive the long strips.

The screw has square thread, is 1⅞" × 8½" with a tempered steel point.

A forward driving spring is removed with this device as follows:

First jack the engine up until most of the weight is removed from the springs, then pass the strip to which the lug is attached up on the *inside* of engine frame, and hook the lug over the top of spring, as far forward as possible. Now pass the other strip up on the *outside* of engine frame, between driving wheel and frame, and hook it over end of lug. To prevent the apparatus from slipping down the spring towards the band, place a stick of the required length between the band and lug, as shown at *A*, Fig. 2. After having placed this stick in position, hook the wings of crosshead through the square slots in lower ends of strips, and pass the screw and crosshead back under the pedestal brace, as shown in Fig. 2, and apply the point of screw to brace.

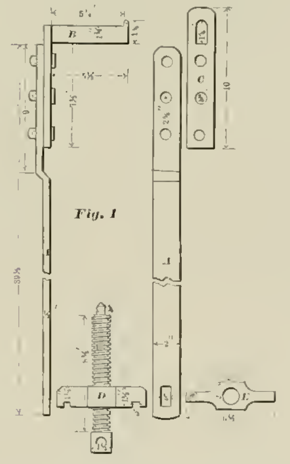


Fig. 1

This appliance is cheaply made, and there is no danger of it slipping or breaking, and injuring a person.

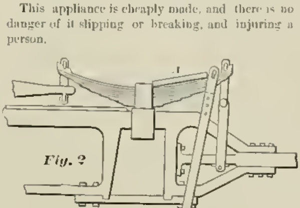

Fig. 2

I give this to the boys for what it is worth, hoping that some one, through your good LOCOMOTIVE ENGINEER, may derive some benefit from it.

Minneapolis, Minn. L. C. HITCHCOCK, "Soo" R. R. Foreman.

A Protest Against White Switch Lights.

Editor The Locomotive Engineer:

One of the most important factors of safety in the movement of trains is a means of readily detecting a misplaced switch. This is provided for by connecting targets with the switches in such a manner as to indicate the position of the switch, either by the color or the shape of the target, or its position in relation to the frame of the switch. At night, however, it becomes necessary to have lights in connection with the switches, which shall be so connected as to show at a glance what the position of the switch is, unless, indeed, it should be the policy of the company to "go it blind," as is the practice on some roads. A switch light seems, however to be a usual adjunct of every switch leading from or to the main track of nearly all roads of the country. In nearly every case, a lantern with plain red and green glasses is in use, and seems to give satisfaction, because a green and a red light are readily distinguished, and would seem to leave nothing more to be desired. Of late, however, some roads are using a white and red bull's-eye lantern, whose use will prove fraught with danger, and, as there are enough risks in a railroad man's life, all unnecessary elements of danger ought to be protested against, and, if possible, eliminated from the service. These bull's-eye switch lights, having concentric circles, serve to disseminate the rays of light in such a manner as to leave a person approaching them in doubt whether it is an extra bright switch light or a dim headlight which he is looking at. Again, on most roads track-walkers make their rounds at night or in the early morning hours, and carry white lights. Most roads are so crowded with business that trains follow each other very closely, and are liable to overtake each other whenever the one fails to make time, from any of the numerous causes which "lay the boys out", this brings, or ought to bring the flagman out, and as they always carry a white light, and in many instances are careless in the manner in which they carry the red light often having both lights in the same hand), we have a condition of things which is liable to lead to disaster. When an engineer sees one of these bull's-eyes at a distance, he has to guess whether it is the switch light burning all right, or a train approaching him with a poor headlight, or the track-walker who has given his lantern an extra trimming, or a careless flagman who is hiding a red light behind his white light. He is therefore "going it blind" for awhile, until he approaches near enough to properly classify the light. Another point is that most of these bull's-eyes are trimmed up so high, and throw so much light as to dazzle the eyes for a moment after passing, and that a red light is hardly discernible, if held in line of vision behind a white bull's-eye.

With all these points of danger, the prayer of all railroad men should be: Save us from all these white bull's-eyes, and give us a plain red and green switch light, for the green is so different from all the other lights, so mild to the eye as not to dazzle, and so readily distinguished from the red. The red can also be seen to a much greater distance, when used with a green, than when in company with a white light. VULCAN.

More Evidence.

Editor The Locomotive Engineer:

In the January issue of the ENGINEER, I see a correspondent from Wisconsin asks in regard to engines splitting their water.

I have had some experience in that little matter, and I cannot say that I was any better pleased at the time than the man from Wisconsin.

It used to be quite a common occurrence on the Atlantic & Pacific R. R. but I cannot say how it is of late years, as I am told they have much better water there now than when I was there. It would most certainly be very easy to burn an engine under the circumstances, but I never heard of its being done, although a great many engines were burned there about 1880 and 1881.

At that time there were quite a number of engineers from Boston running there under contract for a year, and they did not understand handling poor water.

The M. M. used to say that if they wanted to send Boston men out there, they ought to send Boston water with them.

The water was so bad that if you could see water in lower nut of water glass when shut off, you had a great plenty in the boiler, for when you opened the throttle and commenced to work your engine, you would see the water going out the stack. The boiler had to be blown out at every water tank, and washed out at both ends of the division.

The boys used to say they had a disease called "the long neck"—stretching their necks looking for water in bottom nut to water glass. "She was a daisy." MC.

CONTENTS.

On Designing Pea Coal Burners for the Elevated Roads.

With the failure to burn pea coal in the elevated engines, comes the news that officers of several surface roads that do burn this fuel have made the assertion that they, or some of the mechanics under them, could design engines, or boilers, for this service that would burn small coal.

General Manager Hain will, no doubt, give them all a show, but reminds them that the engines must not weigh more than 23½ tons, including 600 gallons of water and 1,800 pounds of coal, and have a wheel base not to exceed 16 feet, and be able to haul 5 car trains, each car weighing empty 23,000 lbs., containing 100 persons each, up grades of 2 per cent. and around curves of 90 feet radius, stopping and starting every fifth block, and making an average speed of 15 miles per hour. Not so easy as it looks.

Manager Hain is a practical mechanic, and was for many years a master mechanic; he commenced his railroad career on the Reading, one of the first, if not the very first road in America to burn anthracite coal. Mr. Hain has designed and had built under his supervision more than 1,000 locomotives, mostly hard coalers, and a few years ago was sent by the Baldwin Locomotive Works as an expert to Russia, to test the hard coal there, and design engines to burn it, which feat he accomplished with honor to himself and his employers. When any of these latter-day, hay-wagon, fire-box designers pose as experts, we would remind them that General Manager Hain is himself an expert of a high order as is also his general superintendent, John Campbell, to whose mechanical ability, as general foreman of the L shops, is due the present high performance of their engines, and who knows more about what these engines have done, can do, ought to do, and cannot do, than any other man in the employ of the Manhattan or any other road.

End of the Strike.

The great strike on the "Q" is over. It is doubtful if either side would repeat it under the same circumstances. It has hurt the road, crippled its motive power, undermined its business, and cost it well up in the millions of dollars, and ends by its officers agreeing not to become criminals by black listing the former employes. To the engineers, firemen and switchmen it has been a lesson, and has taught them several things that will make the orders all the stronger for the trial. Firstly, it has shown that strikes do not pay, that violence will always be attempted in every strike and the strikers blamed for it. It has shown the very bad method of distributing money to strikers—which can be remedied. It has shown the engineers that the firemen are men of their word, and honorable to the last degree, fewer firemen having become scabs than engineers; this lesson has long been needed. It has shown organized labor, far and near, what organizations can stand in case of trouble; it has shown that it is better to surrender half licked than to fight it out and get licked anyway—75 per cent. of the men were offered jobs in the proposed settlement, six months ago.

It seems to us that many brotherhood engineers will recall the fact that, in the eleven years that their grand order won its great name, the confidence of the public, doubled the pay and broadened the privileges of its members, that it had no standing Grievance Committees. Able men as officers, with power to act for the men, have been able to do much for the orders by diplomacy; the committees accomplish little by force.

It will take the road years to recover its losses; the orders will recover all losses in a year, but individuals will suffer longer.

Honest Work.

Clinton B. Conger, our correspondent, has been reappointed mechanical engineer by the Commissioner of Railways of Michigan. Gov. Luce evidently appreciates the work done by Bro. Conger in the past, for in his message to the Legislature for 1889 he says: * * * "In 1887 the Legislature authorized the Commissioner of Railroads to appoint a mechanical engineer as an assistant, whose duty it should be to examine the condition of engines, frogs, guards, switches, bridges, etc. The appointment was made, and I believe has been a great benefit to the roads, and to the employes.

"No difficulties have arisen in our State between companies and men, but, with such a vast system and army of employes, we are warned by experience that there is always danger of troubles and conflicts. The Railroad Commissioner mediates between the public and the companies, and it has been suggested that he and the mechanical assistant be authorized to aid in adjusting troubles, should they arise, between companies and men. And I commend to your consideration the propriety of constituting these officers a Board of Arbitration in company with some one to be selected by the company or companies with whom conflicts may arise."

Possible Cause of Granger Legislation.

Some time since a fit of dividend-requiring economy took off most of the mechanics and laborers on the N. Y., Phila. & Norfolk road. The management seemed to think that section men were an unnecessary luxury, even at a dollar a day, and now the low joints and high centers make the average passenger think he is a deck passenger on a Connecticut tin wagon. We observed that the engineer, on one engine at least, had to run with his hand on the starting lever of the Sellers' '76 injector—the track was rough enough to break it every few minutes. If such management (?) were risking their own lives alone, we would bid them good-by with a "Godspeed", but it is the employes who must toil for bread, and the unsuspecting passengers, who take the risk. It is no wonder that some of our roads have a chance to cry Granger legislation.

Price *vs.* Quality.

Mr. F. H. Stillman, of the well-known firm of Watson & Stillman, manufacturers of the Vreeland Transfer Jack, and other hydraulic machinery, has been appointed purchasing agent of the Gulf, Atlantic & Havana R. R. The road is a small one, as yet, but is liable to need considerable equipment, including a half dozen locomotives. The selection of a mechanic, instead of a cousin of the general manager, for the position of purchasing agent, is in the right direction. A mechanic usually looks to quality first and price afterward, instead of price first, last, and all the time. What our railroad equipment wants, is more quality and more price.

A Reform Needed.

When a railroad official so manages, or mismanages, his department as to make every employe uncertain of his position, dissatisfied, and under so many adverse rulings that they hardly know the official interpretation of rules and orders, that official is incompetent for the work, or the work has grown beyond his ability.

Such a feeling of general dissatisfaction the writer found on the D., L. & W. road, on a recent trip out of this city. Inquiry proved that the cause of all this was the alleged "pernicious inactivity" and unfair rulings of Supt. Andrew Reasoner, at Hoboken, N. J.

The men claim that Mr. Reasoner is no reasoner at all, that he punishes different men for the same offense, where one must be right and the other wrong; that he keeps men off, "pending investigation," for months at a time, and that he hears one side of a story and not the other—that, in fact, he is judge, jury, and executioner. And they cite more than one case to prove their assertions. If the facts set forth are true, and they appear to be, the men have just cause to be dissatisfied.

They say that some time since engineer Isaac Shields was pulling a freight train on a very foggy evening. He was hurrying away from an approaching passenger train, but this train got to the end of its run at Dover. On reaching Dover and doing their work, Shields got a signal to go, and he proceeded to the next station, where he found he had not got all his train. The caboose and several cars ran back to Dover—with no one on them—but did no damage. The conductor, rear brakeman and engineer were taken off, and Shields was kept waiting for a decision *for more than three months*. It was not Shields' fault if the conductor and brakeman were not on the rear of train; it was not his fault that it was so foggy that he could not see his tail lights, yet he was punished, and severely; for at the end of three months he was ordered to go to work *as a new man*. The trainmen were off about the same length of time.

Again, on Dec 6 last, a freight train broke down on the road, and the flagman stopped a following coal train. The head train was standing around a curve that went onto a drawbridge; when the train was ready to go the flagman came to rear of car and signaled engineer Weiler, of the coal train, to come ahead, and the caboose disappeared around the curve. The head train moved less than 200 feet and stopped again, the coal train moved 1,200 feet and struck the caboose—*with no flag out*. Had the flagman walked 100 feet, the coal train could have been seen before it started; little damage was done. Mr. Reasoner ordered the men off for investigation, he heard the conductor's story and the flagman's inside of a month, but he made five different appointments with engineer Weiler, and the latter made five round trips from his home at Port Morris, 500 miles, *and then was never allowed to tell his story*. About the middle of January he ordered Weiler put back to firing, and the crew are still off. Mr. Weiler did not go. Any railroad man would say, as do the D., L. & W. men, that the flagman was to blame, and if he was, Weiler was not. Both are not at fault.

Such work as this makes life a burden to conscientious railroad men, who above all things, want fair play. Why the engineemen of this road do not demand some remedy for this evil is more than we can understand, they must have a world of patience and forbearance. Such work would run against a snag in the West.

Pittsburgh Locomotive Works.

The Pittsburgh Locomotive Works built 96 locomotives during 1888, and rebuilt 14. Most of the new engines were very heavy ones, weighing upward of 50 tons each. These works were established twenty-two years ago, and during the first ten years built but 350 locomotives, many of these doing the works more harm than good, as they were so illy designed as to hurt the reputation of the makers. The writer is familiar with one road that had a few of them, and they had boilers but a little larger than the cylinders. No one would run one if he could get out of it, and the very name "Pittsburgh" was enough to give an engineer or fireman the chills.

Twelve years ago the works were shut down half the year, and the business of the concern at low tide, when the services of Mr. D. A. Wightman were secured as superintendent; he at once commenced to build locomotives of good design and put up in a workmanlike manner. The reputation of the works came up, old buildings were replaced by new ones, old tools went into the cupola and new ones stood in their places, until to-day these works are as modern and as complete as the best.

Now comes the announcement that the company will at once put up extensive buildings, and raise the capacity of the works to 250 to 300 locomotives a year.

The splendid reputation and success of these works are due entirely to the mechanical ability of Supt. Wightman.

Suburban Iniquities.

Everyone who knows anything about it, knows that the suburban train arrangements of American cities are notoriously inferior.

Trains that are run in competition with other roads are, as a rule, well equipped, on time, and moderately fast—to hold the trade. But suburban ticket buyers are, in a measure, helpless; they are the under dog in the fight, and the companies follow Bill Nye's advice, and "never strike a man when he is down—jump on him."

New York has the largest suburban traffic of any city on the continent, if not in the world, and the power furnished, cars used, and time made on a majority of the lines would disgrace the most countrified road in the country.

The trains are over-crowded, the engines small or old, and the speed well-nigh unendurable.

On half the roads a crowded train of commuters will start out and poke along at about twenty miles per hour and spend five minutes at every stop, and stop as often as possible.

Trains that are known to be almost entirely filled by people, for a town 30 miles out, have to stop to let off three or four persons for intermediate towns, and before they reach their destination take a siding and let an express by, that left town twenty or thirty minutes behind them.

What good reason is there that suburban trains should not make express time and make no stops?

Why cannot a train be made up to drop cars at stations?

Now the trains stop, the brakeman crawls under, cuts the hose, and then yanks the coupling apart, unlimbers the bell cord, and yells, "All right here." then the switch engine comes out and puts the car away, this delays five hundred passengers, is expensive, and in the way of express traffic

If the brakeman could disconnect the hose and uncouple the cars on approaching a station where it was desired to leave a car, and had a valve arranged at hand so that he could reduce the air in train pipe, thus setting the automatic brake at will, the car could be dropped from a fast moving train, and, with the help of a switch tender, thrown in safety onto a side track, and stopped either by the hand or automatic brake.

With a reliable man on each car, and two brakes at his command, there need be no fear of the car. Some may say it would be risky, but it can be no more so than stopping a whole train in front of an express to take a siding. What stands in the way of its success?

If all commuters in New York city could be assured that they could go home on an express train every day, the majority would feel just as if they had found a ten-dollar bill.

The long pending suit of Craig *vs.* Hodges & McCoy, which is really Craig *vs.* the Detroit Lubricator Co., for the control of the foundation lubricator patents, described by the Commissioner of Patents as:

"The combination of a lubricator provided with a sight feed, or observation chamber, in which oil rises through water in its passage to the discharge conduct for leading such oil to the part or parts of the engine to be lubricated, with a conduct to lead steam from boiler into condenser of such lubricator, and with another conduct within to lead steam from such condenser into the said oil discharging conduct,"

Has finally been decided in favor of Craig; in this decision the Commissioner reverses his former decision.

At the shops of the Atlantic Coast Line, Richmond, Va., we recently saw a piece of the plating of the Confederate ram "Merrimac," that showed a hard knock by one of the solid shots thrown from the "Monitor" The Tredegar Iron Works at Richmond rolled these plates, and the Old Dominion Iron and Nail Co. recently purchased the wreck and are cutting it up. Benjamin S Herring, who has been for some years a master mechanic on the Mobile & Ohio, was chief engineer of the "Merrimac" when she fought the "Monitor" in Hampton Roads.

At the coroner's inquest into the death of Conductor John C Ryan, killed in the railroad collision near Columbia, Pa., January 22, William Rogers, engineer of the colliding engine, admitted that he had fallen fast asleep, as had his fireman, and was only awakened when too late to avoid the collision. The verdict was that the accident was caused by Rogers sleeping at his post. He had been on duty sixteen hours.

We are indebted to Jno. Shields, M. M., for a photograph of a snow plow at work on the Mineral Range Railroad, of Mich., and also of a wreck on the Hancock & Calumet. Of the last affair a local paper says that Mr. Shields and his men replaced the turned-over engine and tender, and had them running between 1 and 7 P. M.

Books Received.

KINNE'S IMPROVED ENGINEMEN'S GUIDE, TIME AND POCKET BOOK Geo R. Kinne, Hornellsville, N Y

This work is issued by Mr. Kinne, who is traveling fireman of the Erie road. It is got up in a very neat pocket form, bound in red leather, with pocket and pencil. The main part of the book is blank sheets to keep time on, and have spaces for date, number of train, engine number, miles run, time allowed, name of person keeping the book, of conductor of train, and from what and to what station run There are blank leaves for memoranda in the back, and pages for keeping a cash account, and is very handy for any railroad man to have in his pocket. In the front there are some short rules about firing and handling engines, care of different kinds of brakes, the standard signals, and considerable other data, good, bad, and indifferent The explanation of an injector is, to say the least, original Were we firing an engine, we should have one in our inside pocket. It is worth something to know what you have done at the end of a month or a year The price is not stated

PIG IRON Including the Relation between its Physical Properties and its Chemical Constituents By Alex E. Outerbridge

This illustrated pamphlet is an extract from a lecture, delivered before the Franklin Institute, Phila., in 1888. Mr Outerbridge's position as chemist for seven years at the great wheel foundry of A. Whitney & Sons, has given him unusual opportunities for observation and research in this particular line.

COMBUSTION IN LOCOMOTIVE FIRE-BOXES. By Angus Sinclair. National Car and Locomotive Builder, publishers, 140 Nassau street, New York.

This little work of 21 pages is a plain elementary treatise on combustion, written for the average fireman and engineer, and in language they can understand These little books have been issued to the firemen of the N Y, L. E. & W Ry, and a circular accompanying reads:

"I take pleasure in presenting to you, with the compliments of the company, this treatise upon the consumption of fuel by locomotives, which has been prepared by Mr Angus Sinclair, the author of several works on locomotives, editor of the *National Car and Locomotive Builder*, Secretary of the Master Mechanics' Association, and for many years a locomotive engineer

"The economical and efficient consumption of fuel is one of the most important objects to be considered in operating a railroad, and the fireman who gives it the closest attention produces the best results. It is the policy of the company to promote its firemen to engineers as rapidly as the service admits of it, and the record made by each fireman in handling fuel will have great weight in selecting men for promotion to the position of engineers This treatise has, therefore, a personal interest for each fireman, and I trust that you will study it carefully and endeavor to profit by the information therein given

Yours truly, ROSS KELLS,
Superintendent of Motive Power"

Other roads might do something in this line with profit to themselves.

ASKED & ANSWERED

(6) E. C. S, Chuluota, Florida, writes:

My engineer requests me to ask the following: His engine, a Brooks mogul, 32-inch gauge, both while running ahead or backing up, runs to the left-hand rail. What is the cause? He says the left-hand journals are the smallest. *A*—If the engine is low on that side it will cause the crowding, as will also a difference in diameter of wheels or improper tramming; these defects must be remedied early, as, after the tire is worn down near the flange, it is difficult, if not impossible, to make them run on the rail any other place

(7) Jas. Mellen, Peshtigo, Wis., writes:

I am running a wood burner with a balloon stack, but do not like it. We had a straight stack with netting in front, but she threw too many sparks. Do you know of any good plan for wood-burner stacks? *A.*—In burning wood it is necessary to provide a large area of netting, in order to hold or break up wood sparks, the mesh should be as fine as 8 or 10 to the inch, and, in order to allow air enough to pass through, it must have a large area The straight, open stack, with a basket net inside, is the best thing we know of. Perhaps your trouble is on account of size of openings in screen

(8) F S E., Elizabethport, N. J., asks:

What is suction? Is the suction of a pump the same as that of an injector? *A.*—Suction is a name given, in mechanics, to a partial vacuum, however formed. The action of a pump plunger exhausts the air in the barrel and chamber, thus producing a partial vacuum; the pressure of the atmosphere then forces the water into the pump to fill this space The action of a jet of steam escaping through or across the open water pipe of an injector produces a like vacuum, and the water is pushed in to fill it. this is called suction. The means employed to produce a vacuum, or suction, makes no difference with the suction

(9) J. W Debolt, Lufkin, Texas, writes:

Supposing we have three wheels keyed on an axle, the two outside ones larger than the center one, and all placed on rails, the center rail being elevated to make up for difference in diameter of wheels, would there be any slip in the middle wheel in revolving? If so, please explain. For example, the outside wheels are six feet, they would make three times and a fraction of the diameter in one revolution, and the center wheel was only two feet, it would make only one-third the same lineal measure I claim that in the little wheel working from the center of the axle there could be no slip. *A.* If more than half the weight of the three wheels and axle were on the outside wheels, the center one would have to slip; if it carried more than half the weight it would slip the outside wheels Try it with a spool on a stick.

The Locomotive in America.

BY WILLIAM BARNET LE VAN

SECOND PAPER.

The first carriage propelled by steam in America was the "*Oruktor Amphibolos*," or amphibious digger, designed by Oliver Evans, the first regular steam engine builder in the United States.

In 1804, the Philadelphia Board of Health ordered of Evans a steam dredging machine for cleaning the docks of the city. The dredger, when finished, was named by Evans as above, and he determined, when it was completed, to propel it from his workshop to the Schuylkill river, which was successfully done—to the astonishment of a large crowd of people gathered together to see it fail. Before launching, July, 1805, the machine was run during several days around Centre square (the place now occupied by the Public Buildings). Finally the dredger was launched at Market street wharf, Schuylkill, and the engine having been connected with the paddle-wheels, she steamed down the river and up the Delaware to her dock.

The high-pressure engine was applied to turn the wheels of a carriage that carried boiler, engine, etc., the object being to use steam power to turn the wheels, and thereby haul other carriages carrying loads. In plan and principle, the parts and combinations included all that is essential to the locomotive as a tractive, motive power.

The results of the experiment made by Evans were not of a character to make the locomotive date from his acts, but was the step or entering wedge towards the use of locomotives.

The boiler used was the same as was used for driving his high-pressure engines in 1780, and was a multi-tubular boiler, but differed from the present boiler now in use by having the water in the tubes, in place of around them. The Cornish boiler with one flue and the Lancashire boiler with two flues were both invented and used by Oliver Evans.

Peter Cooper, of New York, deserves the honor, among the other honors of his useful life, of being the first to introduce into actual service the locomotive in America

In 1828, Mr. Cooper was in business in New York city, his native place. His mother and grandmother were both born on the present site of St. Paul's Church, Vesey street and Broadway, and his mother remembered seeing the stockade still standing, which had been erected to keep the Indians out of infant New Amsterdam. Mr. Cooper had bought as a speculation the entire magnificent tract of land in Baltimore, now owned by the Canton Company. Baltimore was then a city of 75,000 people, rich and prosperous, and had entered upon the railroad era. On July 4th, 1828, the corner-stone of the Baltimore & Ohio Road was laid, with imposing ceremonies, by Charles Carroll. It was pushed energetically—a little too much so, in fact, for, when *thirteen* miles had been finished, it was found that the short curves around the rocks to save cutting could not be used, experts declaring the line impracticable, as no steam wagon could run around them. Five per cent. had been paid in, and shares had been sold at an advance of *seventeen* per cent., such was the zeal and confidence of the people. But the experts' statements becoming known, operations were suspended, the chill was immense. Mr. Cooper, then thirty-eight years of age, saw new disaster to himself in the depreciation of his tract of land, should the road fail. He proposed to the directors to construct a locomotive that should be available on their line. They were willing, but incredulous. He determined to make the attempt, and brought down from his glue factory in New York city a single cylinder engine, 3¼ inches in diameter and 14½ inches stroke of piston, procured wheels 30 inches in diameter and other appliances from the railroad company, and in a few weeks ran out upon the railroad track the first American locomotive

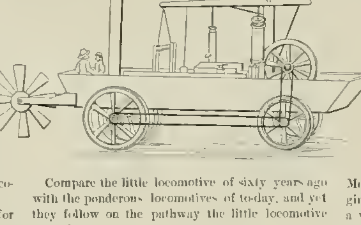
Mr. Cooper, unable to find such tubes as he needed for his boiler, used gun barrels.

This locomotive had a vertical boiler, and the draft was urged by mechanical means—a revolving fan. The wheels were connected to the crank-shaft by gearing. The whole machine weighed less than a ton.

The trial trip was to take place on a day set, but the night before, a thief stole all the copper steam and other connections and brass cocks from the infant machine, and caused some further delay.

The trial trip was run, Mr. Cooper himself acting as engineer; and when his wheezing little baby locomotive threatened to lose too much steam, he held down the safety valve with his own hands. The run was made with one carriage, carrying thirty-six passengers, making *thirteen miles* in less than one hour, and moving, at some points on the road, at the rate of *eighteen miles an hour*. That night all Baltimore was happy.

This locomotive was considered a working model only, and was rated at one horse-power The engine, on the trial, worked up to 1 43 horse-power, and drew a gross weight of 4½ tons.

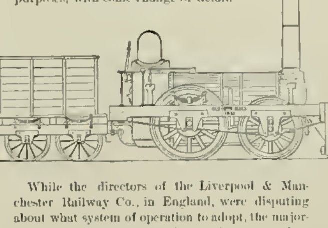


Compare the little locomotive of sixty years ago with the ponderous locomotives of to-day, and yet they follow on the pathway the little locomotive opened.

Ross Winans, writing of this trial of Cooper's locomotive, makes a comparison with the work done by Stevenson's "Rocket," and claims a decided superiority for the former He concludes that the trial established fully the practicability of using locomotives on the Baltimore & Ohio Railroad at high speeds, and on all its curves and heavy grades, without inconvenience or danger.

Mr. Cooper made the above experiment at the *same time* that Robert Stevenson's "Rocket" was run on the Manchester & Liverpool Bailway, England.

The fact is, that applying the steam engine to locomotion was regarded as a much smaller feat in America than it was in England. The representative engine in England, at the time railways were first started, was the heavy, slow-moving, condensing engine of Watt. Radical changes were necessary to convert that engine into a locomotive. America, on the other hand, had the high-pressure, high-speed engine, invented by Oliver Evans, and it was well adapted for land transportation purposes, with some change of detail.



While the directors of the Liverpool & Manchester Railway Co., in England, were disputing about what system of operation to adopt, the majority favoring stationary engines and rope traction, the directors of the Baltimore & Ohio and South Carolina railroads, unanimously decided to operate their railroads with locomotives, and gave their general managers directions to have locomotives built. The second railroad in the United States to use locomotives was the South Carolina Railroad, being built expressly for steam locomotive power.

The first regular American locomotive, the "Best Friend," was constructed in the year 1830, in the city of New York, at the West Point Foundry, then at the foot of Beach street, North River. It was designed by Adam Hall, and was sent to Charlestown, South Carolina, and placed on the South Carolina railroad. It was in successful operation for some months, when the boiler exploded.

The second locomotive, the "West Point," was built in 1830, or early in 1831, by the same works and for the same railroad company. Early in 1831 another locomotive, the "De Witt Clinton," was constructed at the same establishment, and in July of same year it was placed on the then Mohawk & Hudson Railroad, now a part of the New York Central line. The cylinders were 5½ inches diameter, the stroke of piston being 16 inches. The four wheels were each 4½ feet in diameter. The connecting rods worked upon double cranks in the front axle. The boiler had about thirty flues of copper, 5 feet long, 4 inches in external diameter, and one-quarter inch thick. The weight of this engine was about four tons.

On the 4th January, 1831, the Baltimore and Ohio Railroad Co. offered $4,000 premium for the best American locomotive of 3½ tons weight, which should draw 15 tons at fifteen miles an hour on a level. The boiler was to use as fuel, anthracite coal; it was to have four wheels, coupled together, four feet between centers, in order to pass around curves of 400 feet radius. The steam pressure was not to exceed 100 pounds to the square inch, above the atmosphere. The locomotives were to be delivered for trial upon the road, on or before the first of June, 1831, and the sum of $3,500 was to be paid for the locomotive which should be adjudged to be best.

Three or four locomotives were entered for competition; the prize was awarded to Messrs. Davis & Gartner of York, Pa., whose engine was named the "York." The locomotive had a vertical flue boiler and vertical cylinders, with four coupled wheels, thirty inches in diameter. It was altered considerably after being placed on the road.

This firm afterwards built another locomotive, named the "Atlantic," that was the first of what were afterwards known as the "Grasshoppers," which were used for many years on the Baltimore & Ohio Railroad. Some of these locomotives were in use on that road quite recently (1883), and some of them were in continuous service for fifty years.

The "Grasshoppers" were succeeded by what is known as the "Coal-crab" locomotive. In these the cylinders were placed horizontal, and they were connected to cranks in an intermediate shaft, which was geared to a second shaft, which also had outside cranks to which the driving-wheels were coupled. The vertical boilers were retained.

As an example of the performance of the above locomotive, on the 16th day of August 1832, one of the small locomotives ran an excursion train out of Baltimore, consisting of six passenger cars containing ninety passengers, the train ran forty-one miles out and the same distance back—part of the way (for four miles) up-grades, varying between 32 and 57 feet per mile, the speed on these grades being thirteen miles an hour, and for the whole trip each way, including stops, a fraction over thirteen miles an hour.

In 1832, William T. James completed at his establishment, Eldridge street, New York city, a locomotive containing the *first* link motion used in America (now universally used all over the world, and in fact wherever locomotives are in service). This locomotive was run forward and backward across the yard of the machine works, a distance of fifty feet, eight times in sixty-three seconds, including stops. (None but the most efficient reversing gear, such as the link motion is, would have secured such a result.) Each cylinder had two eccentrics, one for the forward and one for the backward motion. The ends of the two eccentric rods in connection with each valve were jointed at a distance of nine inches apart, to a curved link, which could be raised or lowered as required, upon a block jointed upon the end of the valve spindle. The link was designed solely as a means of reversing the engine with certainty when in motion. Mr. James found in setting the eccentrics (the valves having one-half inch lap on each end) that it would cut off the steam; he then used the link to vary the expansion of the steam at different points of the stroke, thus making quite a saving in fuel. The boiler used anthracite coal, and steamed freely. It was run for some time on the Harlem Railroad, where it worked satisfactorily. In 1833, it was sent to the Baltimore & Ohio railroad, but soon after having been placed in regular service, it exploded its boiler. This locomotive also had a "spark arrester," substantially the same as was in use on all American wood-burning locomotives.

In 1832, Adam Hall, of the West Point Foundry, constructed the locomotive "Experiment," the first to which the swiveling truck was ever applied, this application having been made under the direction of Mr. John B. Jervis, the then engineer to the Mohawk & Hudson Railroad. The "Experiment" had 9½-inch cylinders, 16-inch stroke five feet driving-wheels, a truck of four smaller wheels, and being intended to burn anthracite coal, the grate bars were five feet long. The whole weight of the locomotive was seven tons.

The English locomotive on that road, built by Messrs. Robert Stephenson & Co. of Newcastle—the "Robert Fulton"—after a year's run, had the front wheels removed, and a swiveling truck substituted, similar to that of the "Experiment."

This feature of construction adapted the locomotive for service on our undulating and uneven tracks, and also enabled it to pass with facility around our short curves.

Matthias W. Baldwin, the founder of the present Baldwin Locomotive Works, was the first to introduce into the United States the general features of the improved class of English locomotives, as developed upon the Liverpool & Manchester Railway, immediately subsequent to the trial of the "Rocket." Mr. Baldwin had built, in 1831, a working model of a locomotive for Peal's Museum, in Philadelphia. On the 25th of April, 1831, the miniature locomotive was put in motion on a circular track made of pine boards covered with hoop-iron, in the rooms of the museum. Two small cars, containing seats for four persons, were attached to it, and the novel spectacle attracted crowds of admiring spectators. Both anthracite and pine-knot coal were used as fuel, and the exhaust steam was discharged into the chimney, thus utilizing it to increase the draft.

The Philadelphia & Germantown Railroad Company gave Mr. Baldwin an order for a locomotive in the spring of 1832, when it was completed, and open for travel with a double track of iron "T" rails resting in cast-iron chairs, which were securely fastened to stone blocks by means of screw bolts. Four-wheeled cars were used, propelled by horse-power. This being rather a slow process of locomotion, the above locomotive was ordered. This locomotive was completed, christened "Old Ironsides," and the trial trip was made November 23, 1832. (See cut on page 10.)

In the summer of 1833 the Ironsides was run over the road at the rate of *sixty-two miles an hour*—several persons on the locomotive having carefully timed it, among whom was Dr. Patterson, of the University of Virginia. The locomotive ran 2¼ miles, in which were four very short curves, in 3¼ minutes, or at the rate of *forty miles an hour*.

Mr. Baldwin was the first to introduce the fastening of the cylinders to the outside of the smoke-box, and what was much more, he patented and first used the metallic ground joint for cylinders and steam-chest covers and steam pipes.

The "Ironsides" was a four-wheeled locomotive, similar to the English practice of that day, as shown in the "Planet" class, and weighed, in running order, about seven tons.

The Baldwin Locomotive Works have turned out over 9,750 locomotives since the "Old Ironsides" of 1831. That locomotive was nearly a year in building, and the one thousandth locomotive was only completed in 1861, making an average of only thirty-three annually for the first thirty years; the two thousandth locomotive was turned out in 1869, the three thousandth in 1872, the four thousandth in 1876, the five thousandth in 1880. The present capacity of the works is equal fifteen per week, or two and one-half per day.

In the recent trials of pea coal on the L roads in this city, 67 pounds of the cheap coal were burned per mile, as against 47 of broken coal.

In the Roundhouse and Repair Shop.

More Steam Pipe Letters.

TERRE HAUTE & INDIANAPOLIS.

Last from one to three years; use hard brass rings on short fronts, cast-iron on extensions. Front end must be kept air-tight, or joints may not last a month. Time depends on conditions and men; bad joints, two hours. We scrape to a bearing, grind very little. Cost, from $1 to $1.50.

W. A. MILLER,
Terre Haute, Ind. R. H. Foreman.

ST. LOUIS, IRON MOUNTAIN & SOUTHERN.

Time they run all depends on how they are handled. Takes about eight hours to grind; cost, $4.25, sometimes a little more.

A. MUMMERT,
De Soto, Mo. R. H. Foreman.

UNION PACIFIC.

When we want to get out flues, about once in two years. Time depends on condition of pipes; ordinarily four hours. Ordinary cost, $2.50 to grind in four bad joints.

J. E. O'HEARNE,
Omaha, Neb. Gen'l Foreman.

On an average, once a year, regular man does work in from four to ten hours.

C. S. SMITH,
Pocatello, Idaho. R. H. Foreman.

OHIO & MISSISSIPPI.

Only when flues are removed, use an apprentice or handy helper. Time, about a day and a half; probable cost, $4.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 170,000 cars. This includes 75,000 freight cars. Orders have been received for 20,000 of the improved quick-action brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

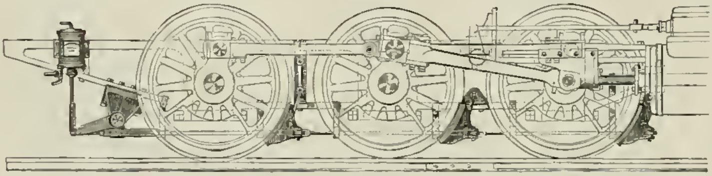
BRAKES Made to Order for any Special Form or Class of Engine.



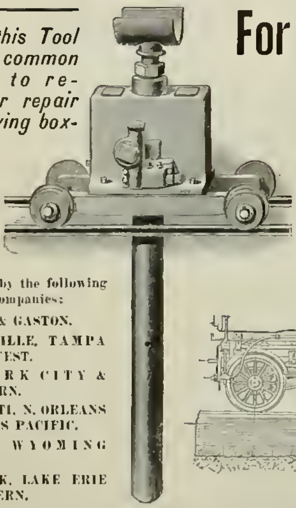
All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear and Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM or AIR.

VREELAND'S TRANSFER JACK

For Removing and Replacing Locomotive Drivers and Trucks

WITH this Tool it is common practice to replace or repair both driving boxes without the Engine losing a trip.



In use by the following Railroad Companies:

RALEIGH & GASTON.

JACKSONVILLE, TAMPA & KEY WEST.

NEW YORK CITY & NORTHERN.

CINCINNATI, N. ORLEANS & TEXAS PACIFIC.

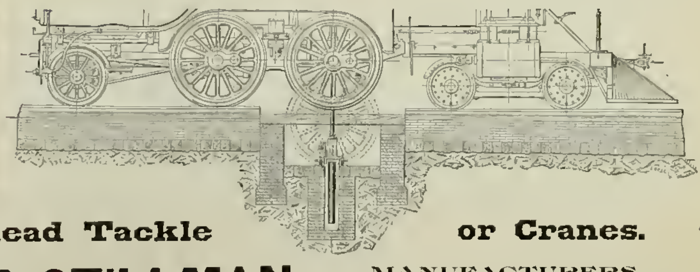
ERIE & WYOMING VALLEY.

NEW YORK, LAKE ERIE & WESTERN.

WITHOUT JACKING ENGINE UP.

NO FLOOR SPACE REQUIRED for THE TOOL.

☞ The Jack is mounted on a truck running in its own pit, at right angles to and beneath the other pits. Driving wheels may be taken out and transferred to any track in the Roundhouse or Shop. *Nothing is in its way, and it is in the way of nothing.*

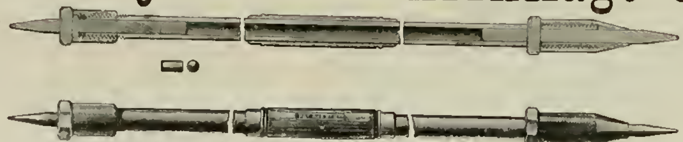


No Overhead Tackle or Cranes.

WATSON & STILLMAN, MANUFACTURERS. 210 E. 43d Street, New York.

Patent Adjustable Shrinkage Gauge.

Pedrick & Ayer, 1025 Hamilton St., PHILA., PA.



Special Tools FOR Railway Repair Shops.

By the use of this Gauge, the boring of Locomotive Tires can be accurately done, and with proper shrinkage to any desired allowance. It is so arranged that wear on the points is entirely overcome, there is no wear on the measuring pieces, they being hardened and ground to micrometer measurements. It is made to conform to the Master Mechanics' Standerd of Sizes and Shrinkages as adopted by them in June, 1886.

TOOLS FOR LOCOMOTIVE BOILER WORK.

The Cut shows our

PATENT PLATE BENDING ROLLS,

Specially adapted to this work.

HILLES & JONES, M'frs.,
WILMINGTON, DEL.

Represents all sizes that are driven by belts.

It is but the work of a moment to balance the top roll and lower the hinge housing to take out the plate when a full circle is bent. The rolls are all made of solid wrought iron, the balance bar being a part or extension of the top roll. There is a cast-iron bed-plate under the entire machine. To save any shifting of belts we put in Friction Pulleys which enable the rolls to be started, stopped or reversed instantly.

THE GLACE LOCOMOTIVE CHECK VALVE.

Three Separate, Distinct and Independent Valves in One Case, insuring Freedom from Sticking, and obviating difficulties experienced with old-style single valve.

The Power Brakes on Brooklyn Bridge Trains.

The cable cars on the great Brooklyn Bridge are equipped with vacuum brakes, the vacuum being maintained under each car by a pump, operated by an eccentric on truck axle. There are four men on three-car trains, and each man handles the brake on his car independent of what the others may do. Between the hours of 1 and 5 A. M., when the service is lightest, the trains are hauled by locomotives and the cable is at rest; then the hose between the cars are coupled up, and the brakes are under the control of the engineer, as well as every car conductor.

The locomotives are 4-wheel connected switch engines, with turtle shell tanks, and are used at each end of the bridge to shift the trains from the incoming to the outgoing tracks—a job that keeps them busy when trains are running from a minute to a minute and a half apart. The men only work eight hours, so that the engines are not only double, but treble crewed.

A throttle gland is not an easy thing to get or keep clean, it gets awful hot, and the studs prevent the back being easily reached, yet it is always in sight. A ring of Russia iron or brass, that will just reach from the boiler to the face of gland, and tight enough to stay on, is easy to clean, looks well, and prevents dirt from collecting where it is not wanted. The joint should, of course, come under and out of sight.

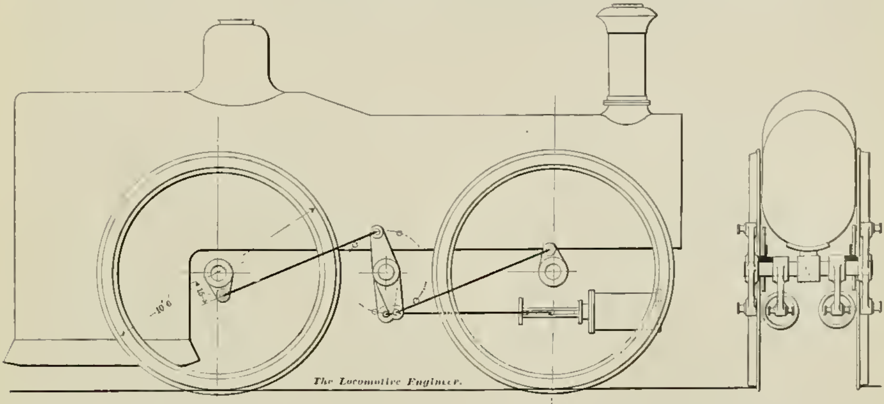
On receipt of the news of the "Q" strike settlement the *Railroad Patriot*, of St. Joe, Mo., dropped dead.

Historical Locomotives.

SIXTH SKETCH

By John J. Bingley.

In looking over your valuable paper, I notice some chapters on historic locomotives. It brings to my mind the time when I was an apprentice at the Railway Foundry in Leeds, England, about the year 1848, and one was built at that works. All engines at that time were built with inside cylinders and crank axles on the main drivers. These axles often broke, causing loss and delay. There was also at that early day a demand for faster trains. To try to remedy the one, and accomplish the other, Mr. James Fenton, the chief engineer of the works, designed a rather strange machine, of which I send you a sketch. We were building some passenger engines with one pair of drivers, and single pair of small wheels back and front, called the "Jenny Linds," as the Swedish Nightingale had just entered on her musical career. So Mr. Fenton called his new design the "Laublash," after a celebrated bass singer of Germany. As well as I can remember, there were two inside cylinders 20 by 30", the crossheads worked in guides, but the connecting rods were connected to two very strong rock arms which were attached to the frame by heavy boxes; on the out ends of these rock arms were double cranks which were about the center of the two pair of driving wheels, which were ten feet six inches in diameter; these wheels were all wrought-iron—hub, spokes and tires. The outside rods, as you will see, were connected from these double cranks to the crank-pins on the wheels, the lower crank to the forward and the top one to the back wheel, at each stroke of the pistons the rock shaft vibrated just enough to cause the cranks to revolve; on account of the height of the wheels, the boiler was built oblong, to bring the top above the wheels. The eccentrics were on the back axles. The engine was built very strong, and very highly finished, and Mr. F. was very sanguine of success in gaining speed, and doing away with the crank axle. It was finally finished and run out for trial and worked very well; some very heavy trains (so considered in those days) were hauled, and a speed of 84 miles per hour was said to be made on one trip. After running two or three weeks on trial, it was brought back to the shop and put in apple pie order for the Government Inspector to pass judgment on it before it would be allowed to go into regular service. He carefully examined it all over and pronounced the work first-class. But the design was not good, the engine having only two axles, he said if one should break, the engine would go over, therefore he condemned it as not safe; this was tried to be remedied by putting a pair of small wheels between the drivers, but this did not make it any better, and I saw her pulled to pieces, cut up, and worked up under the steam hammers. I only know of one man now in this country, E. L. Jones, of Wricksville, Ohio, who worked on that engine; he made the driving wheels and forged the cranks.



The Locomotive Engineer.

The combustion chamber, like the feed-water heater and the traction increaser, has its seasons of prosperity and adversity. It bobs up in the morning like the perpetual motion, but by noon it has been tried and found wanting. Like lots of other things about a locomotive, "it ought to—but it don't."

On the Use of Tin for Journal Bearings.

Block tin is fast gaining headway as a journal bearing. Within the past few years we find it on crosshead gibs and in rod brasses about as much as other metals, and always with better results; as a lining for truck brasses it has no equal.

In the discussion on hard or soft journal brasses under cars, recently held before the Western Railway Club, the statement was made that hard journal bearings ran with less friction than soft, but did not run cool so long, and cost more in the start.

Mr E. P. Monroe, manager of the U. S Metallic Packing Co., has made some interesting experiments during the last few years that have an important bearing on this subject

He experimented with metal of every description, with a view to finding the best friction metal, and attained the same results with all excepting tin.

First he made a pair of face plates so perfectly fitted that the air would lift lower one when its face was in contact with its mate. These plates he was careful to finish and use without a drop of oil. Placing one plate on the other, he pressed it down by hand, and drew it across the other, and then examined the faces with a glass; they showed the lines of contact, and had a fine, dark powder on them, that resembled fine emery; was sharp, but could be crushed, continued the rubbing process, and found that the fine powder gradually worked itself into globules that imbedded themselves in the softer metal. These globules were so hard they could be driven into the face of an anvil, and appeared to be carbon points, such as used for diamond drills Mr. Monroe found that constant friction between any of the hard metals produced these carbon points, some large, some very small, and found, on examination with microscope, that they were imbedded in the metal about three-quarters of their diameters, and composed the *roughness* we find in a cut journal that has been hot.

In turning up old shafts, car axles, pins and wheel tire, the workman will find these hard spots, and must take a deep enough cut to go under them, or cut them out with a chisel—as is often done in tire turning.

In these experiments, tin or babbitt metal (which is 88 per cent. tin) could be crushed by excessive loads, and melted by friction without forming any of these points, either on the journal or the box.

Engine trucks that give trouble from heating with the best of bronze or brass journal bearings are greatly benefited by lining the brass with tin.

Crossheads run well with a bearing of block tin, and will not cut the guides, and for cone rings in metallic packing it is the only metal that will not cut or score the rod.

If you have a particularly annoying pet in the shape of a box that keeps hot—unless it is the fire-box—try tin, it can do no harm, if it does no good.

Master Mechanic E M. Roberts, of the Ashland Coal and Iron Co.'s road, is building a heavy mogul engine at his shops, Ashland, Ky. He recently turned out an 18x24 passenger locomotive weighing 90,000 pounds. Mr. Roberts is the inventor of the Big Sandy sand drier—a good one.

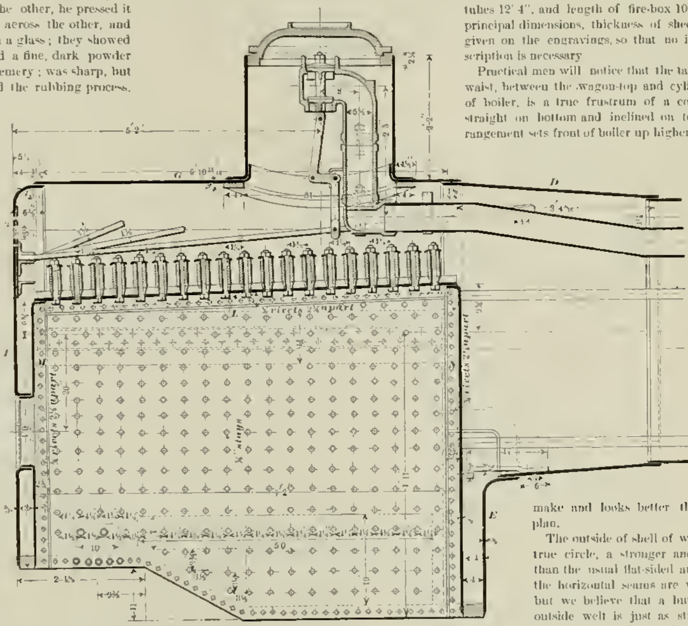
The *Union Pacific Employes' Magazine* comes out with a new cover; the engraving is a work of art.

A Curious Coincidence.

A couple of months ago we wrote up a little account of a visit to the Dickson Locomotive Works, Scranton, Pa., and mentioned that some of the neatest and cleanest engines in the country were the "Watch-charms," built by this company and employed on the Brooklyn Bridge. "Watch-charm" is railroad for a very small, neat locomotive

One of our readers in the far West took the statement literally, and ordered a watch-charm from the works, and just here comes the odd part of the story: Several years ago these works did make watch-charms in the shape of a locomotive, gotten up very nicely, costing some $18 or $20 each. Most of the "charms" they build now weigh upwards of 100,000 pounds. Our Western reader ought to get one of those charms, the works ought to see that this is no advertising medium; and all ought to study railroad Sanskrit.

The *Station Agents' Journal* has suspended.



Compound Locomotives.

The Webb Compound Locomotive is here, and the Pennsylvania folks are making some experiments with her for their own benefit. When she gets into her regular contract—to do as well as the class *K*.'s on less coal—she will be open to calls and criticisms from American enginemen, but we imagine she will have her hands full with her contract. However, in the end, compounding or some other scheme that will let us expand our pressure down much lower, has got to come. The lesson for American enginemen to learn in this matter, is to watch carefully all these experiments, see where they fail, how they lose and where they gain, and be ready to make the best of every device placed in their hands. If all the engineers on earth should condemn compounding, without giving it a fair show, so much the worse for the engineers if compounding has merits and advantages not yet brought out. We hope to present a report on the work of the Webb in an early issue

The new order, the Brotherhood of Railroad Conductors, seems to be gaining ground in the West.

Copyright Ignored.

The Journal of Railway Appliances is getting out an interesting paper. Some of the articles in the January number, four or five, we considered of enough interest to travel several hundred miles to get the data and write up for this paper, and the above-mentioned journal stole the interesting points outright, as well as some of the points made by our correspondents. We wish the editor of the *Directory of Railway Appliances* would hunt up some *appliance* that would enable him to attach the name of this paper in italics to the end of articles lifted bodily from our columns. We are grieved to think that any newspaper man could be dishonest—we thought they were all little he-angels with a bell on.

Georgia Pacific Boilers

On this and page 3 we show some details of boiler construction. These boilers were built by the Richmond Locomotive Works, for the Georgia Pacific R'y.

The smallest ring is 54" diameter, the length of tubes 12' 4", and length of fire-box 100". All the principal dimensions, thickness of sheets, etc, are given on the engravings, so that no itemized description is necessary

Practical men will notice that the taper ring, or waist, between the wagon-top and cylindrical part of boiler, is a true frustrum of a cone, and not straight on bottom and inclined on top; this arrangement sets front of boiler up higher, is easier to make and looks better than the old plan.

The outside of shell of wagon top is a true circle, a stronger and safer form than the usual flat-sided arrangements, the horizontal seams are well secured, but we believe that a butt joint with outside welt is just as strong, neater, cheaper, and easier repaired; the placing of these seams so low down and in the way of side sheet stays, is not usual practice, they are generally placed about on the line of crown sheet, where there are no stays to side of shell, the very latest practice being the rolling of entire shell sheet of fire-box end in a single piece, thus doing away with horizontal seams.

The method of placing ends of crown bars on extended edge of side sheet has its friends and its enemies, and, like cast guides, works well on one road and badly on another. In bad water we should prefer the arched bar, with ends resting on joint of crown and side sheets.

The thimbles under the bars are tapered toward the crown sheet, and the bolts have hexagon heads in fire box, instead of oval rivet heads. The boilers appear to be well made, and are as neat in proportions as we have ever seen on 10-wheeled engines.

The American Railway Master Mechanics' Association will hold its 22d Annual Convention at Niagara Falls on June 18th next. If any of the M. M's are afflicted with high-water engineers, they should bring 'em along and show them that there is no hope of their getting to the top in the high water art. Niagara has the bulge.

Massacred in Cold Blood.

Every week the *Railway Age* collects and publishes, under the head of "Casualties" a list of accidents to train men, and the specimen below is only an average sample of these weekly lists. It will be seen that the great majority of these accidents are caused by the delay or refusal of the railroad companies to apply automatic couplers. If as many passengers as this were killed and maimed every week by some big accident, where the fault could be plainly traced to poor equipment, the friends of the victims and the public in general would make it hot for the roads in more ways than one. Look at this list of mangled corpses and crippled human beings, think of the families that depended on them for bread, think that these men are mostly young, vigorous, valuable men, and think if you have a part or a voice in staying the hand of this awful plague. The *Railway Age* does not, nor cannot, hear of or publish more than half of the victims of the twin juggernauts—crush couplers and fiddlestring brakes. Railroad men far and near ought to petition Congress for a law compelling every railroad in the land to apply, and at once, automatic couplers and power brakes to every locomotive and car in the country. It is a standing disgrace upon our civilization that this people tolerate such a list of weekly murders—for murder it is, pure and simple:

H Bolton, a switchman, was caught by an engine and injured while making a coupling at San Francisco, Cal., Nov. 10.—Benjamin McNally, switchman Southern Pacific, had his foot crushed so seriously that it had to be amputated while coupling cars at Sacramento, Cal., recently.—Joseph Parker, brakeman Pittsburgh, Cincinnati & St. Louis, had his right hand crushed while coupling cars at Columbus, O., Nov. 13.—H L. Gibson, brakeman Louisville & Nashville, fell under the wheels while coupling cars at Maplewood, Tenn., Nov. 13, and had an arm taken off.—Michael O'Brien, switchman New York, Lake Erie & Western, caught his foot in a frog while coupling cars at Hornellsville, N. Y., Nov. 10, and was run over and killed.—Charles Brown, brakeman Fort Worth & Denver City, fell between the cars while switching at Quanah, Tex., Nov. 13, and was run over and his left leg taken off.—A J. Moody, switchman Union Pacific, was run over and had his right leg crushed while coupling cars at Schuyler, Neb., Nov. 15.—William Carter, brakeman Chicago & Alton, was run over and killed by a freight train near Mexico, Mo., Nov. 12. He was setting a brake when the rod broke, letting him fall to the track.—John McCarty, engineer Chicago & Northwestern, jumped from his engine at Escanaba, Mich., Nov. 18, to escape a collision, and fell under the wheels and had both legs cut off.—James Hayes, switchman Chicago & Northwestern, fell from a moving engine in the yards at Chicago, Nov. 18, and was run over and had both legs severed.—Chas. Edwards, switchman Denver & Rio Grande, was run over and had a leg taken off while coupling cars at Trinidad, Colo., Nov. 15.—Michael J. McCarthy, brakeman New York, New Haven & Hartford, fell from a moving train at Hartford, Conn., Nov. 8, and was run over and instantly killed.—George Thain, brakeman Southern Pacific, fell from a moving locomotive at San Francisco, Cal., Nov. 11, and was run over and killed.—A conductor named Webb, on the Gulf Colorado & Santa Fe, had his hand crushed while coupling cars at Weatherford, Tex., Nov. 14.—H Wilson, baggageman Gulf Colorado & Santa Fe, had his hand crushed while making a coupling at Woodstock, Tex., Nov. 13.—Joseph Gorman, fireman New York, Lake Erie & Western, fell from his engine near Hancock, N. Y., Nov. 17, and was instantly killed.—Samuel Gregg, fireman Gulf Colorado & Santa Fe, was seriously injured near Berwyn, I. T., Nov. 19. He was shoveling coal into the furnace, when one of the flues blew out, the steam striking him with such force as to throw him from the engine. Besides being severely burned by the escaping steam, he had his foot crushed and received serious internal injures.—George Sprettle, a switchman, was run over and had a foot taken off by a passenger train at St. Paul, Minn., Nov. 19.—Louis Brooks, freight conductor Pennsylvania Railroad, fell from a moving train near Kinzer's, Pa., Nov. 19, and was run over and instantly killed.—James T. Alvey, track-walker Louisville & Nashville, was run over and killed by a freight train near New Haven, Ky., Nov. 18.

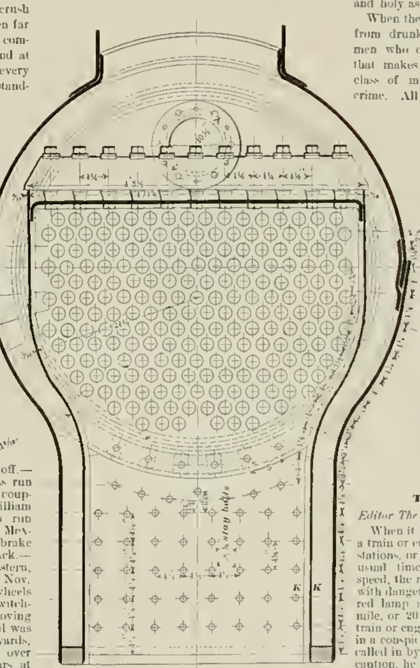
Car builders report a falling off of orders.

R. & A. Shops.

The Richmond & Alleghany shops at Richmond, Va., are the cleanest railroad shops in the city. They are situated near the Tredegar Iron Works, at the foot of Gambel's hill, and, like the road, are not over six or eight years old; the roundhouse is of brick, with an iron girder roof, and a half-finished door arch supported on a temporary wooden brace which plainly says: "To be continued." The tools in the shop are all modern, and arranged with ample room between them.

The motive power is principally Grant engines, and they are kept up in very good order, and above the average for cleanliness.

Master Mechanic Hassman came up from the ranks, having been foreman in these shops a few years ago; he is a progressive mechanic, and shows it in his work; he is the inventor of the benzine tire-heater, a very simple device, that can be made in any shop, and, while not so quick or good a heater as other and more elaborate ones, is also less expensive. General Foreman Henry Evans is a graduate of the Paterson locomotive shops, and the man who insists on a broom for the floor and hot water for the windows.



Steam-heated cars are common now, and seem to have come to stay. As far as uniform heat is concerned they are little if any better than stoves, with the same amount of attention, but are undoubtedly safer in case of wrecks. Some anti-fire heater that is independent on each car would be the proper thing, but that problem is as yet unsolved. With a continuous heater, and careful and intelligent attention in each car—governed by a thermometer in the center, and not by the whims of passengers—good results and comparative safety are secured.

The rocking grates used on the Richmond & Danville road are merely flat bars across the fire box, arranged to rock; these bars are perforated with ¾" holes, giving not over 25 per cent opening, yet they burn soft coal on them very successfully.

Correspondence

Send a Thief to Catch a Thief.

Editor The Locomotive Engineer:

If you read the daily papers very closely, you will notice that, in a bill introduced in the Wisconsin State Legislature, railroad conductors shall examine and report if an engineer takes a drink, on or off duty.

Should the conductor be in the habit of filling up, how could he smell it on the engineer? Have they always been sober, or the engineers always drunk, so as to necessitate the watchful care of the all-seeing eye of the conductor?

This law (?) looks to a man up a tree as if the framer had been convinced that all the engineers were a drunken lot, and all the conductors as pure and holy as a martyr's tombstone.

When the officials of a road cannot tell sober men from drunken ones, they should be replaced by men who can tell. The introduction of any law that makes spies, spotters and informers of one class of men, opens up a chance for abuse and crime. All the honorable men now employed as conductors would refuse to obey such a law, and all the scoundrels would lave in its (to them) refreshing waters.

The Solons of our State are also figuring on a color blind law for engineers—no good engineer wants to run with drunken men, or with men who are not able to distinguish signals—but we should all stand firm for a law asking us to simply distinguish the different colors of flags employed on the road, with no optical delusion rackets whatever. In a recent case in Minnesota, the company doctor declared an engineer color blind, and he was discharged; he at once submitted himself for examination by several prominent physicians, who all declared that he was not afflicted by any color blind trouble whatever. The color blind racket is a very good excuse to pull a man off for personal spite. C. S. C.

Watertown, Wis.

The "Torpedo Nuisance."

Editor The Locomotive Engineer:

When it becomes necessary, from any cause, for a train or engine to stop on the main track between stations, or to stand at a station longer than the usual time, or to proceed only at a slow rate of speed, the rear brakeman must go back instantly, with danger signals (red flag and torpedoes by day, red lamp and torpedoes by night) at least half a mile, or 20 telegraph poles, to stop any following train or engine; he must display the danger signal in a conspicuous manner, and remain there until called in by the conductor. As an additional precaution, he must immediately fasten a torpedo to each rail, which must not be removed, and when called in he must fasten another torpedo to the rail, 10 telegraph poles from the rear of the train.

If the train is stopped on a curve, or if the weather is so foggy or stormy that the danger signals on the rear end cannot be seen for a distance of half a mile, the flagman must not be called in, but must remain to flag, stop, and get on board the following train. In all cases, when called in, torpedoes must be fastened and left to the rails before returning to the train.

Should any detention occur on single track, or the opposite track be obstructed, the baggage master of a first-class train, or the head brakeman of a second-class train, must instantly go forward a like distance using the same precautions to stop approaching trains or engines.

The engineer is authorized, and it is his duty when his train stops, to order the flagman back with danger signals by giving three blasts of the whistle. See rule 11.

Conductors and trainmen have no right whatever, at any time, to presume that other trains are not closely following or approaching.

This rule is imperative, and conductors and engineers will be held responsible for its strict enforcement, and they may command the services of any employe of this company to fully and promptly carry it out.

Engineers when running over torpedoes must come to a full stop, and then proceed slowly with their train under full control, until the cause of danger is known, or the obstruction is reached and passed.

The above rules are clipped from the time table of one of our Eastern trunk lines, and at first sight would appear as if they were calculated to enhance the safety of trains moving in strict conformity with them; but a literal compliance with them would be sure to produce delay in the movement of the trains, and by this delay indefinitely increase the danger to life, limb and property. For instance, a local freight leaves a division terminal two hours ahead of a through freight, but before the trains reach the other end of the division, there is only one hour between their schedule times. Now, it sometimes happens that the local has a rush of freight to handle and becomes late, and in some instances trespassing on the time of the through freight. The flagman of the local freight strews the road with torpedoes, for, according to the rules, he must leave three torpedoes every time they stop, no matter if they are on time or behind their time, and infringing on the time of other trains. Of course, the local train will not be endangered if the rules are obeyed, for the following train will have ample notice of its whereabouts but let us see how about the through freight and its extras or following sections.

As many as *thirty torpedoes* have actually been found on the above line by the through freight, in a distance of that many miles, and that without getting sight of the local. Now, according to the last clause of these rules, engineers must bring their trains to a *full stop* whenever they run over torpedoes. In literal compliance with the rules it would require at least fifteen minutes to come to a stop, have flagman place torpedoes, call him in, and start our heavy freight or coal trains into a fair speed. If this starting and stopping process were to be repeated for the thirty torpedoes, we would have fifteen stops of fifteen minutes each, or 3¾ hours of lost time in a distance of 30 miles, or more than enough to get over the whole division.

The through freight coming upon the torpedoes placed by the local, and making the frequent stops required by them, would be sure to be behind its schedule time, and its extras or following sections would be sure to catch up and follow close, and thus make it a matter of chance whether the flagman of the through train would have time enough to get out a proper distance to prevent disaster, at the so often recurring stops.

Of what use is a torpedo, and what does it say? are the questions raised under these circumstances. The reply to the first question is supposed to be, to indicate danger ahead; but is this true? To answer this let me try to hear what a torpedo says.

No one will attempt to say that a torpedo conveys any further information than the fact that some one, presumably the flagman of preceding train has placed it on the rails, but when it has spoken once, and told you that, it ceases to give you information; if telling you what your time table has already told may be called information, for that (if you consult it) will have informed you that other trains are ahead of you on the road. In regard to the distance which the preceding train is ahead, or the time which has elapsed since the torpedo was placed on the rail, you cannot get an answer, and as these—the most important points—are left in doubt, what good does it do to tell the other fact, which all hands were fully aware of? Torpedoes used in this manner tell nothing, but might be able to convey valuable information if properly used, and their language properly understood. For instance, have it understood that wild cat trains use the left rail, and fasten two torpedoes on that, nearly touching each other. In regard to a regular train, having its schedule time laid down, it should prohibit the use of torpedoes if it is on time, but if behind its time, the use of one torpedo might be understood to mean behind time up to fifteen minutes, two torpedoes between fifteen and thirty, three torpedoes between thirty and forty-five, and four between forty-five and an hour. Torpedoes used like this would afford some practical information, and enable trains to follow each other with a certain degree of security, entirely unknown to the above rules.

Beside this torpedo method, there are at present a number of devices, worked by levers or electricity, which are designed to inform trainmen whether a preceding train has passed a certain point ahead, or how long ago it passed the signal post under observation.

As some of these devices are very simple in construction, and entirely automatic in operation (and never failing or going to sleep like poor humanity sometimes does), it would seem as if a few hundred or even thousand dollars invested in equipping a road with such devices, would prove a far better investment than the ever recurring expenditure for torpedoes, which, in reality, as at present used, are more of a nuisance than anything else.

Items from India.

Editor The Locomotive Engineer:

I am in receipt of all my papers for 1888, and as I have been much interested in details from America,

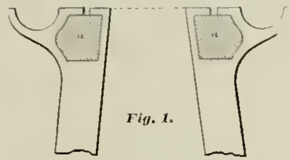

Fig. 1.

I send you a few items that may be of interest to enginemen everywhere.

In your May number you illustrate a variable ex-

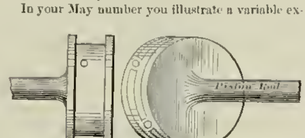

Fig. 2.

haust nozzle—something we do not have. With our engines, the blast pipe is a fixture, the cap is

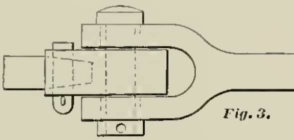

Fig. 3.

cast-brass and serves two purposes; the blast is single, and the flange shown (Fig. 1) is to support

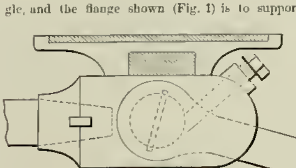

Fig. 4.

spark arrester; it has a cavity cast around it into which the blower pipe is tapped; there are a number of small holes drilled into this cavity, and they are the openings for blower. Diameter for English coal, 4¼", for country coal, 4½". The country coal used here is of several sorts, some hard, some soft, for which we have different spaced fire-bars. For English coal, air space between bars is ⅜"; best country coal, ⅝"; indifferent quality, 1¼". English coal costs here £3 ($14.35) per ton; best country, £2; indifferent, £1. Our best home coal comes from the northwest of India, and is called "Rumsigurige." I saw also a device for holding piston bolts. With us, pistons are solid on rod (Fig. 2), the rings are cast-iron, sprung into recesses of head and held from turning by studs in bottom of recesses.

Our crossheads I attempt to show in sketch (Figs. 3 and 4). On our Dubbs (Scotch) passenger engines, outside cylinder, the crossheads are of wrought-iron, solid; the little end of the main rod is forked, going around central block, and this block carries the piston in front and is jointed to the slides of the crosshead by the case-hardened pin that holds the front end of rod; the top and bottom of crosshead slides are lined with white metal.

Sohagpur, E. Indies. Locomotive Foreman.

Clubs are Trumps.

Editor The Locomotive Engineer:

Some sanctimonious reader may attack me for using such a phrase, but it is very expressive on this occasion, so we hope he will defer, unless we commit a worse wrong.

Yes, clubs are trumps, and we refer to the kind of clubs which hold forth every month in the East, West, North, South and center, if you please, for the purpose of progressive railroading. There you will see (or if you can't see them, you may read what they say) our wide-awake S. M. P's, M. M's, and M. C. B's, all primed up on some subject relating to the maintenance of the rolling stock and machinery under their charge. The exchange of views generally brings about a *mean* from what each man claims is the best, because it is *his* way. And they are never at a loss for subjects; for in the continual march of progress there is always a chance to discuss something.

Now, it has often occurred to me what a grand thing it would be if locomotive engineers and firemen would establish such monthly habits for the discussion of the practical every-day occurrences, as well as the design and construction of the locomotive. They need not go to any expense, for they already have meeting rooms, and if but one hour of their regular meeting was devoted to such a purpose, it would not be long before we would have to address some as M. M. But suppose no such advancement came, would it not be a satisfaction to be well acquainted with your engine and duties? Why, I actually saw a man who had been firing a locomotive fourteen months, and he did not know what or where the eccentrics were, and he was a poor guesser, too, for I asked him what he supposed they were, and he pointed to the link.

Within a radius of one mile of Troy, N. Y., there are about one hundred engineers and firemen; if but one-tenth of these would make a start, and mean business, it would not be long before they would have quite a following. You don't have to be an orator or statesman to give an account of some tussle with the air brake or steam heating apparatus, although one would cultivate the use of more choice language in such a place than we sometimes hear about the roundhouse.

Let some one make the start, and I will wager the child will grow to full manhood the first year.

Green Island, N. Y. C. F. R.

A Good Gauge Lamp.

Editor The Locomotive Engineer:

After reading the last LOCOMOTIVE ENGINEER I made a bee line for the roundhouse, drew a new gauge lamp globe, and had it painted precisely as Mr. Conger directed. The next trip it was ready, and I made it a point to get to the engine and do the scratch act before my engineer showed up. He came late and hurried into his overclothes, and oiled around, backed into the train, tried the air and pulled out.

After we were out of town he noticed the lamp and examined it very carefully, then said: "Where did you catch on, Squirt?" I told him I read the receipt in your paper, and he pulled out a dollar bill and told me to have that paper sent to him. It is the boss lamp, and all the boys ought to fix one up.

JAS. ARCHIBALD.
St. Louis, Mo.

One Reason that Locomotives are not Square at All Points of Cut-off.

Editor The Locomotive Engineer:

In looking over the back numbers of LOCOMOTIVE ENGINEER I found a "Valve Motion Sticker," from "A Reader," Wilmington, Del. It was in regard to an unequal travel of valve with lever at different points of quadrant.

I would offer my experience with the same "sticker," as I "stuck" to it until I found at least one reason for the inequality of travel.

It was simply the disregarding of offset in lower rocker-arm, when, according to correct principles of designing valve motion, this should always be taken into consideration. In the link motion, as used on locomotives, the center line of motion—a line drawn from center of shaft to center of link block pin—is not parallel to the center line of the engine—a line drawn through the driving shaft and parallel to the center line of cylinders.

My experiments were made with a full-sized Richardson model. I first took a motion curve that showed exactly equal cut-off for both ends of the cylinder for all positions of lever and then changed the model, giving improper offset with the following result:

ROCKER-ARM IN LINE.		ROCKER-ARM OFFSET.	
Head end.	Crank end.	Head end.	Crank end.
23¾"	23½"	23¾"	23⅛"
18¾"	18"	18¾"	18⅝"
12¾"	12"	12½"	12⅞"
9"	8"	8"	8⅝"
7"	6"	5½"	6¼"

Which shows more equal cut-offs when rocker is given proper offset, although I believe the difference is so slight that a great many builders, or rather a great many engines are built, with the matter of offsetting disregarded when the amount of offset is less than ⅜".

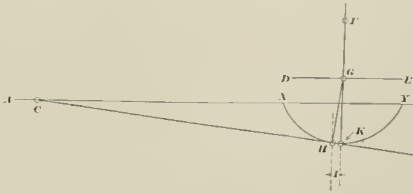
The way we obtained the correct offset was as follows: (See sketch below.)

Let C be center of main driving shaft, A B a line drawn through center of shaft and *parallel* to the center line of cylinder, D E a line drawn through center of rocker-box and *parallel* to the valve seat, F center of upper rocker-arm pin, G center of rocker-box.

The radius of arc X Y equals length of lower rocker-arm. Then a line drawn through C and tangent to—or, what is plainer, touching the arc X Y in but one point—will be center line of motion; then a line drawn perpendicular to the center line of motion *and through* the point G will touch the arc X Y in the point H, which is the position of center of lower rocker-arm pin, when upper arm is perpendicular to valve seat; then, instead of K being its position, it should be drawn toward the main shaft the horizontal distance L. I did not set out to explain how to design or lay out link motion, but only to give one reason why the valve will not travel, in some cases, equally each side of center of valve face for all positions of reverse lever.

CYRUS F. RICHMOND.

Troy, N. Y.



What Ails the Headlight?

Editor The Locomotive Engineer.

There are a great many points about a headlight that both old and young runners get onto by very little experience. Then there are some defects which are not so easily discovered and remedied, and which makes a runner ask, why the headlight on the "old 11" gives such a good light, and the brand new one on the "66" is no good at all?

I am not a practical headlight maker, but I have fixed over several headlights that would not show a switch target three car lengths off, so they would plainly light up the fifth telegraph pole from the cab—about 40 rods—and if these observations are not just what the headlight makers think they should be, we will be pleased to hear from them.

In the first place, a headlight is constructed on a scientific plan, and if it is not just right, no amount of work in cleaning and trimming will make it show a good light very far ahead. If the flame does not come just in the focus of the reflector, the rays of light will not go straight ahead, but will be diverted from their proper course and go every way but the right one. The shape of the reflector is generally right, but a great many of the burners are not soldered on just where they belong, so the light does not come in the proper place in the reflector. Some of the reflectors have a little prick punch mark exactly in the middle (measuring from the outside edges). When the flame is burning at the proper height to give a good light, the center of the flame should be exactly on a level with this mark, and if it does not come there, have the burner shifted so it will. Then, the rays of light coming from the flame and striking the reflector will be reflected straight forward where you want them instead of outside of the right of way—enough light will go out there without sending it. The diagram No. 1 shows one way, and No. 2 the right way.

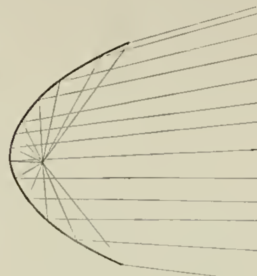


Fig. 1.

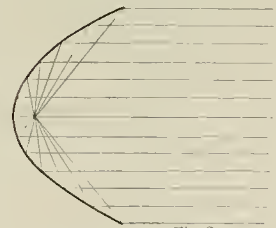

Fig. 2.

Then after the burner is set right have the headlight case painted white on the inside, except on the top and the glass. Paint the back of the reflector and the projecting rim around the glass where the light strikes it *sure*. If the headlight is very high up from the rail, as is the case on our modern express engines, it is a good plan to tip the top of the headlight case a little forward, and put a wedge on each side on the bracket. This will throw the light towards the track where you want it, instead of up in the sky.

The first time you put in a new wick, show your fireman how it is done so he will know something of the construction of a burner. Tell the first man that comes around with some patent polish which will rub all the silver off your reflector in two cleanings, that lampblack is good enough for you, and stick to it. Keep a piece of pipe in your head light case to blow it out, and then the hostlers won't turn it down to put it out. And right here I must say, that the engine that needs the best headlight and has the poorest one is the switch engine.

Lansing, Mich. CLINTON B. CONGER.

The Rogers Locomotive Works, Paterson, N. J., are working on short time. Lack of orders is the reason.

About Sizes of Nozzles.

Editor The Locomotive Engineer:

I am stuck. Last month I made an agreement with an old machinist in the shop—an ex-runner—that I was to come to him every trip, and he would give me a question about engines; I was not to come with an answer till I was sure I had the right one, and could tell the *reason why*—in fact, pass a sort of examination on the subject—for each and every question I missed or answered wrong I was to pay 25 cents.

To date I have answered nineteen questions, and am out 25 cents and *in* that many dollars' worth of information. Now he has got me up a tree, simply because I don't know how to figure. The question is

"Suppose you were running an engine on construction, away from shops, and got an order to measure the double exhaust nozzles, and order a single variable nozzle that had the same area of opening as the double nozzle, when wide open, size of central plug 2", what would be the outside diameter of the single nozzle, provided your double nozzles measured 2⅜ each? TEXAS.

Galveston, Tex.

[To find the area of a circle, square the diameter (multiply it by itself), and multiply the product by .7854. By doing this you will find the area of a 2⅜" circle is 4.4301", twice this is 8.8602", the combined area of the nozzles. Now, you want a single nozzle of the same area with a 2" plug in its center, by the above rule we find that a 2" circle has an area 3.1416", we add this to the area of nozzles, and find we have 12.0018"—practically 12". A circle containing 12" of area would be 3.9625—practically four inches.

We think your plan of study a good one, and thank you for the suggestion to others. Be sure you get a good man as reference.]

Nothing Like Printers' Ink.

"The value of advertising was demonstrated this morning, when Messrs. Becker & Lathrop received a letter from an engineer at Sohagpur, East India, ordering an engineer's clock. The engineer had read the advertisement in an engineers' paper, which had found its way to Central India, with the above result. The letter came by way of Bombay, Brindisi, London and New York, and came inside of thirty days. American wares beat the world."

Editor The Locomotive Engineer:

Above find clipping from the *Syracuse Daily Journal*, which will speak for itself.

I think Becker & Lathrop have acted wisely in resuming their advertisement in your valuable paper, for, judging from the letters and orders that Mr. Lathrop has shown me from all over the country, they will do a good business in the line of locomotive clocks.

From Central India to Central Missouri is covering lots of territory.

Syracuse, N. Y. W. F. RELYEA.

Intelligence and the Coal Bills.

Editor The Locomotive Engineer:

I noticed in your February issue that the Supt. of M. P., on N. Y., L. E. & W. R. R. had presented the firemen on that road with copies of Sinclair's work on "Combustion in Locomotive Fire-Boxes." I think this is a step in the right direction; if some of our western superintendents of M. P. would follow the example set by Mr. Kells, they would find that the company's coal bills would be smaller than now. When I commenced firing, the engineer who broke me in used to tell me to load her; after we had got over thirty miles of the road the engine would not steam, simply because I had overloaded her. One day I got hold of Forney's Catechism of the Locomotive, and read what he says on combustion. I learned that, by feeding the furnace with just as much coal as it required, and admitting the requisite amount of air above and below the fire, that it was possible to make long runs and have plenty of steam. I followed Forney's advice, and have been successful; I now make the same runs with 25 per cent. less coal. FRED. TAYLOR,

Marion, Iowa, Fireman C. M. & St. P. R'y.

A Spring Remover and a Substitute for a Broken Hanger.

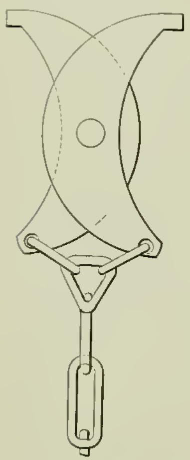
Editor The Locomotive Engineer

The spring kink described by Mr. Hitchcock, of Minneapolis, is a very fine tool, but rather expensive, and of too many pieces. The same tool can be gotten up much cheaper, and within the reach of many who do not enjoy the machine and blacksmith facilities he no doubt does. I enclose you a sketch of a tool that should be carried on all engines, especially American passenger engines. It is constructed of two pieces of 2"x¾" iron, with gib end turned up to give more strength, and prevent the three ⅝-bolts from shearing. The two pieces are bolted to a wrought or cast block, 5" long, by 4" wide and 2" thick. The pieces are bolted with three, or even two ⅝ bolts, tapped into the block. The side pieces should be 48" long, with three sets of holes at end to put a ⅞" key bolt through on top of spring. The screw is steel, 10" long, 1½ diameter. When an engine stands on a pit, it can be slipped up from pit, if on track, the three small bolts are taken out, and block and one side put in position, and then other side to be bolted in place, and bolt put across spring on top, and the jack is ready for business.

A. T. Hooker,

Gen'l Foreman E. T., V. & G. Shops.

Chattanooga, Tenn.



To Remove Cellars.

Editor The Locomotive Engineer:

I send you a sketch of a little device we use to take out driving box cellars; it may not be new to all, but I think it will to some. All roundhouse men have had trouble in removing cellars; they are hard to get at and dirty. We have found none that have failed to come down with this device.

It is made of spring steel, the points hooking into the cellar bolt holes, and the chain long enough to reach past the pedestal brace, and having a hook to catch the bar.

F. C. Robinson,

Gen'l Foreman Wabash Shops,

Danville, Ill.

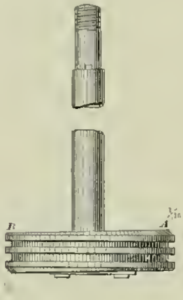
A Little Practical Air Pump Theory.

Editor The Locomotive Engineer:

How many will agree or disagree with me on the following theory? Here it is: About six months ago I gave a six-inch pump a general overhauling. In doing so it became necessary to bore the steam cylinder and make a new piston and rod. There being no casting on hand, the piston was made of wrought-iron, and was turned $\frac{1}{16}$" smaller than the bore of cylinder. After taking extra pains to put the pump in good shape, I put it on engine 565, N. Y. C. R'y, and the first trip she made the engineer complained about the pump groaning, no matter how much oil he gave it. I thought the oil cup might have something to do with it on account of not feeding steady; so I took it off and put on a new one, which fed all right, but the pump still groaned or chattered continually. Thinking that perhaps the piston might fit the cylinder a little too close, I took it out and turned off another $\frac{1}{32}$", making it $\frac{3}{32}$" smaller than the bore of cylinder, but it did not stop the chattering. After taxing my brain to its full extent I came to the conclusion that the fault must be in the oil cup, so I put on a fine working sight-feed oil cup, but, although it helped it some, it did not entirely stop the chattering. Well, I concluded to let it run for a while, thinking perhaps it might improve with old age, but no go.

I now became desperate, and vowed a vow that I would make that pump run smooth or bust it, so I took the piston out again, and rolled it along on the bed of my lathe to see if the piston ran true with the rod, and to my satisfaction found what I believe to have caused the chattering, it was this: The piston had been roughed out on a mandrel first, then put on the rod, turned to fit the cylinder and sent to me from the main shop (where the job was done), and pronounced all right. Now the mandrel on which the piston was first turned could not have been true, because, when I rolled the piston rod on the lathe bed the piston ran out about $\frac{1}{16}$", that is to say, it was not faced off, but was turned so that the annular surface of piston was parallel with piston rod, leaving it in the shape of the drawing, which you will find enclosed.

Now, my theory is (if it may be called a theory) that, when the piston was on the one stroke, the point *A* being lower than the point *B*, the steam forced the piston toward *A*, and when on the return stroke toward *B*, which caused the chattering.



Now for the remedy: I took the piston down to the shop, told the general foreman my trouble and theory, and asked him if he would have the piston faced off so that it would be true with the piston rod. Well, he laughed at my theory, and said he did not *take any stock in it, but would do the job to please me*. The piston was faced off, I put it back in the pump, and after the engine had made a trip I asked the engineer how the pump worked. He said it worked perfectly smooth with much less steam, and he did not hear a squeak or a groan out of it. And it has worked perfectly smooth ever since I had the piston faced off.

I hope some practical man will give his opinion on my theory.

W. F. Relyea.

Syracuse, N. Y.

Air Brake Practice.

By J. E. Phelan.

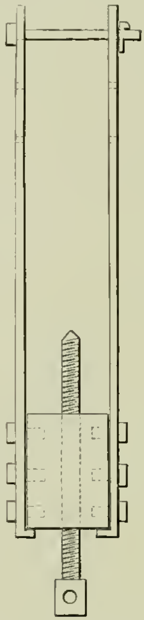
TENTH PAPER.

Knowing how to keep an air-pump in good order, and maintaining the proper pressure and volume of air, the next most important matter is to know how to properly apply the air in handling the engineer's brake valve.

With recent changes in design, probably no part of air brake appliances seems more a matter of interest than the engineer's brake valve.

On various railroad systems you will find several designs of engineer's brake valves. The original engineer's brake valve or 3-way cock (see first paper on Air Brake Practice in Locomotive Engineer, May, 1888,) and many of same design are still in use at certain points in the country (see second paper, June, 1888). The main function of the engineer's brake valve is to act as a sort of union depot or common transfer station for the compressed air. The air-pump gathers the air from the atmosphere and deposits it in the main reservoir. The engineer's brake valve then controls its future actions as manipulated by the engineer, subject to needs of the service. The function is to draw on the main supply and distribute same through train pipes and auxiliary reservoirs under the cars, and once the latter is supplied, it controls not only the main supply, but the disposition of, and action of, all that may be stored under train as well as in main reservoir.

The original engineer's brake valve or 3-way cock consists of a socket in which rests a plug, with handle attached. From the socket, openings run in three directions—one to main reservoir, one to train pipe and auxiliaries, and one to the atmosphere. The plug has a slot running through from one side to the opposite, and another slot running out from center of the through slot to third side, thus leaving one side blank.



Spring Remover.

The control of air and its passage through this medium of exchange is as simple as business done at a transfer having but one daily train each way. But when simple and light work ceased, the use for this simple device entered the shady past.

When indefinite numbers of cars began to be coupled in air brake service, this simple device would not meet the requirements. The principle on which automatic air works is that of the greater pressure controlling the lesser. If triple valves are forced down to bring brakes to action by a given pressure, it naturally requires a greater pressure to force this valve up into release position, against the original given pressure with which it was set.

Say, with the original device we have 70 lbs. in main reservoir, and an equal pressure in train pipes and auxiliaries, when brakes are set. To set brakes, we simply close communication with main reservoir and allow air to escape from train pipe; this reduces pressure under piston of triple valve, and allows pressure on top of piston and in auxiliary to force piston down, until opening into brake cylinder is uncovered, when air rushes from auxiliary into an empty cylinder. (See third paper, July, 1888, and fourth paper, August, 1888.) It naturally strikes one that this air, rushing from a full auxiliary into an empty cylinder, will reduce the compression and pressure to a certain extent, similar to opening an engine's throttle and filling empty cylinders with steam from boiler, when fire is not very hot. For when this action takes place, supply to auxiliaries is shut off. Now the point is right here: if your pump has not increased pressure in your main reservoir to a degree, while it has been cut off from communication with train pipes, to refill into train pipes the amount let into atmosphere to set brakes, what occurs? You realize that the air, as it flows from main reservoirs to partially filled train pipes will come under similar conditions to that going into empty cylinders. Again, if the triple valve pistons on first cars are forced up into released position, air quickly commences to feed into partially emptied auxiliaries, and by the time the volume of air reaches the vicinity of rear cars its energy is lessened and pressure reduced, even below that in auxiliaries, and the pistons of triple valves remain down and brakes set, for want of proper pressure to release.

To ensure a volume and pressure of air in main reservoir, that would always reach all cars with sufficient energy and pressure to release all brakes, the engineer's brake valve was improved, so that it would automatically retain 20 lbs. greater pressure—more or less—in main reservoir, than it transmitted to train pipe and auxiliaries. This improved engineer's brake valve was naturally called a 20-lb. cock instead of a 3-way cock.

This improved engineer's brake valve retains the transfer principle intact as a medium of exchange.

Instead of a simple plug and socket, the improved 20-lb. cock was made up of a valve body or chamber, in which there comes in use a top valve and spring, to hold the top valve to its seat, a main valve and spring for similar purpose, and below the main valve a feed-valve and spring. The feed-valve and its spring automatically acts to retain the 20 lbs. greater pressure in main reservoir than transmitted to train pipes and auxiliaries, when the handle of engineer's valve is set in proper position. The top valve is for the purpose of controlling the opening to the atmosphere, subject to condition of its spring and action of the engineer. The main valve controls the openings from main reservoir to train pipes practically, as the plug is 3-way cock. With handle of engineer's valve in release position, this main valve holds a free opening through two fair-sized ports for passage of air from main reservoir to train pipe. When handle of engineer's brake valve is brought around, so that the end of handle spring rests against the first stop or notch, these ports are closed, and all air passing from main reservoir to train pipes must pass through the feed-valve and through quite a small opening into train pipes.

It is often difficult for some engineers to get into the habit of carrying valve in this position while running. If there happens to be a neglected coupling or leak in pipes at any point in train that may waste air in such quantity that the small opening leading from the feed-valve may not transmit air enough to supply the leak and needs of the auxiliaries at the same time it becomes difficult to hold valve in such position and keep brakes released, but the leaks should be stopped and engineer's brake valve always held in this position while running.

The balance of the work is in principle the same as the original 3-way cock. When handle is carried around toward third stop or notch, it answers opening from train pipe that allows air to escape into atmosphere and apply brakes.

About midway between the point of setting brakes and that for supplying train through feed-valve or position while running is the place or point for blanking. When handle of engineer's valve is in this position, the main valve covers all ports, so there is no communication between main reservoir and train pipes, and none from train pipe to atmosphere. This is the position to always place engineer's valve when train has been broken in two, or when brakes have been applied from conductor's valves in coaches. In this position it holds your accumulated pressure in main reservoir, where otherwise it would flow through and escape through uncoupled hose or through conductor's valve, if left open. If engineer's valve is held in this position while trouble is being located, just as soon as stop cocks are shut or cause of setting brakes from train remedied, the brakes are finally released and bleeding not necessary. When engineer's valve is in this position, and coupled in double header with air pipes through to front end and coupled to forward engine it gives the middle engineer an independent supply of air (see sixth paper, October, 1888,) and allows air to flow directly from forward engine to control all brakes in train, including tank brake on middle engine.

When properly cared for and handled, the faults of this engineer's valve were few. Like all other appliances, it would wear out in time and need occasional repairing, especially after a season of neglect.

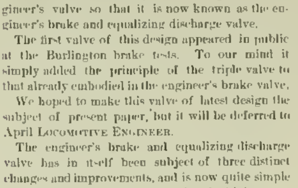
The main fault seemed to be with long trains in applying brakes. When not carefully handled, a larger volume of air than necessary would escape in applying the brakes. This air, having a sudden release from train pipe, the air from forward end would escape first, and after engineer's brake valve would be blanked, the flow of air from rear cars coming to forward cars would be stopped abruptly and the concussion would increase pressure and release brakes on forward end, and cause not only waste of air, but poor braking.

This point was made subject of improvements and caused a radical change in the design of the engineer's valve so that it is now known as the engineer's brake and equalizing discharge valve.

The first valve of this design appeared in public at the Burlington brake tests. To our mind it simply added the principle of the triple valve to that already embodied in the engineer's brake valve.

We hoped to make this valve of latest design the subject of present paper, but it will be deferred to April LOCOMOTIVE ENGINEER.

The engineer's brake and equalizing discharge valve has in itself been subject of three distinct changes and improvements, and is now quite simple and effective. We hope to relate its kinks as we have observed them.



A New Car Journal Lubricator.

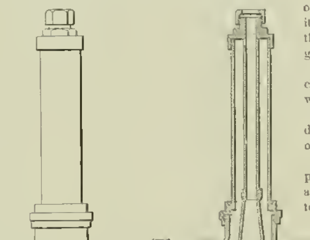
This car journal lubricator is a cup or receptacle for oil, made of vulcanized rubber from a pattern to fit the journal box, and which, from its shape and nature of material, can be placed in position—in most cases simply by squeezing it through the door of the box and underneath the journal, when it will at once resume its proper shape and position; it is then filled with oil which is conveyed to the journal by wicks or feeders of wool, cotton or other suitable material, running from the inside of the cup through openings at the top, thence down around the side and lower part of the journal through slots in the opposite edge of a rubber bar, running lengthwise at the bottom of the cup, thence back and through the same openings at the top to the oil inside; these wicks or feeders cross each other alternately, running around the journal from the top of the cup on one side to the bottom on the other, and are held in contact with the journal by the elasticity of the rubber bar at the bottom. No oil can escape from the cup except by way of the wicks, which will be constantly saturated, but absorb only what oil is necessary to replace that taken off by the journal, hence no more oil will be drawn from the cup than is absolutely necessary to properly lubricate the journal. The lubricating surface of these wicks will vary from eight to fourteen square inches, according to the size and position of the journal in the box, the number or width of the wicks can be regulated to supply the proper quantity of oil and no more. The oil being thus enclosed in the rubber cup inside, the journal-box will be kept clean and free from dust, sand, cinders or dirt of any kind. The extreme simplicity of its construction, the ease and facility with which it can be applied, renders it cheap, convenient and durable, no part of it being exposed to any movement, motion or wear except the wicks, which can easily be replaced if found worn.

The cup itself, with ordinary care, should last for several years, and should save much of the oil now wasted.

This box is the invention of Arthur W. Wright, of Detroit, Mich., who furnishes this description.

Bryant's Strainer Cleaner.

The device here shown is the invention of Master Mechanic J. T. Bryant, of the Richmond, Fredericksburg & Potomac road, and has been in use there for four or five years; it is also in use on the Petersburg road. Fig. 1 shows the outside appearance of the device. It is placed at the end of feed pipe, and between it and the tender hose, the union of the latter screwing upon it. As will be seen by Fig. 2, a plug cock controls the flow of water to the strainer located above it; this strainer can be as large as desired, from the top of the strainer a ¼ pipe is carried to an independent heater cock on the boiler head.



BRYANT'S STRAINERS

Should the strainer become stopped up on the road, the runner pulls up a rod connected to the handle of the plug cock, this shuts off the water from the tank, and opens the feed pipe and strainer to the atmosphere, through the opening shown at bottom, then, by turning steam on from the independent heater pipe, the *inside* of the strainer is cleaned by steam at boiler pressure, should the holes of strainer be full of foreign matter, the injector heater can be turned on and the holes cleaned out. All this takes but a moment, and can be done while the engine is running.

To empty the tank, the handle is turned clear over, but this cannot be done unless a man goes at it deliberately; in some of the earlier valves made, this was part of the upward motion, and men forgot and wasted the water.

In addition to its use as a strainer, it is an air chamber, and prevents the breaking of the injectors when water is low in tender.

The engineers on this road say they never take down their hose, except to show the device to some one.

It is a pity that some firm in the business is not putting this device on the market, as it is certainly a time-saving, danger-decreasing device, and a boon to enginemen, especially where open track or scoop tanks are in use.

The Union Pacific will build new general shops at Cheyenne, Wyo., and transfer the mechanical headquarters from Omaha to that place This is as it should be, Omaha is the eastern end of the system, and the end is a poor place for general shops, then the present shops are crowded into very close quarters, and cannot expand for want of room; at Cheyenne they can have all out-doors to grow in. If the new shops are built to suit the ideas of the present able and experienced head of the mechanical department—as they should be—they will no doubt rival other shops in the West, and average Western shops put average Eastern shops away in the shade.

A club of young mechanics at Boston have organized themselves for the study of steam engineering. They have adopted as a text book and reference, "Indicator Practice and Steam Engine Economy," by F. F. Hemenway. Mr. Hemenway ranks second to none in a thorough understanding of steam engines of every class, and possesses the happy faculty of writing intelligently on the subject without resort to algebraic formulæ. Students of steam engineering can do no better than to secure his writings on this subject.

CONTENTS.

Oh, My Prophetic Soul—I Told You So!

The daily papers were aflame on Feb. 21 and 22 with telegraphic news that the Brotherhood of Locomotive Engineers was going to pieces—all because it was announced that a division of Reading engineers at Philadelphia had given up their charter. Interviews were published in the N. Y. *Times* of the 21st, with prominent Reading officials, who announce that the order is doomed, especially on their line, that the only reason the men remained in the order was on account of the insurance, and that now the Company's Relief Association furnished that, so that the men were beginning to "show their manhood," etc. If one regiment of an army of four hundred regiments desert, or are killed in action, it does not follow that the army is disbanding. If it is "showing manhood" to let railroad officials or any one else—friends or enemies—tell a man what orders, church, or campaign club he shall belong to, God save us from that breed of "manhood."

When the Reading gave notice that they would meet any and all employes who came to headquarters with a grievance, but would not meet any organized grievance committee of any order, we did not blame them much; but when they begin to select their engineers on account of their *not* belonging to labor organizations over which the Reading officials have no control, and *for* belonging to the Relief Association over which they do have control, instead of their ability as enginemen, then we say that the officials who assume this autocratic authority are knaves, and the men who submit to it are fools.

The Brotherhood of Locomotive Engineers is not dead enough for a wake or a funeral; its liver is out of order, and it suffers a little from water on the brain and enlargement of the gall. What the order needs in general, is a healthy revision of the by-laws, the abolition of grievance committees, more statesmanship and less representation in convention, and convention dates further apart.

The individual members need a bath in a liniment composed of equal parts golden rule, brotherly love, devotion to duty, and that kind of manhood that insists on furnishing first class work for first-class pay, and in being their own judges as to what they shall and shall not belong to.

The lodges need fewer factions and more valve motion models; less discussion about men and more about things; less jealousy of others, and more reliance in self, from a knowledge of superior information received in the lodge room discussions on engine running, firing, and general railroad work.

A man is not dead or disbanded because he has jaundice or has his leg cut off.

For a dead institution the B. L. E. is yet a breathing, kicking, and altogether lively corpse.

Electric Locomotives.

The Daft electric motor, that has been running for some months on the Ninth avenue, has been taken off, the experiments for which it was run having been completed. The current is conducted to the motor car through a copper rod outside the rails, and it is claimed that it is in no way dangerous, as a person cannot receive a fatal shock, and can only receive a severe one by forming a conductor of the body between the copper bar and the rails.

This motor has hauled three empty cars between 14th and 59th streets, for several hours a day for three months and has not held a single train.

The Daft Electric Company are now building a 20-ton motor that is expected to do the regular work of a locomotive on this line.

The elevated is peculiarly adapted to motors of this class; it is above the streets and crossings, has no obstructions, and already employs as heavy locomotives as the structure will bear. The peculiar advantage of the electric motor is in its increased tractive force—an acknowledged fact as yet rather mistily explained. Mr. Daft believes it is on account of a momentary molecular change in the metal in contact. To prove his theory he built a four-wheeled truck, the wheels being set in motion by a small motor carried on the frame; this truck was mounted upon a level track and fastened to a stationary object by a dynamometer and the wheels caused to revolve, the pull on the instrument showing exactly the tractive force exerted by the machine, then a current of electricity was passed through the wheels and rails, and the instrument at once registered some 80 per cent. more than it did before. This machine was exhibited at the patent office and patents allowed on the application of electricity for increasing traction. If they can build a motor of the same weight as the locomotive, with 80 per cent. more tractive force, it will, of course, pull a proportionately heavier train.

Mr. Daft does not expect to pull any trains on surface roads or trunk lines with present appliances; he says he can handle the service on the elevated, and will, no doubt, be given a chance to try.

He says that his company and himself made the mistake, in starting out, of claiming that their motors for street cars could be run by cheap labor; now he sees that the locomotive engineers are the men, and the only ones, fitted to run motors; the running is much the same as in a steam locomotive—a man must know the running rules and be familiar with operative railroading; a stopper and starter only is no good on any motor, be its motive power electricity, steam or soap.

In conducting the current, or power, from the steam plant to the cars, there is a loss of over 25 per cent., but it is claimed that high duty compound engines are that much cheaper on fuel than locomotives developing same power.

The substitution of electricity for steam locomotives would, we believe, require more men employed in its maintenance than at present, but whether it can compete economically in the general carrying trade remains to be demonstrated. All progressive mechanics will watch the experiments with interest.

A Beggar on Horseback.

Some time ago the management of the Santa Fe system came to the employes of the road with a statement that the road was losing money from various causes, and asked them to stand a temporary cut in wages.

The members of the various labor organizations, as well as employes outside these orders, called meetings, discussed the matter, and voted to help the company out by a uniform reduction of wages for the winter. Considering that the Santa Fe has never been noted for high wages, this was fair, and showed a fraternal feeling as far as the men were concerned, that has been heralded abroad as "a policy that kills strikes," an "insurance of higher wages in good times," etc. So far, so good. Now comes the annual statement of the road, which says:

"The profit of the Atchison system proper for the eleven months ending November 30, after providing for all fixed charges of interest on bonds, rentals, taxes and sinking fund requirements, was $1,066,000.06. The dividends declared during the period amounted to $2,625,000, leaving a deficiency as of November 30, of $1,558,999.94."

The payment of unearned dividends of over a million and a half shows that, whatever the men will stand in the shape of less wages, the stockholder proposes to have his interest on bonds—water and all.

The Santa Fe built several hundred miles of road last year that paralleled other lines, in a country that could not support both, a financial mistake that they ask the men to stand.

There are many times when fair, honest management gets into a tight place financially, and would be benefited, and perhaps saved from bankruptcy, by the help of the employes; but such disclosures as the little game on the Santa Fe will tend to prevent more deserving managements from drawing from the same source.

When men come out and say they will take less wages for a given time, to help out the company, they simply agree to live less comfortably for that length of time, that the company may not get hopelessly behind in its fixed charges, not that London and Wall street stockholders may be paid unearned profits.

John G. Eckman, foreman of the Florida Southern roundhouse at Bartow, Fla., writes us that he has had much the same experience in water splitting that others have who have written on the subject.

Statistics.

When records are kept of the number of accidents, the deaths, the injuries sustained, the axles broken, or the misplaced switches on a road, or on the roads of a State or a nation, that is called statistics—it is history. Men who are fond of carrying out all things by the addition of ciphers will pounce upon a list of historical figures—or statistics, if you like—and go on to prove, by what has happened, just what will happen next year and the year after.

Don't get in the habit of paying any attention to this breed of "statistics." If we have a small road, say employing 100 men, on which, in 1887, there were two men killed and in 1888 twelve men killed, it does not follow that, because the increase of fatality was 500 per cent. that year, that it will increase in the same ratio in '89 or '08. There are a whole lot of cranks in this country that want to prove—by figures—that the laboring men are very badly off, and need *laws* enacted to help them, this before election. Immediately after election they at once produce figures to show that workingmen are 400 per cent. better off here than any place else. They will say that forty years ago, 30,000 pounds of wheat could not have been hauled by team from Ohio to Massachusetts in less than seven months, or for less than $2,000. Now it can be hauled in three days for $50, and as a car of wheat will support life in a workingman for eighteen months or eighteen years, he is so many thousand per cent. better off than were his ancestors. They can just as well prove that food is not a necessity, but a habit, and produce figures to show how much better off men would be if they did not eat—and there would be just as much sense in it.

The workingmen of America do not want statistics compiled or *laws* passed for their benefit; they are, in most cases, a burden for them—a law cannot be passed making work plenty and pay fair.

Let us reverse the order of things, and commence to un-make laws. Repeal laws that allow a private concern to train and arm an army to shoot people for pay—and punishes the people for shooting back.

Repeal the laws that let one man, or a number of men, fence in whole townships, and make people work for them.

Repeal laws that declare a strike of employes a conspiracy, and a strike of employers a lock-out.

The Metric System.

The National Car and Locomotive Builder very properly shows up some of the disadvantages of the metric system, and the loss and confusion that would occur in a great manufacturing country like this, through its adoption. A club of New England car builders have made a proposition to the Car Builders' Association, to have that body declare in favor of the adoption of that system of measurement.

If we were a people without a standard measurement, or had many standards, as Germany had before the adoption of the metric system, and as China has now, it would be well enough to look into the merits of the meter, but it has no advantages to offer over the standard inch, and the inch can be expressed in decimals of hundredths or thousandths, with fewer figures than can the same measurements be expressed by the metric system. There is no great danger of its adoption in the workshops of America, because to adopt it would mean the expenditure of large sums of money without any returns whatever—the best of all reasons.

Relay Stations and Fast Time.

At first thought a railroad man used to soft coal would say that the changing of engines on passenger trains at Bound Brook, N. J., on the Reading and Central of N. J., on Bound Brook line, was a time-losing feature. As a matter of fact it is a time-saving feature. With hard coal a clean fire is a necessity for fast time, and the exchange of engines not only allows the man coming into the relay station to sacrifice water level, and allow his fire to become dirty or steam to go down in order to come in on time, but has an engine ready, with a clean fire, cool journals, a full boiler and a hundred and enough to bounce it to a fast train to the end of the run. Between Philadelphia and New York the two lines, the Bound Brook and the Pennsylvania, are striving to beat each other and come as close to making the 90 miles in 90 minutes as possible, and they come pretty near it.

Several years ago some of the engineers on the Pennsylvania wanted the management to make a relay station at Monmouth Junction and let every passenger engine stop there one train, giving her crew time to clean her fire, oil around, get a fresh tank of water, fill up and blow up ready for the next train. The management wanted the engines to run right through, but there is little doubt that the scheme proposed by the engineers would result in comfort to the crews and better time.

ASKED & ANSWERED

(10) Kline, Germantown, asks:

What difference is there in the heating qualities of hard and soft coal? *A.*—With a good quality of both kinds of coal there is very little difference in the heating qualities, pound for pound.

(11) C. L. Green, Blauveltville, N. Y., asks:

Will you please tell me the weight of a passenger engine and a freight engine? *A.*—Weight depends entirely upon size; average weight of modern eight-wheeled passenger engine 65,000 to 75,000 pounds. Consolidation freight engine about 90,000 pounds.

(12) D. E. S., Rawlins, Wyo., writes:

In what way does the Strong engine differ from other engines? *A.*—The novelty of the Strong engine is in the boiler and the valve gear. The boiler has two fire-boxes lying side by side; they are simply corrugated tubes 38 inches in diameter and about 8 feet long, and are enclosed in two cylinders of boiler iron; these tubes come together forming a large combustion chamber; the boiler resembles somewhat a pair of pants inflated, the legs being the fire-boxes, the waist the combustion chamber, beyond and in front of which the waist is extended to hold the small flues; the grates are set up a little below the center of the tube furnaces; water entirely surrounds the fire-boxes. The furnaces are of much less diameter than the main part of boiler. The cab is placed ahead of the furnaces. There are no stays in the boiler whatever. The forward end is carried by a double truck, and behind the drivers a pony truck supports part of the weight of the furnaces. The valve motion is derived from a single eccentric on a side, and is a type of radial gear; the exhaust and steam valves are independent of each other; they are multiple-ported; gridiron valves working vertically in plugs set in the steam passages near the end of cylinders; there is no steam chest. The entire valve motion is supported on the main driving box.

The Locomotive in America.

By Wm. Barnet Le Van.

THIRD PAPER.

In 1834, William Norris bought the interest of his partner, Col. Stephen H. Long, and commenced what afterwards became one of the largest locomotive building establishments in the world, in which one hundred and fifty locomotives have been built in one year. In conjunction with Long, Norris had patented—December 30th, 1833—the use of the separate expansion valve, working directly on the back of the main valve—a feature long afterwards preserved in the Norris locomotives. In July, 1836, Norris had completed a locomotive, the "George Washington," embodying considerable advances in proportion, arrangement and construction, upon previous plans. This locomotive weighed 14,390 pounds, and on July 10, 1836, it drew an additional load of 19,200 pounds up an incline of 2,800 feet in length, and rising at the rate of 369 feet per mile, or *one in fourteen;* the rate of speed up this incline was 15½ miles per hour, the run of 2,800 feet being accomplished in *two minutes and one second.* The combined gravity and friction of the whole weight—33,590 pounds—on the incline of one in fourteen, would be about 2,600 pounds, which amount of adhesion was nearly or quite one-third of the entire weight on the driving wheels. Such a feat in 1836, as was achieved by the "George Washington," took the engineering world by storm, and was hardly credited. The directors of the Birmingham & Gloucester Railroad, of England, became so convinced of the efficiency of the Norris locomotive, as to order several for working the Lickey Incline, where they performed successfully until further improvements had rendered them antiquated.

In 1835, Garrett & Eastwick built a locomotive with outside cylinder connections—then not much in vogue—running gear after the Baldwin type, with one pair of driving wheels behind the fire-box, and with four wheel truck in front. It had the dome or "Bury" boiler. When finished it was called the Samuel D. Ingham, after the president of the Beaver Meadow Railroad.

This locomotive had, for the first time, the rear platform covered with a roof, to protect the engineman and fireman from the weather.

In 1836, Henry R. Campbell, "in order to distribute the weight of the locomotive upon the rails more completely," patented the duplication of the driving wheels, placing one pair behind and one pair in front of the fire-box, using the swiveling truck in front of Baldwin's and others.

On February 5th, 1836, Mr. Henry R. Campbell, of Philadelphia, designed and had built a locomotive having four wheels coupled—one pair in front and one pair behind the fire-box—and a four-wheeled truck in front. This locomotive was commenced by James Brooks, of Philadelphia, on March 16, 1836, and completed May 8, 1837.

This was the first eight-wheeled locomotive of this type, and from it the standard American locomotive of to-day takes its origin. Mr. Campbell was the chief engineer of the Germantown Railroad when the "Ironsides" was placed on that line, and had since given much attention to the subject of locomotive construction.

The Campbell locomotive lacked, however, one essential feature, flexibility vertically. There were no equalizing beams between the driving wheels, and nothing but the ordinary springs over each journal of the driving axles to equalize the weight upon them (the plan still adhered to by the English to this day); as a result it was not successful. The trucks gave it flexibility laterally, but on our then rough roads it needed vertical flexibility.

In July, 1837, Messrs. Eastwick & Harrison remedied this defect when building the locomotive "Hercules," with the same arrangements of wheels as Campbell's, for the Beaver Meadow Railroad, by introducing equalizing levers between the springs, which was patented in 1838.

This firm introduced many minor improvements in the "Hercules," one of which was the introduction, for the first time into steam machinery, of the bolted stub end instead of the old-fashioned and unsafe mode of gib and key, for holding the strap on the connecting rods, now universally used in the connecting rods of all locomotive engines.

Norris at once adopted the coupled drivers with equalizing spring levers, and with the separate expansion valve, and other features already embodied in his plans, his locomotives of 1840–46 may be taken as the standard type of America—locomotives to which other builders gradually approximated.

From 1842 forward the Philadelphia builders built six and eight wheels coupled locomotives.

In 1845, the "John Bull," an English passenger locomotive, formerly called the "Robert Fulton," was rebuilt by Walter McQueen, and called the "Rochester." The first application of air vessels to both the forcing and suction sides of the locomotive pump is believed to have been made at this time, Mr. McQueen having taken portions of the four-inch copper flues of the "De Witt Clinton" to form these vessels. The arrangement thus introduced is now universal in American locomotives.

In 1846, Septimus Norris designed the ten-wheeled locomotive now in general use, and in January, 1847, the first one was placed on the Reading Railroad.

In 1849 a most important step was made in the progress of American locomotive practice—the introduction of the link motion. Although this device was first employed by William T. James, of New York, in 1832, as before stated, and eleven years later by the Stephensons in England, and was by them applied thenceforward on their locomotives, it was not until 1849 that it was generally adopted in this country.

In 1849, Edward S. Norris, of Schenectady, built for the then Utica & Schenectady Railroad, the "Lightning" Crampton, with 16-inch cylinders, 22 inches stroke, and a single pair of 7-feet wheels, which ran at the rate of 60 miles an hour in the year 1850; but it only ran a short time.

Messrs. M. W. Baldwin & Co., in August, 1849, delivered to the Vermont Central Railroad a locomotive, the "Governor Paine," with 17-inch cylinders, 20-inch stroke, and a pair of 78-inch driving wheels, and subsequently sent three Crampton engines of smaller dimensions to the Pennsylvania Central Railroad, in September, 1849.

Norris Brothers made seven locomotives for the Camden & Amboy Railroad, each with a single pair of eight-feet driving wheels and a six-wheeled truck, a cut of which was on the first page of your February issue, showing the "John Stephens."

In the year 1849, Ross Winans, of Baltimore, built a single locomotive for the Boston & Worcester Railroad. It was for an experiment in coal burning, and constructed to burn anthracite coal. This locomotive was named the "Carroll of Carrollton." It had one pair seven-foot driving wheels, and was intended for very high speeds. It had two small steam cylinders placed on the sides of the boilers, over the bearings of the driving axle, by which the weight on the drivers could be varied from three to twelve tons.

The seven-foot drivers were cast with chilled rims, and were of extremely light pattern; in fact, they became broken after running six weeks. These were replaced with a set of imported wrought-iron wheels, the first of the kind brought to this country.

The speed of this locomotive, under favorable circumstances, was one mile in sixty seconds. It was run between Albany and Boston, and the train consisted of from seven to eight cars, and made a mile a minute with ease. The engineer, J. H. Jackman, says: "Since I ran her, in 1849, I have traveled many thousand miles on locomotives, and have seen some high speeds made; still I never saw the locomotive that could lay right down to it and outrun the "Carroll of Carrollton." When I ran her we made many stops, and therefore could not make better time than locomotives having smaller driving wheels. But give me fifty or sixty miles on a clear run, and I could outrun a thunder-storm if it was going our way. In those days we had no air brakes, and to run at such high rates of speed sometimes became dangerous. I remember one instance, in the night time, of rounding a curve at about sixty miles per hour, when a danger signal met my view. I shut off steam and whistled down brakes, but they did not seem to check me. I whistled again; still the speed kept up. I gave the third signal for brakes, and then reversed my engine, saying to her: 'Do your duty, my beauty,' or in twenty seconds it is good-by to railroading. We came to a standstill eighty rods from a train on the main track, having run one mile and a quarter from the place where I first discovered the red light. A locomotive engineer, to avoid trouble, must take time by the forelock—in other words, must anticipate possibilities."

In 1849, Mr. Thomas Rogers, of the Rogers Locomotive and Machine Company, introduced the link motion in his practice. Other builders, however, strenuously resisted the innovation, and none more so than Mr. Baldwin, of the Baldwin Locomotive Works, Philadelphia.

Mr. Rogers may be fairly said to have done more for the modern American locomotive than any of his cotemporaries. In America the standard wood-burning locomotive stands precisely where he had brought it in 1852, and where he left it at his death, in 1856. His influence thus strongly exercised was not that of original invention, but of sound judgment—a practical appreciation of what was best among all the diverse details of construction which he had found in the current practice, or which arose in his own effort for improvement.

A 3-Cylinder Locomotive.

Since the publication, in November, of the fact that there were in use 3-cylinder locomotives, we have had several requests for working details.

These locomotives were designed and patented by John B. Smith, now president of the Erie & Wyoming Ry., in 1880. They have three cylinders, each 8" bore by 12" stroke, four driving wheels 34" diam.; steam ports $\frac{3}{4}$" by 6", $\frac{1}{4}$-inch lap of valve, one inside connecting rod, two outside connecting rods, and weigh 4 tons.

It is claimed that these engines have hauled 98 tons up a grade of 45' per mile, at a speed of 8 miles per hour, with 130 pounds of steam.

Suppose you are standing on the left side of engine; Fig. 1 represents the piston of main rod and side rod on the right side; Fig. 2 the center engine and its connections, and Fig. 3 the left engine and its connections.

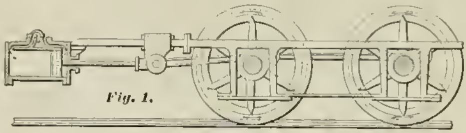

Fig. 1.

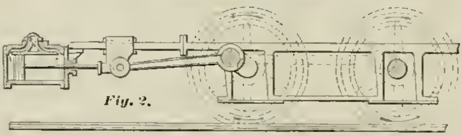

Fig. 2.

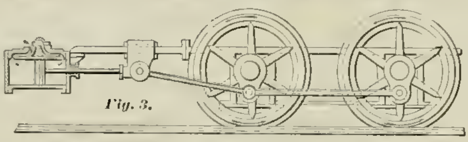

Fig. 3.

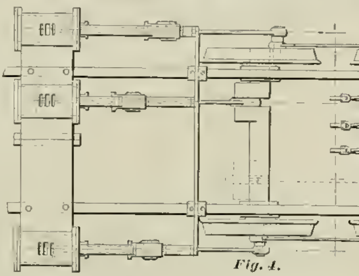

Fig. 4.

Fig. 4 is a plan showing the location of the cylinders, the three sets of eccentrics, and the inside side rod.

The inside cylinder is placed out of the center, so as to make room for the inside paralleled rod. From the illustrations the whole plan will be plain to any mechanic.

Positively the Last

GRAND TRUNK.

It is very rare with our Standard engines to interfere with steam-pipe rings, as the pipes are so constructed that flues can be taken out without interfering with pipes.

Some engines have been running here over five years, and rings have not been interfered with.

When they require doing up one advanced apprentice can do them easily in ten hours, at a cost of from 80 cents to $1. W. D. ROFF,
Belleville, Ontario. R. H. Foreman.

Your letter of the 25th, addressed to me at Fort William, received to-day. In reply I would say that, during my time there (four years), in no one instance were steam pipes removed for the purpose of remedying a leak, as none existed. The engines principally in use there are built by Dub & Co., Glasgow. The steam pipes are held in place by four bolts at either end, with rings of very much softer metal than in general use on American engines; that is, a larger proportion of copper. The round joints to all appearances had never been ground, as, when removing pipes in several instances to take out tubes, the tool or "chatter" marks in the sockets were plainly discernible on the rings; the flat surfaces appeared to have been well faced and ground. In replacing the rings, the flat joints were ground and the circular joints were cut down to a bearing not more than $\frac{1}{16}$" wide, which was not ground, but crushed by the force of bolts to place. I have never tried it, but see no objections to making the joints on both sides of the ring in this way. A. F. PRIEST,
M. M., E. Ry. Co. of Minn.
West Superior, Wisconsin.

LOUISVILLE & NASHVILLE.

Grind when found leaking—generally indicated by engine not steaming. Have done the work and sent engine out in eight hours, estimated cost, $5.
C. F. GILES, M. M.
Pensacola, Fla.

About once in two years; never had occasion to do this work after engine was in road service. Time, about ten hours, steam and exhaust pipe; skilled labor not necessary, use a helper. Cost, steam pipes, $1.75. THOMAS WALSH,
Mt. Vernon, Ill. M. M.

KEOKUK & WESTERN.

Only when engines go in for repairs. An apprentice and helper only on this work, time, six days for all joints from the throttle to the exhaust.
Foreman in charge, K. & W. shops
Centerville, Ia.

OREGON SHORT LINE.

No general rule; most of our engines run till flues are changed. Time, 5 to 12 hours, depending on condition of joint. Cost, from $3 to $5.
G. SPOUGBERG,
Montpelier, Idaho. R. H. Foreman.

LAKE ERIE & WESTERN.

Very seldom, except in back shop. It takes two men about twelve hours; machinist and helper, $5.10; boiler maker, $1.25. A. A. ORR,
La Fayette, Ind. R. H. Foreman.

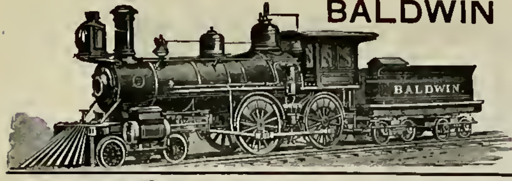
CHICAGO, MADISON & NORTHERN.

About once a year; have a special set of wrenches for this work. Time, ten hours; cost, $4.
STEVE H. O'NEILL,
Freeport, Ill. R. H. Foreman.

NEW YORK, LAKE ERIE & WESTERN.

Grind in once in six months; sometimes they last longer; time one day. Cost about $3.70. G. W. NORRIS,
Carbondale, Pa. R. H. Foreman.

The Brotherhood of Engineers of the A. T. & S. F., at Newton, Kan., recently held a largely attended ball, the proceeds of which they will devote to the establishment of a new lodge.



BALDWIN LOCOMOTIVE WORKS.

ESTABLISHED 1831.

ANNUAL CAPACITY 650

LOCOMOTIVE ENGINES,

Adapted to every variety of service, and built accurately to standard gauges and templets. Like parts of different engines of same class perfectly interchangeable

Broad and Narrow-Gauge Locomotives; Mine Locomotives by Steam or Compressed Air; Plantation Locomotives; Noiseless Motors for Street Railways, Etc.

Illustrated Catalogues furnished on application of customers.

BURNHAM, PARRY, WILLIAMS & CO., Proprietors, PHILADELPHIA, Pa.

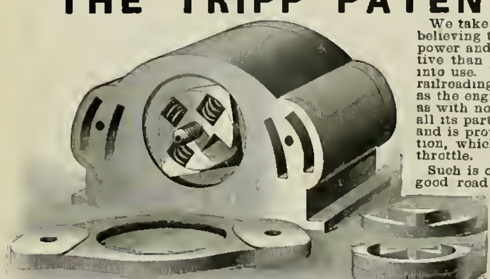
THE STANDARD STEEL WORKS

PHILADA., PA.

THE TRIPP PATENT PISTON VALVE.



We take pleasure in presenting this Valve to Railroad men and others, believing that its use on a Locomotive Engine will effect a greater saving of power and expense in the maintenance of the working parts of the Locomotive than has been accomplished since the Locomotive was first brought into use. We also believe that its use will add largely to the safety of railroading, and prevent the destruction of many lives and much property, as the engine can be reversed as easily with 160 lbs. pressure on the Valve as with no pressure, it being a **Perfect Balance Valve.** The Valve in all its parts is as durable as any of the working parts of the Locomotive, and is provided with a relief device, simple in its construction and operation, which relieves back pressure instantly when running with closed throttle.

Such is our confidence in this Valve that we will furnish a pair to any good road for trial, on their furnishing following dimensions: 1st. Diagram of cylinder face showing ports. 2d. Travel, inside and outside lap of valve. 3d. Distance from cylinder face to center of valve stem. 4th. Size of valve stem. 5th. Length, width and height of steam chest from cylinder face. Internal measurements.

Said Valves not to be paid for until they have demonstrated their value to the satisfaction of the road.

Prices, terms and additional information furnished on application to

THE TRIPP ANTI-FRICTION JOURNAL BEARING CO., 33 INDIA WHARF, BOSTON, MASS.

The Locomotive Engineer.

Devoted to the Special Interests of Locomotive Engineers and Firemen and to Locomotive Maintenance and Repairs.

VOL. II, NO. IV. NEW YORK, APRIL, 1889. $1.00 per Year. or 10c. a copy.

A Long-Felt Want.

This item is written with a pencil sent out by Pedrick & Ayer, Railway Repair Shop Tools, Phila., and bearing their ad. on its sides and a nickel-plated rubber tip on its north end. What the roundhouse and repair shop foremen of the country want is a pencil with an 8x10 swab on top, that will take finger marks, abbreviations, elbow prints and tobacco juice off the work book, and keep 'em off. If Pedrick & Ay——there, lead broke.

Arizona has passed a law making train robbery a crime punishable with death. Train robbery is petty larceny as compared with train wrecking. The deliberate placing of obstructions on a railway track is to all intents and purposes attempted murder, and should be dealt with as such. Dealing with train robbers and train wreckers is like cooking rabbit—first get your rabbit.

The conductors and other trainmen on the Mobile & Ohio road have been provided with Winchester rifles to protect their train from robbery.—*Conductors' Monthly.* Good chance for the conductor to get his work in on the spotter—but the spotter is after train robbers too.

The *Railroad Patriot*, late of St. Joseph, Mo., was only in a trance, and has come to life at Denver, Col. Its epitaph is not yet cut, and we hope it never will be. The *Patriot* proposes to look after western railroad news and fight for fair pay, reasonable hours, and against detectives and spotters. Success to it.

The Webb Compound Locomotive.

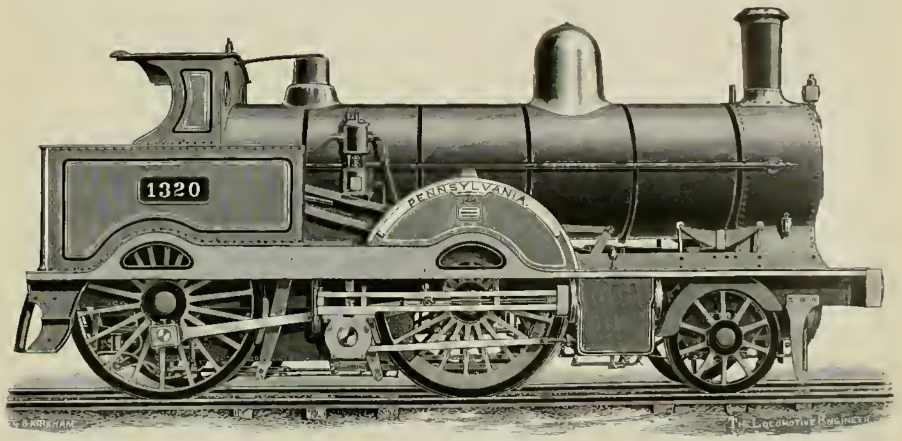
The Webb Compound Locomotive has arrived from England, and is being limbered up on the P. R. R., at Altoona. Through the courtesy of Mr. F. L. Sheppard, Superintendent of Motive Power, the editor of this paper was given a chance to inspect the engine in the shop and ride on her over the road, and the following description, comments and criticisms are from an engineer's standpoint, and in comparison with American locomotive practice.

The principle of the compound engine is to take the exhaust steam from one or more cylinders and use it in another or other cylinders. In the Webb system two high-pressure cylinders exhaust their steam into the chest of one large, low-pressure cylinder. The engraving on this page represents the engine just as she was on her arrival. Since she was put in service the large hooks, or life guards, as they are called, in front of her leading wheels have been removed and a P. R. R. standard pilot put on, the small head-lamp has been replaced by a somewhat larger one of the same pattern with a gong behind it, with a bell cord to the cab—there are no bells on English locomotives, a small whistle being used instead. The tender has also been fitted with a scoop, to take water while running, and a Janney draw head.

The high-pressure cylinders, 14 x 24, are located between the drivers and are coupled to the back pair of wheels—no side rods are used. The low-pressure cylinder, 30 x 24, is located under the smoke arch, and the main rod coupled to a center crank in the forward axle.

Both pairs of driving wheels are 75 inches in diameter, the leading wheels 44—with this system it is not necessary that both pair of drivers should be of the same size.

Steam is sent from the dome through the front end, down beside the low-pressure cylinder and back to the high-pressure chests—which are underneath the cylinders—through a pair of 3¾ copper pipes. The exhaust steam from the two smaller cylinders is carried to the smoke box by a pair of 5-inch pipes; these enter the front end at the bottom and are carried in each case entirely around the inside of front end and enter the top of the low-pressure steam chest. In operation, steam is admitted to the high-pressure cylinders and exhausted into the low-pressure chest to further expand and do additional work. Only the exhaust of the low-pressure cylinder is heard or has action on the fire, and it sounds very odd to hear the exhausts so far apart at high speeds.



There is a gauge in the cab, that registers the pressure in the big cylinder, and we noticed that, in working hard on the heavy grade out of Altoona west, that this pressure was from 30 to 40 pounds when the steam was following the piston in the high-pressure cylinder for about ¾ of the stroke—the low-pressure cylinder being worked full stroke all the time.

The valve motion is of the Joy type, much used in Europe and peculiarly adapted to these engines. Fig. 2 is the adaptation for the inside cylinder, and is like that on the outside cylinders, except the latter is turned upside down to get the motion to valves, as they are under the cylinder.

The diagrams will make the motion clear—the rods are hid in the large engraving. The Joy gear has no eccentrics, return cranks or other actuating motion on the axle, but takes all the motion from a pin located near the front end of the main rod. In Fig. 2 the motion of the main rod is repeated on a smaller scale by the arrangement of linked rods; the lower or radial rod being fast to the back head of the cylinder, the motion of the rods simply shoves a die block up and down in the slotted block shown; to this die is fastened the valve rod, and it is plain that if the slot were straight up and down no motion would be given to the valve stem; but, as it is inclined, the rod will have a motion forward and back, and if this motion cuts off the steam properly when the top of the link is inclined toward the cylinder it will be reversed when it is inclined from the cylinder, the reversing is done and the travel controlled by changing the position of the slot. In the outside arrangement the slot is hung in the center of the motion plate shown under back end of guides, and the motion controlled by swinging the block containing the slot. Fig. 3 shows the arrangement of this motion.

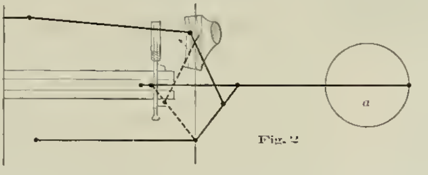


Fig. 2

This engine weighs 99,000, about 27,000 of which is on the leading truck wheels and the rest on the drivers. It is evident from the way the engine rides, and the ease with which the back pair of wheels slip, that there is much more weight on the forward drivers than on the back pair; this seems to us a serious fault, as the back wheels slip badly on the start, and, if the low-pressure piston is on the center, the engine is very slow to move—indeed, she was recently stuck at the coal chute under these circumstances while light. In starting, the train is jerked severely when the low-pressure cylinder takes steam.

The cab is the most interesting part to an American engineman; this engine's cab is only different from the regulation English engines in having the reverse gear on the right side.

The high-pressure valve motion is handled by a screw-wheel in the corner of cab, and the low-pressure by a lever located back of the engineer—in most of the engines on Mr. Webb's own road the gears are connected and handled by one motion—which would seem a much better arrangement, yet by the present plan the low-pressure cylinder can be full stroked, while in the high-pressure cylinders steam is being worked expansively.

The throttle, or regulator, stands up at the front and top of boiler head, and has a motion from the engineer to open, looks like a grindstone crank, and is worked wide open. On each side of it there are water glasses—no gauge cocks used. On the outside of the glasses and near the water line are located the checks, with large hand wheels over them to force them to their seats, if necessary, the feed pipes come up from underneath the deck and the delivery or branch pipes extend from the checks through the boiler to near the front.

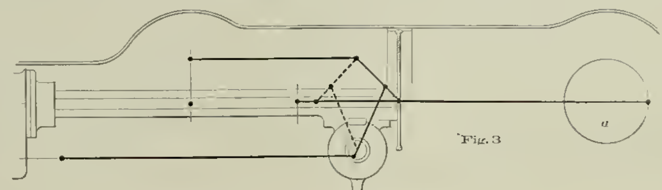

Fig. 3

The engineer's brake valve is located in front of the runner and just above the screw reverse gear, the air gauge being located on the front of cab on the right side, the steam gauge on the left—pressure 180—and the low-pressure gauge on the right side of the cab. In front of the engineer is located a lever that is used to open communication between the high-pressure exhaust pipes and the atmosphere, as without this the engine will not drift down hill very fast, as the pumping action of the pistons creates vacuum enough in the high-pressure cylinders to check the speed.

On the boiler head is one oil cup with pipe running through boiler to oil the valve of low-pressure cylinder, the cups for high-pressure cylinders being on running board outside.

There is also a lever on the right side to open a small steam connection to low-pressure cylinder to warm it up, and possibly help start.

Below the screw reverse and on the deck is a lever to open some very large cocks on the steam chest, exhaust pipes and connections under the engine—there are 14 cocks under the 3 cylinders and their connections, with several levers in the cab to manipulate them.

On the foot plate is located two levers for controlling the foot cocks to injectors—these are Gresham non-lifters located under deck, and on this particular engine are too large or have little range, as they had to be worked full, and then shut off—a method of working that makes it very hard to maintain an even boiler pressure. Modern injectors with range to suit the requirements of the engine would do much to make the engine more satisfactory in its steady steaming and water carrying.

The fire-door opens inwardly from the top, thus becoming a deflector when open, it is handled by a short lever with a spade handle located on the left side and above the door, it will remain open any degree as set on the quadrant, but automatically closes by merely releasing the latch. The door proper is a simple casting without machine work—easily replaced for a few cents. This one was red hot all the way up the hill, but we are informed that they run from three to eight months without renewal. The cab lamp is located on a shelf just over the door, and does not show any of the gauges or water glasses. On the back of cab roof there is a small piece of bright tin supposed to reflect the light from door upon the gauges—in England they use a mirror for this purpose.

The edge of the cab all around is an oval section of finished iron, the cab proper is of ⅛-inch steel painted black outside and drab inside.

Immediately over the center of boiler, and forming part of cab, is a box containing both whistle valves and both injector throttles, with their four levers extending into cab; just outside of the cab is a pair of encased Ramsbottom pops. The seats are plain plank, too low to sit on with comfort—there is a book of rule order on the home road of these engines, London & Northwestern, that the crew shall not sit down.

The running board is wide and the cab narrow, the engines being easy to get about over, no wood is used except a temporary wooden desk. The boiler is covered with a wire air space and a blanket of asbestos cloth, and then a jacket of ⅛ steel sheets painted jet black with a very light red stripe along the edges of the bands.

The front end and doors are models of fine wrought-iron work, and the excellent finish and plain paint of the whole engine is of a nature that gives the machine the appearance of thorough excellence in workmanship and material, not seen in this country—there is nothing fancy, not a single piece for appearance.

In front of the forward wheels will be seen some large pipes extending nearly to the rail; these are open in the front end and used to carry off cinders.

The engine is provided with independent sand pipes for both pairs of drivers, and also has a pair on front of tender, to use in backing up.

The round glass windows in front of cab are hinged at the top, and can be fastened to top of cab in pleasant weather.

On each driving wheel cover is a brass box with oil pipes leading to the driving boxes, with cocks to control the flow of oil—there are few, if any, points about the engine that cannot be lubricated while in motion.

The wheel centers, crossheads, motion plates and in fact most all the pieces usually made of cast or wrought-iron, are made of cast-steel. Just back of the stack there is a safety valve that prevents a pressure of over 75 pounds from being reached in the low-pressure chest.

The driving boxes are solid and have no wedges.

The front truck is of a peculiar construction patented by Mr. Webb. The boxes on both sides are fast in a heavy wrought yoke extending across the engine frame from side to side; this double box casting does not cross the frame in line with the axle, but is itself a segment of a circle struck from the center of the frame some distance back of itself, thus, when the engine strikes a curve the swing of the axle advances the wheel on the outside of curve and retards the one on inside, this swinging frame has a motion each side of the center of about two inches, and is held centrally by huge coil springs under the center of axle and fast to the frame of engine. The engine curves very well.

This locomotive was not made at the London & Northwestern shops at Crewe, but by Beyer, Peacock & Co., Ltd., Manchester, Eng., and was sent out in charge of one of their machinists, Mr. Ned Barker, who set the engine up.

The L. & N. W. road sent an experienced engineer, Mr. Benj. Hitchen, who has been running on that road for more than 30 years and handling compounds ever since they were put in service. Mr Webb is to be congratulated on his selection of this engineer, as he is a whole-souled railroader all the way through, with none of the bluster and blow that usually characterize English mechanics sent to this country. He sees the case as it is, comments intelligently on the difference between our practice and theirs, and has as many warm friends among the Altoona engineers as anybody could have in the time he has been there. The repairs of the engine are under the charge of Mr J. E. Howard, a young English mechanic, who has been for some months an employe of the P. R. R., and who is thoroughly familiar with the compound system, from having worked on the engines in Europe; he is a good match for engineer Hitchen, and carries a very good brand of cigars.

The engine is handled, and very nicely, by engineer Hart, the duty of the English engineer being simply to ride on the engine and see that the boys don't get stuck. There is a chance for this among all the handles used.

The compound is only being "limbered up" on the hill, and will be tried on trains and track better adapted to her construction. She should show up the best on the division between New York and Philadelphia, where it is comparatively level, and on trains making the fewest stops—the start is where she loses time and jerks badly.

On the trip up the hill the throttle was wide open, yet the engine steamed well, standing up at 180 with remarkably light firing, what she will do alone with a fast train remains to be seen.

It is our humble opinion that this engine will not be counted a success on our roads, and do not believe that the P. R. R. will buy or build any more of this particular kind. We hope that if she does fail to do all claimed for her that it will not condemn compounding in this country. If a compound engine were built with but two cylinders, and in the same place they are, on our ordinary engines, with rods, pins, etc., of the same weight on both sides, but one cylinder much larger than the other, and there was provision made for working high-pressure steam, through a pressure reducer, in the low-pressure cylinders, so that in starting and on heavy grades the engine would be to all intents and purposes the same as we now have, and then had provision for compounding after train was worked into speed, instead of hooking back till steam is cut off at 6 or 8 inches, and expanded down and released just as the pin is on the quarter and doing some effective work. By admitting the steam in the high-pressure cylinder for three-fourths of the stroke and then using it in the large cylinder, we ought to be able to do more work with less fuel and at the expense of no extra parts to keep up.

The tender is about the size and shape of ours on and above the deck, but a plate frame is used with three pairs of wheels, instead of our double truck. The gangway is wide, and a pair of rods extend from the deck to an extension of the angle iron around tank, that make very nice hand-holds. A screw brake is used.

The boiler is about fifty inches in diameter with a copper fire-box, 66 inches long. The boiler is built on Mr Webb's well-known plan—no foundation ring being used, but the water space extending clear around under the grates, doing away with the use of an ash-pan.

Of course the railroad boys could not see so strange an engine around without giving her a name, and the P. R. R's Webb compound will go down to history—among the rank and file—as "Jack-the Ripper."

The Strong in Actual Service.

The Strong locomotive, A. G. Darwin, recently built at Hinkley's, is now running on the Erie, and, so far as we are able to learn through the engineers and firemen, has not done any surprising work as yet. On long runs it is claimed that her fires clinker badly. She hauls one more car than the best engines, but this is a small increase of load for her extra size and weight. Some of her valve motion is reported light, with frequent break-downs. Of course the proper sizes for all parts of a new device cannot be established without trial, and the trouble now experienced may be overcome. The hauling of 30 loaded cars at the rate of 80 miles per hour, and the engineer *holding her back* all the time, that was promised by several railroad papers just after her trial trip, seems to be some distance away yet.

The Eclipse Lubricating Oil Co., Limited, Franklin, Pa., have issued a neat, leather-bound note-book, with patent removable pads. The book is intended as a memorandum for their oil-users, to whom it will be furnished free. Inside the cover they give directions for the use of their oils, and make the proposition that those doubtful of the merits of their cylinder oil try it for six months on one side of a locomotive, using tallow on the other, and decide on its merits this way. This seems like a fair proposition.

Alexander's Ready Reference tells engineers what to do in an emergency. Plain, short directions, without any superfluous words or explanations. The work is so small that it is easily carried in the pocket, and is always ready to help a fellow out in a break-down. We were surprised recently to see the record of sales. There must be thousands of these little books in the hands of our enginemen.

A correspondent sends drawings of a lubricator with a pipe attached to draw off the water of condensation without use of a dish or getting the boiler head dirty. If the makers do not put on drip pipes the men generally do. The device hardly needs illustration.

Judging by the way orders are now coming in for bound volumes for last year, the present edition will be exhausted in a few months, and the books worth $5 in a couple of years.

Balanced Valve Kink.

The Pennsylvania road are using a large number of Richardson balanced valves, embracing some new features, the ideas of assistant M. M. Jos Davis. They formerly had trouble with the balancing plate being sprung out of shape, either by its own four bolts or by the cover being sprung in bolting down, they believe they have entirely overcome this difficulty by holding the balance plate by a single central bolt. The long packing strips are grooved out slightly on top, leaving the edges about $\frac{1}{32}$d wide; this allows the strip to wear itself to a bearing sooner than if it was full width at the top. The long strips are also let into the end strips enough to make a side bearing on the corner joint as well as on end bearing.

A Packing Ring Kink.

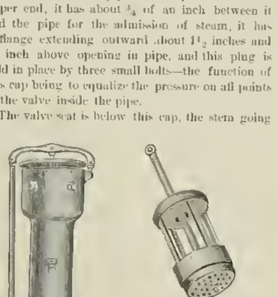
General Foreman Owens, of the R & D. shops at Manchester, Va., had some trouble with the blanks for cylinder packing rings springing—they hold them in a 3-jawed chuck—and overcame the trouble by having a brace cast at one end of the blank, as shown in the sketch. By placing the jaws of chuck opposite these braces the springing is avoided. The usual practice of casting lugs on the outside of blank, to bolt to face plate, is not so handy or as quick as the use of a chuck.

Lozon's Throttle Valve.

This valve is the invention of Chas. Lozon, a machinist in the Michigan Central shops at Detroit, and is described by him in substance as follows:

The straight stand-pipe has a cap fitted into the upper end, it has about ¾ of an inch between it and the pipe for the admission of steam, it has a flange extending outward about 1½ inches and ¾ inch above opening in pipe, and this plug is held in place by three small bolts—the function of this cap being to equalize the pressure on all points of the valve inside the pipe.

The valve seat is below this cap, the stem going



LOZON'S THROTTLE VALVE.

through it; the valve is loose on the stem and can turn around so that it does not necessarily seat itself in the same place every time.

The levers are so arranged that the valve is always lifted squarely from its seat.

The object of the invention is to insure a tight joint at the seat and make a thoroughly balanced valve.

Any further information can be obtained from the patentee as above.

The gilded walls of the sanctum of the philosopher of this sentiment foundry are now adorned with a large photo of Richardson's valve motion model.

During February the railroad across the Brooklyn bridge carried 2,540,564 persons and 167,613 walked across the foot-way.

A Fast Scotch Engine.

Mr. Hugh Smellie, locomotive superintendent of the Glasgow & Southwestern Railway, has recently built some heavy passenger engines that are making remarkable runs.

The distance from Glasgow to Carlisle is $115\frac{1}{4}$ miles and the time two hours and thirty minutes, less seven minutes station time at Kilmarnock and Dumfries, this is 49 miles per hour over the whole division, and the line has several long hills where the grade is one in sixty seven for several miles, and two five-mile stretches where it is one in one hundred. These engines are 8-wheelers, with 27,300 pounds on the truck and 57,200 pounds on the drivers. The cylinders are $18\frac{1}{4}$ x 26 and the driving wheel 80 inches in diameter. Length of ports 16 inches, travel of valve, $4\frac{3}{4}$ inches, lead, $\frac{1}{8}$ in full gear, lap, 1 inch. The valve travel and length of parts is much less than usual American practice.

The designer of this engine believes that for heavy service, long stroke and large wheels do much better than by reducing the size of wheel and running at excessively high piston speed, and the success of his engine seems to bear him out. It has long been the opinion of the writer that American freight engines would do better work with longer stroke and larger wheels, they would not have to make the turns in a mile, would ride easier, last longer, be easier on their valve motion, journals and the track.

The boiler of Mr Smellie's engine is but 50 inches in diameter with a fire-box $62\frac{3}{4}$ inches long by 40 inches wide, containing 106 square feet of heating surface and $17\frac{1}{4}$ square feet of grate, with 238 $1\frac{5}{8}$-inch tubes, containing 1,082 square feet of heating surface. This boiler would be considered small in this country for the cylinders used.

Air Brake Practice.

BY J. E. PHELAN, M. M.

About air brake appliances nothing at present seems more interesting than the new engineer's brake and equalizing discharge valve. This is the latest indulgence in improved design for the purpose of automatically assisting the engineer to apply brakes moderately and skillfully for ordinary stops.

The principle of the original engineer's brake valve and its later improvements, embodying the 20-pound reserve principle, are all preserved in the engineer's brake and equalizing discharge valve. But in outside appearance and inward design radical change is apparent. This new engineer's brake and equalizing discharge valve seems to have added the automatic principle of the triple valve to its mechanism, *i. e.*, the principle of the greater pressure controlling the lesser.

Where valves in the engineer's valve or 20 pound cock are held to seats by springs, valves in the new design are held to seats by air pressure, excepting the 20 pound reserve or feed valve, which is held to its seat by a spring.

This engineer's brake and equalizing discharge valve was started in at the Burlington brake tests, but has undergone two changes in design within its mechanism since. We will attempt to explain the latest design first, and make notes in retrospect concerning the two of previous design.

The main purpose of this new valve seems to be to insure a more easy and uniform application of brakes the entire length of cars, or brakes in use, and by establishing an easy and gradual reduction of air from train pipes to atmosphere, avoid the sudden reduction of pressure from forward cars, and consequent release of brakes by concussion of air from rear cars.

How this automatic reduction of pressure from train pipe occurs will appear further on.

The engineer's brake and equalizing discharge valve, now being furnished by Westinghouse Co., is comparatively simple and effective.

In action its parts for controlling air pressure commence with the handle and handle spring, same as in common engineer's valve, or 20 pound cock. This connects on with rotary valve key, which acts in placing rotary valve in position, as indicated by position of handle. The rotary valve comprises the functions of the former top valve and main valve of 20 pound cock. Below the rotary valve is the air chamber of valve body. Attached by piping to this chamber is a small auxiliary reservoir for purpose of adding air capacity. Below the chamber is located the piston valve with ring, similar to any piston in principle, fitting into cylindrical part of valve body connecting to train pipe. The lower end of this piston and rod forms a seat on a projection from side of body and leading to opening to atmosphere. This piston valve is the part acting automatically when brakes are applied in service stops.

Then we have the 20 pound or feed valve, set in independently at side of valve body. This comprises the mechanism of the engineer's brake and equalizing discharge valve.

A former design of this device had openings through piston for air to pass into train pipe from source of supply—these openings being controlled by a check valve and spring fastened to rod on lower side of piston. There is also a stop-cock on side of valve body to control opening to atmosphere. This was intended to be closed by hand in event of any substance lodging under seat of piston valve and preventing its closing. It should be borne in mind by those handling this class of engineer's valve, that this stop-cock should be left open when operating the brakes.

The engineer's valve in use at Burlington tests, in addition to above had a slide valve attachment on piston rod, somewhat similar to slide valve of triple valve.

But let us return to rotary valve as moved and controlled by engineer's valve handle. This rotary valve controls the ports and acts in principle as the common plug in engineer's valve, or as the main and top valves in common engineer's valve, or 20 pound cock.

You can note that on common engineer's brake valve, the main reservoir pipe connects on the bottom, and train pipe connection comes in on side of valve body; while on the engineer's brake and equalizing discharge valve, the main reservoir pipe connection comes in on side of valve body and delivers air from main reservoir to top of rotary valve, while train pipe connects at bottom of valve body. In old design, air passes down through rotary valve, thence through piston and past check valve, in reaching train pipe and auxiliaries. In latest design air passes through passage known as direct application port in reaching train pipes and auxiliaries from main reservoir. This direct application port is formed inside of valve body similar to passage leading from main reservoir on sides of valve body. The passage from main reservoir leads into valve body over the rotary valve; the passage to train pipes, or direct application port, leads down from rotary valve seat.

Let us move the handle of the engineer's valve as far as handle spring will allow it to go toward the left. This is known as release position. In this position main reservoir is in full opening and communication with train pipe and auxiliaries. Take the rotary valve and examine its face; you will find a fair sized blank cavity cut into its face. You will find near one end of cavity, but separated from it by bridge on face, a port of oblong shape; this port passes through the rotary valve. By examining valve seat, you will find a blank cavity in seat directly under this supply port, and when in release position, practically a part of it. The supply of air from main reservoir, coming in on top of rotary valve, passes down through this port into the blank cavity, on seat, and passes along this cavity past the bridge, and then flows up through the hollow or cavity in valve face, until it reaches direct application port, or train pipe opening, when it flows thence into train pipe and auxiliaries. This gives a direct and free passage of air from source of supply to train appliances.

We will now move handle to position while running, by bringing handle spring to first slot to right of release position. In this position 20 pounds air, more or less, will always be retained in main reservoir, over and above amount of pressure transmitted to train appliances while handle is in this position. When in this position you will notice the supply port cut through rotary valve simply feeds into blank cavity in valve seat, and has no further outlet. But near side of rotary valve you will find a small round cavity running through the valve, and when in this position this port lays directly over a similar port in valve seat. Through these ports air passes down through small passages cored in side of valve body, passing 20 pounds or feed valve, thence by this cored passage into side of direct application port or passage leading to train appliances.

To the right of this feed port in valve face, is another port of similar size leading through valve seat. This is intended as an equalizing port, and acts in supplying chamber, and small auxiliary reservoir connected with chamber, with air. It also supplies pressure on top of piston valve, and keeps this valve on its seat. Air flows to this equalizing port from train pipe, through cavity in rotary valve face, when handle rests in release, or feed position, while running.

To the left of the feed port in side of valve seat you will find two small round ports close together. One leads to atmosphere and the other through valve seat to chamber. We will now move handle around to position for application of brakes, service stop. In this position, handle spring resting against stop at the right of middle guide-way, you will find that air is shut off from feeding through equalizing port, and that it flows from chamber and small auxiliary up into a small, narrow groove or cavity in side of rotary valve face. This cavity at one end (when handle in service stop position) connects at one end with port from valve chamber and at other end with atmosphere; hence air passing into it from chamber passes directly through the opening, into atmosphere, or through the preliminary exhaust port. When from 3 to 8 pounds of air has escaped in this manner, turn handle to left until handle spring rests against stop to left of middle guide-way. This is on lap or blanked position, where all communication between ports controlled by rotary valve are shut off. The amount of air escaping from preliminary exhaust simply escapes from the valve chamber and small reservoir. This reduced pressure on top of piston valve allows air from train pipe to force it off its seat and escape past uncovered seat into atmosphere, through application port in side of valve body at lower end. When an amount of air has escaped from train pipe by piston valve opening, equal to that having escaped from preliminary exhaust opening, the piston valve should return to seat automatically, while handle is yet on lap or blanked position. But you may find that if considerable air has escaped from preliminary exhaust, the piston valve seems tardy about returning to its seat and shutting off the automatic flow of air. This can be easily controlled and remedied by pushing handle and spring a little past the stop to left of middle guide-way and holding it midway between lap and feed positions for a moment or two. This brings action of air from train pipe to bear through equalizing port, and, acting with pressure remaining in chamber and small reservoir, quickly seats the piston valve. But if air is exhausted from preliminary exhaust port very lightly, this necessity may be avoided.

We believe that handle of engineer's valve should never go past service stop position to the right, except to avoid accident.

In position for application of brakes for emergency stops, or with handle spring resting against stop to extreme right, the blank cavity in face of rotary valve connects at one end with train pipe ports and at the other with direct opening to atmosphere at back of valve body. When in this position air flows freely and directly from train pipe to atmosphere, and acts as our Western R. F. recommended, "alle same bursting a hose."

Principle of action with this engineer's brake and equalizing discharge valve when connected as double-header in mountain service, etc., should be treated here, but will come in with future paper.

Hassman's Tire Heater.

The tire heater here shown is the invention of William Hassman, M. M. of the Richmond & Allegheny Ry., at Richmond, Va.

The device consists of a tank, generally an old air drum, filled with some porous material—sponges, etc., generally excelsior—and the air pipes.

The pipe and hose provided with coupling head is attached to a locomotive train pipe hose and the supply of air furnished by the pump, this pipe goes nearly to the bottom of tank, the pipe to hoop is tapped into the top and has a check valve near the tank to prevent air from entering the drum. In use, the tank is partially filled with hydro-carbon liquid—preferably gasoline of 86° fire test—the hoop with perforations for flame jets adjusted to the tire to be expanded, and the air pressure turned on. The air agitates the liquid, and rises up through the saturated porous filling, and appears at the flame jets as a highly inflammable gas which burns freely.

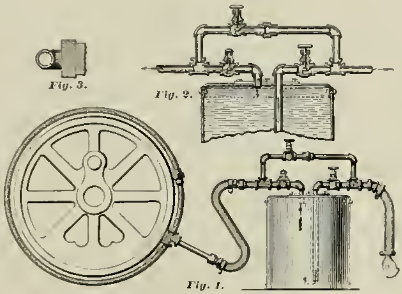


Fig. 3. *Fig. 2.* *Fig. 1.*
HASSMAN'S TIRE HEATER

In adjusting new work, when the tire is expanded and in place, the valve in the air supply pipe is closed, and that in the top connecting pipe opened; this shuts off the supply of gas, and sends a blast of cold air directly on the tire, thus cooling it uniformly and quickly.

As will be seen, the device is extremely portable—in fact the whole apparatus can be moved about the shop on a barrow or truck—it is made of material always on hand about railway shops, and is therefore cheap.

Fig. 3 shows a brace to keep the tire at proper distance from hoop, and the method of piercing hoop to insure a wide heating surface.

Headlight Signals.

The Baltimore & Ohio R. R. have adopted a new scheme for signal lights on their locomotives which has merit in it.

On each side of the front glass in the headlight, in the beveled ring that holds the same, is set a bull's-eye lens at an angle of about 45°. These are provided with hinged covers to close and make a dark lantern with red glass in, to use when a section is following. They use them dark when running "wild."

With this arrangement there is no danger of the signals going out unobserved; the head lamp furnishes light for all three, and, should that go out, the engineer is apt to discover the fact some time before morning.

[A subscriber sends us the above item; we would say, in addition, that this style of signal lamp is in use on several western roads, and while it has merit, it has a serious fault. The bull's-eye can only be seen from the front of the engine, and when the wind is blowing steam and smoke ahead, or when it blows the steam and smoke from the engine on siding it hides them from view. If the tin ring between the headlight case and the bull's-eye were replaced by a ring of red glass, the signal could be seen from in front, the side, and some time after the engine had passed the observer.]

The P. R. R. folks are working on the drawings of an American Compound.

Correction.

Last month, on page 5, the types made our correspondent, C. F. Richmond, say that he set up a valve motion model so that it gave "exactly equal *cut-off* for every position of lever." He wrote *travel* instead of cut-off; it is impossible with the link motion to get exactly equal cut-off for all positions of the reverse lever.

Bending Iron Branch Pipes.

Just why copper branch pipes should be used for pumps and injectors is not clear. They are very expensive and hard to keep clean if left bright, and look no better than iron when painted. Iron pipes look clumsy when put up with elbows, but when neatly bent they are as sightly, stronger, cheaper, and just as good for the purpose as if made of sterling silver. Some very neat work in this line is done at the Manchester shops of the R. & D. road; they bend their pipes by filling with sand, plugging up the ends and heating.

The Pennsylvania Steam Car Heater.

The system of steam heat for cars that has been recently tried on the P. R. R. (it is said with success) is what is known as a circulating system. Steam is taken from the boiler, and also the exhaust of the air pump, and goes through the coils or radiators in the train; there is another and direct line of pipe and couplings from the rear car back to the locomotive. On the locomotive is a steam-driven, vacuum pump (its exhaust pipe also leads into the heater pipe), which keeps up a partial vacuum in the return pipe; this draws back all the water of condensation to the tender. In cold weather this pump will keep up a continual flow of steam through the whole system, the return steam being condensed in its receiver, in the water-tank. It is believed that this system will be adopted by the Pennsylvania.

India Items.

We are under obligations to Mr. Fred W. Bedford, locomotive foreman (M. M.) of the Great Indian Peninsular Railway at Sohagpur, C. P., East Indies, for photographs, of some of the engines under his charge, and also one of the India Midland. The G. I. P. engines are 17x22 outside connected, and built by Dub & Co., of Glasgow. Their chief peculiarity is the cab, being simply an iron canopy over the men, much resembling the roof of our cabs, the sides being provided with curtains.

The I. M. engine is an inside connected 8-wheeler, by Kitson, the front truck being mounted on roller bearings.

Two views of a derailment also accompany the others, derailment caused by a cut rail, but the native "driver" having been declared asleep, be was fined £2.

Brewer's Lathe Chuck for Turning Eccentrics.

The device shown is a lathe chuck for turning eccentrics, designed and patented by W. T. Brewer, a machinist employed by the Savannah, Florida & Western Ry., at Waycross, Ga.

The device consists of a circular face plate with a slot cut through its center. To this face plate is secured by means of four T-head bolts, an eccentric plate provided with a rib on rear side, which engages and works in slot and guides eccentric plate on face plate.

The eccentric plate is adjusted on the face plate so as to arrange it either concentrically or eccentrically, by slacking the -head bolts (which work in slots in face plate) and operating screw. The eccentric plate has a pointer which is adapted to sweep over the scale and indicate exactly the position of eccentric plate on face place. In securing the eccentric which is to be turned on the eccentric plate, it is placed thereon, and the bolts, which have their heads secured in countersunk recesses, are passed through openings cast in eccentric. Clamps are then placed on and nuts tightened.

The use of this device is obvious to machinists. An eccentric is bored and turned at any desired throw without moving work, but simply by operating screw. This device requires no mandrel, a feature not common in similar devices. No laying off of throw is required, this being done by pointer when screw is operated. It is claimed that an eccentric can be completed easily in two hours by any ordinary lathe man. No bent tools are necessary, as the face plate is only a very little larger than eccentric. If desired, two castings may be clamped together and turned simultaneously.

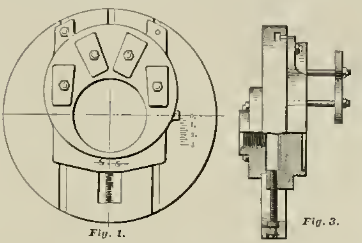

Fig. 1. *Fig. 3.*

Brewer's Eccentric Chuck.

Correspondence

A Pair of Kinks.

Editor The Locomotive Engineer:

The engineers on the D. & H. R. R. used to have some trouble with their signal lights going out when running at 40 miles or more an hour, and one of them, George Hydorn, got up a little rig to hold the lamp steady on the pilot. It was a circular piece of iron for the lamp to set on, and three lugs to hold the flange of lamp stand; two of these were riveted fast, and the third had a sliding motion toward the center and held in by a spring—just like the catch on a cupboard door. The boys say the lamps do better, and do not jiggle themselves out. George has a set of tin flags, red, green and white, with his engine number painted on them; these are kept painted bright, never wind up around the staff and hide, can be washed off when "showered," and are always in sight when out.

These flags have loops to slip over stationary staffs, can be kept under the headlight if necessary, and don't flap themselves loose and blow away like rags, and thus are cheaper and better. The flags are neatly bound with $\frac{1}{16}$ wire, and are as neat as new after six years of service.

Trojan.

John Alexander's Confession.

Editor The Locomotive Engineer:

Dear Sir and Fellow Sufferer I am sitting by the parlor stove at the stilly hour of 3.10 A.M., warming my uncovered shins and a bottle of condensed milk and keeping cases on four chairs full of little white flags of unbleached muslin—white denotes safety. But if it is safety for a fellow's wife to up and have a bran new baby eleven years and four months from the last, and after saying upon her word and honor 9,000 different times that she wouldn't, why, white flags are wrong—ought to put out red to signify "stop," or at least green to signify "run slow, look out for obstructions." But this idea of blocking the crossing of a man's life with a ten-pound obstruction and then swinging him down with white flags after he has got his pony truck under the fire-box, his boots full of boiling water and a reverse lever jabbed into his vitals, is mighty poor railroading—but Mrs. A wouldn't make a railroad man if she lived forever, ain't built right.

It isn't much use to go to bed, for I have to watch that little Alexander pretty close—got such an infernal small boiler that I don't more than get my eyes shut before the low water alarm begins to screech and I can shut it off only by putting a couple of gauges of condensed milk through the heater and into the slumbering volcano that turns its puggy nose up to the chandelier and don't care a continental dam whether I sleep now or next fall.

And now, as I have it cooled down again, both dampers shut and the door open, my thoughts turn back to the science and the rules and the whys and the wherefores of railroading.

If the laws of railroading are like those of nature and cannot be disobeyed without suffering for the disobeyer, then I ought to be in the pillory; for of all these laws, written and unwritten, I am here to confess there are none I have not broken. But if these laws are like those of the Creator, and can be forgiven or forgotten, why I want to confess right here and make you my agent—to give you the benefit of the commission and the experience—you may need to do some confessing yourself. I was just looking over my file of 1888, and I see considerable about reverse levers that you can adjust to a hair, then I have re-read my books on locomotives and other papers with one hand and warmed milk with the other, and in all of them the writers keep poking at the engineers of the country about using steam expansively and saving coal, etc. Then I shut my eyes and I see again the little old log Sunday-school up in the country, and the little old motto, worked with variegated stocking yarn in a perforated card-board, that hung over opposite me, when I used to be a good little boy that had to go where he didn't want—to that same S. S. That motto read, "Love your neighbor as yourself." Now both of these laws or theories are, to me, impossibilities. I never did my work honest on freight with the reverse lever nearer the center than would cut off steam at eight inches, and I never loved a neighbor hard enough to sit up all night and warm milk for his month-old baby.

Mr. Editor, did you ever run on a road where they run double-headers or where they have pushers? You have. Well, can you run your index finger along through your grimy brain and put it upon the memory of a man who always double-headed with the Johnson bar in the six-inch notch and the throttle in the tank? Can you shut your eyes now, scooch down your head to keep the cinders out of your neck, and, metaphorically, look ahead and see that engine hippity-hopping along on tiptoe, rocking from side to side and not pulling hard enough to get a porous plaster off a dead hen? Can you see his fireman sitting on the clothes-box throwing coal at the telegraph insulators with the coal boards all in yet, while your boy is scraping down the cinders from around the manhole of the tank?

Ah! you know him. You had just as lief have the dropsy as go out with him—so would I. Mr. Editor, I don't care a continental who says so, this idea of a full throttle and the reverse lever back of eight inches pulling a train is no good. The engines will not steam working this way, they won't pull, they ride harder, and they are seldom worked this way, eyether. Engineers are, as a usual thing, required to do a certain amount of work, pull so many cars at such a speed, and they are going to do it in the easiest and best way with the means in their hands—if an engine would do her work better on the center or in the corner, there she goes. I have always noticed that these wide-open-high-up men have to *abuse* their pet engines when they are running alone.

Now, I am not a full stroke fiend; I believe in working an engine as far back as she will do her work, steam well and make time.

If I was building freight engines, I would not have a notch between the center and $\frac{1}{4}$-stroke, then I would have them as close as possible. I would let the men put the throttle where it would do the work, but I would have the throttle valve in the nigger-head in front end It is all right enough for you fellows who are sitting behind a desk to write about full throttle and four-inch cut-off to us fellows who are pulling the trains—it is theory, and pleases those who are above us, and who think we are too lazy and stubborn to save twenty per cent. of the fuel when we could as well as not—but it won't do for me; my M M would be apt to call me up in his office and point out to me on the monthly performance sheet my four-inch cut-off coal bill with that of the man who don't believe in it, and ask me why I don't burn less coal.

I don't say you have got on this hobby-horse, but you will have lots of temptation to ride, but you keep right along with us fellows with overclothes on, and we will try every theory you ask us to, honest and fair, and we will do our work, take care of our scrap-heaps, make time and save all the coal we can—but we can't save it all and pull the cars, and we can't pull them with the reverse lever on the center.

Say, do you think opium in small doses, say four ounces every half hour, would make a healthy infant sleep and not impair its draught or circulation?

JOHN ALEXANDER.

On Burning Bituminous Coal.

Editor The Locomotive Engineer:

Average bituminous coal contains about 80 per cent. carbon, 5 per cent. hydrogen, and 15 per cent. of incombustible material, such as cinders and clinkers. In order to produce perfect combustion, sufficient air must be admitted to the furnace to combine with the gases, which are expelled from the coal. The amount must be determined by experience; if the supply is insufficient, some of the gases will escape through the tubes unconsumed; if too much is allowed to enter the furnace, the temperature will be reduced.

One writer on the subject says that every pound of average bituminous coal requires 1.8 pounds of air to burn its hydrogen, and 9.6 pounds for the carbon, so that the amount of air required for the combustion of average bituminous coal may be estimated at twelve pounds per pound of coal.

To produce the best and most economical results with the coal used in the Western States, the layer on the grates must not be too thick, the furnace should be fed with regularity, and three or four shovelsful of fuel at a time; the grates should be moved frequently to allow sufficient air to enter the fire-box, and to prevent the formation of clinkers on the grates, some of the air should be admitted above the fire-box to combine with the gases, which would otherwise escape through the flues unconsumed. After being as careful as it is possible to be, there is still an enormous waste of heat from the loss of unburned coal in the solid state, caused by the fine coal falling through the grates, being carried through the flues, and from the loss of heat by the hot gases which are carried through the smoke-stack. There is also considerable heat lost by radiation and convection from the different parts of the boiler which are not covered by lagging.

In regard to correctly supplying the 12 pounds of air required to combine with the gases expelled from 1 pound of coal in order to produce perfect combustion, it is a difficult matter to always regulate the supply to suit the demand. All experienced men know that on a road having grades, some eighty and others forty feet to the mile, causes the demands of a locomotive to be very irregular. At one time it is worked to the utmost of its capacity, at other times it is not worked so hard. The harder the work, the more coal is consumed, so, consequently, more air must be admitted to the fire.

This is my method: If the fire-box has got large grates, I do not admit so much air above the fire as I would if they were small. If the boiler is not making sufficient steam, I open or shut the front damper, or admit more or less air above the fire, and watch the steam gauge for the results. With small grates I always try to get about 20 per cent. above the fire—our fire-boxes are without arches or hollow stay bolts, but have got perforations in the door.

FRED TAYLOR.

Marion, Iowa.

Examination of New Men.

Editor The Locomotive Engineer:

I have been asked to give my views on the examination of a fireman, both before he goes on an engine in charge of the scoop, and afterwards when he is promoted to the other side of the machine, and the responsibility for the way it is handled.

When railroads were first operated in this country, firing or running a locomotive was an occupation requiring but a small part of the skill needed to-day. There were few trains on the road, the runs were short and in daylight only. Then it rose to the dignity of a trade, and, like other trades, had to be learned by both observation and experience before a man could be successful.

At the present day it is a science, and just as much one of the professions as law or medicine. Probably the lawyers and doctors won't believe this statement, but it requires just as high a degree of professional skill to handle trains nowadays as it does to perform surgical operations or divide up estates, and this skill can only be acquired by practice and experience, while it is certain that there are as many quack doctors and shyster lawyers disgracing their honored profession, to get along in the world, as quack locomotive engineers.

While the locomotive engineer may not possess the polish, or precise and eloquent manner of expressing himself on matters relating to his profession, yet he must have the knowledge and experience, or he will be a decided failure.

The engineers of to-day are aware that the uneducated man who does not try to find out "the reason why" of everything connected with his business, is falling behind each day, and cannot keep up with the procession.

Now, as the men who are made firemen to-day will likely be engineers at some future time, if the grade of the service is to be raised none but the best talent should be employed. It would be useless to employ a man as fireman to-day who has not the ability, when his time comes for promotion, to take charge of an engine on the main line, and handle a train with courage and discretion.

Therefore when a man presents himself for employment as a fireman, he should be required to make out an application in his own handwriting, stating his age, the occupation he last followed, and what trade he learned if he has one. This will look like red tape to some, but the only way to do away with extra red tape is to get a body of intelligent employes who have education enough to express themselves clearly, and not need a set form to assist their ignorance. An engineer of to-day must be something of a clerk, to make out the various reports and forms connected with his daily trips.

Then he should be examined in a common sense, way, without any doctors—professional scallops—to see whether he can tell a green flag from a blue or red one *every time*, and also if he is *dead sure* about the correct colors of lamp signals at night. If his eyes are weak or defective in any way, he should not be allowed on a locomotive for any purpose.

During the time he is firing, which will be three years, and on some roads where promotion is slow four or five, it would be a good plan for the M. M. or traveling engineer to ask him questions connected with his duties, not to puzzle him, but to find out what he does know, and to instruct him in what he does not know. Before he is promoted, even as a hostler or on a yard engine, he should be carefully examined by some one who knows how it is himself, about the rules, handling trains under various difficulties, train rights on the time card or with telegraph orders, what effect certain signals, when carried over any portion of the road, have on other trains; what to do in case of break-downs or wrecks, etc., and if he don't know *he should know before he is promoted.*

Some say that most of these things can be learned out of a book by a bright man so he can answer the questions better than some old engineers. Maybe so, but if all these things can be learned out of a book so easily, will not this same book help out his experience a little?

Because some men have made successful engineers who had little or no education, it does not follow that very many more will. If the natural abilities of the man had been aided by an education, he would have been even more valuable in his profession, and gone up the ladder higher than the usual round on which all engineers with no education must stop. There is always "room at the top," and if, by a careful culling out of the poor, inefficient men, who think they will be able to learn enough to run an engine, but never do, the grade of the profession is raised thereby, so much the better for both the employes and the corporations.

And right here I would say to those young men who are on the firemen's list, whether just employed or ready for promotion, study up the operations of your machine under all the varying conditions of every-day service. It is not necessary that you have hold of the reverse lever to know that the action of the links tends to pull it down in the corner, but it is necessary for you to think about it some before you find out why. If your engine does not steam well with a heavy fire and a large exhaust tip, why cannot a thinner fire be carried, instead of choking the engine down with a small nozzle so she cannot run at a good speed when necessary, in order to cut a fire that is two feet thick? There are lots of things that concern you more than being allowed to handle the engine when switching, or going to and from the coal dock and trains. It may be pretty hard work to find out some things from a man who never thinks for himself, but there is some one who knows enough to give you a pointer, and then exercise your own brains to some purpose.

There are lots of books on the practical operation of locomotives. Get them, read and study them, and if you only get a few ideas out of each one, it will set you to thinking, sharpen up your reasoning powers, and teach you that knowing something and having the "big head" are two radically different conditions.

The conditions of train service are growing more exacting every year, and the appliances devised to assist an educated engineer more numerous and certain in their action. So the old style of hiring a man to fire an engine, and if he is no good when he gets to be an engineer, turning him adrift to be a drag on some one else, must give way to the more intelligent plan of taking nothing but good material, treating it in an intelligent way, and making intelligent engineers that will be a credit to the profession, and the examination should disclose the amount of ability possessed by the fireman at the different stages of his service.

CLINTON B. CONGER,

Lansing, Mich. M. E. Ry. Com.

Probable Cause of Water Splitting.

Editor The Locomotive Engineer:

I notice in two or three numbers of your paper articles on water splitting, and have not seen any cause assigned for it.

I will explain it according to my idea and practical knowledge. During the late war I ran an engine on the Nashville & Chattanooga R. R., that would split water, as they call it. Sometimes she would show water in the middle gauge cock and none in the bottom or top, and then again it would be *vise versa.*

Then again she would carry tolerably good, but not as good as she ought. I complained that her dry pipe or throttle pipe was too long and too close to dome cap. The M. M. said that would not make any difference. Of course she had one of the old slide valves on top of the throttle pipe. We took up dome cap and found out she had just clearance enough to let the valve slide, so we cut it down, and gave it 2½ inches clearance. From that time out she carried water as well as any engine I ever saw with wagon top. Now perhaps those engines that are mentioned in your paper had the old Rogers throttle valve in the smoke-box, hence the dry pipe was too close to the dome cap. This trouble has never been found in my experience since the balanced throttle came out.

E. A. CAMPBELL,

Supt. M. P. & M., H. E. & W. T. and S & H. R'ys.

Houston, Tex.

A Nut to Crack.

Editor The Locomotive Engineer:

The company for which I work have two "Fairlie" engines—double engines having two fire-boxes, four cylinders, etc. In 1887 No. 1 was put in for repairs. Both fire-boxes were taken out and repaired, and the outside shell also repaired—everything being then replaced as before. But when brought out she would only run four days without priming. Formerly she ran three or four weeks all right. No. 1 did most of the work, No. 2 being used as a standby. When No. 1 was put in for temporary repairs in the following summer, No. 2 did the work, and would run four weeks without priming.

In '88 No. 2 was overhauled precisely as No. 1 had been—two new fire-boxes being put in, but on taking her out, she primed just as No. 1 had done. Water from the same well was used throughout. Can't understand it. Can you explain?

D. McLENNAN.

Lorway, Cape Breton, Can.

[A boiler with new work on it will often prime for a few days, on account of oil used on the work, but why she should prime worse after a few days we cannot see, unless some of the conditions were changed, such as more flues or flues closer together, difference in fire-box, or a change in arrangement of steam pipes.]

After "Squab."

Editor The Locomotive Engineer:

I see in the February number a rule for setting a slipped eccentric signed by Squab

To follow the rule of Squab one would have to have a blacksmith to lengthen out eccentric rods in some positions.

It is a poor rule which won't work both ways; so, according to his rule, when engine is known to be all right, taking out pin in link will not affect the link when the rod is put back to position. His idea for "some of the boys to try it and let him know how it works" is good—like the quack inventing patent medicine; when he thought up a mixture he tried it on his wife, if it didn't kill her it was all right.

If "Squab" was in earnest about his rule, he must be an engineer on a narrow gauge wheelbarrow W M ECKERMAN.

Leavenworth, Kan.

On the Proposed License Law in Illinois.

Editor The Locomotive Engineer:

The Chicago *Times* says that the bill introduced by Senator Lehman in the Illinois Legislature, making it unlawful for any person to run or attempt to run a locomotive engine in the State without having first passed an examination, and received a certificate of qualification, is not regarded with favor by railway managers. One of them said yesterday: "It is a scheme to place the railroad companies in the power of the Brotherhood of Locomotive Engineers. It requires that a man must have three consecutive years' experience as a locomotive fireman before he becomes eligible for engineer service, and must have served on the line of the company by which he is examined; also that he must have had one year's experience in the freight service before he can take a passenger train. It is simply an outrage. If it becomes a law, no company in the State will have any voice in the selection of its men, and the Brotherhood will absolutely rule that branch of the service. Suppose such a law had been in effect at the time of the Burlington strike. The company would have been tied hand and foot, and the strikers would have had it all their own way."

Mr. Editor, what is your opinion of this law? Don't you think that it is just what shippers and the traveling public have long needed? The sooner it is adopted in every State in the Union, the safer will be the lives of those whose business compels them to travel by rail. The national laws compel marine engineers to pass examinations, and prove themselves to be competent men. Why should not the locomotive engineer be compelled to do likewise? The great army of men engaged in handling the throttle are daily entrusted with thousands of dollars worth of property in addition to the lives of vast numbers of our fellow citizens. Any intelligent, thinking person will thus see the necessity of allowing none but competent and reliable men to occupy such a responsible position.

Marion, Iowa. FRED TAYLOR.

[If the law is going to provide an examination for locomotive engineers, let it also provide that no man shall be eligible for examination who has not had three or more years' experience on a locomotive as engineer or fireman—this much is right. This would insure the public against the employment of men in any emergency who had no railroad experience at all. As a general thing, the management of a road are careful in its selection of their men—it does not pay to employ grossly incompetent men—they do too much damage.

We can not see how it would be possible to enforce the law requiring that the applicant shall have served on the road for which he was examined. This would prevent the employment of experienced engineers from other roads, and would injure the order and the engineers worse than the companies.

We fail to see what good or what hurt the law would do that required a man to pull freight one year on a road before he could pull passenger—almost any man who can make time and handle air can pull passenger; he has a clear line, light trains, the best engine and the best fuel on the road—it is the men who successfully pull heavy freight trains with poor coal, green firemen and old engines, who need to be skillful. They must avoid all first-class trains, meet and overcome more varying conditions, and exercise more thought, skill and judgment, work harder, and, in fact, use more and a better class of railroad knowledge than any other men in the service.]

A Simple Relief Valve.

Editor The Locomotive Engineer:

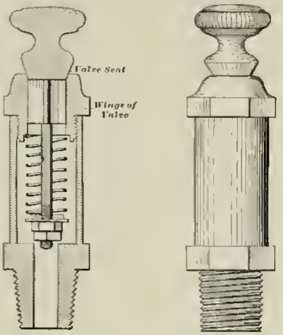
Before the steam governor for air pumps came in use, the Westinghouse folks furnished a relief valve to be attached to air pipe to prevent excessive pressure, but it did not give the best of satisfaction, so I designed and made one to suit myself, and it worked so well that I put it on all engines equipped with air brakes. I attach it to the drum-pipe just below engineer's valve. If it gets gummed up it can be loosened by taking hold of the top of the valve and turning it. I guess the sketch needs no explanation.

Syracuse, N Y. W F RELYEA.

Water Splitting Theory.

Editor The Locomotive Engineer.

The last three numbers of your valuable paper contain a vague account of *engines splitting their water*. Let us call this an emphatic kick of the boilers in question against cruel treatment. Neither your



A SIMPLE RELIEF VALVE.

three correspondents on the subject nor your readers at large make an attempt to explain so weighty a matter or guard against a repetition of same that leads to overheating, bagging and burning of crown sheets with an excuse therefore.

Supposition and mystery belong to the past. We live now in science and fact. In the name of the latter two, let me call this "water-splitting" the "spheroidal state" of water, which, by the way, is the same in the open air on a hot stove as it is in a locomotive boiler under pressure. It is a state of affairs entirely different from priming and from foaming, and may be induced in any style of boiler with any kind of water; and it can be observed. As a gauge-glass only indicates the fluctuations of water level, so we will put a circular sight-glass in boiler-head. Then raise petticoat pipe, fire hard, pull a heavy train up grade, and you will often see the condition of affairs as recorded If the sight-glass in boiler-head is objected to, a quarter-inch pipe with a cock outside can be put through shell and jacket by means of a suitable stuffing-box over crown-sheet, so it can be lowered or raised. Then, when engine is working hard, the quarter-inch pipe touching sheet, the cock open and showing water—it is there.

Houston, Tex. DE BRETON.

On Heating Feed Water.

Editor The Locomotive Engineer:

"Theory is all very fine, but when theory neglects to take into account the saving of fuel, lighter firing and better combustion that results from feeding with boiling water, theory is apt to be, as in this instance, away off

"Take, for example, the difference between feeding with water at 32 and 212 degrees. Theory will tell us that the saving will be 15½ per cent., but there is not a practical engineer in the country but knows that, aside from other advantages, the saving will be nearer 33⅓ than 15½ per cent. B"

The above matter is quoted from a paper devoted to stationary practice, and causes me to increase the confidence in Smith's heater illustrated last year. There is little doubt in my mind that Smith's report of saving of coal was correct. Many old runners in the country still contend an engine steams better with a pump, as compared with an injector. They are positive in their statements. How much better would they do with hot water? The writer has seen crossheads badly worn on side carrying pump plunger, while on other side guides and crossheads were in fine shape and little worn; an injector had been substituted for a pump and crosshead that did not carry a plunger run the longest with least wear.

With a temperature of 500° or 600° in front end, the heat radiated by same, and thus lost, would heat considerable water The boilers of Silsby fire engines do better since they bleed the exhaust and heat their feed water. A plan to heat the feed water other than taking live steam as with an injector, or unduly robbing front end, as the *Locomotive* maintains, will no doubt be hard to arrive at. However, some front ends show to the casual observer—when firemen state that they can't keep anything on them only stove polish, on account of the intense heat—they can no doubt spare enough of this heat to heat the feed water The variable exhaust nozzle or Luttgen's damper probably do this same thing in another manner. J. J Bingley advocates checking the blow-off of safety valves and turning it into the tanks to save the heat in the steam; quite proper. If an engine is steaming well, throwing cinders all over the country, burning the paint all off the front end, also blowing off, why not bleed the exhaust and put it into the feed? The heat lost by exposed front ends is no trifle; all admit it is hot air we want in fire-boxes; plenty of it can be furnished from a space around front end; same space would heat water.

A fire certainly will burn slower evaporating a given amount of water, from hot water feed, than if same amount was fed in cold, or, less fuel on the grate would be necessary, which certainly means economy. The back pressure on piston from port to nozzle grows less and less as it nears the orifice or tip of nozzle, when it, the pressure, is all merged into velocity. Steam taken from a point below nozzle and led into a heater similar to Smith's would register a pressure on the heater which means heating the water from pump to boiling point or over according to pressure. C. S C

Watertown, Wis

[If some feed-water heater were devised that uses the heat *radiated* from the front end it would probably use some heat now going to waste, but taking it out of the front end, we believe, will not pay. No one disputes that a saving would be effected by the use of a heater on an engine "blowing off, throwing cinders and working on less than her capacity", but when it comes to pulling all the cars they can, and working hard, we doubt if taking heat from the front end to heat water is not robbing Peter to pay Paul. A saving of 33⅓ per cent. by the use of a heater is beyond the range of possibility, even in stationary practice.]

H K Porter & Co., locomotive builders, Pittsburgh, Pa., have made their second annual payment of profits to employes. This year every man, no matter what his position, pay or time of service during the year, received 10 per cent. upon the wages he earned during the year If a man earned $1,000 his share of profits would be $100 This method of apportioning makes it an object to every employe to put in all the time he can. This extra money is duly appreciated, and comes in handy, and is better than wages alone—where they are the same—yet profit sharing is not the solution of the labor problem. At best it is a remedy, not a cure, a patch, not a new boiler.

Engineer Cook, who has been on trial for manslaughter for his part in the Mud Run disaster, has been acquitted.

CONTENTS.

Captain John Ericsson.

This venerable man, the greatest inventor of the age, died at his home in this city on March 8.

Captain Ericsson was born in Sweden, and trained as a civil engineer, having been a leveler on the great Swedish ship canal at the early age of 13. He entered the army and was detailed on engineering work and made a machine for drawing copper-plate maps that were pronounced the finest military maps then extant. He invented the flame engine in 1825, and went to London to exhibit it; here he resigned his commission and was made a Captain, in recognition of his service. He entered the competition for furnishing locomotives and built the "Novelty," to compete at the Rainhill trials in 1829, where Stephenson's "Rocket" won the prize.

The "Novelty" was defective in adhesion, but was the best built and best finished engine at the trial. Strange to say, this engine contained none of the principles now considered essential in locomotive practice; she had a vertical boiler and vertical cylinder, while the "Rocket" had cylinders in line with axle centers, a tubular, horizontal boiler and the exhaust in the stack—fundamental principles that have always been retained.

Capt. Ericsson's inventions number up in the hundreds, and some of them revolutionized the practice of the world. Perhaps his finest inventions are the engineering instruments but little heard of in connection with his name. He invented the hot air engine, much used for small power. He invented the screw-propeller, that revolutionized the commerce and the navies of the world.

He was the first to build a war vessel with all her machinery below the water line, and introduced forced blast on shipboard. In 1828 he equipped the steamship "Victory" with condensing apparatus that returned its water of condensation to the boilers. In 1829 he built the first steam fire engine—a service to mankind that can hardly be estimated. He was one of the earliest users of the link motion—some claim its inventor. The refusal of the British admiralty to use his screw propeller, declaring that "a vessel cannot be steered with the power applied to the stern," was indirectly the cause of the inventor's removal to America in 1839.

In 1841 the U. S. war ship "Princeton" was equipped with the screw, and had all her machinery below water line, and the navies of the world had to be rebuilt on her plan. His idea of a partially submerged war vessel with a revolving gun turret was offered to Napoleon in 1854, but refused as impracticable. The civil war again brought the idea up and the "Monitor," now famous in history, was built to Ericsson's plan in 1862, and sank the iron-clad "Merrimac" in Hampton Roads, turned the tide of the war, prevented foreign intervention in favor of the confederacy, and again called for a rebuilding of navies.

In 1881 the "Destroyer," a ram carrying a submerged gun 16 inch diameter and 30 feet long, shooting a projectile weighing 1,500 pounds and containing 300 pounds of high explosive, was built. This vessel Capt. Ericsson firmly believed can destroy the heaviest iron-clads afloat.

His latest great invention, the Sun engine, is already in use in Egypt and other hot countries pumping water for irrigation, etc., but was not yet perfected at the time of his death. His will provides for the carrying out of the work in hand by his associates and employes.

In the 85½ years of his life, Capt. Ericsson has given to the world more valuable inventions and done more for mankind than any other inventor the world has ever seen.

In his research he has never been very badly hampered for money, and has been able to carry out his ideas and demonstrate their value. He built and equipped the "Destroyer" at his own expense.

He was an admirable draftsman, and proved all his theories by correct mechanical drawings. He lived frugally, took a certain amount of nourishment, sleep and exercise, and worked steadily up to within two or three days of his death.

The immediate cause of his death was affection of the kidneys, combined with a general exhaustion of nature.

It is announced that the Reading are buying a number of locomotives with the Wootten fire box.

An Unjust Accusation.

Some of the western papers or their correspondents are trying to curry favor with the Knights of Labor by denouncing Geo. W. Cushing, lately appointed Sup't. Machinery of the Union Pacific, as an enemy of labor organizations, and characterize his appointment of a prominent knight as his private secretary as a bid for favors and a scheme to "pacify" the knights. The editor of this paper happens to know Mr. Cushing and his position on the labor organization question. Being a friend, a believer in, and a member of labor organizations, we can only wish that organized labor had no worse enemies than Geo. W. Cushing.

Occupying the positions he has in the past and does at present, it cannot be expected that he will advertise as a believer in the employment of men because of their affiliation with some labor organization—he has to accomplish results with men selected for their ability in their profession—and we believe he will in the future—as he has in the past—judge men by their work, not by their membership here or there. Mr. Cushing's time on the P. & R. was brief, and if the truth were known, the straw that broke the camel's back and brought about his resignation was the order to select men for his department who did not belong to labor organizations.

Years ago Mr. Cushing remarked that labor organizations did cause some trouble, *but not as much as individuals did before their organization.* To the men in the motive power department of the U. P. we would say, do your duty, be temperate, ask for what is right and do not ask for what is unreasonable, and rest assured that Geo. W. Cushing will never question you about what you do or do not belong to. Mr. Cushing used to be a locomotive engineer, and knows how it is himself.

Selecting Good Material for Good Work.

We take the liberty of publishing part of a private letter from Clinton B. Conger, engineer of the State Railway Commission of Michigan, on the subject of promoting firemen. Mr. Conger is a practical locomotive engineer, one who stands high in his profession and who has the best interests of the men in it at heart.

The subject of the selection of engineers, however, covers a good deal of ground, so that I could make another chapter or two out of it and still not step off the edge. If the next set of engineers are to keep up with the requirements of the business, none but the most capable and intelligent young men must be employed. They must be young men of strong body, strong mind, with courage that open switches or bulldozing officials can't shake, cool and clear headed in presence of the dangers that beset them every trip, and minds that will detect the real values or faults of the different devices that are crowded on them every day to test, must be sober and temperate both in speech and habits, and above all *tell the truth every time*, if they know it. I have no earthly use for a man on an engine who can't or won't do that. Maybe my standard is pretty high, but I tell you the business is "way up," and climbing higher every day, and I am proud of it.

I am glad to see your paper taking the stand it does, and will help you all I can till I run out of ideas that are not old or are better expressed by some one else.

Like the Insanity Dodge.

Every broken-down bridge in the country is laid at the door of broken axles and wheels. Curious thing that we so seldom hear of broken axles and wheels, except when a rotten old toothpick bridge breaks down. In the past ten years 50,000 and 60,000 pound locomotives have been replaced by others weighing upward of 100,000. Cars have more than doubled in capacity and weight, speeds have advanced from an average of 20 to nearer 40 miles per hour, and trains have multiplied like rabbits in Australia, but the same old bridges are considered good enough—passengers don't see them—and they stand the racket till a broken axle paralyzes them.

These bridge disasters are coming thick and fast, and a few wholesome verdicts by coroners' juries would do much to get them propped up or replaced by modern ones adapted to the service.

Our Torpedo Signals.

While we doubt the safety of depending on men's ability to tell on which rail a torpedo is exploded, our correspondent, "Vulcan," touches a timely topic, in our last issue, on the abuse of the torpedo system.

On a recent western trip we talked with several engineers on a road where trainmen are provided with a device for putting out torpedoes from a running train. They abuse the safeguard placed in their hands, and commence to drop torpedoes as soon as they get a little behind, or during a fog; one passenger engineer said he ran over something like 16 the night before in a distance of 13 miles, all placed by one train. A stop for all these, or even a slow-down, would have seriously delayed a first-class train for a train that had no right on the time of the passenger.

A torpedo, like a red flag, should be used only as a danger signal, and should mean "stop," and a flagman should be there to explain the cause of the danger signal's display.

The Caution Signal.

In all countries and on all roads where they have a safe and entirely successful signal system there will be found no "caution" or "slow" signals. It is either go or stop. The failure to give entire satisfaction of block signal systems in America has been, we believe, the persistence with which we stick to the caution signal. This device placed in the hands of the signal man is a sort of ease-off for his conscience if he is taking chances and keeps important trains from making time. The rules of the road and the education of the engineers tell all the points where caution or reduced speed is necessary. If a block is not clear it is not safe to go, and if it is clear, the white signal is the one.

The Old Colony have tried a device for automatically opening a cock in the train pipe and setting the brakes, regardless of the engineer. The device is simply an incline rod near the track that strikes the handle of a valve. It is attached to a switch or signal lever for operation, and there is also a wooden block for the same purpose, to be carried by track men and put out instead of torpedoes. The cock is located on right side of pilot, and after the brake is set by it, it can only be released after closing the cock by hand.

The Pennsylvania has issued an order that the conductors and engineers must read train orders, while operator reads office copy aloud; the engineer must show his copy to the fireman and the head brakeman, and the conductor to rear man. This is business. Orders should be understood by every man on the train. It is an element of safety.

Have your paper addressed to a box number or a street. We have considerable complaint about missed papers and almost always find them addressed to some shop or roundhouse. Every care is taken in this office to get the address correct and plain. The Locomotive Engineer is too popular to keep long in a roundhouse mail box.

Devices for burning petroleum under boilers are now reasonably perfect, and could be used successfully on locomotives; the reason that it is not adopted and will not be adopted, is that petroleum fuel is more expensive than coal. In Russia, where crude oil is a drug on the market, it is used with fair success.

The next meeting of the M. M's Association will discuss papers on three very interesting subjects, to wit.: Best Proportion of Flue and Grate Area in Locomotives, Driving Brakes, and Best Boiler Covering to Prevent Radiation.

The railroad commissioners of several States have taken up the subject of couplers, and propose to try and stop some of the killing and maiming now done by the link-pin-and-deadwood guillotine. Success to them.

ASKED & ANSWERED.

(13) J. B. B., Chatham, S. C., asks:

What is the rule for determining proper length of link? *A.*—There is no rule. Average length for standard 8-wheeler, 11 to 16 inches

(14) I E. H, Escanaba, Mich., asks:

Is there any law against minors running locomotives? *A.*—In some States there are laws against the employment of minors on railways without consent of parents, but we know of no law against their promotion.

(15) W. T. W., Brooklyn, asks:

What is the best preparation for putting on extension fronts and stacks to keep them black and sleek? *A.*—Boiled oil darkened with a little lampblack is most generally used There are heavier paint preparations that are sometimes used, but they generally scale and make a bad looking front and stack, and cause the fireman unnecessary work in cleaning them

(16) C. F. D., Tracy, Minn., asks:

Do you know of any patent cup or device for oiling engine trucks through the box? If so, can you send me drawing? *A.*—A common kind of cup for this purpose is made of sheet metal with a wick feeder. We believe the N. P road use the McNaughton and Beardsly cup for this purpose (illustrated in our Nov. '88 issue).

IN THE ROUNDHOUSE AND Repair Shop.

Items Picked up in the Altoona Shops.

On a recent visit to the shops of the Pennsylvania Railway at Altoona, the philosopher noticed several things out of the usual run. The P. R. R. owns 1,320 locomotives for its own line, and something like 3,000 when you include its controlled lines, and, as Altoona is the principal shop, most of the building and rebuilding is done here.

The locomotives are all built to a standard size for each class, and this systematizes matters considerable.

In the erecting we noticed that there was a large sheet metal pipe temporarily fastened onto the exhaust nozzles, extending out in front of engine some ten feet and then down to sewer, by using this, they can blow out an engine and test all joints of steam pipes, etc., without filling the shop with steam, and before the front end is closed up, the cylinders or chests cased or the boiler lagged.

In this shop most of the work is done on the piece-work system, but the work is so systematized that it is much easier for the men and the foremen. The system is fully explained in another article.

In the blacksmith shop they are using very successfully a new gas-making device of very simple design, something on the plan of water gas retort, in which they inject a jet of steam under the coal in the retort and pass the products of combustion through heated flues of fire-brick. The affair is said to be simple and easily handled, makes an intensely hot fire free from sulphur, and does not scale the iron. In this shop much of the standard work for locomotives and cars is made in dies and kept in stock, such pieces as the ends of arch braces, link hangers, eccentric fork ends, etc, being formed at a single blow under the steam hammer. In the erecting shop there is a very ingenious portable milling machine for slotting out all the port holes in cylinder casting at one operation, and always to a standard width of port and bridge. This little machine is held in place by the four corner steam chest studs, and is driven by a rawhide rope with compensating weights, that allows it to be run in any position anywhere within a floor space of ten feet from the driving pulley It is the invention of Mr. Jos. Davis, assistant to M M Strattan. Since the introduction of metallic packing the road has had some trouble with leaky stuffing-boxes, the casting on steam chest was found to leak regularly and to cut out badly by use of tallow. This trouble has been obviated by bushing the box with brass in new as well as old chests and cylinder heads.

The car shops here are very complete, and use machinery for more purposes than usual in such shops. They use bulldozers and formers for most of the iron work in trucks and frame, and have in use a very ingenious machine for making car links. The weld is formed on the side of link, a great number have been broken in the testing machine, that show that the weld is the strongest part of link. The man operating the machine gets one cent each for links, and makes 500 per day.

This shop is building a very handsome dining car, finished internally in white and gold.

Although the Altoona shops are the largest in the country they are building an entire new plant, complete in itself, for the manufacture of locomotives, with a capacity of 150 per year; this, it is hoped, will relieve the pressure on the repair shops.

A committee of master mechanics and other officials of the road are now looking up the matter of equipment, and expect to put into the new shops only the most modern tools. There are several roundhouses, very large, furnished with steam turn tables, steam boiler washing and testing apparatus, telescoping smoke-jacks, etc.

A few years ago this road put on a great number of steam reverse gears, but since the introduction of successful balanced valves they are taking them off.

Pedrick & Ayer, builders of special tools for railway repair shops, Philadelphia, are building a new shop near their present quarters. The building is of brick and stone, 40x160, two stories (with provision for a third) and a basement under part of the building. The new shops will have a boiler and engine room, casting storage room, elevators, swinging cranes, over-head tracks and trolleys, and all modern improvements, the heavier tools steam hammer, etc., having special foundations built for them. It is a pleasure to record this evidence of prosperity, for these gentlemen are practical mechanics who took hold of a special line of railroad work, and by doing good work, advertising intelligently, using judgment and employing brains and ability, and keeping abreast, if not a little ahead of the demands of the trade, have built up a reputation and a business they may well be proud of. Hope the new shop will be too small.

Some of the daily papers, in speaking of the recent tests of steam-car heaters on the P. R. R., said

"The practical advantages in this system are its simplicity of construction and thorough safety, and secondarily, *its economy, the only expense attached to it being the first cost of placing the apparatus in the cars.*"

Now here is the future successful car heater, or any other kind of a heater. After it is once in the car no expense for fuel to produce heat. We will give one year of our life—and cut it off right now—if the owners of this patent will place one in the basement of our house beside the hungriest and coldest furnace that ever smiled and smiled and was a villain still.

At the Renovo shop of the Penna road they use a Rieppel drill for drilling and reaming all holes for bolts holding front end to cylinder saddles. This simple drill frame is clamped to the front end sheets and centered when—without further adjustment—it can be made to drill and ream every hole, always true and from a common center. After cylinders are placed under the boiler a machinist and helper adjust the drill, and drill and ream all holes in about four hours. We believe if this tool was better understood it would be used by our master mechanics and pay for itself every year in the quantity and quality of work done.

One of the three great oil refineries at Franklin, Pa, recently made an estimate, showing that, out of about 55,000 miles of railroads situated west of Chicago, St. Louis, and St Paul, their product, "Galena" coach, car and engine oil, is used upon nearly 50,000 miles, the remainder being kept slick by local dealers.

A little inquiry into the many cases of locomotive boiler explosions—crown sheet affairs, most of them—go to show that some of our big roads are as prone to use boilers 20 years old as enginemen are to lose sight of their water level—the usual verdict in all such cases.

Sensible Locomotive Builders.

We are in receipt of the advance sheets of H. K Porter & Co.'s new catalogue for 1889. This firm build light locomotives for a hundred purposes, and the new catalogue contains a working report from the owners of some 500 of their engines in all kinds of service and in every section from the equator to the Arctic circle.

The book contains about 150 pages, and has a great many rules for finding grades, curves, weights of rails, and a hundred other things of interest to enginemen; it is given away to interested parties, and would be a valuable addition to any engineer's or fireman's library.

These builders have had experience with all kinds of enginemen, and the following shows their ideas of what is needed in this line:

"We wish to urge upon capitalists and organizers of new motor lines the necessity of having not only good motors, good cars and good track, but also of having some competent, experienced railroad man, who will know how to keep everything in running order. The lack of such a man may mean failure, and is sure to involve a loss of more money than his salary would amount to. On small roads, running but one or two motors, he may also serve as engineer On motor roads the service is always severe, mud, dust, sharp curves, uneven grades, and constant stopping and starting demand good care of machinery; small engines on short runs with frequent stops are expected to make a greater mileage than is made by large locomotives on long roads. It is very short-sighted policy for a motor road, after demanding and getting the very handsomest and most efficient machinery, with all the latest improved appliances, to let their motors and cars lie out in the weather without protection or care. It is a very costly economy to hire the cheapest engineers, or to let the track get out of line and sunk into the mud, or to jump trains over rails at crossings."

Careful Engineers.

In a recent letter to Mayor Grant, of New York, Jay Gould makes this remarkable statement:

"Up to the 1st of January, 1889, the lines operated by the Manhattan Company have transported 1,069,487,620 passengers, of whom but one has been killed while in the cars, and those who have lost their lives upon the structures of the company are but 47 in all, not one of whom, the officials of the company claim, was free from some act of negligence which directly contributed to the fatal result."

Touch and Go.

The *Locomotive*, published by the Hartford Steam Boiler Inspection and Insurance Co., states that there were 246 boiler explosions in the United States in 1888; number of persons killed outright, 331, number injured, 505—fully 100 of them fatally. This is a total of 836 killed and maimed during the year, this does not include the many minor accidents not reported.

A First-Class Stack for Less than Ten Dollars.

As neat straight stacks as are to be seen on the Richmond & Danville are hard to find. They are made of cast-iron of neat design and symmetrical outlines, as shown by our engraving; the stack shown is the second of three sizes, and is the one used on the 18 x24' cylinders; it is 36' in height; 13' at the smallest, and 20' at the largest opening, weighs 390 pounds; the saddle weighs 85 pounds.

These stacks are made by using a green sand core, swept up on a cast core arbor.

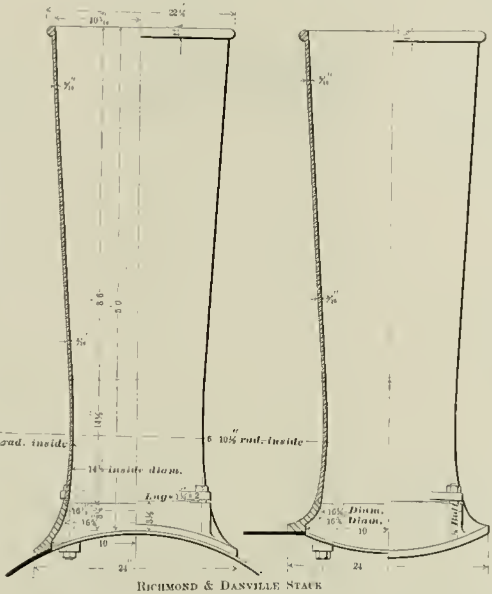
They are cast, cleaned, the bottom joint turned, lugs drilled, and sent to the storehouse, complete, with bolts, for $9.25; with saddle, complete, ready for smoke arch, for $11.

Any iron will do for stacks, if the bottom is soft enough to admit of turning—indeed, at the Manchester shops they are made of old brake shoes.

In addition to being neat and cheap, they prevent expensive repairs in accidents. A common, wrought stack, with a heavy base, is strong enough to bend or break the sheets of the front in case of rear collision, etc., while the cast stack breaks off at the weakest point—the neck—seldom disturbing the base.

A first-class wrought stack, with cast base and Russia jacket, costs upward of $50, and is inferior to the cast stack in every way. With cast stacks there is no waste metal; when broken or worn out they are so much metal for the cupola.

The automatic torpedo placer is a very simple and efficient attachment that places a torpedo by the movement of a signal rod or switch lever, and are being placed on a good many roads. They are a great protection in fog.



Richmond & Danville Stack

A Grand Record.

An English paper gives a life sketch of Mr. Robert Billingham, a locomotive engineer on the Great Northern Railway, and says: "Mr. Billingham commenced railroading in the year 1838, and has been in active service from that period to the present, over half a century. During some of the revolutionary wars of France he was engaged in that country as a locomotive engineer, and many and various were the hair-breadth escapes which he encountered from bridges being burned and the track torn up by the opposing forces. After the wars of the revolution ceased, he returned to his native country and commenced running for the Great Northern Railway Company, in whose employ he has remained until recently, when, owing to ill health, he was obliged to retire from the service. During the whole of his career he has not had one single accident of a serious nature, but he has prevented several. Once, while standing in front of a station with his train, he saw another train ahead coming down the track at a terrific rate of speed. With great presence of mind he backed his train out of the way of the other, just in time to prevent an accident, which must have resulted with the loss of a number of lives.' Mr. Billingham has two sons in the railroad service of the United States, one being employed in the capacity of traveling engineer on the lines of the C., M & St. P. Railway, west of the Mississippi river.

Since our illustration in January issue of the Weaver spark-arrester, Gen. Supt. F. M Baker, of the Addison & Pennsylvania R. R., Addison, N Y, is putting one on a locomotive for trial on his road. As Mr. Weaver, who is M. M of the Lehigh Valley at Sayre, Pa., has used the device successfully on 140 locomotives burning both hard and soft coal, Mr. Baker's experiment is not a very risky one.

Watson & Stillman, of this city, are getting out patterns for a small size of Vreeland's Transfer Jacks designed especially for removing the intermediate pair of wheels in 6-wheeled trucks. The present method of jacking car body off the truck and then the truck above the central pair of wheels is expensive and takes time.

The McConway & Torley Co., of Pittsburgh, have placed on the market a new rail joint that has some novel features. It consists of angle splice bars to maintain the line, and a heavy clamp that wedges the lower flanges and plates firmly together by a heavy bolt. This secures surface, and prevents the action of the wheels from battering the end of the joints. In an 18 months' trial, in which 17,048,440 wheels passed over the joints, they remained intact, with but one tightening and one surfacing of track.

All the new consolidation engines on the P. R. R have the Belpaire fire-box, but we notice that the corners of wagon top are turned on a larger radius than usual; they have a little trouble with broken stays, a complaint we have not heard of from this class of boilers in other quarters.

Last winter the Richmond & Danville folks made an experiment with metallic packing on the slip coupling on Martin steam heater. The fibrous packing at each end of the cars soon burns out and leaks; the metallic packed joint was put on rear of a tender, and has run till now without attention and without leaks.

Rebuilding Locomotives on a Time Schedule.

In all railroad repair shops great delay of work is often caused by the neglecting or forgetting of some piece of work, for which a locomotive is obliged to wait one day or more.

It is very hard for foremen and gang bosses to so arrange their work and place their men as to avoid getting one class of work in the way of some other class, or of men employed on one job from having to wait for another before they can proceed with theirs.

At the Altoona shops of the P. R. R. great trouble was experienced in this way until Jos. Davis, Assistant M M., conceived the idea of running the engines through the shop as they were run on the road—on time.

As most of the work at Altoona is done on the piece-work system, and all of it is done by special gangs of men for each class of work in separate shops, Mr. Davis arranged a general time card for the erecting shop, that provided for the stripping of the engine, and the distribution of the parts to the different shops, and also for such work as was necessary on the parts not removed from the erecting room.

When a locomotive comes in, a clerk makes out the following time card for the erecting shop:

PENNSYLVANIA RAILROAD COMPANY

GENERAL REPAIRS TO ENGINES.

ERECTING SHOP.

.....Division Engine No......Class..... ...
Repaired by................ .. ..
Class of Repairs.............

Taken in Erecting Shop	Sent to Boiler Shop.	Out of Boiler Shop.	Out of Erecting Shop	Sent to Paint Shop	Out of Paint Shop.	Ready for Service.

DAY	OPERATION.
1st.	Stripping Engine.
2nd.	Cleaning and Distributing Machinery
"	Steam Pipes taken out.
"	Renewing Bolts in Frames.
3rd.	Facing Pedestals.
"	Refitting Pedestal Caps.
"	Facing Cylinder Joints.
"	Smoke Stack base and Headlight bracket fitted on Boiler.
4th.	Re-boring Cylinders.
"	Back Cylinder Heads put up.
"	Fitting and laying out Shoes and Wedges.
5th.	New Cylinders fitted to Boiler.
6th.	Crosshead Guides set.
"	Valve Seats Faced
8th.	Hopper fitted to Smoke-box extension.
"	Injectors put up.
9th.	Driving Boxes fitted.
"	Sand-box Finished and fitted on Boiler.
"	Smoke-box Extension finished and put up.
10th.	Driving Springs and Rigging put in place.
"	Truck Repaired.
11th.	Truck and Driving Wheels in place.
12th.	Steam Pipes put in and Dome closed.
"	Pilot put up and Braces attached.
13th.	Valves set and Eccentrics keyed on.
14th.	Boiler Front and Door put up.
16th.	Main and Truck Wheel Covers put up.
17th.	Ash Pan, Drop Grate and Damper finished
"	Number Plate and Side Badges put up.
18th.	Engine to go on trial.

This time card the foreman follows, and on the second day the parts are distributed to the different shops. The clerk also sends to each shop foreman the following time cards, the top of cards giving dates work must be out of each shop, being the same on all.

BOILER SHOP.

2nd.	Boiler and Fire-box examined.
5th.	Smoke-Box Extension finished
8th.	Boiler repaired.
9th.	House Irons fitted to Boiler and Cab.
10th.	Cistern repaired and sent to Cab shop.
11th.	Air Reservoir tested.
12th.	Fire Door Repaired and put up.
13th.	Boiler tested.
14th.	Ash Pan repaired and put up.
15th.	Apron repaired and put up.

FLUE SHOP.

3rd.	Flues taken out.
4th.	" cleaned.
5th.	" scarfed and welded.
6th.	" brazed and annealed.
7th.	" marked, cut off and opened.
8th.	" put in boiler last time.
11th.	" caulked and water grates put in.
"	Arch Pipes put in.
16th.	Engine piped.

LATHE SHOP.

3rd.	Facing Cylinder-head Joints.
4th.	Sand-box Base finished.
"	Driver Brake Pads planed and slotted
"	Driver Brake Hangers drilled.
"	Shoes and Wedges planed.
"	Crosshead Guides planed.
5th.	Crosshead Gibs planed.
"	Cam Screws turned and Crossheads slotted.
"	Lift-shaft Bearings bushed
"	Driver Brake, Cylinders, Pads and Braces drilled.
"	Rocker Bearings planed and bored out.
"	Shells in Driving Boxes and Boxes planed.
"	Pistons and Followers trued up.
"	Crossheads and Shoes planed.
"	Pump Plunger trued up.
"	Valve Rods and Link Pins turned.
"	Reverse Lever and Reach-rod Pins turned.
6th.	Steam Chests, Lids and Casings faced.
"	Guide Blocks and Bolts finished.
"	Truck Boxes bored out.
7th.	Driving Boxes bored out.
"	Main Valves planed.
"	Stems of Valve Yoke trued up.
"	Rod Brasses planed.
"	Valve Yoke Glands bushed.
"	Steam Whistle repaired.
8th.	Pump Gland bushed.
"	Piston Gland bushed.
9th.	Steam and Water Cocks repaired.
"	Sand Box and Gearing repaired.
10th.	Bell Bearings repaired.
13th.	Boiler Front and Door finished.

VISE SHOP

3rd.	Machinery examined and distributed.
4th.	Valve Yokes refitted to valves.
5th.	Crosshead Guides trued up.
"	Crosshead Shoes lined.
6th.	Guide Yoke repaired.
"	Rockers refitted to bearings.
"	Lift-shaft Bearings and Reach-rod Jaw fitted to shaft.
"	Eccentric Straps refitted to Eccentrics.
7th.	Valve Rods repaired.
"	Injector repaired.
8th.	Pump repaired.
"	Boiler Check repaired.
"	Throttle Lever repaired.
"	Relief Lever repaired.
"	Crossheads repaired
"	New Lever fit to Whistle.
9th.	Piston repaired.
"	Reverse Lever and Quadrant repaired
10th.	Dome Cap repaired.
11th.	Links repaired and put upon Engine.
12th.	Main Rods repaired and put on Engine.
15th.	Main and Truck Wheel Covers finished.
17th.	Main and Side Rods repaired and put up on Engine.

SMITH SHOP.

2nd	Closing Pedestal Caps.
3rd.	Driver Brake Pads, Links and Cam Screws forged.
"	Driver Brake Hangers, Crossheads and Braces forged.
"	New Stems welded to Valve Yoke and fitted to Valve.
6th.	Draft Iron repaired.
"	Driver and Truck springs reset and tested.
7th.	Equalizing Beams, Posts, Links and Gibs repaired.
"	Main Frames and Braces welded when broken.
8th.	Tender Irons repaired.
9th.	Pilot repaired.
10th.	Damper Rigging repaired.
12th.	Pilot Braces adjusted.

WHEEL SHOP.

6th.	Smoke-box Extension faced.
7th.	Tires turned, Journals trued, and Pins renewed.
"	Truck and Tender Wheels finished.

TIN SHOP.

6th.	Jacket put on Cylinders.
7th.	House Irons fitted
11th.	Spring covers repaired and put up (Pass engine).
13th.	Injector Pipes finished
14th.	Main and Truck Wheel Covers finished.
"	Bridge Pipe cased.
15th.	Jacket put on Boiler.
"	Jacket put on Driver Brake Cylinders.
16th.	Air Brake Pipes finished.
"	Three Way Cock Pipes put up.
"	Lift Pipe and Netting fitted in Smoke-box
"	Dome Casing fitted on Engine.
17th.	Smoke Stack finished and bolted on Boiler.

AIR BRAKE SHOP.

8th.	Air and Steam Gauge repaired and tested.
10th.	Driver Brake Pads and Cylinders repaired and put up.
15th.	Auxiliary Reservoir repaired and put up.
"	Driver Brake Clogs and Cams repaired and put up.
16th.	Three-way cock put up.
"	Air Pump and Main Reservoir repaired and put up.
"	Air Brake Pipes clamped

CAB SHOP.

2nd.	Tender stripped and made ready for Boiler Shop.
6th.	Lagging put on Cylinders and Wood underneath (Pass. engine).
"	Bumper put on when new
8th	Foot boards and Cab put up.
"	Floor laid and Step put up (Pass. engine).
9th	Pilot repaired (Pass. engine).
12th.	Pilot set up
"	Tender finished and sent to Paint Shop.
14th.	Lagging put on Boiler.
15th	Running Boards put up.
"	Head-light Board put up.
"	Moulding put on underneath Wheel Covers.
"	Lagging put on Dome.
32nd.	Seats, Boxes and Sash put in Cab.

PAINT SHOP.

22nd.	Engine received in Paint Shop.
32nd.	Engine out of Paint Shop.

ON TRIAL.

19th	Engine made ready for trial.
20th	Engine on trial.
22nd.	Engine tried and sent to Paint Shop.
33rd.	Engine ready for service

We do not doubt that many master mechanics and shop foremen will be able to pick up valuable hints on the proper time to have work done, in order not to interfere with other work, and we give the time cards complete, as it is the first systematic plan for rebuilding on time that we have seen.

The Locomotive in America.

By WILLIAM BARNET LE VAN.

FOURTH PAPER.

In all American standard locomotives the outside connections are universally adopted. The cylinders are placed nearly or quite level—truck wheels being spread to about 4 feet 10 inches between centers, to give the required room, as well as to secure steadiness in running. The framing is forged solid with pedestals welded on. The springs of the driving wheels are always connected by equalizing levers, excepting in six-wheel combined locomotives, where one pair of springs are sometimes independent. The shifting link-motion is almost entirely used—the steam slide valves being on the upper sides of the cylinders, and worked through the intervention of a rocker-shaft. The pumps are, in the majority of cases, "full-stroke," being worked directly from the cross-heads. Air chambers and suction chambers are always provided to secure a steadier flow of water and to ease the strain on the pumps. Of late years all locomotives are fitted also with injectors. The crosshead and guide-bars are almost universally of one pattern. The regulator or throttle is almost always in the smoke-box. The house or cab, the pilot or "cow-catcher," the bell, and the spark arrester are appendages which belong exclusively to the American locomotive. The boiler is the usual form known as "wagon-top." In size, while the boiler and cylinder are varied to suit the work, the wheels are less variable in diameter. Five feet is a common size of driving wheels for all classes of work, although five and one-half and six feet are used to some extent for passengers. Freight locomotives with six and eight coupled wheels have drivers of from forty-three to fifty-six inches diameter, two railroads, the Baltimore & Ohio, and the Reading, have a large number with wheels of forty-three inches diameter.

On American roads of ordinary grades and traffic, the principal difference between the passenger and the freight locomotives is a difference of six inches in the size of the driving wheels, and an excess of from ⅛ to ¼ inch of inside lap in the valves of the freight locomotives.

The experience which has determined the standard plan of American locomotives may be stated as follows: As compared with English railroads, the loads moved are heavy and the permanent way is weak, so too the grades or inclines are long and steep, and the curves numerous and sharp. Hence the greatest power must be exerted with the least injury to the track. Thus, instead of a single pair of driving wheels, as formerly used in England, bearing one-half the weight of the locomotive, two or more pairs of coupled driving wheels are invariably used, taking two-thirds of the whole weight, with *thirty-three per cent.* less weight on a single point of bearing on the rail. Thus a twenty-four ton American locomotive has, say sixteen tons adhesive weight, with but four tons on any one driving wheel.

The office of the forward truck is apparent, in turning curves of short radii—often of 200 feet, while 650 feet is a very ordinary radius. The truck also, by its four wheels, distributes the weight of the forward end of the locomotive, and as its support is at or forward of the center of the smoke-box, it throws more of the weight of the locomotive upon the drivers than would a pair of leading wheels placed behind the smoke box. To reduce the friction of swiveling, and to take the weight equally on each truck wheel, the truck frame generally carries its load on its center. To secure the full power of the engines when required, the valves have moderately short lap on the steam side—seldom over ⅛ inch at each end, and generally but 1/16 inch for a valve of five inch maximum throw. Thus the admission can be made equal to ninety per cent. of the full stroke, while very few engines are arranged for as little as thirty per cent. admission, thirty-five per cent. being the more usual minimum.

All American locomotives are outside connected, from the fact that they are more *get-at-able*. There is no peculiarity in the adaptation of the locomotive to wood burning, as compared with that for coal burning, except that in the first case the grate bars are of cast-iron and in the second they are generally formed of tubes through which a constant circulation of water is maintained, and that the blast pipes are smaller. The proportions of the boilers are the same as are employed in England with the exception of the grate surface, which is larger, due to the use of anthracite coal in the place of coke and bituminous coal; but American boilers are built of thin iron in the fire-boxes, or of ¼ to 5/16 inch steel instead of copper; the tubes are almost always of iron, as they are found to remain tight better than brass under all the contingencies of rough setting and hard work.

A considerable advantage is found in the equalizing levers between the springs, especially on rough roads.

Full stroke pumps are used with air vessels on both the suction sides. They fill surely and work easily, as to the pipes and joints. Each locomotive is fitted with an "Injector" as an auxiliary in case of failure or damage to force pump, and in recent practice injectors are employed to the exclusion of pumps. To employ still more of the adhesion, and to distribute still more weight on the rails, locomotives with six and eight coupled driving wheels have been much employed. For very heavy traffic, like that of coals, and on very severe grades or inclines, the "Consolidation" locomotives, having eight driving wheels coupled and a "pony truck," has obtained the preference over the "ten-wheeled" locomotive formerly used. The "Consolidation" plan is preferred for locomotives of about 100,000 pounds' weight—88,000 being on the drivers, of which 11,000 pounds only are on each wheel. Practically, there is a little variation of the weight distributed respectively by the separate pairs of wheels, but no more than is due to the difference in weight of counterbalances and other attached parts in the wheels themselves. For lines of sharp curvature this type of locomotive is built with two pairs of flanged driving wheels, either the front or rear or the main and rear pairs.

The other two pairs of coupled wheels have tires without flanges. The pony truck has a swing bolster and radius bar. The total wheel base of locomotives with eight-wheeled tender is 47 feet 10 inches. At the present time, 1889, the Baldwin Locomotive Works are building a new style of locomotive, the "Decapod" type, for extreme mountain grades, having ten coupled driving wheels and a pony truck. The arrangement of flanged and plain driving wheels will permit of broad gauge locomotives of this type traversing curves of 330 feet radius. From all the experience upon American railroads, locomotives without trucks are considered to strain the track.

On some of the older engines on the Petersburg Railway (Atlantic Coast line) there is a cast-iron box on each running board, just over the guides, to hold the signal lamps.

It is said that Master Mechanic John Campbell, of the Lehigh Valley, at Delano, Pa., will build the largest 8-wheeled passenger locomotive yet constructed in this country.

Locomotive building is dull now—a very good time for the different works to put in new tools and make needed repairs. It is also a good time for roads in need of power to get bids.

One of the handsomest catalogues of the season is the 200 page bound book sent out by Hilles & Jones, Wilmington, Del. This firm make a specialty of tools for boiler and bridge work. Some of their tools have reduced the first cost of locomotive boilers one-third.

A Hogisher Hog.

The humorist and the soberist and all the other ists that push newspaper pencils, have had their jab at the railroad hog who is always pictured as a low-browed villain with a penitentiary scowl, two whole seats and part of the aisle. On recent excursions among our constituency, the philosopher has observed that there is another and a worse railroad hog that wears skirts, Langtry bangs and earrings. She holds forth in the sleeper, and she arises betimes, and, locking herself in the ladies' wash room, gets both feet into the trough and stays two hours.

There is more than one kind of hog—for instance the men who will run their engines 22 hours a day and make $297.38 for a month and let an honest man on the extra list starve.

The Fitchburg Railroad Company, through superintendent John Adams, has presented a gold watch to engineer Edwin Warren, "for meritorious conduct at Gardner, Mass., Jan. 11, 1889." Mr Warren is the engineer who was on that day in charge of an inward bound express train at 10 P. M., going at the rate of 30 miles an hour near Gardner, when he saw several cars of a broken freight train backing down the steep grade on the same track toward his engine. By reversing his engine and gradually backing he caught and stopped the freight and avoided a serious accident. A letter was presented to him also from President Phillips, couched in words of commendation.—*Ex.*

Even the P. R. R. get behind the times in shop practice—we noticed several old Sellers & Bancroft lathes of the 1854 patent running in the Altoona shop.

We understand there are two Strong locomotives in course of construction for the A., T. & S. F., at the Schenectady Locomotive Works.

GEO. WESTINGHOUSE, JR., PRESIDENT. T. W. WELSH, SUPT. JOHN CALDWELL, TREASURER. W. W. CARD, SECRETARY. H. H. WESTINGHOUSE, GENERAL MANAGER.

THE WESTINGHOUSE AIR BRAKE COMPANY,

PITTSBURGH, PA., U. S. A.

MANUFACTURERS OF THE

WESTINGHOUSE AUTOMATIC BRAKE.

The WESTINGHOUSE AUTOMATIC BRAKE is now in use on 20,000 engines and 170,000 cars. This includes 75,000 freight cars. Orders have been received for 20,000 of the improved quick-action brakes since December, 1887.

The best results are obtained in freight train braking from having all the cars in a train fitted with power brakes, but several years' experience has proven conclusively that brakes can be successfully and profitably used on freight trains where but a portion of the cars are so equipped.

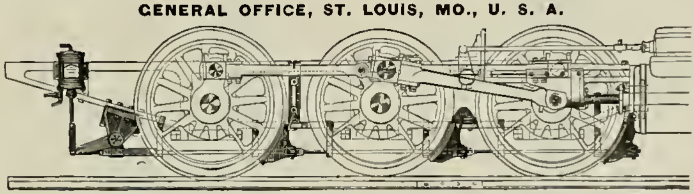
BRAKES Made to Order for any Special Form or Class of Engine.

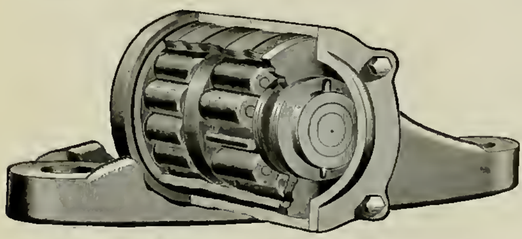


All Power Utilized and Equally Distributed. Maximum Pressure. Minimum Wear and Strain to Parts of Engine.

Standard Outside Equalized Pressure Brake, for two or more pairs of Drivers, furnished to operate with either STEAM or AIR.

EDWARD SMITH & CO., RAILWAY VARNISHES, 158 William St., NEW YORK.

THE TRIPP ANTI-FRICTION JOURNAL BEARING.



This bearing is constructed on an entirely new principle, by which the axes of the rolls are always kept in line with the axis of the shaft. The journal boxes are absolutely dust-proof, and we guarantee that one lubrication will answer for one year's constant service. By recent tests with the dynamometer upon the tracks of the West End St. R'y. of this city we have demonstrated a saving in power over the ordinary journals of from 30 to 70 per cent. We are prepared to furnish these bearings for trial, and invite correspondence.

For prices, terms and additional information apply to

THE TRIPP ANTI-FRICTION JOURNAL BEARING CO., - 33 India Wharf, Boston, Mass.

MATCHLESS VALVE AND CYLINDER OIL.

Warranted not to corrode the iron or destroy packing, and to make more mileage than tallow or lard. Sold only to Railroad Companies direct or through our authorized agents. MATCHLESS CYLINDER OIL CANNOT BE BOUGHT OF DEALERS. In use on 60 Railways.

OILS FOR RAILROAD USE A SPECIALTY.

MASON REGULATOR CO., Boston.

JENKINS BROS., Agents, New York, Phila. & Chicago

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

ROSS REGULATOR VALVE

FOR CAR HEATING.

Low in price and always reliable. No complicated parts. Easily understood. Durable. Has no equal.

ROSS VALVE CO.,
TROY, N. Y.

THE VANCE LIGHTNING FLUE CUTTER

Is just the tool for removing old flues from boilers and locomotives. Will cut 50 an hour. *Sent on approval* to Railroad Companies.

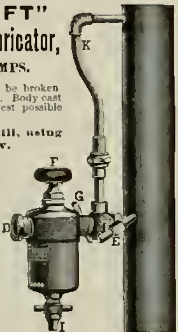
CAN BE OPERATED BY HAND OR BY FLEXIBLE SHAFT.

No Revolving Cutters. Plain Knives easily Ground. Leaves Flue Ready to Weld without Scarfing.

Manufactured and Sold by
VANCE TUBE CUTTER CO.,
GENEVA, N. Y.

The "SWIFT" Sight-Feed Lubricator,

FOR AIR PUMPS.



Has no glass tubes to be broken. Flush Feed readily seen. Body cast in one piece, and fewest possible joints.

Feed will not Chill, using the hardest Tallow.

Sight-Feed Glass is a disk, and can be instantly replaced while running.

Send for photograph and circular.

SWIFT LUBRICATOR CO.,
ELMIRA,
N. Y.

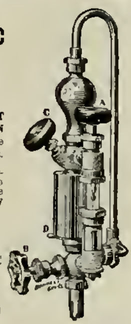
IMPROVED UNIQUE AUTOMATIC SIGHT FEED LUBRICATOR.

Guaranteed to be the **SIMPLEST AND BEST WORKING DEVICE ON THE MARKET** for lubricating the valves and cylinders of air pumps.

All our air brake cups are furnished *complete* and are ready to attach when received. There are no valves or pipe to be supplied by the user.

ALL WE ASK IS A TRIAL.

Send for illustrated pamphlet, fully describing above, before purchasing.



Unique Lubricator Co.,
MANSFIELD, OHIO.

SINGLE CONNECTION.

HAWKINS' PATENT JACK,

Lever and Toggle Joint Combined.

The Best Lifting Jack in the World for all purposes.

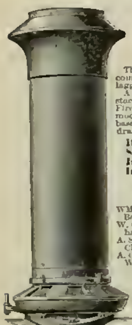
We also manufacture

A SPECIAL JACK
—FOR—
TRACK USE.

We expect to introduce these jacks on their merits, and on application will *FURNISH* one or more pair of any size to any responsible company *ON TRIAL*, billed *SUBJECT TO APPROVAL*.

Communications by mail will receive prompt attention.

MANUFACTURED ONLY BY THE
RAILWAY SPEED RECORDER CO., Kent, Ohio.



LUTTGENS' PATENT Variable Exhaust Damper.

This device provides for the inside of a Locomotive Boiler what the application of lagging and casing provides for the outside.

A circular valve is opened at the base of the stack, so that the cold air does not enter the Fire box, the Flues or the Smoke-box, but it modifies the draft by admitting air at the base of the Stack or at a point where the draft is produced.

It effects a reduction in the coal bill.
Softens the exhaust.
Is a complete Spark Arrester.
Improves the steaming of the engine, and proves a comfort to the Engineer and Fireman.

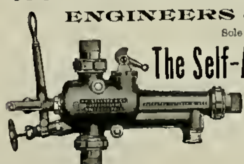
The Self-Acting Injector of 1887.



Range of Capacity over 60 per cent., and can be regulated, therefore, to work continuously for light or heavy trains. Never fails to promptly lift hot or cold water.

No service on a locomotive sufficiently severe to permanently stop its working.

IT WILL RE-START ITSELF

should the Jet break from interruption of the steam or water supply, as soon as the supply is resumed.

ADJUSTS ITSELF

to varying steam pressures without waste of water. Increases quantity of water with increase of steam, and vice versa.

Very easily operated—Started by pulling out the lever, and stopped by pushing the lever in. Descriptive Circular & Price List sent on application to Office & Works,

PHILADELPHIA, PA.

THE LOCOMOTIVE ENGINEER.

DEVOTED TO THE SPECIAL INTERESTS OF LOCOMOTIVE ENGINEERS AND FIREMEN AND TO LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO. V. NEW YORK, MAY, 1889. $1.00 per Year, or 10c. a copy.

'Cording to the Pay.

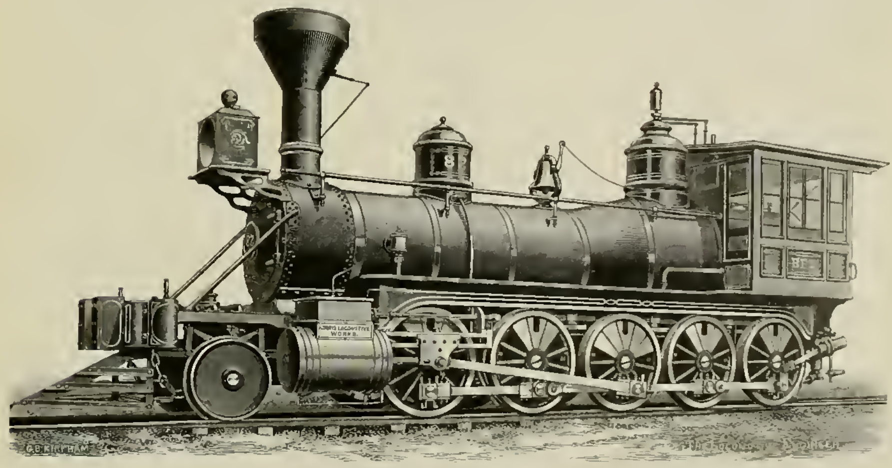
"Johnnie," said the old machinist, as he used the back of his hand to wipe a little sweat off and a little grease upon his manly brow, "Johnnie, you are in your second year as 'prentice now, ain't you? Well, when you went from 75 cents up to $1.10 a day you ought to shove your hand out a leetle furder on that hammer helve; yes, 'bout there. Next year you'll be gettin' $2.15, then shove her out perty nigh the end, and when you get a real live jour's pay, $3, why, git clean out—lap your little finger over the end and hit hard. Work your leverage 'cording to your pay, Johnnie, 'cording to your pay. You're younger nor me, Johnnie; git down in that pit, and git my cape chisel, that's it, boy, that's it; you are going to make a first-class machinist some day, sure as you live."

Long Runs for Locomotives.

The Strong engine is getting a large dose of cheap advertising on account of a run or two on a slow day express over the Erie, between Jersey City and Buffalo, 423 miles, the claim being made that she takes the place of four engines. To be sure, running one engine over the four divisions does not require four engines, neither do all three of the regular engines lay still while the fourth is at work. There is many an engine in the country, getting "chain-ganged" out of more than 400 miles per trip, and as for long continuous runs, 400 miles is nowhere. As long ago as 1876 the Jarrett & Palmer train made its great trip across the continent, and on the Central Pacific road, Engineer Henry Small took an old Schenectady engine and pulled that train from Ogden to San Francisco without a rest, a distance of 895 miles, and much of this mountain.

The Pennsylvania road is running an engine on express between Philadelphia and Washington that regularly makes 10 to 12 thousand miles per mouth, and has made 17,000.

M. N Forney has resigned his position of secretary of the Master Car Builders, a position he has long held with credit to himself and profit to the association.



Historical Locomotives.

SEVENTH SKETCH

We present on this page an engraving of the "Bee," No. 82, Lehigh Valley Ry., the first Decapod locomotive ever built.

This locomotive and her mate, the "Ant, 81," were built by the Norris Locomotive Works, Lancaster, Penna., in 1867, went into service in August of that year, and ran without change until 1883. They were first suggested by Gen'l. Supt. R H Sayre, and the details were worked out by Alexander Mitchell, now Supt. and M M of that road at Wilksbarre, Pa., and Mr. J. A. Durgin, then superintendent of the works that built them. Mr. Mitchell had designed and built the first consolidation locomotive the year before, a class that has since become the most successful heavy freight engine devised, and now used in almost every civilized country in the world The Decapods were designed for heavy mountain service, and were very heavy locomotives for that time, weighing 97,600 pounds.

They had wagon top boilers of $\frac{3}{8}$ iron, with a 50-inch ring at smallest part, with a sloping fire-box 120x34 inches, a combustion chamber 16 inches long and 180 2-inch flues 12 feet long.

Cylinders were 20x26, steam ports 18x1$\frac{1}{2}$ inches, exhaust 18x2$\frac{11}{16}$, travel of valve 5$\frac{1}{2}$, lap $\frac{7}{16}$, inside lap $\frac{1}{32}$. There were ten driving wheels 48 inches in diameter and a pony truck with 33-inch wheels

Rigid wheel base, 13 feet 6 inches, wheel base, on drivers, 18 feet 3 inches; total wheel base, 25 feet 6 inches. Total wheel base engine and tender, 48 feet, 5 inches The driving axles were 6$\frac{1}{2}$ inches in diameter These engines were a success in every way except that the long rigid wheel base caused the flanges to cut very badly on the crooked track where they were run.

The following letter from Mr. Mitchell makes this account authentic, and places the credit of the origin of what may yet be an important class of mountain locomotives where it belongs:

Editor The Locomotive Engineer:

Loco's Ant and Bee, Nos. 81 and 82, were suggested or proposed, and ordered by Rob't H Sayre, Esq., who was at that time, April, 1867, Gen'l. Supt. of the Lehigh Valley Railroad, and were specially intended for service on the grade of 96 feet per mile, for 12 miles on this road between Sugar Notch and Fairview. The details for these engines were worked out by John A. Durgin, deceased, and the undersigned Mr. Durgin was then acting as Supt. of the Lancaster (Pa). Locomotive Works, which were owned and operated by Edward S. Norris, Esq. The engines were put in service in September, 1867, and were used continuously until November, 1883.

A. MITCHELL, Div. Supt.

The engraving was made from a photograph taken at the Lancaster shops in 1867, and shows a handsome design and good proportions far above the average locomotives built twenty-two years ago. As will be noticed, the stack had a damper, and the old style half-stroke pump was employed. In 1883 these engines were rebuilt, received new boilers and had a pair of driving wheels removed—the Bee now having a pony truck at each end.

Decapod locomotives are in use on the Northern Pacific Ry., in crossing the Sierra Nevada mountains, and are also largely used in Brazil, and that the subject of this sketch is the first one of that class ever built, makes it an interesting and a historical locomotive.

Davis' Cylinder Head Tester.

At the Altoona shops of the P. R. R. can be seen a neat little machine for testing cylinder heads, the invention of Jos. Davis, Assistant M. M.

Considerable trouble was experienced from finding blow-holes and other leaks in cylinder heads after they were in place on the engines, which caused delay, as the head had to be removed to repair leak.

The engraving shows the machine, which is simply a pedestal with cap fitted to receive cylinder heads of different sizes and pipe attachments to bring water or steam under it.

Where a back-head is tested, there is a block, as shown, to bolt into stuffing-box.

In this shop water is used, and heads are usually tested to 200 pounds pressure; steam could be used to find leaks if necessary. This device also shows the deflection of the head under the various pressures, and thus points out defects in design.

The arrangement of starting valve, gauge and relief cock are plainly shown.

The lower joint allows the substitution of a different top to test steam chests or other forms of work, and the basin around base keeps the waste water from making shop floor wet and uncomfortable.

We believe a device of this kind will pay for itself in a very short time in any repair shop, in saving extra work and delay.

Care of Locomotive Boilers.

A PAPER READ BEFORE THE NORFOLK (NEB.) LOCOMOTIVE DEBATING CLUB.

By JAMES H. DAVEY.

In this paper I wish to give what experience and theory leads me to believe is the best practice for firemen, hostlers and engineers in the care of boilers.

Let us take a trip to Missouri Valley. We will inspect our gauge-cocks, and as we have at least one gauge of water and not more than three, we will fire up in ample time to get out of the house without working the blower, recollecting that the different parts of the boiler are of different thicknesses, consequently expansion and contraction are unequal unless the application of heat is uniform, and at first slow.

Getting out in the yard, we have our fire and steam all ready to leave on time; just before starting, the fireman opens the blower just far enough to keep the smoke out of the cab, and puts in coal enough, so as not to be obliged to open the door while pulling out on a fresh fire, thus avoiding a rush of cold air into the unprotected flues.

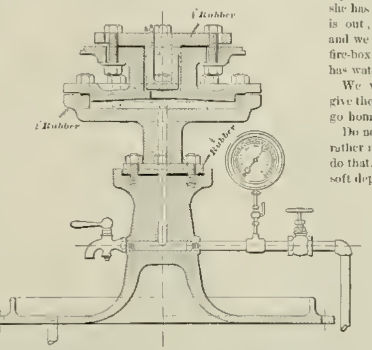
Getting out to the mile board, our engine—one of the F. E.'s best—shows signs of blowing off. So we put on the injector, setting it where experience has shown us it will just supply her. The fireman begins feeding her two scoops of coal at a time, causing the man on the second section just behind, and who, by the way, is firing four scoops, to wonder how the dickens that engine is running without smoke, while his is hiding the sun, and the chickens are going to roost, under the impression that night is coming. Yes, yes, Mr. Dissenter, we know that four scoops is easier firing, but this stoker is a member of the Norfolk Locomotive Debating Club, and is bound to take the coal premium.

Our fireman has been on with us several trips, so he knows where we shut off for Stanton, and his fire has no fresh coal when we push in the plug, and steam has dropped back about ten pounds; he drops the damper, and the injector works for a minute or two, until we think she will not pop off. Right here we would say these are the only occasions when the injector works while the damper is down, and then only for a minute or two.

After stopping at Stanton a few minutes, the fireman—who is watching the hind end while the engineer tries to borrow a little black oil from the brakeman to help out his oil record—sees indications that they are about ready to go, so the blower goes on very gently, and in goes from four to six scoops of coal, and away we go, having plenty of time to ring the bell for all those street-crossings, look out for teams, and see that the caboose is coming.

Well, after all, our fireman is only human; so, just on top of the grade, four miles east, he gets her too hot and she begins to sputter. If our boiler was in the least predisposed to leak, he lets her pop; but she is all right, and he swings the door to and fro a few times and she gets reasonable again.

Everything goes on all right until we get to Hooper. Here we are laid out four hours for a work train, and our water gets low; steam is up to 130, but we drop in more coal and work the blower while the injector is on. May be she will blow off



a little when the squirt is shut off, but what of it? We are taking care of boilers now. Here comes the work train at last, and we are off again. Our fire got spoiled lying at Hooper so long. Some firemen would open both dampers, but ours don't. He knows that the area of his front damper is large enough when the ash pan is clean—and it is never any other way on this engine—to furnish oxygen, nitrogen, hydrogen, or any other kind of gin, for the biggest hog that ever climbed Blair hill.

Fremont at last, and, just as usual, two hours switching. At it we go; pretty soon fireboy thinks a few scoops of coal is needed. Does he wait until we start out of a siding, with fifteen or twenty cars, and then open the door and slam it in? Oh, no! He thinks too much of those precious flues. Yes, 'tis true they ain't his flues, and the company has lots more, but he expects to stay on this engine, and he's a little bit lazy anyway and don't want to shovel any more coal than he has to. And say, did you ever notice how hard it was to get some of those new flues put in? He has another scheme: Just before he expects to get a stop signal the blower goes on very easy, the "shack" three cars back can't hear it, but it's on. Then here comes the signal. Whoa! down he jumps, fires in two scoops, and is on his seat again quicker than you could say Jack Robinson, repeating it on the next stop if necessary. He has not missed a signal, and if he has, what's the odds? You are not going to smash any cars by taking your eye off the gun on a stop signal. Meanwhile we have been losing water, we put on the injector, working it as fine as we can, but still it throws too fast for switching; so we knock steam down ten pounds, then shut it off. Cast-iron rule: Never knock down more than ten pounds of steam with an injector.

Going over Arlington hill, our engine did not steam very well, owing to dirty fire, and we were obliged to let the water drop until she showed but one gauge after tipping over the summit; with blower on and damper open she was in good shape again at Kennard.

We get to the coal dock with 100 lbs. of steam, three gauges of water, drop damper and get off, and now—for home? No; let's stay and see the hostler operate. What makes the exhaust sound so funny as he runs her over the clinker pit? Yes, just as we expected, he is working steam with dampers closed. We must give him a pointer about that. Hostler goes off on other business, and up steps his helper, puts on blower full force, opens fire-box door, and looks in, then recollects that he forgot to bring up the slash-bar and starts to hunt it up, leaving door open. Pretty soon he returns with it, pokes at fire for a while, then goes on the back end of the tender for the tongs. Door still open. Give him a gentle hint that it would be better to work blower light and keep door shut, when not knocking out clinkers.

Be careful how you speak to him, for he is very sensitive, and is apt to ask you, "Who owns this engine, and how much did you pay for her, anyway?"

Hostler puts her in the house and goes to working injector. We kick on that right off. "Why," he says, "she has 100 lbs. of steam." Don't care if she has a thousand: don't work injector when fire is out, the flues contract faster than the sheets, and we don't want rollers and calking tools in our fire-box. Ascertain before knocking out fire if she has water enough to go in the house.

We want our boiler washed this trip; so we give the boiler washer a few instructions and then go home.

Do not blow the steam off my engine; I would rather not have it washed out if you are going to do that. The sides of the boiler are covered with a soft deposit of lime salts which will turn into scale if the steam is blown off, leaving the metal hot. A piece of scale from the side sheets of a boiler habitually handled that way will show how many times she has been washed out by the number of layers there are in it.

This plan also bears rich fruit in the shape of broken stay-bolts and cracked sheets, the cause of which is too obvious to need discussion.

Wait four or five hours, then open blow-off cock under the cab, and when the water is about half out, connect your wash-out hose to injector pipe and cool her off gradually, leaving blow-off cock open, of course. Some boiler-washers, having a deep-rooted dislike or uncontrollable aversion to physical exertion, will leave the plugs in boiler head and upper hand-hole plates severely alone. We hope you are not one of that kind. Put about a gallon of black oil in boiler before filling; it will do much to prevent the formation of scale, and the valves won't cut the next trip, either.

Well, we have a clean boiler; consequently we save a bucket of coal on our next trip.

Right here I wish to say that, in my opinion, the company gets better returns from the money they pay the boiler-washer than from any other investment.

[This club was formed upon the suggestion of THE LOCOMOTIVE ENGINEER, in March, and already numbers over 50 active members. We are glad to publish this paper, as it goes to show the way roadmen take hold of such subjects. The case cited is local, and the practice might not be just the thing for other roads under other circumstances. But the reading and discussion of such papers by the enginemen of any road is worth money to the company, and such clubs ought to have encouragement and support. Engineers and firemen who take part in any such entertainments are helping themselves up in their profession.]

The Beals Brake Co. have been fortunate enough to secure the services of J. H. Vreeland, late M. M. of the Eric shops at Jersey City.

A Rip Van Winkle Shop.

The Fitchburg road recently passed a dividend (without paying it), and stockholders desiring an explanation can find an illustrated one in the Troy shops. This museum of antiquity, by courtesy called a shop, would be a disgrace as a country blacksmith shop in Patagonia. It is over 25 years old, of rough boards, with windows set about four feet from a high hill on one side, and none on the other, there are a couple of tracks through its center, and a turn-table behind it; in little sheds against one side of the main structure there are blacksmith forges and the master mechanic's office; on the other the machinery. One beauty of this shop is its location; it is built right in the way of the main line tracks, which are run around it

They have here an old screw-wheel press, a few old lathes, a planer (brought over in the "Mayflower"), wooden drill presses, and a boiler shear—worked by a pole and held down by a timber placed against the roof.

They turn drivers on an old lathe of large swing, working on but one tire at a time. They bore car wheels by chucking them in a lathe, and other work in proportion In the shop they were rebuilding an old Hinkley, inside-connected scrap, that would not bring 35 cents on any road in the country.

Mr. Davis, the M. M., and his foreman are not as old as the machines around them, or the dirt floor under them, and know that there are wheel presses and wheel lathes and boring mills that would do their work in half the time for half the money, and do it twice as well, and are not the ones who are responsible for the place.

If a photograph of these extensive works of prehistoric ages were furnished to stockholders, it would be all the explanation necessary for the postponement of dividends until this shop rots down—which, judging from present appearances, ought to occur some time before frost comes again.

Indicating a Locomotive.

By CYRUS F. RICHMOND.

FIRST PAPER.

You can talk about balloon ascensions, Rob Roy canoe trips and wheelbarrow rides across the continent, but for real excitement and novelty of adventures, I think a trip on the front end of a locomotive beats them all

GETTING READY.

Our occasion for such a trip was for the purpose of making a series of tests, to determine the amount of water evaporated per pound of coal consumed, and the power developed in each cylinder. The tests were made in six consecutive days, while the engine was hauling a regular passenger train of about seven cars.

The sketch shows plainly the apparatus used on front end for making the test. It was designed and arranged by Mr H. G Manning, who conducted the test, and has some features not always used, for instance, the arrangement to tell where reverse lever is, and the steam gauge—these arrangements do away with the necessity of a man in the cab to note pressure and point of cut-off. These tests were made in September, 1888, on engine 88, Central Vermont R R.

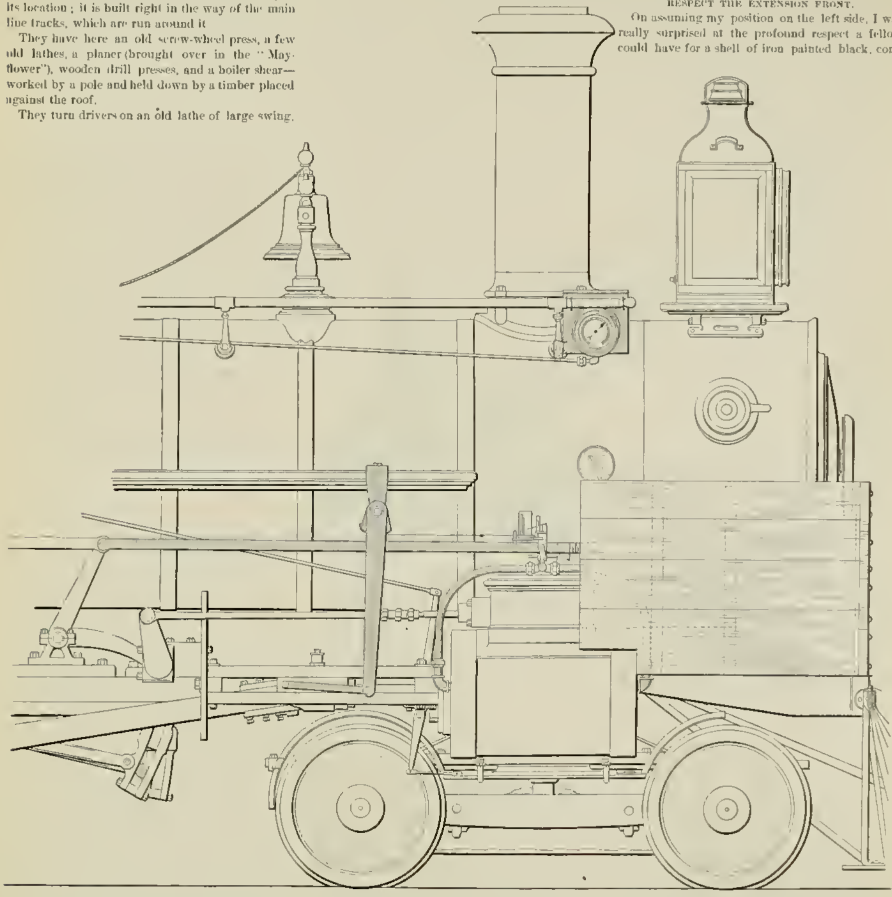
Of course, the cut only shows one side of engine; would say that the other side was rigged up the same way, with the exceptions of the steam gauge shown tied to hand-rail, and rod attached to upper lifting-arm pin reaching over top of steam chest, to show in what notch the reverse lever was at all times.

The rigging up had to be done in one day, consequently, my partner and I were somewhat afraid some little detail might have been overlooked, so we were up at 4.30 A. M., with clear heads, to go over the rigging before starting out. But, with such caution, it is always the unexpected that happens. So the reader may profit by our experience, and be ready for such ordeals, should he ever have occasion to indicate a locomotive.

RESPECT THE EXTENSION FRONT.

On assuming my position on the left side, I was really surprised at the profound respect a fellow could have for a shell of iron painted black, commonly called the extension front, and let me assure you I maintained that respect throughout the tests, and never once tried to fondle or embrace it, but settled right down in the space allotted me, and as we moved along at such a rapid rate, with so much ease and grace, I began to feel charmed, and imagined I was journeying heavenward, until we made a stop, then I thought the engineer had stopped at the wrong station, for a fellow can't stand between the smoke arch and boiling hot sun, boxed in like that, without bringing up old memories of Sunday-school stories of a place they don't wear overcoats.

One of the first unexpected things we had to grapple with was a great leak of steam which I was unable to locate from being boxed in so, but it was close enough to me to make it so uncomfortable that I had to go back to the cab and wait until



we made a stop. While sitting on the fireman's seat and watching the clouds of vapor rising from an unknown quarter, I was startled to see the top of the indicator shoot up like a skyrocket and land in the grass on the road side, which was unexpected No. 2.

I left unexpected No. 1 for my superior to look out for, while I got off at a near-by station, and with an army of boys and a section gang started in search of the truant indicator top. After an hour's search it was found by the ever-present small boy, and to my surprise nothing wrong with it.

Would say right here that we had to watch them close after that, as the only means provided for screwing them on was with the fingers, and the jar would work them loose quite frequently.

There should be a half-round Spanner wrench, with a teat on end and a hole in knurled collar to receive it, then it could be screwed down tight.

THE RELIEF VALVE.

The engineer said that I must be a "Jonah," for after I left they had no more trouble with the escaping steam, and it looked that way to me, for on the return trip my indicator cord broke, and while holding a new piece in my hand, ready to adjust as soon as we slowed up, I let it hang carelessly, and when I was about ready to tackle the great contortion act of adjusting it, the old steam leak appeared again, and I thought it must surely be the devil on my side, for something had hold of one end of my cord, and wouldn't let go, so I followed down to the end of the cord and found that it had been sucked up in the relief valve when steam was shut off, and as soon as the steam was let on again it pressed the valve down, with the cord caught up in it. Here was our unexpected No. 1 unraveled. To share the cuss words, my partner got his watch-chain caught up in the valve on his side, and I verily believe be would have been drawn up himself if he had been attached to the chain.

All this was remedied by boxing around the valve shell *tight*; we had boxed around it, but left a few loop-holes for waste, paper, string, watch-chains, and possibly men to be drawn up and squeezed down again.

Speaking of indicator cord, it is always best to have a few cut the right length, rigged handy to adjust, for they are liable to break, and it generally happens when you have the least time to spare.

ARRANGEMENT OF SIGNALS.

We had a sort of primitive telephone rigged from one side to the other, but it was difficult to hear, on account of noise, etc., so my superior tied a string to one of my wrists to signal me when to take cards, but it didn't work, as he would yank my hand when it was near the oil-cup on top of steam chest, and leave a red-hot impression on my hand—as well as my mind—and also bring out a red-hot expression. So we let the string go rather than be prematurely cremated, and replaced it with a small gong, which, with proper signals, understood, worked nicely.

HOW TO COUNT REVOLUTIONS.

Counting the revolutions—or chewing lightning, as it sometimes seemed to me—was another sticker for me, but not for my partner. It is all well enough when they are not over 200 per minute, but when they run above that, it takes an experienced hand to get them correct. Practice is all that is needed to become an "experienced hand," so I practiced in my leisure moments. There is a suggestion that is worthy of notice for one who has difficulty in counting, and that is, to count up to ten, and instead of saying eleven, twelve, etc., commence with one again and count 9, then say twenty and commence on one again, count 9, then say thirty, and so on. In this way it will soon become easy to count as high as 80 in fifteen seconds. I believe there is no counter made for this purpose, to use on locomotives, that can be relied on, so it is necessary that one should be capable of accuracy in rapid counting.

The last and most trying to the patience of the experimenter, and yet, after all, the most amusing, was the number of questions from a curious public we had to answer. One in particular I call to mind now, was from a real honest-looking hayseed, who put the query to my partner after this fashion: "What yer got thar, a hog-pen?" (pointing to the boxed front end) which was probably suggested to his mind by the appearance of its occupants, after several showers of soot and cinders, mixed with sweat and wrath.

In next paper I will try to briefly describe the indicator and its action, and explain how to take the cards, and how to read them after they are taken.

Light Steam Hand Car.

We present on this page a cut of a very small locomotive of standard gauge, intended for inspection work and roadmasters' use. It is the invention of Mr John Doyle, general roadmaster of the Detroit, Lansing & Northern Railroad, and is being introduced by The Ionia Steam Hand Car Co. of Ionia, Mich. As will be seen, the little upright engine drives the forward pair of wheels by means of a chain, or linked belt, and sprocket wheels. All the parts are as light as possible, the whole machine, ready for the road, weighing but 700 pounds. The car is built to carry four persons, but can be rigged to carry more. The water-tank holds 16 gallons of water, and the coal bunker a couple of scuttles full. The boiler is a quick-steaming one, and can be got ready for service in from 10 to 15 minutes. The average speed is 15 to 20 miles per hour on one gallon of water, and from one to two pounds of coal per mile; they have been run at 30 miles per hour The car is so light that one man can take it off the track on a road crossing, and two men can handle it any place. Something of this kind is needed now-a-days to enable track, bridge, fence, and tele-

graph men to go over the road at a good rate of speed without the employment of a regular locomotive, train orders, or a crew. With this little locomotive an inspector is his own boss, can stop where he pleases, as long as he pleases, and go when he pleases.

A few of these little fellows along a road would be a great help in case of accidents, to send out with physicians, take orders, or bring in crippled people. If one of them gets against a full-grown locomotive, the damage is slight in comparison with ordinary locomotives in collision.

A New Valve Motion Model.

We have received a very handsome photograph of a valve motion model, built by W. H. Ermentrout, of Reading, Pa. The design of the model is much like the Richardson, but it is gotten up on a cheaper plan, being mostly composed of hard wood. It is adjustable in almost every way, except the radius of the link The price is not stated.

A Victory for Contracting Chills.

The Central Railroad & Banking Company of Georgia have placed with A Whitney & Sons, Philadelphia, an order for 10,000 car wheels, to be cast in contracting chills—enough to keep these great works in full blast for several months.

John Alexander's fit of modesty has become contagious. Master Mechanic Phelan and Ry. Com'r M. E. Conger request the dropping of their respective titles; they want to be just "one of the boys." Modesty is a good thing to have—modest ourselves.

Correspondence

From the Pacific.

Editor The Locomotive Engineer:

Herewith find enclosed one dollar for the renewal of my subscription to THE LOCOMOTIVE ENGINEER. Could not do without it, each one of John Alexander's letters is worth more than the subscription price for one year. Come again, John; the boys in far-off Oregon relish your letters. And by the way, he speaks of a locomotive riding bad when cut back with full throttle; and for the benefit of some of the readers of THE LOCOMOTIVE ENGINEER, we would ask why it is that an engine gets up this side motion and seems to labor against herself when cut back with full throttle. I claim that it is back pressure. If wrong, please correct.

McMinnerville, Oregon. "OLD TIMER."

Room for Improvement.

Editor The Locomotive Engineer:

There seems to be an impression among engineers and firemen, that there is no use for them to try and invent or patent any improvement in the line of their work, and often say that it is no use for them to think of it, when master mechanics and superintendents of machinery have been working in the same line so long.

Keep thinking, and when you have an idea work it out, and be sure it will work before you announce it. Don't be discouraged by apparent obstacles—sometimes a little light from another source will make apparent failure a success, so do not be afraid to ask advice. If you look back to the record of past achievements in locomotive, steam engine or machine designs and improvements, most of them were made by men in the ranks, and not by experts Don't dream, like our friend John Alexander; dreaming never made an invention, but solid thinking has. I know you can't get up a patent every time you think, but keep thinking. There is room for improvement. F. W. K.

"Signals."

Editor The Locomotive Engineer:

Often when sitting comfortably in a good seat in the smoker enjoying a cigar while the gentlemen in the cab were doing their best to make up that 10 or 20 minutes we had lost, the importance of having good signals has occurred to me. As we roll around a curve, and dash by a freight standing on a side track, I think of the possibilities arising from that switch, should it have been left open to the side track, and no semaphore or other signal in such a position that the engineer could see it in time to prevent our making a serious reduction in the surplus of the road—if it had any. I do not suppose that the engineers are consulted very often on the matter of signals, but I am prompted to write this by the belief that they can give to those who are interested in such matters many valuable hints gathered from every-day experience. I know of no one more competent to judge of the best form of signal by day or light by night, than the men upon whose shoulders rests the responsibility of knowing the meaning of every signal on their run.

It is the opinion of the writer that the subject of signals is receiving more attention in this country to-day than ever before, because of the rapid increase of traffic, and consequent addition to the number of trains run on the majority of roads, and the advantages shown by those roads which have good signal systems in use.

I wonder how many trains would leave or arrive safely in the Grand Central station, New York, in 24 hours, if the present system of signals was abolished, and they returned to the old-fashioned switch-stand and target.

I hope some of your correspondents may find time to tell us how they think a danger signal should appear so as to prevent them from doing that which might result in loss of life and property. SMOKER.

Poughkeepsie, N. Y.

Simple Rule for Setting a Slipped Eccentric.

Editor The Locomotive Engineer:

I see in the paper different rules for setting slipped eccentrics, but none just my way, which I think the simplest.

For a back-up eccentric, place that side of engine on the forward center, put the throw of eccentric *down*, and then move it toward the pin enough to give the amount of lead, and fasten.

For a go-ahead eccentric, place engine on *back* center, and proceed the same.

It is no trouble to set eccentrics, if a man knows where they ought to be; a young runner will generally have more trouble to tell which one is slipped, and my way of setting will show him what one is off as soon as he gets the engine on the center.

I recently saw a young runner trying to set a slipped eccentric by the cylinder cocks, when the real trouble was a broken follower head.

Charleston, Ill. C. W. K.

The Reading Relief Association.

Editor The Locomotive Engineer:

By your inquiry as to whether the employes of the P. & R. R. R. Co. take kindly to the Relief Association instituted as adopted by the company, I infer that you are familiar or acquainted with the relief system as it is practically conducted by railroad corporations of the present day. In reply, therefore, if I may be allowed the comparison, I should say they take to it as kindly as a chicken would take to a body of water it might by accident fall into. In connection it might not be inappropriate to assume that a couple of foxes were on either hand with an eye single to the ultimate good to accrue to themselves as the result of the chicken's misfortune.

From the foregoing you might be led to think that there were some urgent methods brought to bear, compelling the employes to identify themselves with the scheme. I am constrained to inform you that such is not the case and, as nearly as possible, quote you in proof President Corbin's own words, found in a circular published and issued to the employes about the time the organization was being effected, in which he said: "I wish it clearly understood that all our present employes are free to become members or not, as they please, and none need have any hesitation in declining, if they desire to do so." In view of this position taken by Mr. Corbin, what appeared most singular, after hearing the numerous sarcastic and unfriendly comments on the project, as expressed by the employes, was to note in how remarkably short a period of time, with few exceptions, almost every employe had filed an application for membership. Indeed, I question whether there has ever been any similar distinctively beneficial organization in existence that has in so short a time received such large accessions to its roll of membership, and apparently three-fourths of them joining much against their will.

I will intrude on your time no further than to add that, as there are always two sides to a question, this subject would admit of a large and varied discussion *pro* and *con*; but you have, no doubt, gathered enough from the tone of this communication to appreciate the true circumstances of the case.

In conclusion I would earnestly solicit an expression of your opinion on this subject, to be published in your next issue, in connection with the above.

Reading, Pa. SUBSCRIBER.

That Bent Main Rod.

Editor The Locomotive Engineer.

It is a late day to find fault, but I believe in the old maxim, "Better late than never." I am not satisfied with your answer to my question in November number, 1888, about that bent main rod. I believe yet the bend was caused by the engine catching herself on sand, when she was working steam. In your answer you say no (and I believe, without giving the subject any thought,) that the main rod could only receive the pressure of steam on piston. Now we all know that when an engine is passing the bottom quarter in going ahead, the action of steam is pushing on piston and rods, and, in passing top quarter, is pulling. Now in my case my sand would run only when fed out by hand, and I had a man out for that purpose. Now, suppose she commences to slip, and before I can close the throttle, he drops some sand and it catches her when the pin is about passing the lower quarter and the rod is in an angular position. Now I claim that the sand, in having a tendency to stop and steam to continue, causing the engine to slip, working in direct opposition to each other, might cause the bend. Of course it might be caused some other way.

I would like to have the opinion of our M. M.'s, etc., on the above. If my theories are wrong, I wish to be corrected. If we don't fight over this rod, I will tell the boys in some future number how we took the bend out of that rod.

McArthur, O. W. R. CLINE.

[If the engine was slipping badly the sudden checking of the momentum of the moving parts might have thrown more pressure on the rod than that due to the steam pressure, but how it would tend to bend the main rod instead of bending or breaking the guides or crosshead, does not appear plain.]

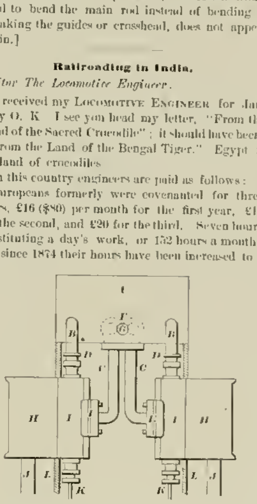
Railroading in India.

Editor The Locomotive Engineer.

I received my LOCOMOTIVE ENGINEER for January O. K. I see you head my letter, "From the Land of the Sacred Crocodile"; it should have been, "From the Land of the Bengal Tiger." Egypt is the land of crocodiles.

In this country engineers are paid as follows:

Europeans formerly were covenanted for three years, £16 ($80) per month for the first year, £18 for the second, and £20 for the third. Seven hours constituting a day's work, or 152 hours a month, but since 1874 their hours have been increased to 8



per day, or 205 per month. £16 is 160 rupees in Indian money.

If a man works short of a month and is always available, he is paid the full month and Sundays at 7 hours per day overtime. If his engine is under repairs and he only works the four or five Sundays in the month, he gets one month's pay, ordinary time, and Sundays overtime. He gets 10 rupees per month, good conduct money—this is payable quarterly.

He also gets coal and oil premiums, provided he keeps time and runs lower than any one else.

With Indian coal my passenger engines are running on 35 pounds of coal per mile, and about 6 quarts of oil per 100 miles; average load 14 vehicles.

We have several classes of coal; the best is Rambilli, equal to best Newcastle coal and it takes measurement at 42 cubic feet per ton. With this coal a very light fire is carried; only enough to cover the fire bars is sufficient to give plenty of steam. We use smoke plates and brick arches for all classes of coal.

I expect to leave this station for another this month, and will notify you, as I want the paper sent me—I like it very much.

I see a great many foremen write you about steam pipe repairs. We use pipes that are glanded on to the steam chests, as are also the exhaust pipe; this allows for a certain amount of expansion.

You will see by the sketch that we set the cylinders back of the smoke-box, as in English practice; this allows of the use of a large, single, leading wheel.

For the benefit of young Americans not familiar with this style of engine I designate the parts in the plan. *A* is the smoke box, *B B* steam pipes, *C C* exhaust pipes, *D D* steam pipe glands, *E E* exhaust pipe glands, *F* breeches pipe under exhaust pipe proper, *G* nozzle or blast pipe, *H H* cylinders, *I I* steam chests, *J J* motion bars (guides), *K K* eccentric rods (valve stems), *L L* plate frames. Main steam pipe in the boiler generally lasts the engine's life, *i. e.*, 50,000 miles to first boiler examination. The steam pipe joints in smoke-box generally last 14 days, but according to work; if on heavy flagging, less time, to disconnect and make joints, 1 to 2 hours. This is on Dub's passenger engines.

FRED. W. BEDFORD,

Sohagpur, C. P., E. India. Loco. Foreman.

Some More Kinks for Young Runners.

Editor The Locomotive Engineer:

John Alexander says that he has invented a great many "kinks" in locomotive practice, some of which were successful when put in practice, while others were conspicuous failures. There are others of us in the same fix, but our surroundings have a great deal to do with the success or failure of most of the devices for getting ourselves out of troubles brought on by poor machinery, bad roads, etc. What will be described in the following lines probably will not be of much use to a man on a first class road, with plenty of machinists to do the work, a shop at each end of his run, and everything in apple-pie order. But for the men on roads where the train dispatcher is in charge over the master mechanic, or where the engines and men are on the "chain gang," or where the only shop is in the middle of the road, and at the end of a trip the engine is put on a rotten old wooden table, hand-spiked around, run into a wooden shed with no pit in it, and a sand floor to do your work on, there is where some kind of kinks come very handy. When you get in at night after monkeying along with a hot brass all the way it is not very cheerful to think of having the same trouble all the way back again the next day. If you are troubled that way, get a bar of solder from the tin shop, commonly called "half-and-half," a little vial of acid from the same place, and some emery paper. When you get in at night, throw a link into the fire-box where it will get red-hot. Take out your brass that has been hot, rub the bearing surface bright, wet it good with acid, fish the red-hot link out of the fire-box, and lay Mr. Brass on it so it will get hot, too. When the brass gets hot enough to melt the solder, rub the end of the bar on the bearing surface till it is tinned over good. It should be a little thicker in the middle of the bearing than at the edges, so it will run cool, and, if you do a good job, that brass will be pretty certain to run cool till the tinning is worn off. Try it. I hear that the patent for lead-lined brasses covers this process, if it does, it is no good, for I have used this plan for fifteen years.

Some men have an idea that an engine, with two injectors and no pump on, has to be filled up with a hose, or with a pail through the top of the dome. If your engine gets cold this summer, and the water drops down so low you dare not put a fire in her, and there is another engine there that can tow her around, hitch on to the dead one, oil your valves and cylinders good with oil—not tallow—hook the reverse lever the way the engine is going, open the throttle wide, and when the engine is moving, the cylinders of your engine will take the air out of the boiler; if the tank is full and *all* steam and water connections to both injectors are open, the water will soon fill it. I have seen an empty boiler filled up in this manner, in one trip up and back, in a 50 car siding. If the air leaks in through the whistle, or relief valves on the steam chest, wet some waste or a pair of overalls, and tie around them, to keep the air from getting into the boiler that way, for if the air gets in as fast as the cylinders take it out, the water won't have to go in. I have used this plan myself several times, and it works well.

Now these kinks are for the use of the men who are learning the business; and it may seem useless to the old, experienced engineers to write about them, but just the same, there are some old engineers that think the right way would be to reverse the engine and pump air *into* the boiler, and use air to work the injectors. That won't do it, for compressed air won't work an injector. Steam will do it, just as long as the stream of water will condense all the steam, and no longer, and that is the reason why very hot water will not work through an injector readily. If the steam does not take up all the water, it comes out of the overflow only warmed, if the water does not condense, or take up all the steam, it will "break." You may theorize all you please, but the injector depends for its action on the complete condensation of the steam, which is the propelling power that sends it into the boiler. No matter how small the leak, if the injector draws air it will break, because water won't condense air as it does steam. Another kink is to fasten the nozzle of your squirt, for wetting the coal, so a little stream of water will run on the rail behind the drivers, and wash off the sand you have to use on a hill, and make the cars come along easier. The best place to fasten it is with a loop of telegraph wire on the lazy cock, if your hose is long enough to reach down there. On the outside rail of a curve, it will help you enough so you can get around with a train, that would otherwise stall you, and make you double the hill. One master mechanic thinks enough of the plan to have a little jet of water thrown on each rail behind the drivers, and he has a special set of pipes to do the work in a first-class manner. He did not get the idea from me, either, so you see the plan is not new.

Next winter, when you find your frost glasses troubling you, by "sweating" on the "inside," fill in the space between the two glasses with alcohol, and it will be clear as air, and won't freeze, either.

CLINTON B. CONGER.

Lansing, Mich.

About Steam.

Editor The Locomotive Engineer:

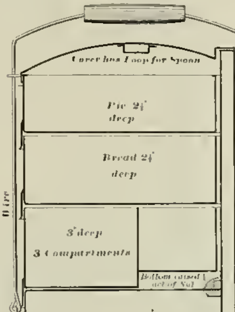
Don't you think that it would be better for us all, as enginemen, if we would, through the press, or in some other way such as might be deemed advisable, relate to each other our experience on and our knowledge of our engines, the construction and working of the different parts of the machinery? We all know the name of the invisible and powerful agent which propels the locomotive with its train of cars along the iron track. We see it toiling for the human family in every land on the face of the globe; it has been connected with most of the great engineering works of the past century. Some of us have seen that great masterpiece of engineering skill cut across the African desert, connecting the waters of the Red Sea and the Mediterranean; and as we stood on the deck of the steamer, and viewed with wonder and amazement this great work of the century, we felt convinced that, without the aid of this mysterious power, the Suez Canal would never have been cut, the short highway to India would have never been opened. It brings to our shores and lays at our feet, and distributes in every city throughout the land, the products of foreign countries. Spices from India, the teas and rice of China and Japan, and a thousand more of the necessaries of life. Through its agency the Atlantic voyage between Europe and America has been shortened from weeks to days; we see it turning the wheels of our factories and our mills, we find it heating our public buildings, our churches, our schools, and our homes; it is employed on all the great highways of commerce, both on sea and land. Every boy and girl knows that this great friend of the human race is called steam. Some men have been in close communication with it for years; they have thousands of times opened and closed the throttle by which its mighty forces are held in submission; they have heard its shrill voice as it was released from the cylinders and safety valves; but ask them the question, What is steam? and they are silent; they don't know. Steam is water changed into gas by means of heat, and in its true state is invisible; it will, like all other gases, expand if it is enclosed, and its pressure will be equal on all sides of a cylinder in which it is enclosed. There are two kinds of steam, called saturated and superheated steam. Saturated steam is in contact with water, if it is separated from the water, it can be heated to a higher temperature; it is then called superheated steam. When we were boys at home, we have often watched the white cloud escaping from the spout of the kettle, as the water it contained was boiling over the fire. Since we became men, and commenced locomotive work in order to earn our daily bread, we have often seen this same white cloud escape from the exhaust pipes and cylinder cocks of our engines. But this is not true steam; it is then in a state of condensation, through coming in contact with the atmosphere. Now if we take water, and boil it in any open vessel, the steam which escapes from the water, as it boils, will have a pressure equal to that of the atmosphere in which it is boiled. In ordinary cases, such as on level or low lands, the atmospheric pressure is 15 lbs. to the square inch; on high elevations it is lower, and below the surface of the earth, in mines or deep wells, it is higher than it is on the surface. If we admit steam of 140 lbs. pressure into a cylinder, this is called absolute pressure; if we deduct from this the atmospheric pressure, 15 lbs., we have 125 lbs effective pressure. In graduating steam gauges the atmospheric pressure is disregarded, so that if we speak of having 140 lbs of steam, we mean effective, and not absolute pressure.

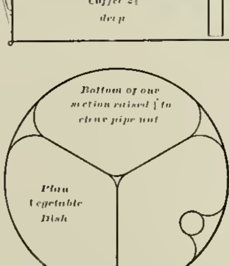
F. TAYLOR.

Marion, Iowa.

John Alexander's Dinner Pail.

Ever since John Alexander gave a description of his ideal dinner pail, we have been receiving letters asking if they could be purchased, if we had a picture of one, would we please give Mr. Alexander's address, and one man sent $2 and said, "Get me one, if it costs $10." We wrote to our festive correspondent, and depicted our woes to him, and he answered as follows:





Editor The Locomotive Engineer:

"Uneasy lies the head that is a clown's.' This is the eleventh letter from you about dinner pail. Can't a fellow say what he wants, without all the people in the land rising up as one man, and saying they want it too? Did I tell everybody from Dan to Bersheba that I had dinner pails to sell or give away? I had one of these pails made, as near as a country tinner could build it, with no other facilities than a soldering iron and a piece of rosin, and it looks a little (not very much) like the sectional sketch sent you herewith. I don't know which is the worst, the drawing or the pail, as I have no means of comparison—some fiend in human form nipped the pail the second trip out—I wouldn't care so much, but I had left a quarter section of cream pie to top off on after I registered, and the deep-dyed villain took that, too.

Well, here are directions for building and operating the device, such as it is. The bottom is 2¼ deep by 8 inches across, and the brass nut is soldered into it and tinned over, to keep it clean. The pipe is ½ inch copper, and tinned or nickel-plated, outside and in, this makes it easy to clean. It extends to top of pail, so that a man can drink without taking the pail apart or getting cinders stuck in the larinx, or something, of his Adam's apple. The next story is partitioned off into three compartments, as shown in the separate sketch. These are for vegetables, and when the pail is put on a stove or the boiler head to get the coffee hot, it gets the whole lunch warm. I would place the hole for pipe in one of the partitions, but for the fact that one of the sections has to have its bottom raised to clear the pipe nut, corners are rounded.

The other sections are shown and sizes marked on, in sketch; any one that knows enough to eat a lunch can see that he could open one of these sections without the other, by raising up and swinging on the pipe. I did think the bail should snap around the pipe, but the plan shown works O. K. It would be better if the pipe extended through the cover and had a cap on it, but I preferred the style shown, because it was easier made and kept clean. If there is as much talk as all this about a jim-crow dinner pail, it would seem to a man up a gooseberry bush as if it would pay some outfit to make a few and dispose of them to the meek and hungry car hands who read the L. E. Should any tin peddler come to you with propositions tending to make him the bloated monopolist and millionaire manufacturer of John Alexander's great and only fodder can, inform him that I seek the good of all mankind, and will therefore sell, barter or bequeath all my right, title and interest in the aforesaid dyspepsia dispenser for a small consideration in the current coin of the realm.

JOHN ALEXANDER.

Not in Canada.

Editor The Locomotive Engineer:

I should like to see the opinion of a few others upon the practical working of a close cut-off with link motion. J. Alexander's idea of "hippity-hopping on tip-toe" just about hits the mark. I am running an engine which, with the lever in first notch forward from the center, cuts off at about 3 inches, and I find it goes fine on a slight down grade; but on a level she slows up till the exhaust gets about the same volume as when working with the steam wire-drawn from a throttle almost shut and the lever in the next notch below; whilst the old lady wriggles and prances on the rails, something like a high-fed colt in want of exercise. So, in consideration of a slab frame and side play in the boxes, this notch is not polished very much. It does not save coal a cent's worth, either; besides, if she happens to get down on one of her springs you have to listen if one of her exhausts is going down onto the track somewhere, instead of up the stack. No, sir; if a man wants to get his name up for cheap running, he had better go dodging along the road, letting other men take side tracks, etc., etc., or have an understanding with the coalmen to dump extra good coal into his tender, especially if he has very cold weather to pull against as we have in.

CANADA.

Montreal, Can.

Thoughts on the Center Notch.

Editor The Locomotive Engineer:

In the technical department of a certain monthly journal it is asserted, in substance, that reverse lever in the center notch and throttle wide open is proper. My experience on the road convinces me that there is nothing in it, and nothing to be gained or saved by running an engine on such principles. My experience in the back shop, facing valves and doing other valve gear work, is that it is injurious to the engine and a detriment to her on the road. Let us suppose a case. An engineer pulls out of a station, say, with a heavy passenger train; by the time he has run a mile (if the road is level) he has the lever up in the center and the throttle wide open, and nine times out of ten the minute this occurs the valve stem and piston rod will begin to blow, and he is at least two or three miles from the station before the engine is making card time; and it is a struggle, yank and twist, with the engine, to handle the train; but suppose, when all is said and done, she is not making time; we drop the lever down a notch or two; if we do the throttle must be closed in proportion, or she will pull the fire to pieces; and if such is the case—and experience tells us it is—why is it not a great deal easier on the engine? and she will pick up her train quicker, by cutting back and opening the throttle by degrees, giving the engine just what steam she requires to do her work and run along smooth.

If an engine will not keep increasing her speed (with an ordinary train) with the reverse lever in the center and a full throttle, it proves conclusively that the principle is wrong. I make the claim that throttle and reverse lever should be in such a position in relation the one to the other as to leave us some margin to fall back on in a pinch. I tried the experiment once (with an ordinary train) by running my engine with the lever in center and full throttle; she would only run so fast, I did not change the reverse lever, but closed the throttle a little, when she began to pick up in speed; I was convinced at once that it is not right to throw the whole boiler pressure on the valves and increase the friction by making them carry an unnecessary load. It is a good rule to run with the reverse lever as far up as is consistent with the work to be done, and the throttle in such a position as to give the engine just what steam she requires, and no more. I have faced valve seats that were cut down one-eighth of an inch in center, and the planer tool marks still visible at the extreme full travel of the valve; all this wear being done in one trip of 214 miles, and the whole thing could be traced to the evil of working the engine with the lever in the center notch too soon after starting.

A certain build of engines were put on a certain road to do passenger work; some of the men running them said they were no good, I happened to ride a few miles on one of these engines; she was run on the extreme center notch and full throttle principle; she would just get a good swing on the train, when it was time to whistle for the next station; there was a first-class engine with cylinders 18x28 doing bad work by bad handling; patent valve gear, extension front, sight-feed lubricators and all modern improvements—everything to insure good work, but the engine was choked down in the early part of her run, and then condemned, because she did not furnish the engineer with brains. Show me a man who is always packing valve stems and piston rods, and nine times out of ten I will show you a man who runs on the center notch and full throttle principle. A great many firemen learn this from their engineer, and keep right along in the old rut. I must not be understood as claiming that it is a universal practice; happily it is not.

W. de Sanno.

Tulare, Cal.

In Favor of Full Throttle.

Editor The Locomotive Engineer:

John Alexander's letter, in the April number, was a disappointment to me, although I am only a fireman, and am not supposed to have any opinions.

Now, I do not wish to be impertinent, but, thanks to Mr. Sinclair and Mr. Forney, and the growing number of men who carry their theories into such successful practice, we firemen are beginning to look with disgust at the man who throttles his steam, because we know it means work.

Every one knows that there is a class of engines—which, luckily, are disappearing—that cannot be worked full throttle. Such a class are those engines of former days—the little engines with small boilers, small nozzles and steam ports. But take the modern locomotive with its 50-inch boiler, 4½-inch single nozzle and large steam ports, and I think many older men will agree with me that full throttle is the best.

Let me give an instance. Probably the best freight runner on a certain railroad was an engineer we will call Will. I fired for him once for a short while, and learned why. The freight engines were eight wheel, 17-inch cylinders. Over a 60 mile division our summer trains were 36 loads of bulk and 40 loads of merchandise freight. There are two water tanks, the last being 15 miles from the end of division. During the time I fired for him he never stopped at the second tank for water, and never was the coal-gate taken out going north (we burned slack coming south). His was the only engine that did it, as a usual thing.

How did he do it?

After the first few exhausts, the engine was cut back to half stroke, full throttle; in a train length to ¼ stroke, and after that, where possible, to 6-inch cut-off. When he wanted to kill time, back she went to 4-inch, and only when the engine was doing more work than was necessary there, did he partly shut off the throttle. He rarely carried more than three scant gauges of water, and this to me seems to be the secret of the expansive use of steam—the use of dry steam.

This man could work injectors where others could not, because he had read their description and understood their principle. Although one of the youngest engineers, he was chosen to run as through passenger runner, because, as the superintendent said, "He has never failed to do what we have told him to do."

I never noticed that his engine rode harder than others worked differently, and I generally had steam. When we came to a side-track he would shut off his guide-cups. As a result of this and other care, he ran 120 miles to 4 pints of engine oil when 8 pints were allowed. His engine never ran hot, and he never stole any oil to do it with.

On this same division, within the past year, four firemen have been promoted. Two are doing good work and two are on extra list. The first two are full throttle men, and the last two are not. Another runner on this same road won't work his engine "high up," because it might wear the valves "spoon-shaped."

When I began to fire for our friend Will, I was a beginner. I thought all that was necessary was plenty of smoke. I soon learned that smoke was an abomination to him, and so also was "popping." I saw the reasonableness of it, and tried to prevent them, succeeding in the end pretty well. But I have since learned that a fireman cannot do this unaided.

I do not deny that some of the most successful runners on many roads are men with John Alexander's ideas, but take runs where you have to scheme for water and coal as well as to make fast time, I am skeptical as to their ability to compare with my man. When railroad officials want a fast run made, they rarely figure on the capacity of the tank, or the distance between water tanks. They expect the engineer to do that.

I will add that "Will" is a constant reader of your paper, as well as myself.

Grant.

Dayton, Ohio.

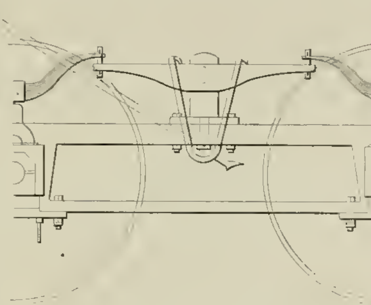
Kink for Removing Driving Springs.

Editor The Locomotive Engineer:

Enclosed please find sketch of an old spring kink. This, no doubt, will be very old to most of roundhouse men. But it will be a cheap and handy tool to those who have not used it. It consists of two hooks, being turned on a piece of 1¼" round or square iron. It should be 18' long, and spread wide enough at top to straddle the equalizer stand. It can be used to strain down equalizer to get gib out. The old spring once out, the new one put in position, the rigging coupled up, apply one or two bars, and come down on them. If men are not plentiful, lengthen out lever indefinitely by putting a pipe on bar. A spring can be replaced in a few minutes. The higher engine is raised on the jacks, the easier the job. This cheap tool could be carried on 8-wheel engines to be used on road. It costs nothing, and is always ready. The only trouble will be to keep one, as they will walk off after engineers see how handy they are, especially old-time men, who run before the spring companies made springs that cannot be broken, and such springs as are now under the majority of 8-wheel engines.

A. T. Hooker,
Gen'l Fm. E. T., V. & G.

Chattanooga, Tenn.



Spring Removing Kink

Where They Make Slide Valves.

During a recent visit to Troy, the writer called at the shops of the Estate of F. W. Richardson, where a specialty is made of building locomotive slide valves with Richardson's balancing device, plain valves as well as Allen valves being built.

These shops have recently been enlarged by the addition of a large two-story building; part of the lower floor is occupied by the Ross Valve Company, builders of pressure regulators and water motors, and the upper floor is occupied by the machine tools, some ten planers, boiler, engine, half a dozen lathes, drill presses, etc. A very ingenious device is used to keep the floor level, on top of the supporting pillars, under the central floor girder, is a heavy wrought screw, working in a cast cap on top of posts, this allows of the leveling up of the floors as they settle.

Almost every road of any size in the country uses balanced valves, and there are more Richardson and Allen-Richardson balanced valves in use than all other kinds combined. Many roads make their own valves under a royalty, but most of them buy the valves and plates ready for service, especially on new work. These works have a capacity of ninety sets of valves per month, and often make that many.

Here also they have a big trade in high grade coil springs, especially adapted for safety valve work, being of a very uniform size and strength, guaranteed to give a certain amount of resistance for a corresponding amount of pressure as well six months after use as upon first trial. In the spring department they were making some very heavy springs, to withstand a pressure of six tons for ½ of an inch compression. All the springs used by the Consolidated Safety Valve Co. are made here.

Mr. H. G. Hammett, the manager of these works, is a live man, and a planer that can't carry an honest cut at 20 to 22 feet per minute, and get back at the rate of 50 or 60, is set one side for one that can.

Foreigners at Baldwin's.

The Baldwin Locomotive Works are completing 30 locomotives for South America. There are 12 saddle-tank, six-wheel connected switching engines for the provincial government of Buenos Ayres. They have outside connected driving brakes, on the English plan, iron cabs, copper fire-boxes, and a peculiar excuse for lagging, one-inch angle irons are placed around the boiler like hoops, and a jacket of $\frac{1}{16}$ iron is placed over them, no non-conducting material being used.

There are also several freight and passenger engines for the Argentine Republic. After being put up and tested, these locomotives are all taken apart and carefully boxed. In the shop we noticed a very small engine for Cuba; one narrow gauge, domeless coal mine engine with Wootton fire-box, several little street motors, and the usual dozen or so of ordinary engines for our own roads.

The N. P. are fitting two engines with the Smith feed water purifier.

A Useless Expense in Locomotive Building.

Half the master mechanics in the country—yes, two-thirds of them—express their opinions pretty often of the inability of engineers in general to appreciate or fairly understand the "improvements" constantly being applied to their locomotives. When a runner wants any little change made on his locomotive for his or his fireman's comfort or convenience, they say he is a crank and don't know what he does want, and if let alone would spoil the "standard" of the locomotives, and make them cost twice the contract price, before they were contented. Sometimes the M M. is right. However, people who live in glass houses should not throw stones.

The slight departures from general design in ordering locomotives, made by the majority of master mechanics to meet ideas of their own, has raised the cost price of locomotives from 15 to 25 per cent., and the cost of repairs to several times that amount. This statement we do not believe can be successfully refuted. When a man makes radical changes to meet the requirements of the peculiar service of his road, that is necessity, and there is an excuse for it; but when a man furnishes drawings for all the parts of his locomotives, and insists on their being built to them so close that he won't accept a cylinder casting of the works' standard pattern, because there is a fillet in some angle where he has none, he is going to lots of expense for nonsense. Any locomotive works in the country will bear evidence that it is necessary to make new cylinder patterns for almost every order they receive. If the order is for one engine, the entire expense of the pattern must be added to the price; if for a hundred, the price is proportionately less per engine.

What is true of cylinder castings is true of most of the other standard parts.

If the Master Mechanics' Association, or an association of builders, would determine the best average proportion, weight, size and material of such parts of standard engines as cylinders, wheel centers, frames, valve motion, axles, boxes, etc., and buyers would order to these standards, the roads would secure cheaper and better engines in much less time, and the repairs would cost far less at home and on other roads.

For instance, if the proper size and weight of a cylinder for a 17x24-inch engine was decided and agreed upon for all 8 wheeled locomotives of that size, every works in the country would build, finish and keep in stock cylinders ready to be used at a moment's notice; so they would frames, wheel centers, axles, pins, rods, etc., and so they might boilers, but the great difference in fuel and water makes changes in this line more excusable than in the running gear.

If builders could keep in stock standard parts for two or three sizes of the different types of locomotives, the parts could be made for stock in slack times, and not under pressure for hurried orders. They would be made in quantities, and consequently cheaper; more time being taken and better and more thoroughly understood drawings being used, a better class of work would result.

If an order came in for locomotives calling for standard parts, the work would be half accomplished by assembling the parts, where now the first week or ten days is lost in the pattern shop.

The standards already established by the master mechanics are, we believe, counted as good ones, and most of the members of the association seem to agree that they are all right—except when they order new locomotives, when they try something of their own.

Railroad companies are combating the public demand for power brakes, automatic couplers, and steam-heated cars on the ground of expense; but there seems to be no attempt to reduce the first cost and running expense of locomotives by a systematic adoption of standard sizes—to reduce the outlay in the motive power department, it is considered necessary to discharge shop men or reduce wages.

Promoting Mechanics.

At the Altoona shops of the Pennsylvania road they have what are called "special apprentices"; these are young men who have graduated from some technical school, and are then taken into the service. They are worked in different departments of the shops for a short time, and then placed in the test department; here an elaborate system of testing all material used in construction is conducted; wood, iron and steel are tested for strength, etc., chemical tests are made, men go from this department to indicate engines, make dynamometer tests in locomotive trials, etc.; and when the Pennsylvania Railway are in need of a foreman, a superintendent, or any other officer, the "specials" get the preference for promotion.

A representative of this paper recently met a young man who occupied a prominent position on another road, and was told by him that he was raised on the Pennsylvania, studied his business, and made enough show with his work to attract the attention of the officers of another road; he was offered a higher position and higher pay, but, hoping to stay at home and finally receive promotion there, he brought the matter to the attention of his superior officers. He was told that his work had been well done and was appreciated, but that, as he had no technical education, he could not hope to be advanced any further than the position he had already reached.

Of course, under these conditions, any ambitious man would resign and seek more appreciative employers. This young man took service on another line, and has since been promoted to the general supervision of his department. By any arrangement of this kind the Penna. is the loser and the other road the gainer.

The promotion of railway men for the management of the motive power, transportation on maintenance of way, should be made from the rank and file, just as cream is secured from milk—by taking what comes to the top.

The older and most successful officers of the P. R R were not graduates from technical schools, yet they were and are the best of men for their places. They came from the ranks.

The fact that a man who has the natural qualifications and the practical experience is a graduate of a technical school, would rather tend to his benefit and success than otherwise; but the man with the education and without those other and necessary qualifications, stands a poor show of success.

The trouble is that men who wait to get the education before they learn their trade, seldom learn the trade thoroughly enough to deserve and receive journeymen's pay away from their home road, and those who have to scheme hard to make both ends meet financially, while learning their trade, do not have the time or money to get the technical education.

A combination of both qualifications is desirable, but we do not believe it of any use to preach to the shop boys of the country the necessity of going to a technical school after they have learned their trade. Few will be able to do so, for financial reasons.

What they want to do is to get all the education they can in their line, while learning their trade. With one, and not the other, the practical mechanic has the best chance of success in railroad work.

Relief Associations.

One of our correspondents asks our opinion of the benefits of relief associations as established on the B. & O., Reading, and the Q., and we are in receipt of several private letters asking the same question. We will let this reply to all

As relief associations are now conducted, we believe that they are a good thing for and a relief to the companies, but not to the men.

The general plan is to establish hospitals, hire doctors, and formulate some sort of a sliding scale for benefits in case of accident or death, and, perhaps, a fund for superannuated members. These expenses are met by reserving a stipulated amount out of the pay of all employes, sometimes so much per month for all, and sometimes in proportion to the pay received. These funds are placed in the hands of an officer appointed by the company; and, in some cases, the company pay into the treasury a certain per cent. on the tithings assessed on the employes.

The idea is held out that these institutions make the men more contented and insure them employment, which is just as true as the statement that the moon is made of cheese. We do not know of a single association or fund of this kind that is not controlled entirely by the company. We do not know of one where the men have any voice whatever in the management of the fund, where they elect officers, physicians, or even receive a statement of the receipts and disbursements of the funds they have paid in. On most roads membership is compulsory, and on those where the men join "of their own free will and accord," men are given to understand in more ways than one that it would be better for them if they did belong.

The main idea in the establishment of relief associations is to secure the company against labor troubles, keep the employe where he is wanted, and make money out of the whole scheme.

Men are no more secure in their positions where a one-sided relief association is assessing them monthly, than on a road where they have to relieve themselves. Charles Francis Adams proposes, among a lot of impracticable things, some very good ones, the best of which is the taking out of the hands of petty officials the power of discharge, and giving the employe the benefit of a trial—the right of appeal. This rule should be established on all roads, whether they have relief associations or not.

It is human nature for men to want to conduct their own business, and it is right that they should. All railroad men should be insured, but they should be able to insure when, where and how they please.

If these associations were so conducted that those who pay the expenses could have a voice in the selection of officers and the disbursement of funds, it would not be so bad.

The legislature of Maryland has annulled the charter of the B & O. Relief Association, because it was unconstitutional.

Scheming officials think, and recent developments on the Reading prove, that if they can make the relief insurance high enough, and the assessments hard enough, and membership compulsory, that men will draw out of the Brotherhoods and mutual insurance in their own orders. The insurance of the B. L. E. and B. L. F. are the only ones where a man gets his insurance in case of disability from any cause, and is, therefore, worth more to railroad men than other insurance; we would urge them to keep it up. This paper described a plan of relief, (July, '88), and gave the full text of the by-laws whereby employes can secure the services of their own physician, and pay for them, and providing a burial fund in case of death, by this plan the members elect their own officers, and receive the benefit of every cent paid in, and are furnished with a statement of accounts every year.

Where relief associations are not too expensive, are not compulsory, do not make it necessary for men to withdraw from any order, let them employ their own family physician at the expense of the association, instead of the contract doctor, let them have a voice in the management, and pay back, in case of dismissal, a certain per cent. of what they have paid in (unless they have had more than the amount in benefits) they are good, and we would advise joining them, where they call for the surrender of one single atom of independence or manhood, we would advise against them.

The manner in which they are conducted is enough to condemn them. This paternal business is not what is wanted on American railroads; the way to secure the best men, keep them in the service and prevent strikes is to treat them fairly, require the best service, and pay such wages that the men will be enabled to care for themselves and families, and have no desire to seek other less remunerative and less desirable occupations.

The *Railway Age* evolves the following.

"By far the largest share of the earnings of railways goes directly to labor, the capital invested getting but a very small per cent. No class is so deeply interested in having the railways receive fair wages for transportation as the great army of their employes."

The great army of railway employes are interested in having the roads get fair prices for transportation; but the army will always wonder why the poorly-paid capitalist does not haul in his securities, sell his private car, and enlist in the army of favored and affluent autocrats who tamp ties and run trains.

ASKED & ANSWERED.

(17) H. H. H asks:

What are the best remedies for cutting of guides and crossheads? *A.*—Line up carefully, and tin the gibs or crosshead.

(18) "Inquiry," Kingston, Can., asks:

Could you give me a process for welding steel locomotive flues? *A.*—As far as we know, steel tubes are not harder to weld than good iron ones, and the process is the same

(19) Student, Stuart, Iowa, asks

In case of a broken rocker arm, does it make any difference which end of guides you block the crosshead at? *A.* If an engine has a driver behind the guides, it is often necessary to block the crosshead where the pin cannot strike the key or other parts It is always better to block at the back end, as, in case the piston should get steam on it, and get away, it would be cheaper for it to break the front head than the back with the guide connections, etc

(20) B. F. M., Ft. Snelling, Minn., asks.

1. How many roads have adopted the standard signal code? 2. What do you think of the benefits, to the men, of relief associations as established by the Reading and the Burlington? 3 How is water taken "on the run"? *A.*—1. We do not know; being adopted slowly 2. See editorial headed Relief Associations 3. A shallow trough of iron is located in the center of the track on a level district, trough is about 4 inches deep, 15 wide, and from one-half to one and a half miles in length; this is supplied with water from an ordinary tank; the tender of the locomotive is provided with a large iron spout about 6x12 inches internal measurement; this spout is shaped something like a comma (,) the point terminating in a cast mouth, reaching to within a few inches of the track, and located in center of tank between the trucks; this point is jointed and is raised up out of the way by a system of levers controlled by a handle on the tank On approaching a tank, speed is reduced to 20 or 25 miles per hour, and the fireman drops the spout, or scoop, and the force of the train drives the water up through the spout and empties it into the tank through the upper end.

IN THE ROUNDHOUSE AND Repair Shop.

The Schenectady Locomotive Works.

Next to Baldwin's, the Schenectady Locomotive Works are the largest in the country. The works occupy quite a tract of land, and the buildings, which are of brick, are large and of modern construction; the blacksmith shop, boiler shop and office have been doubled in size and the machinery all rearranged within the past year, and this without losing an engine.

Supt. Pitkin is one of the few successful superintendents of locomotive works, and has able lieutenants in Assistant Supt. White and Chief Draftsman Lane.

Mr White has immediate charge of the machine department, and showed the writer through the shops, which are equipped and the work handled in altogether a different manner than we have ever seen at other locomotive works. The first thing that catches the eye of a mechanic is the big chips rolled up on the milling machines in the fitting shop. Mills are used for many purposes, especially on brass and wrought iron.

Milling machines of almost every pattern are used, one man runs two universal millers and does all the work on rod brasses, finishing them complete and in a very thorough and workmanlike manner. It was found that, with ordinary spiral mills, in cutting out the sides and bottom of the space for strap, that the thrust of the tool and strength of the material would stick the machines with anything like a heavy cut. This has been overcome by a change in the construction of the cutters These large cutters are divided in the middle, and fit together in the shape of a spiral clutch, so that when the end teeth are ground the two pieces can be packed apart and the exact length maintained; by this construction one clutch jaw drives the other and makes the tool practically one piece. The thrust of the tool caused by the spiral cut of the teeth was overcome by cutting a coarse thread right through the face of the teeth in an opposite direction from the spiral; this makes a series of smaller teeth, and cuts the brass chips up into short pieces instead of long, heavy ones, braced at both ends against the sides. The uses to which milling tools are put are almost endless. Mr. White found great difficulty in using long mills of moderate diameter in heavy wrought-iron work, caused by the constant breaking of the teeth. They have very little trouble now, and have cured the breaking by slightly drawing the temper of the mill by placing a red-hot iron in the arbor hole after tempering.

Very little attention is paid to the forming of parts in the blacksmith shop; they simply take pieces of iron and cut out locomotive parts with machine tools, and claim they can finish the parts ready for use for less than elaborate blacksmithing costs. All such parts as eccentric blade forks, link hangers, guide blocks, links, etc., are simply cut out of chunks of iron, with little shape to them

We have never seen wrought-iron cut and handled as it is here, milling machines and slotters taking most of the work, but many planers getting there with big cuts Every machine that cuts wrought-iron is provided with a pump and a stream of water, suds or oil runs on every tool. Almost all of the machines have had new tables put on them with arrangements to carry all the drip back to the pump tank

Solid-ended rods come from the hammer shop without much shape to them, and the bosses around pins are formed in a slotter, and the bushing hole bored out on a mill in very short order. These holes are cut through with a tool that simply bores around the outside, leaving a core blank, those from large rods are made into pin collars for smaller rods; the sides of rods are finished at a single cut in a milling machine. Any mechanic who is disposed to believe that lathes and planers can be made to compete economically with modern milling machines and slotters should visit this shop

They grind up such surfaces as the tops and sides of guides, guide yokes, link hangers, links, etc., with emery wheels, and have a wheel for this purpose rigged upon a planer bed for guide work Solid emery wheels running dry will get hot, and get work hot, and have to be dressed very often to keep them true enough for guide work. Here they use an iron wheel with a light rim, not more than one-half inch thick, on a wheel 12 inches in diameter and four-inch face. This iron wheel has a square thread cut in its face, about four threads to the inch, and then the face of wheel is cut across the threads with same sized tool, leaving the face covered with little projections of iron about ¼ of an inch square. These wheels are coated with glue and rolled in emery until the coating is about ¼ of an inch thick on the face, and are found to run cool and cut better than solid wheels, they last from 10 to 40 hours without re-coating. Very small wheels of this construction are used to grind out hardened work, such as the holes in link blocks, hangers, links, and eccentric blade forks. It is difficult to run wheels as small as an inch or an inch and a quarter fast enough to do good work, and this trouble is cured by centering the work on a lathe and running it at fastest speed in one direction, while the wheel is run on an arbor held in a frame on tool post, and run in an opposite direction by an independent belt to a drum over the lathe, this allows the wheel to be handled on the lathe carriage, just as a tool would be, and case-hardened or tempered work is ground very fast and very accurately.

Such pieces as steel pins for motion work with a bearing surface in the center and taper fits at both ends are ground on a machine for that purpose.

A great many small duplicate pieces of iron or steel are made on a new turret lathe for such work, and solid screw cutting machines do the work of thread-cutting formerly done on lathes A new heavy screw cutter was making locomotive jack screws, three inches in diameter, and cutting the thread in good shape about as fast and as noiselessly as an ordinary bolt cutter would cut a thread on a half-inch bolt. This machine, in the hands of a laboring man, threads and finishes the screws and taps the standard on thirty jacks in four days.

The forge shop is ventilated and cleared of smoke by two large exhaust fans, and much of the work is done by bulldozers and heavy punches. They weld frames in a new way that would seem to insure good work, a jaw is not welded to the frame proper, but a piece is drawn down from the frame and the weld made in the jaw itself. This and the frame pieces are scarfed in V shape in the direction of the length of frame, and a weld made; the frame is then returned to the fire and a welding heat made, when a small strip of metal is laid on the jaw and welded down and the same operation repeated on the other side. This makes three welding heats to each weld, with an introduction of new metal at each heat, that ought to insure all their frames against breaks in the welds.

In the boiler shop, steam riveters, punches and shears are on every hand. We noticed that all trimming shears used on tank work, etc., not only cut the strip off the edge of the sheet, but cut the strip up into short pieces at the same time, making them easy to handle and keep out of the way.

A new electric light plant has been added to the works, and an incandescent lamp with a wire guard hangs over every tool.

On every hand new tools are to be seen, some not yet belted up; no old tools are to be seen in operation, and one reason for the success and reputation of these works can no doubt be traced to this rule of the able superintendent in charge, to have every new tool that could produce work quicker, or cheaper, or better than the ones in the shop. These works turn out an average of one locomotive a day, and as each man on a tool does one kind of work continuously, no elaborate system of keeping tools in the tool room is maintained. Men in the tool room grind and repair the tools, and keep extras in stock, but when they are issued to a man in charge of a machine, he keeps them as long as they are in condition for service. In the erecting shop they are getting one of the Strong boilers up, ready to assemble the work on her, pieces of which are to be seen all through the shops.

They have just turned out a heavy passenger locomotive for the C. M. & St. P. R'y. This engine has six wheels connected, a double truck in front, and a pony truck under the fire-box. She has cylinders 19x24, with ports 18x1$\frac{5}{8}$, exhaust 18x3, Allen-Richardson valves, drivers 69 inches diameter, truck wheels 30. Weight on drivers, 85,000 pounds; on trucks, 48,000. Rigid wheel base, 12' 6'', total wheel base, 27' 10''.

The boiler is a wagon top, is 56 inches in diameter at the smallest ring, has a fire-box 102x42$\frac{1}{4}$ inches, 247 flues 2" diameter and 12' 6'' long; steam pressure, 165. The engine is provided with the American outside equalized brake to be operated by air, and uses the Ross-Meham brake shoe.

This engine, which was designed for fast, heavy trains between Chicago and Milwaukee, was tried for several days on the N. Y. Central, and found to work satisfactorily.

In the back shop they are building a large 12-wheeler (8 wheels connected and a double truck) for the Beach Creek road, five 6-wheeled switches for the Long Island, two 19x24 8-wheel passenger engines for the C. & O., six 20x24 consolidations, and a large 6-wheel switcher for the Duluth and Iron Range; two 18x24 10-wheelers for the Fairhaven & Southern, nine 19x24 moguls, and five 19x24 10-wheel passengers for the L. S. & M. S.

In the drawing room the card system of shop drawings is used, much the same as at Baldwin's. But Chief Draftsman Lane has a very complete system of record books of his own design. All drawings are duplicated in books and preserved in vaults. Many of the processes of manufacture at these shops are extremely interesting, and will be treated separately at another time.

We are under obligations to Clement E. Stretton, C. E., for a copy of a plate representing 30 locomotives built by Robert Stephenson & Co., Newcastle-on-Tyne, commencing with "Locomotion," 1825, and showing the various evolutions in English locomotive practice, up to 1887. The plate will be useful in our collection of historical locomotives.

President Setchel, of the M. M.'s Association, has accepted a position as agent with the Pittsburgh Locomotive Works.

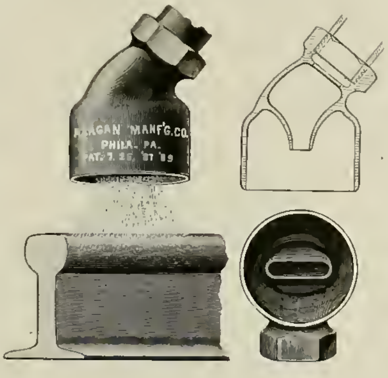
The 24-Hour System.

The 24-o'clock system of computing time is slowly gaining ground, and is a safeguard against mistakes in time cards that must sooner or later be adopted. It has been in successful operation on the Intercolonial of Canada for two years, and on the Western divisions of the Canadian Pacific for more than three years, and the system will soon be extended over the entire line.

A committee on standard time recently reported to the American Society of Civil Engineers, that, of ninety-nine replies received from railway officers, sixty-one were in favor of the 24-hour system, thirty-eight were not in favor of the system, but twenty-four of them would adopt it if connecting lines did.

The principal objection to the 24-hour system of computing time is the prejudice against a change.

Division No. 1, Brotherhood of Locomotive Wipers, has been organized, with twenty charter members, at Newton, Kan. We are in receipt of a very handsome invitation to their first annual ball, which was given April 25th; the usual silk ribbon on the invitation is replaced by a piece of waste. There is no good reason why the boys who groom the iron "hoss" should not be organized, as well as those who ride.



Anti-Clogging Sand Pipes.

On this page will be found cuts of a new anti-clogging tip for locomotive sand pipes, being placed on the market by the Reagan Manf'g Co., of Philadelphia, Pa.

All runners know that the movement of the locomotive over the track produces a partial vacuum at the end of the sand pipes, causing them to gather moisture, and the first attempt to feed sand through them coats the interior of pipe with a stiff coating of wet sand, and all know that in damp weather it is a regular job to pound sand pipes—there are monkey wrench marks on 40,000 sand pipes to prove this.

The device shown has an enlarged cup that gathers all the moisture, while the sand jet is located in the center of this cup, and high enough in the pipe to avoid the suction; the sand opening is in the shape of slot, and crosses the rail, thus being sure to get sand where it is needed, on curves and over frogs.

The opening being small and the pipe large, a man can fill the pipe and it will feed a small quantity for some time, without further churning of the sand lever. This device is in use on the Pennsylvania R'y.

Angus Sinclair recently delivered a lecture on the compound locomotive, before the New England Railway Club, at Boston. Mr. Sinclair believes in the efficiency of compound locomotives, but not in the forms now in use.

Air-Brake Practice.

By J. E. Phelan.

TWELFTH PAPER.

In following up the principle of action of the engineer's brake and equalizing discharge valve in mountain service, it practically stands in same relation to train appliances in principle as former engineer's brake valve.

It is when connected in double heading service on mountain grades, or other grades, for that matter, that we note difference worthy of statement.

As this equipment has been furnished on new engines by certain locomotive works, this feature in double heading service has been very prominent, and as many engines are now in service in this condition, remarks may be of value.

For leading engine, handling air, the valve is all right. For the assisting or helper engine, there is need of care and discretion to avoid interfering with pressure of leading engine. The simple remedy, no doubt, has been to let the engine next the train do the braking; but such practice often proves disastrous.

The Locomotive Engineer, in issue of April, 1889, gives in Air-brake Practice notes of difference in detail between engineer's brake valve and engineer's brake and equalizing discharge valve.

As engines have been equipped, the pump governor connects directly with main air pipe—economy with the piping apparently being main object in view. Main reservoir is connected directly with indicator of air gauge (see paper No. 3, The Locomotive Engineer for July, 1888). The latter as it should be. The train pipe indicator connects with chamber and auxiliary of valve body.

When engineer's brake and equalizing discharge valve is blanked or on lap, the rotary valve closes all ports, and air from main reservoir flows in on top of rotary valve and there stops, awaiting an outlet.

It follows that while in this position the chamber and auxiliary of engineer's brake and equalizing discharge valve are cut off from main reservoir and train pipe as well, and pressure in chamber lies dormant, and naturally less than that existing in either train pipe or main reservoir so long as valve is blanked.

You will notice in double heading with valve in blanked position when pump governor connected to the train pipe, your main reservoir pressure on helper engine indicates what the pump governor permits on train pipe—your train pipe indicator connected with chamber indicates a dormant and uncertain pressure, as noted before.

Your train pipe being supplied by leading engine, your pump and governor come under control of the leading engine wholly.

We will not state remedy until we go into conditions more fully.

It can be noted with former engineer's brake valve, having its various valves controlled and held in place by springs, that when in blank position, its feed valve is completely cut out of service.

The main valve held to its seat, with ports blanked, by the main valve spring and pressure from main reservoir.

The top valve, when in blank position, by having had handle controlling it moved to right, and raising handle screw controlling this valve and its spring, has made the spring less contracted; yet the spring's tension ought to be sufficient to hold top valve to its seat, in resistance of pressure bearing on it from train pipe while in such position.

Hence air from source of supply on leading engine simply passes through the air pipes of helper engine, same as though helper engine not equipped with air pump, etc. Air braking up in pipe connecting with engineer's brake valve simply fills in blind space, without affecting source of supply on helper engine, excepting as governor may be controlled by leading engine. But the pressure thrown into pipes by leading engine in recharging or releasing brakes, can have no escape, if top valve spring in good order, except by flowing into proper channels and recharging train appliances.

Air gauge connection with train pipe is always made with train pipe through an indirect and small opening, and in our service pump governors are connected with *air gauge pipe*, connecting with train pipe. In this way the action of leading engine's air supply is not so abrupt in acting on governor as it would be if directly connected to train pipe by ¾" pipe.

This condition of affairs allows helping engines to keep up about maximum pressure in main reservoir, ready for use at any time if called on to assist leading engine in recharging train, or taking full charge of train in event of leading engine's supply of air, or means of supply failing. In such event the engineers in charge simply alter conditions by transferring control from one to the other.

You will note in engineer's brake and equalizing discharge valve there are no springs controlling valves excepting one controlling feed valve. This, as in former engineer's valve, is out of service when in blanked position.

As noted in previous paper, train pipe connects at base of valve body, reversing matters in this particular compared with former engineer's brake valve.

Summing the matter up in as few words as possible, in order to insure the engineer's brake and equalizing discharge valve being as passive when in blanked position, and in use on helper engine, it will be necessary to gain and keep in main reservoir to bear on rotary valve an equal or greater pressure than that which may be transmitted through main pipes by leading engine in recharging or releasing train brakes.

It may be a comparatively easy matter to hold rotary valve to its seat.

Let us now return to the point where we digressed.

While rotary valve is held to its seat by active pressure from main reservoir, the piston valve is held to its seat simply by the dormant pressure in chamber and auxiliary of valve body.

Hence, when pressure backs up train pipe and strikes under this piston valve, pressure meets but little resistance, and unseating piston valve there is a waste of air into atmosphere through exhaust port for service stop.

Here is where the stop-cock in service stop exhaust port can be used to advantage by closing it while in such service.

It is our belief that the pump governor should be connected to the air gauge pipe leading to chamber, and thence connecting with train pipe pressure. This secures it from abrupt influence from pressure of leading engine.

You will note the dormant pressure, however, would remain in the chamber, and pump of helper engine could gain pressure in excess of that handled by leading engine, and so long as remaining in blanked position, the rotary valve could be held to its seat, but, without the stop-cock in service stop exhaust port, the piston valve would be the weak point for waste of pressure, in hazardous mountain service.

In absence of stop-cock, in service stop exhaust, the piston valve can be controlled and held to its seat by following plan, stated in April LOCOMOTIVE ENGINEER, for reseating it, *i. e.*, pushing handle to left, so that handle spring may rest midway between lap and position while running. In this position equalizing port is put in communication with train pipe.

To avoid confusion and insure most effective work, we believe it advisable to connect pump governors with *air gauge pipe* leading to train pipe, and put on a stop-cock in train pipe, in convenient place just below base of valve body. Then, when in helper service, or double heading as helper engine, you can simply turn the stop-cock and carry your engineer's valve in feed position, and hold maximum pressure plus 20 pounds more or less reserve in main reservoir for emergency.

The Baldwin Locomotive Works have built somewhere in the neighborhood of 100 locomotives, with the form of boiler designed by N. W. Sample, superintendent machinery of the D. & R. G. road. The wagon-top is extended far enough ahead of the fire-box to place the dome over the flues, thus allowing the use of radial stays in place of crown bars in boilers with wagon-tops.

The West Albany Shops of the N. Y. Central Railway.

These shops are the largest railroad shops in New York State, and do almost all the locomotive repairing for the N. Y. C. & H. R., as well as the West Shore roads; they also build most of the cars here for the great four-tracked system.

The shops are on the west side of the river, and some three miles from the city, occupying a large tract of land and a small village of buildings; yet they are crowded for room.

The engine and boiler house occupy a central position among the buildings, and the power is supplied by two different engines. An old-fashioned condensing, beam engine originally supplied all the power, but many years ago was relieved of the burden of the machine shop and given the woodworking machinery alone, while a slow-moving horizontal was placed beside her, to turn the shafts in the iron shop. These engines, and the room in which they are located, are kept scrupulously clean, as, indeed, the whole shops are.

The machine shop is a very large building, with one central line shaft running the entire length, and the machine tools arranged on either side. All the machines are painted a wine color and striped with red, and, being kept clean, look like an army in uniform.

There are a good many old tools there, but the great majority of them are only middle aged, and some are new. In the back shop, or pit shop, the pits are not so close together as is usual, and a machine tool is located between most of the pits, a lathe, a drill press, or a forge located thus saves lots of running where work is done on the cut and try plan, as is almost necessary in repairing old work.

The Central still build most of their engines with independent cylinders bolted to a central casting, but having all the exhaust and steam passages cast into the cylinder castings, the central piece being simply a support.

They make their eccentric castings with a heavy collar on the sides that carries the set screws, making them easy to get at, and also giving a large bearing surface on the axle and the key.

Extension fronts are covered with a piece of sheet iron held away from front enough to make an air space, and then are covered with Russia iron, making a neat front.

The new consolidation engines are very heavy, provided with American driver brakes, and having flanges on both the forward and rear drivers, making a very long, rigid wheel base, we noticed several badly cut flanges.

They are putting in a new turn-table, and fixing up the roundhouse so as to take in these modern freighters.

We noticed in the supply house extra main rods for consolidation engines. These rods have a solid front end with solid brass bush. Mr. Buchanan, M. M. in charge, says they run about ten months without any trouble.

None so Blind as Those who will not See

The *Journal of Railway Appliances* "talks back," and says that it only took four lines out of this paper in January, and this was just repeated out of an old scrap book of theirs, and were chestnuts any way. If the good little editor will look back to his January number he will find that he made a couple of headed articles out of our account of the piece-work system at Renovo shops, lifted bodily the article on Manual Training Schools, and citing the Spring Garden Institute, Philadelphia, and stole a 7-line item out of the center of a correspondent's letter on Driving Brakes.

They must like "chestnuts."

The Ross Valve Co. have recently perfected their pressure-reducing valve, so that it will handle steam down to one pound pressure. In the end, instead of having one reducing valve at the engine, our steam-heated cars will have to have a pressure-regulating valve at each car, and the valve that can be regulated the closest will have the best show of success.

Pointers on Setting Up Injectors.

The Rue Manufacturing Co., Philadelphia, Pa., have got out a new catalogue of their injectors, ejectors, boiler washers, testers and general jet apparatus. The "Little Giant" is one of the best known injectors in the market, and without exception the easiest repaired and cleaned. Under the head of General Instructions, they give a few fundamental rules for putting up injectors of all kinds, that, if heeded, would save lots of trouble, and stop some of the *mysterious* agencies that go to make injectors cranky; the following are a few samples.

"When attaching injectors, the pipes should be short and straight as possible, internal diameters must never be less than the fittings on the injectors, and if over ten feet in length, they should be at *least* one size larger. Steam to be taken from highest point in boiler.

"When the pipes are ready for the injector, they should be thoroughly cleaned out by allowing steam and water to flow through before coupling the injector to them.

"The water pipe should be provided with a screen with holes of less diameter than the smallest part of the injector, and sufficient number to allow plenty of water to pass through when the larger part of them are clogged up, which is often the case. When water is to be lifted, the *pipes* must be *perfectly* air tight. Lifting injectors will raise water from 5 to 15 feet, according to circumstances. When lifting injectors are used, they should be placed as close to the water as possible. High lifts reduce the capacity of all injectors, also their reliability."

J. E. Lonergan, of Philadelphia, manufacturer of oil-cups, checks, gauges, etc., is building a new factory, beside his present one on Race street. The new building will occupy 44 front by 114 deep. The fourth story will be occupied by the brass foundry, one of the floors by the shops of the Rue Manufacturing Co., and the others by the machine shop, finishing, assembling and storage rooms. It is pleasing to note this evidence of success as a manufacturer, of an old locomotive runner. Mr. Lonergan used to eat cold lunches and take grief on the Central Pacific.

A. Van Guysling, who has been engineer at the West Albany shops of the N. Y. C. & H. R. R'y for the past twenty-four years, has recently patented a reversible oscillating engine of very simple design. He has had several built, and has one, an 8-horse-power, running in his engine room. It occupies a floor space of but 15x15 inches, and requires but 24 inches head room, making the design a desirable one for yachts and to drive machinery in crowded places. The railroad company have recently built a pair of them to operate their big transfer table. This machine works admirably.

The Pond Machine Tool Works, Plainfield, N. J., recently turned out their first driving wheel lathe. It was built to the order of the C. R. I. & P. R'y (Rock Island), and had several departures from the usual styles of this kind of tool. The lathe was extra heavy and large, being 79-inch swing, it was tried in the shop and proved all that the designers or the buyers desired.

The employes of the Westinghouse Air Brake Works went to work at reduced hours on April 8th, in order to keep all the men employed.—*Railway World.*

The largest electrical conductor in the world is now being put down along the tracks of the Ninth avenue elevated road in this city, by the Daft Electric Co.

It is stated that wire ropes can be kept from rusting by using oil, thickened with graphite, much better than by the use of paints or tar.

The Grand Trunk has recently put in several Gentry & O'Brien tire heaters at their different shops.

In the East Albany Shops of the B. & A.

At the East Albany shops of the B. & A. road they are very quiet, and the dull time has given them a chance to rig up a little, although, like all railroads, the master mechanic, foremen and men can make all the improvements they are a mind to, provided they are all evolved from the scrap heap, and cost the company no money.

At this shop, Master Mechanic Purvis and his son, who is general foreman, are ingenious men, but they are like lots more of the same kind—hobbled.

The large consolidation engines have broken a great many rods, mostly at front end of main rod, caused by a strap end, the key being inserted from underneath, and held by a lug on the end of the only strap bolt; when this bolt breaks, the whole thing is loose and falls off.

These accidents happened so often that a stock of rod straps and back cylinder heads had to be kept on hand; to make these duplicates, templates were fixed up with hardened steel bushes to drill through, and all time and expense of "laying out" work avoided.

They have recently put up a water crane, such as illustrated in THE LOCOMOTIVE ENGINEER in May, 1888, which is used to handle wheels and axles for a hydraulic wheel press.

Modern wheel presses have a large and a small pump, the larger one to handle the ram quickly up to its work, and the smaller one to force in a high pressure. These shops have an old style press with only the small pump, but a pipe connection from the press cylinder directly to the water works' main does the work of a large pump very quickly, by simply moving a valve lever.

This road has in use a great many old engines, built by Mr. Eddy years ago; they are domeless, using a perforated pipe to draw off the supply of steam; they are said to carry water remarkably well. A peculiarity of these engines is their short ports, freight engines having but 10-inch ports.

The present Supt. of Mach., Mr. Underhill, is also a believer in short ports, and has some 17x26 engines running with ten-inch ports, and many large passenger locomotives with ports but 14 inches in length.

These shops are clean; in fact, they don't seem to have enough to do to get them dirty. In the blacksmith shop there are large hexagonal chimneys, built up from the ground, having the fires arranged in openings around them, so that considerable room is given to handle work, as the space in front of each anvil is larger than if the fires were arranged in rows.

The spectacle of a machinist chucking and boring a few car wheels per day in a common lathe, when a $1,000 tool can be bought capable of taking the wheels from the floor, chucking, boring to gauge, facing off the hub and replacing the finished wheel on the floor again at the rate of one in seven minutes, with no other help than an intelligent boy, is not likely to impress a practical mechanic as either modern or economical practice.

The B. & A. shops at Albany, are far from being the owners of or operators of the poorest machine tools in their part of the country, but a wholesale procession of ancient locomotives and antediluvian machine tools from the back shops to the cupolas is a much needed move on almost all the roads in the New England and Eastern States.

The old muly saw-mills of the 18th century can not compete with modern high-speed circular saws in the manufacture of lumber, and locomotives and rolling stock can not be kept up with old chain-feed lathes or wim-wam drill presses with slippery elm frames.

Watch this Prophecy.

Pretty good locomotives used to be built and run with wrought-iron tires, but since the introduction of steel no maker or no road can be found who will use wrought-iron, simply because the steel is safer and better, although it costs more.

We venture the assertion that, in ten years from now, cast-iron car wheels made in the common chill will stand just about the same in comparison with those made in contracting chills, as wrought-iron tires stand with steel. The contracting chill is not an experiment; it actually gets smaller when it gets hot, and hugs the wheel, making a deep, uniform chill, and insuring uniformity in size and rotundity. 60,000-pound cars must have carefully turned steel tired wheels, or else a great deal better and safer cast chilled wheels than can be made by the old process.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

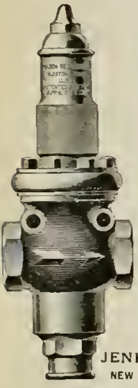
Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

AIR PUMP REGULATORS



The cut herewith shows our new pump pressure regulator for air brake pumps. During the past nine months we have thoroughly tested them on engines of the Boston & Albany R. R. They have not required a particle of attention during this time. We now guarantee them. As the air pressure chamber is entirely separate from working parts any dirt in train pipe cannot get into working parts. Weight 7 lbs. Sent on trial.

Mason Regulator Co.,

BOSTON.

JENKINS BROS., Agents,

NEW YORK. PHILA. CHICAGO.

THE VANCE LIGHTNING FLUE CUTTER

Is just the tool for removing old flues from boilers and locomotives. Will cut 50 an hour. *Sent on approval* to Railroad Companies.

CAN BE OPERATED BY HAND OR BY FLEXIBLE SHAFT.

No Revolving Cutters. Plain Knives easily Ground. Leaves Flue Ready to Weld without Scarfing.

Manufactured and Sold by

VANCE TUBE CUTTER CO.,

GENEVA, N. Y.

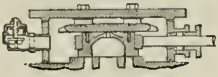
BALANCED SLIDE VALVES.

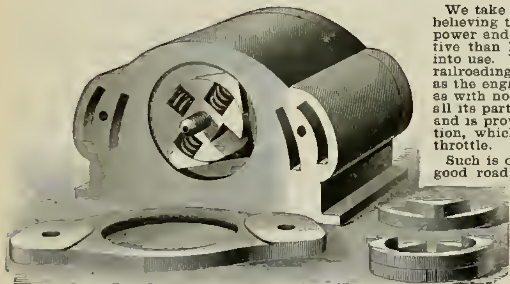


Used by 140 Railroads. 4,000 Locomotives Equipped. Great saving in wear of Valves, Valve-Seats and entire Valve Motion.

Manufactured Complete for any Locomotive.

Estate of **F. W. RICHARDSON**, Troy, N. Y.

THE TRIPP PATENT PISTON VALVE.



We take pleasure in presenting this Valve to Railroad men and others, believing that its use on a Locomotive Engine will effect a greater saving of power and expense in the maintenance of the working parts of the Locomotive than has been accomplished since the Locomotive was first brought into use. We also believe that its use will add largely to the safety of railroading, and prevent the destruction of many lives and much property, as the engine can be reversed as easily with 160 lbs pressure on the Valve as with no pressure, it being a **Perfect Balance Valve**. The Valve in all its parts is as durable as any of the working parts of the Locomotive, and is provided with a relief device, simple in its construction and operation, which relieves back pressure instantly when running with closed throttle.

Such is our confidence in this Valve that we will furnish a pair to any good road for trial, on their furnishing following dimensions: 1st. Diagram of cylinder face showing ports. 2d. Travel, inside end outside lap of valve. 3d. Distance from cylinder face to center of valve stem. 4th. Size of valve stem. 5th. Length, width and height of steam chest from cylinder face. Internal measurements.

Said Valves not to be paid for until they have demonstrated their value to the satisfaction of the road.

Prices, terms and additional information furnished on application to

The Locomotive Engineer.

Devoted to the special interests of locomotive engineers and firemen and to locomotive maintenance and repairs.

VOL. II, NO. VI. NEW YORK, JUNE, 1889. $1.00 per Year. or 10c. a copy.

Difference Between the Mouth and a Shovel for Firing.

When any master mechanic finds a man who is always lecturing on how ignorantly his locomotives are fired and handled, he should send him out on several different locomotives to fire—not to tell some one how to fire. If he can show a saving in fuel, a steadier pressure of steam without allowing the pops to sing excessively, if he prevents black smoke, or does a small per cent. of what he says can be done, then he is a valuable man, whom it would pay to commission as instructor. But if he discovered, as the most of them would, that cars actually have to be pulled over the road by the use of steam, generated by heat, caused by the combustion of coal, and that theory or scientific firing would not pull them alone; and if he found, as we fear he should, that locomotives are not like stationary engines in any way, that where a 100 horse boiler must be forced to supply steam for 500 horse-power engines, worked up to the very limits of its capacity one minute, then the engine shut off, the average economist would find it very hard indeed to prevent popping and the rolling of black smoke.

The firemen of the country are sadly in need of proper instructions as to economical methods in maintaining their fires; so are the engineers, for that matter, but it will be best for railway officials to select such men as instructors who can get upon a locomotive and do the actual firing with a scoop. There is a heap of difference between the mouth and a scoop for firing a locomotive in actual service, and keeping her smokeless, popless, and altogether lovely.

One is a pen picture of Adam enjoying the garden of Eden before the fall—the other a tableaux of him humping his back for a living after the light went out.

We have tried both plans, and know whereof we speak.

The sample room of The Locomotive Engineer office has been livened up by a nickel-plated rod cup, of the Northern Pacific persuasion, presented by Pedrick & Ayer, Philadelphia. We are glad it has a feeder in it—some railroader would be tempted to steal it for a snuff-box.

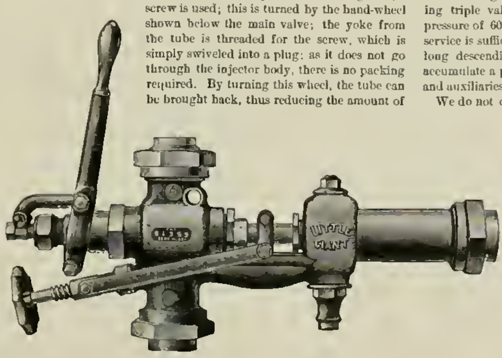
The Boyden brake—a recent improvement of the class where a fluid pressure is used to keep the brake off, and the reduction of which allows powerful springs to apply the brake—is being tested at the Westinghouse air-brake shops in Pittsburgh.

Little Giant Injector of '89.

The Rue Mfg. Co., of Philadelphia, have brought out a new form of their well-known "Little Giant" locomotive injector. While no changes have been made in the interior, the manipulating levers have been so placed as to enable the runner to adjust them quickly, without being obliged to fasten any part in place by set screws, and all of them arranged on the back end of the instrument, so that it can be placed through the cab without using rods to connect to outside levers.

The starting valve, which also operates the primer, is the same as in the older style, except that the lever is placed over and ahead of the valve stem, instead of behind it, this saves considerable room.

Instead of a lever to adjust the combining tube, a screw is used; this is turned by the hand-wheel shown below the main valve; the yoke from the tube is threaded for the screw, which is simply swiveled into a plug: as it does not go through the injector body, there is no packing required. By turning this wheel, the tube can be brought back, thus reducing the amount of water delivered, or entirely back for use as a heater, and is not liable to derangement, as the screw will stay in any position, and, of course, a finer adjustment can be secured while running.



Little Giant Injector of 1889.

The line check has been placed in the body of the instrument, thus reducing the number of parts and the length. This makes the instrument conform to standard practice, and it is interchangeable with all other standard injectors, without re-arrangement of pipes.

The center of gravity has gone up to almost twice the height originally considered safe in locomotive building, and a 60-inch boiler, with its center six feet above the rail, is now very common. The large passenger engine built by the Schenectady Locomotive Works for the C., M. & St. P., and described in these columns last month, has the center of its boiler 8 foot 9 inches above the rail. How is that for high?

The boys on the Erie have dubbed the Strong engine the "Missing Link."

Air-Brake Practice.

By J. E. Phelan.

THIRTEENTH PAPER.

One important point to be considered in connection with air-brake practice is amount and degree of pressure carried in train pipes and auxiliaries, and in main reservoir. In this particular, note eighth and ninth papers in January and February issues of The Locomotive Engineer for 1889.

When air-brakes are properly handled, an average pressure of 70 pounds in train pipes and auxiliaries will insure reliable and economical results for general service.

For average freight service, and with quick-acting triple valves and old style mixed, an average pressure of 60 pounds in train pipes for ordinary service is sufficient. When approaching steep and long descending grades, it may be necessary to accumulate a pressure of 80 pounds in train pipe and auxiliaries.

We do not doubt that the average rustler will get 80 pounds, and as much more as the pump governor will permit, or the pump supply. But 80 pounds air pressure, when applied in full force for braking power, will prove on an average very damaging to wheels, even with carefully adjusted leverage. More than 80 pounds pressure may prove destructive to wheels when applied with full force.

Where 80 pounds air pressure is maintained and used with judgment in service stops, or used expansively through medium of the small valve within the slide valve of the triple valve—note fourth paper in August, 1888, The Locomotive Engineer—when used in such manner, 80 pounds pressure will do no harm, but usually can be relied on for fair and effective work.

But where the engineer's brake valve is handled like a meat axe, such pressure is not economical in practice. Such pressure is not safe to keep in store for a sudden application; often to save a ten dollar cow will damage a hundred dollars worth of wheels.

It is our belief that amount of pressure transmitted to train pipe and auxiliaries should have a maximum limit of 70 pounds for mountain grades as well as ordinary roadway.

For mountain grades we would advocate maintaining this limited pressure, but increasing the volume by having double storage capacity for air in main reservoirs, *i. e.*, where necessary, simply add another main reservoir, and carry two instead of one, making them tributary to each other and train appliances.

In our way of thinking, this increased volume of stored-up air would lessen the necessity of accumulating high pressure in order to maintain an average and effective pressure in descending long grades.

Provision for maintaining medium pressure, and enough of it, means economy in all directions.

We once fired an engine designed to handle three passenger coaches. This engine was equipped with a main reservoir, with capacity about equal to the needs of three air cylinders; but, as I viewed it, not equal to combined capacities of three auxiliary reservoirs if the auxiliaries should be emptied in making ordinary stops.

With this main reservoir, after a stop when auxiliaries were re-charged, pressure would run low, and the pump, in consequence, quite fast.

It seemed a perennial jumping from garret to cellar—up and down.

Occasionally we went out with an extra engine, while our regular engine was in for repairs. The extra engine was equipped with a standard main reservoir. The results were apparent in a moderately running pump, more uniform pressure, and more effective and desirable service.

With the smaller reservoir, pressure was quickly gained, but suddenly lost. With the larger reservoir it would take longer to get pressure required, but once gained it proved lasting, and not apt to desert us when urgently needed.

The natural suggestion to my mind is to apply this principle to the indefinite coupling into one long string of air-brake cars.

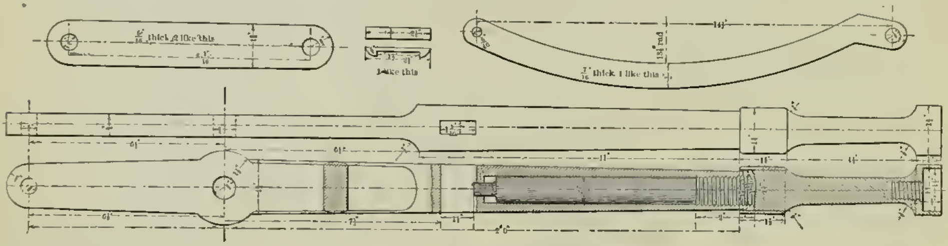
If we aim persistently in providing for and insuring proper results, the future will show most efficient air-brake practice. To gain this important end,

The usual programme is to start out with full equipment of brakes until first stop is reached, sticking commences, and the brakemen begin bleeding and cutting out one or several brakes at a time, until number remaining in use corresponds with capacity and ability of engineer in charge to handle them; this point reached, everything goes along in proportion to energy on hand. The engineer don't have to exert his mind beyond its limit, and the brakemen enjoy the industrial repose in sweet content, while the conductor simply dreams of one needed advance to make life free from care, *i. e.*, transfer from caboose to Pullman.

But to get back in the line of horse sense, there can be no avoiding the fact that, in order to have effective working brakes, and to insure the service in emergency for which automatic brakes are designed, a degree of skill is required, and constant perseverance on part of all employes in charge or connected with air-brake service necessary.

We often hear of engineer's brake valves failing to keep reserve pressure in main reservoir; engineers often declare it impossible to keep brakes from setting when engineer's brake valve is set for feed position.

Where such opinion exists, let engineer in charge set valve in feed position with full air pressure, and pump working; then get down and hold uncoupled air-hose at rear of tank, and open stop-cock. Trying the feed in this way when stop-cock opens, the accumulated pressure escapes suddenly, then the gradual and uniform feed continues through feed valve. One can feel amount of air passing out, that, when coupled, passes back to



Richmond & Danville Throttle Lever and Latch.

careful and persistent effort must be required of all in charge of appliances.

The easiest way to tell a successful and competent air-brakeman is to note results accomplished.

Some men are always crying about brakes sticking, and while cussing the appliances and lack of repairs, and rawhiding the train brakemen for not bleeding sticking brakes, they fail to hear the emphatic remarks of the train brakemen concerning practice, or lack of practice, in hand.

Somehow, brakemen have absorbed the idea that air-brakes ought to be released from the engine, and by the engineer in charge.

They seem to gain this idea from the fact that some engineers pull them frequently, and never require bleeding of brakes. Other engineers, with the best of brakes, require a regular and systematic bleeding of brakes at all points, and an occasional forced stop requiring brakemen to get down, bleed a brake, and cut it out.

With the application of air-brakes to freight trains, brakemen come into a heritage of what may be called industrial repose.

Of course, many engineers consider it cruel to disturb a brakeman's rest for the purpose of bleeding brakes, or any other form of exertion, and when certain engineers carry this cruelty to extremes, brakemen on air-brake trains naturally infer that, if some engineers can release brakes, all engineers ought to.

We would suggest practicing such cruelty in requiring brakemen to locate and remedy leaks about appliances on cars, thus before starting aiming to avoid sticking of brakes.

Meeting a freight train equipped with air-brakes in ordinary repair, one can, by casual inspection and counting number of air-brakes cut out, judge the capacity of men in charge.

train appliances for needs of brakes; and this amount can be relied on to be sufficient for usual requirements, unless leading pipes waste more air than the volume passing through feed valve can supply.

This opening and trial practiced occasionally insures cleaning of feed valve and pipes; for the air rushing out, to begin with, finds free and easy passage, and continuing to flow freely, carries with it any light deposit or dirt in passages.

When coupled up, and flowing against counter pressure in train pipes, this clearing will not occur

We have noted this practice often remedies complaint concerning defective feed valve.

Richmond & Danville Throttle Latch.

The best and simplest throttle latch that we have ever seen is in use on the Richmond & Danville road, and we are indebted to T. W. Gentry, master mechanic at the Manchester shops, for the blue print from which the accompanying engraving was made.

As will be seen, the quadrant is simply a piece of steel of square section, curved to the proper radius, and fastened to the boiler head or brackets, where used on side of boiler; this quadrant works through a slot in the lever, which is fastened rigidly to it by an internal screw, as shown.

The cut shows only the iron-work; upon the end is fastened a wooden handle, fitted to the ferrule shown, and held in place by a stud passing through a cone-shaped nut on the outer end. This makes a good handle to grip, and is always cool. The runner loosens the latch by twisting the lever toward him slightly; this slacks off the large screw in the lever; the throttle is adjusted just where it is wanted, and fastened there securely by a simple twist of the wrist. There are no projecting screws, rods, pins, latches, notched wheels or sectors; the throttle is as plain and simple on the outside as a common one without its set screw. It is therefore easy to clean, and not liable to derangement.

As the screw bears against a steel gib, it does not mar the bar. These throttle levers have been in use on this road for a number of years, but the motive power officers do not claim to have originated it. It is so superior to the common breed, so simple, so cheap and so safe, that we would like to see more of them in use. The engraving is plain, and the sizes being given thereon, any mechanic who can get to a lathe can make one from it.

Air-Brake Valve Models.

Through the kindness of the Westinghouse Air-brake Co., this office has been provided with one of their new, quick-acting, triple valves, and an engineer's brake and equalizing discharge valve. These are full-sized valves, with portions of the case cut away to show the action of the mechanism.

By the use of these sections a student of the subject can see just what takes place under certain conditions, and can learn more about the valve in one good look and explanation, than they can in forty explanations without the models.

The models are on exhibition at this office at all times, and the writer will take pleasure in showing them, and explaining their action to the best of his ability, to engineers, firemen, or any others interested in air-brake subjects.

Railroad Geography.

Railroad men should see that their children are provided with good geographies.

Teaching them from railroad maps and folders would be liable to distort their knowledge of such matters, and make them think Baffin's Bay bounded Missouri on the east, and the Mississippi emptied into the Mammoth Cave, or Salt Lake.

We were recently shown a well-executed map of the United States that showed the country almost in the shape of a fan, the Atlantic States being the handle, and the Pacific the top.

These maps showed one of our Southern roads, with Eastern connections at Baltimore and Washington, to be almost a direct line West, and reaching, centrally, into the great Western States.

These maps were made for foreign distribution, to induce immigrants to buy tickets direct over this line.

We are informed by map engravers that there are very few railroad maps made that do not have the geographical location of cities, rivers or boundaries distorted to show that the particular line of road issuing them is the "great and only air line running through, vestibuled cars, without change, from Halifax to Honolulu."

W. E. Lockwood, him of the hammer blow, has got out his pet engine, the Shaw 4-cylinder machine, and is going to give the Strong a whirl on the Bound Brook. The Strong weighs just about twice as much as the Shaw, but it is thought she will handle four cars about as well as her big rival.

The Cooke Locomotive and Machine Works, Paterson, N. J., are moving into their new shops.

Air-Brake Notes.

The new shops of the Westinghouse Air-Brake Co., some 12 miles out of Pittsburgh, are not yet near completion, and will not be ready for occupancy for several months.

Work is slack, the shops being run but four days per week. Many experiments, and some changes in detail of the new quick-acting brakes have been made of late, until now it would seem that there is nothing further to be desired.

They have recently adopted a cock for bleeding the auxiliary drums that is operated by pulling a wire at either side of the car, making it unnecessary to go under for that purpose.

The engineer's brake and equalizing discharge valve has been simplified, the loose valve or dashport on the piston has been done away with, and the accumulation of gum and dirt prevented.

During a recent visit to Pittsburgh, we had the pleasure of a visit to the company's instruction car, which was just back from a 3,000 mile trip through the south, and which has since been sent to the Santa Fe system.

This car was designed by E. W. Newell, chief draftsman for the company; it is sixty-eight feet long, and is divided into two compartments, the office containing two Pullman bunks, a desk, cupboards, wardrobe, sofas, etc., and the instruction room, containing the apparatus.

In one corner of the end of this room is located a twelve-horse Westinghouse boiler, in the other a Westinghouse engine and a dynamo; this dynamo furnishes the current for some sixty incandescent lamps; on the wall, beside the boiler are two pumps for furnishing air; through the center of the car there is a frame containing 30 complete sets of automatic brakes, set in an upright position to save room; on the sides of the cars are tender and driver brakes, and also a fifteen car equipment of automatic whistling signals. On the walls and in other convenient places are located sections of the valves and other working parts of the brakes, enabling the instructor to show how and why the different devices operate as they do.

Engineers and firemen can handle the actual brake in the car, and also see by a section just what has taken place in the mechanism.

The car is heated by steam, has a water tank of 700 gallons capacity, fire apparatus, and is so equipped that, when in a train, the brakes can be operated from the car, or air furnished if the engine pump fails.

There is a six-wheeled-truck under the end where heavy machinery is located, and a four-wheeled truck under the office end. Ross-Meehan shoes and Westinghouse steel brake beams being used.

The interior of the car is finished in quartered oak, and is as handsome as a Pullman, the beauty and convenience of the whole thing reflecting great credit upon the designer.

The car is under the charge of W. H. Hartman, an eminent and progressive young engineer, who formerly ran on the Vandalia, but has been for the past five years an instructor in practical mechanics at the Rose Polytechnic Institute at Terre Haute, Ind.

The car is sent without expense to any road using the brake, an intelligent runner who knows the men appointed to assist, and lectures given on the subject. Mr. Hartman is thoroughly up in brake science, but is a practical engineer, and gladly answers any questions asked. If this car comes within your reach, don't miss it. It will be worth money to you.

The Pittsburgh Locomotive Works are preparing the ground and putting down concrete foundations for their new shops.

Weaver's Grate.

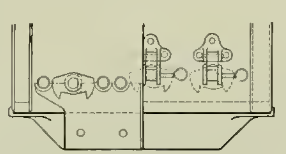
The accompanying engraving shows a plan of rocking grate adopted by Master Mechanic J. N. Weaver, of the Lehigh Valley road, for some large 12-wheeled locomotives.

The grates lay between water bars, and are independent of each other, and differ from other shaking grates in that they have no coupling bars or shaking rigging.

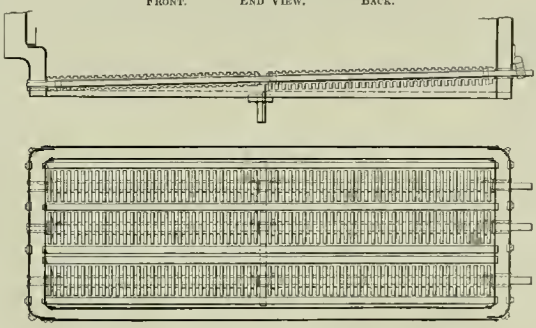
The shaft of each bar projects through a thimble in the back head, and is rocked by applying a socket wrench to its squared end.

It would seem as if it were impossible to cock such a grate, as each section is independent of the other, while the doing away of all operating rigging under the deck and in the ash-pan is an advantage that will be appreciated on the road. The grate must be easier to shake, as a man does not have to lift the entire load of fuel on the grate.

The grates are inclined as shown in the end view, and are held from turning by hinged forks that drop over the square ends.



FRONT. END VIEW. BACK.



WEAVER'S GRATE BARS.

Jack the Ripper.

The Webb compound locomotive, Pennsylvania, *nee* "Jack the Ripper," is pulling the Paoli accommodation out of Philadelphia. This is one of the hardest runs in the country for a compound; they pull five and six cars, run 20 miles, and make 19 stops in 50 minutes.

If the compound can make this run on time, she is a daisy on the start—we do not think she has or can do it. She will soon be tried on the New York division, where she would have some show of proving what there is in her.

The new Canadian Pacific connection across the northern wilds of Maine to Halifax is completed and opened. The first train was all day going nine miles. Gray caterpillars by the thousands got on the rails and greased the right of way enough to skid all wheels. Western railroaders will smile at this, and remember the circuses we used to have with grasshoppers.

Our correspondent, F. C. Robinson, late general foreman of the Wabash shops at Danville, Ill., has been appointed General M. M. of the Atlantic and Danville Railway, with headquarters at Belfield, Va. Progressive men get the responsible places—and keep them.

Bee Line Shops.

During a recent visit to Indianapolis, we visited the Bee Line shops at Brightwood. These shops, when built, were no doubt considered fine railroad shops, but they have depended upon their reputation for superiority in later years. The shops are good ones, roomy, and not crowded too close together, but the most of the machinery is comparatively old.

They were cutting up four old scraps that have done service ever since the line was started, old-fashioned 8-wheelers with incline cylinders fastened to smoke-box.

The new engines for passenger service are mostly Brooks' build, although some very fine-looking Schenectady engines were in the house. Most of the freight engines were built at the Cleveland shops, or rebuilt there, losing their original identity in the process.

This road has used for years a peculiar form of sand-box, set up on a small central support, and having the pipes fastened to the bottom by a union; the new engines have common, every-day sand-boxes, however.

The shops are clean, as are also the yards about them.

In the back shop a number of locomotives were being rebuilt, some getting new boilers; they had just got a half re-built mill back on her blocks after having slipped on the jacks and turning over, fortunately catching none of the dozen or so of men at work on her.

They employ here a very neat draft iron for the rear of tenders, that has a heavy lug on its upper side, and a wrought-iron buffer plate hinged to it. A fixed buffer plate on a passenger engine often makes it impossible to couple to a freight train, and an engine ahead of a passenger train with a foot or two of slack and no driver brakes, can knock all the care and skill out of the best handled air brake on earth.

The company owns and operates a hotel, the "Brightwood Home," near the shops; it is intended for the men entirely, and has convenient sitting rooms, provided with reading matter, etc. It is a big improvement over the common hash foundry with bar attachment, but it would be lots more enjoyable if it was scrubbed out occasionally.

An English Opinion of the Webb Compound.

Clement E. Stretton, C. E., an eminent mechanical engineer, of Leicester, England, writing to the Engineers' and Firemen's *Journal*, of Leeds, says:

". . . It is a fact worthy of note that in this country the working of the compound system has never been fully and fairly compared with the working on ordinary engines; the compound has always had the advantage of 25 or 35 pounds more steam pressure.

"Compound locomotives have 175 pounds of steam in their boilers; they are provided with the best coal, best oil, and kept in first-rate order; the ordinary engines have only 140 lbs. steam pressure, and have to burn any coal. . . . .

"American engineers will test the compound sent over there with one of their locomotives capable of carrying 175 lbs. pressure, in order that the comparison may be perfectly fair

"Already the advocates of the compound system are beginning to consider that the Americans ought to come to the trial with one of their ordinary engines with only 140 lbs. pressure.

"It will be very interesting to watch the results obtained in America by the Webb engine, but it is to be regretted that, if the Pennsylvania Company desired to purchase an English locomotive, it did not obtain one of the best standard patterns of English practice."

The South Australian Government has agreed to pay £10 ($48.70) to every engine driver who runs his train two years without an accident.

A New Belgian Locomotive.

On this and page 5 will be found a plan and elevation of a new design of passenger engine, recently adopted by the Belgian State Railway Administration, for practically level roads. This engine was designed and built by the Société Cockerill at Sening, and is exhibited by them at the Paris Exposition.

The engine was designed for burning slack of a poor quality, and it is claimed that engines of this class make 68 miles per hour in regular service; and the designers claim that by the peculiar style of equalizing they get extra good results, in easy riding, at this high speed.

At a speed of 59 miles per hour this engine pulls a train weighing 180 tons, including a tender, 6-wheeled, carrying 3,080 gallons of water up a grade of 1 in 200.

The dome is flanged near the bottom, instead of the top, so that when the cover is taken off the throttle and pipe are entirely exposed.

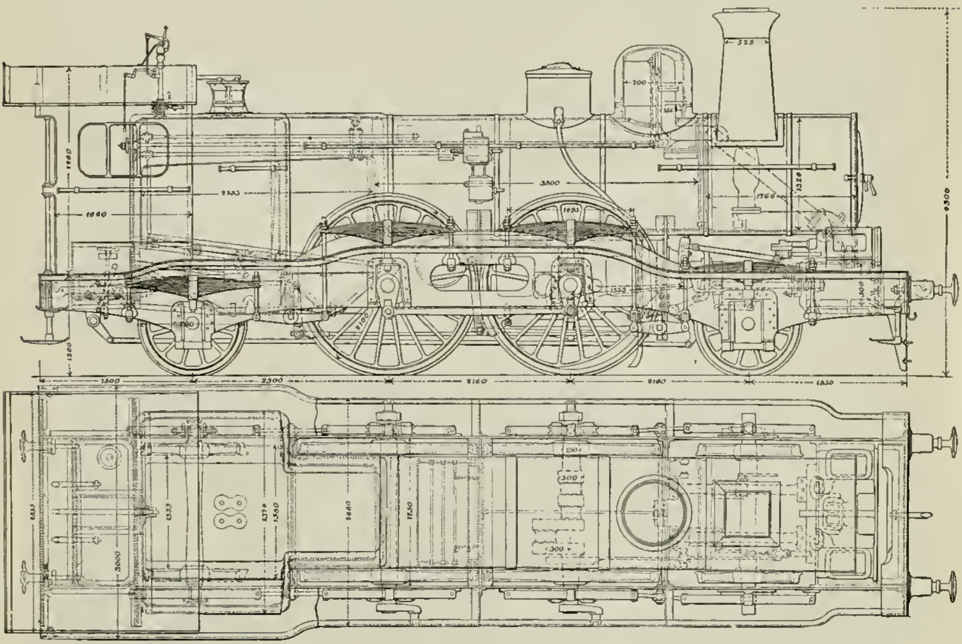
The outside plate frame and side rod cranks are peculiar to European practice.

A modification of the Walschaert valve gear is used, and the inclined steam chests, set about half their length ahead of the extension, are a novelty to Americans.

The principal dimensions are as follows:

Heating surface, fire-box	130	sq. feet
" " tubes	1,237	" "
" " total	1,367	" "
Grate area	53⅝	" "
Cylinders	20x24	
Diameter of drivers	83	inches
" " truck wheels	48	"

We are indebted to *The Engineer*, London, for our cuts and data.



A NEW BELGIAN LOCOMOTIVE.

There is a spring over every box on the engine, those over the drivers being 5 feet long; the springs are equalized together, something seldom done in that country; the equalizers between the leading wheel and forward driver are pivoted to a cross-equalizer, which is pivoted in the center to a rigid brace from the boiler or frames. The springs are simply straight pieces of steel cut to the required lengths, no drawing down of ends being required for this form.

The fire-box is on the plan of the American, hay-wagon, slack burner, but is narrowed up in front to allow the large driving wheels a chance to work beside, instead of under it. The boiler has the Belpaire, square top, fire-box, which is nearly 10 feet long ($2\frac{1}{2}$ meters); the cylindrical part of boiler is 12 feet 6 inches long, containing 242 iron tubes, 1¾ inches internal diameter.

An extension front is used, and a very large, square stack. As will be seen, the steam pipes extend to front of extension to join the cylinders, which are located ahead of the leading wheel. The total length of engine over all is 35 feet 6 inches; wheel base, 25 feet 6 inches.

The total weight in running order is 49 tons.

The engine is equipped with the Westinghouse air-brake, and driving brakes are used.

A Lively Little Shop.

It has been our experience in traveling about the country that big railroad shops are about all alike, and not very modern or interesting, except when new, but that small shops, required to keep up considerable power with few tools, poor facilities and no money, usually develop men, and the men develop methods both original and interesting.

At the O. I. & W. shops, in Indianapolis, we found a little shop hustling around and doing more work on fifty square feet of territory than half the big shops do on an acre.

The shops are small, but all departments are worked up to their capacity.

The locomotives used in passenger service are 8-wheelers, mostly Rhode Islands, and are kept up very nicely. Many consolidation engines are employed on freight. Extension fronts are employed and run from one year to another without sparking, and this, too, without throwing cinders or burning the paint off the front end.

These shops are under the charge of Master Mechanic John King, a practical engineman, and his trade-marks are everywhere.

The road is a combination of several small lines, and, of course, there were originally many different kinds of locomotives to contend with, but these have been brought up to the times, and as near standard as it is desirable to have engines. Mr. King makes solid rods of his side rods by taking out the key and putting on a new strap. All rod bolts have square heads, making them easier to handle without the monkey-wrench gouging the corners off. Fluted, or I section side rods, are made as cheap, or cheaper than ordinary rods, by leaving the rod the same side throughout, and not finishing up a stub-end at all. This saves lots of machine work, but makes a pretty heavy rod, or one with extra large and heavy straps and brasses, but it is intended in the next ones built to make a wide rod, but to let the strap into it flush instead of putting it on outside.

Some Healy, 8-wheeled, 17 x 24 engines, 7 feet between centers of driving wheels, have recently received new boilers, much larger in diameter than the old ones, and two feet longer, the drivers being spread to nine feet. These engines are very hard to beat, being free steamers and very smart.

Mr. King is putting an angle piece of $\frac{1}{16}$ steel, in the shape of a try-square, under the corners of the packing strips of Richardson balanced valves, to prevent the springs from cocking one piece up, and binding its corners against the others. Many of the engines are equipped with the Bristol roller valve, a plain slide valve supported on steel rollers placed in a frame, and resting upon the valve seat at end of ports. They work very satisfactory there—one engine having made 4,000 miles per month, on passenger, for two years without repairs, and in good condition yet.

They run cheaper on oil here than at any place we have yet visited, and use for everything, except valves and cylinders, crude oil, costing but six cents per gallon. On engines coming in from long runs you see no oil slobbered all around the pin collars. The cup used on rods is illustrated in this issue.

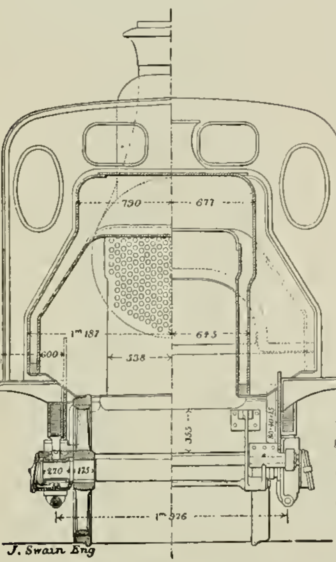
Like almost every road in the country using heavy locomotives with small wheels, they have had trouble with the counterbalances—engines riding very hard at fast speeds. All the consolidations have had extra counterbalance weights riveted into the wheels at each end of the weights cast in, and the men claim a big improvement in the riding qualities.

There are being built in the shop a couple of 6-wheeled switchers of heavy design, that, so far, show extra good work. The boilers are splendid specimens of work, all longitudinal seams, double riveted with welt, inside and out. All the stay bolts in side sheets and back head are the same length, and the top sheet is flanged and double riveted to the dome; in some new boilers to be made there will be two rows of rivets in the mud-ring. The frames are forged solid and finished all over, and a generous fillet left in every corner.

Four-inch tires are to be seen everywhere, Mr King being a believer in their superiority over thin tires, in safety if in nothing else.

In the passenger engines lengthened out, the frames beside the fire-box were stiffened by putting an I piece in the center between the frames, and running a brace in the shape of an arch-bar from the lower rail of the frame and the pedestals over this I piece, with both ends fitted against the jaws, and secured by fit and taper bolts, it makes as strong a job as a heavier frame.

They make a splendid steel frog here for the small sum of $13 each, using a malleable iron filling of their own pattern; this filling fits the sides of the flange and head of rail, and the bolt holes are cast into it large enough, so that the bolts do not touch the filling piece, hence do not shear or wear off.



All injectors have overflow pipes screwed into them solid; there is no slobbering of water, steaming of windows, rusting of jacket, and scalding of paint from the steam and hot water that always offers up burnt offerings from every open overflow in the country.

The firemen have a trick of painting the barrel of stack, and sometimes part of front door, with plumbago, that gives the iron the appearance of silver at a distance, and polished iron nearer. It looks very neat with the jet black of front end.

The Strong is wrestling with a four-car express train on the Reading, between Philadelphia and New York. If she really could pull 30 cars at 80 miles per hour, and the engineer "holding her back," it ought to be no trick at all for her to make an even hundred miles per hour—especially if the engineer could be induced to let her out.

Barnum's circus, 40 cars, was the first paying train to cross the great Poughkeepsie bridge.

At the Pittsburgh Locomotive Works.

The Pittsburgh Locomotive Works are preparing for the foundation of their new shops; these will cover much of the ground now used as a yard, and the new machine shop will be built over the present machine shop site. This will call for the removal of the hundreds of heavy machine tools, with their maze of shafting and belting, the erection of the new building where the old one stands, and the setting up of the machinery; and all this while doing their regular work.

Locomotive building is comparatively dull now, and Supt. Wightman is improving the time by rebuilding machine tools that are in need of it. The machines are brought into the tool room and thoroughly overhauled, strengthened where weak by new or heavier parts, gears changed to make the speeds or power what is required for the work, etc.

These works do a great deal of forging to required shapes for locomotive work, and the hammer shop is full of dies for this purpose.

At the time of our visit, there were in the erecting shop a number of 10-wheeled engines of heavy pattern, two 8-wheelers, and several little 7x12, iron cab, small wheel crabs for work about steel works. They were also rebuilding some old engines.

We noticed on cylinders for 20-inch bore and high pressures, that a cylinder head with heavy spoked braces is used.

They drill a hole back of the key-way through the sleeve of the valve rod where it couples to the stem, so that a punch can be introduced to force the stem out in disconnecting.

Many manufactories in Pittsburgh have gone back to the use of coal as fuel, on account of the increased cost of natural gas; this comes from two reasons: first, the control of the gas by monopolies, and second, by the reckless waste of gas by the workmen.

Coal has to be shoveled into a furnace, and the men are glad to take every advantage that will prevent exertion in shoveling, but gas goes in itself, and they simply "let it hum."

Fearing that a considerable reduction in pressure would be annoying in the works if piped as usual, Mr. Wightman piped these shops with 4-inch gas pipes, so that in event of low pressure, he would have a large volume to draw from, but soon found that every furnace was run with all the gas they could get, arguments were useless, the men declaring they could not get a heat in any other way; gaskets with a hole only an inch to an inch and a half were placed between the flanges of the pipe at each furnace, and has apparently met with no other result than the reduction of the amount of gas consumed.

J. H. Setchel, President of the Master Mechanics' Association, and lately superintendent of the Brooks Locomotive Works, is now connected with the Pittsburgh works as agent.

Vandalia Shops.

The shops of the Vandalia line, located at Terre Haute, are old ones, and not out of the general run of shops built in a hurry 25 or 30 years ago in the then West.

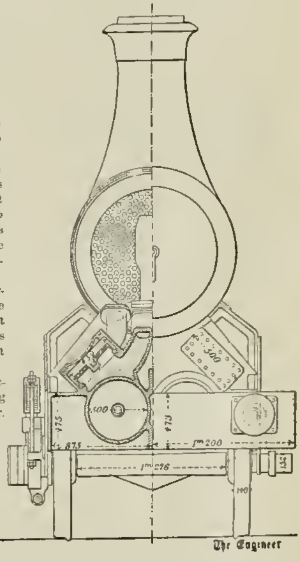
The roundhouse is a complete circle, containing 30 stalls, and has an open center; most of the roundhouses through that section of the country are cursed with a pall of darkness in the shape of a covered center. The road is remarkably free of old locomotives in road service, as compared with other roads of its age. Most of the new locomotives are Pittsburgh build, and heavy 10-wheelers are used on freight, old scraps for switching purposes. The road uses the Janey coupler on passenger cars, Westinghouse brakes and signals. The erecting shop is separate from the machine and other shops, and has in it a turntable, a transfer table, and a power hoist for picking up a locomotive bodily to remove her wheels—a rather cumbersome and expensive process as compared with modern transfer jacks.

The machine shop is small, fairly well equipped with tools, but most of them would be grey-headed if they had hair.

The power is derived from an old-time, long stroke, independent cut-off engine that has been in its present position and in charge of the same man since 1852.

They have some modern tools in the boiler shop, and had, at the time of our visit, a couple of new boilers completed for new switch engines; these shops have built some fifteen new engines in the past two years.

The company build their own cars and coaches, and a new paint shop recently erected is especially well arranged; tracks are laid over very shallow pits of cement, the cement extending outside the rail far enough to let all drip from sides of car fall upon it, instead of the floor. The cars stand close together, and there are two rows of posts between each track; on these posts are arranged simple folding brackets that allow the painters to fix their painting stages at any height, and the full length of the car.



On some of the locomotives Cooke bell ringers are used, and on others the White bell ringer—a device worked by air.

Some of the engines are still provided with Supt. of M. P., Prescott's sparking arrangement for extension fronts; this is a cast-iron soap kettle fastened under the arch and containing water; it does not work well enough to pay for its maintenance, as they are being side-tracked as fast as the engines go in. They run the deflector out ahead of the nozzles now, put in netting with a large mesh, and the sparks go out of the stack—where they belong.

We are in receipt of a communication from an old marine engineer at Racine, Wis., who objects to the way some correspondent refer to "Drivers on the Water," about a year ago, and states some of the difficulties in the way of, and requirements of a marine engineer, that locomotive engineers could not cope with. A marine engineer would be about as useful on a locomotive as a locomotive engineer would on a steamer; they are both good men in their places, but when any engineer claims to know everything about all classes of engines, he can be set down as a little out of balance.

An Economical Oil Cup.

We present on this page a cut of a simple, cheap and effective oil cup, in use on all the locomotives on the O. I. & W. road.

They are plain brass cups, with a square cap for wrench; the feeder is independent of the cup, simply has a ball joint at the bottom, and consists of a brass shell, into which is driven a copper tube, long enough to reach through the cup almost to the pin. Through the sides of this brass post and its tube a number of holes are drilled, and a wick is drawn tightly through it, and a cork placed in the top. The brass post extends up into the cover, forming a guide that prevents crossing the threads in putting cover on. The feeder can be removed from cup by the fingers, and oil used directly on pin.

On this road they use three sizes of these cups, the larger being 2¼" in diameter and 4" high, the smallest 1½" in diameter and 2¼" high. Small size is used on side rods for consolidation locomotives, and with crude oil, costing but six cents per gallon, they run from three to six weeks with one filling. A cup was taken off an engine for our examination on the 13th of May, that had been filled on the 1st; it was about ⅞ full of oil, and had run over 1,000 miles.

The cups cost but a trifle over $1 each, and are much stronger and neater than the average cup in use.

Correspondence

Not Always the Notch that Counts.

Editor The Locomotive Engineer:

I am glad to see some of the boys are working the throttle and lever question. But it seems some of them have got too many notches. While I believe in working the steam expansively, I know there is such a thing as going too far. It has been my experience that if an engine will do her work at ½ stroke, and a good stiff throttle, she can't be changed to advantage. This question of notches is no comparison; most of our engines cut-off at 6" or 7" in first notch; one of the boys in Canada says his is 3". I once ran a passenger runner on another road, handled a train of five coaches, in the first notch *back* of center, and she worked good and strong.

———, *Ohio.* SKIPPER.

[The writer had a little experience like this, but found out afterward that the reach rod was two inches too long.]

A Few Facts.

Editor The Locomotive Engineer:

It is a fact well known to all railroad men that their respective companies get an economical streak about once a year, and nine times out of ten when retrenchment comes it strikes the locomotive department first, under the plea that the operating expenses are too high; cut down the mechanical force, use less coal and oil on the road, pinch and squeeze at the spigot, but let the leak at the bung continue. Are the operating expenses too high? We admit they are, under certain circumstances. The general office goes after the general M. M.; as he is not omnipresent he goes after the Div. M. M., in a circular letter, and he, again, jumps the foreman, and he bounces a lot of men. Expenses, in regard to wages, have been reduced a little, but the running expenses are still high. A notice is posted on the bulletin board, signed by the Div. M. M., that engines are using too much coal and oil per mile. Right here comes the injustice to engineers; we well know that it takes coal to pull heavy trains, "and if you drop her down and knock it to her," it takes more coal; it also takes oil to keep things cool; "time freight" and fruit must not be delayed; extra coal and oil used under such circumstances are legitimate. But show me an engine that is always howling at the station, and I will show you an engine that has a lot of dampers hanging loose, admitting air enough, when shut, to keep the engine popping all the time, and if the air-pump is kept running it is so much worse; that engine is burning lots of coal, and doing no work to show for it. Show me an engine that burns lots of coal on the road, but is not steaming and doing her work in proportion, and I will show you an engine with packing or valves blowing. Is it any wonder that such engines are expensive to operate? At the same time the engineers get notice that they must run with less coal and oil; how are they going to do it? They are not supposed to do their own running repairs, and they cannot get them done. Dampers and ash-pans should be as near air-tight as a front end; it is the foreman's place to see that they are so made, but he don't do it. Perhaps he wants to talk to some one, and don't have time to attend to his business, and very often don't know his business. There are plenty of good men in such positions, and some not worth the powder to blow them up. An engineer reports his valves or packing blowing, the cover or cylinder head is taken off, when this modern Solomon looks in, looks wise, says *they* are all right, and walks off. A request is made to have an engine's valves squared (and we all know that almost any engine that is square, with valves and packing tight, will do good work;) but it is not done, and the engineer goes out and tries to make time with an engine that won't make time, by being handicapped by the cussedness and ignorance of the foreman.

What reflects more on the ability of a Div. M. M. and his foreman than to hear an engine go limping and wheezing over the road?

KING'S OIL CUP.

Running a locomotive may not be classed as skilled labor, but it takes brains; and I venture the assertion there is not a class of men connected with railroads who are subject to so much worry and anxiety as locomotive engineers, providing, of course, that he cares a continental how things do go.

If some of the men who get into position as Div. M. M. or foreman (not on their own merits, but by virtue of the "power behind the throne"), knew what it is to have to nurse and coax a defective engine to get her over the road, and to have the train dispatcher hounding to know why do you not run faster or knew how to run a locomotive at all, they could appreciate an engineer's troubles on the road, and see that his engine was right when she went out; but they don't know, and care less.

The foreman of a division shop should be a practical machinist and engineer, and know each branch well enough to put up an engine, take her out on the road and run her successfully; and if he does not know these things he has no business in the position.

If a little "civil service" was used in putting men into positions on railroads, it would be better for all concerned. W. DE SANNO.

Tulare, Cal.

About the Swinerton Locomotive.

Editor The Locomotive Engineer:

If you will look on page 408 of the *Fireman's Magazine*, you will see that even so old a railroader as Mr. E. J. Rauch can have his eye shut very easily.

He has been riding on the Swinerton Flat-Driver locomotive, and endorses her as a great and good invention. Says she beats other engines of same dimensions, that the flat spots give her more surface in contact on the rail, and thus more adhesion, and that she has worn her driving tire down an eighth of an inch, still preserving the facets. I have not only been on the Swinerton, but about her for many days, and will simply say that Mr. R. has been misinformed about the weight on drivers. I understand that some of this weight has been taken off, as the driving-boxes run hot all the time, but the original weight was 41,000 pounds on drivers, and this could be increased by traction increaser to 47,555—considerable difference between that and 24,000.

Now, about those facets. I cannot find one, except some interested person shows it to me (?) and, if, as Mr. R. says, an ordinary wheel rests on the rail only in a mathematical line, the Swinerton would not touch at all when going from one facet to the other; and if the surface in contact determines the amount of adhesion, instead of the weight controlling it (as all laws of physics declare), why not make the rails ten or twelve inches wide, and the drivers the same?

Now when Mr. R. tells us that a driving wheel, with 105 little flat facets milled upon its tire, can run for a year, and wear down an eighth of an inch, *and still keep the flat spots intact*, why—I don't believe it. I would not believe it if I told it myself; it is not natural, it is not mechanically possible—it would wear off those corners, sure.

I send you herewith a photo of the "Onward," with all her weights noted.

Lexington, Mass. A FIREMAN.

Schemes and Schemers—John Alexander's Warning.

Editor The Locomotive Engineer:

If you have got through dodging all those fellows who have shied a brickbat at you for letting me say I didn't believe in *always* working a locomotive wide open and hooked back, why, just lop your ear over here—I want to pour something into it. I'm mad, Mr. Editor, mad as a bay bull at a county fair—who wouldn't get his dander up to go and be fined for drunkenness when it was one of his pesky neighbors who he never spoke to that was drunk, and not him at all?

Wouldn't you go on the war path yourself if the town authorities sent your children home from school and guarded the house because Tom Collins' kids had the small-pox or the 'leven-year itch?

'Sposen Flat-wheel Ellis burned the crown sheet out of his old pelter, and you was called up with all the rest of the gang and fired for it? Wouldn't you get hot? I know you too well to think you wouldn't, neighbor, too pesky well; I know what you'd do—you'd swear, that's what you'd do; 'en you'd rase up them lily white hands to high Heaving, and swear by the Continental Congress and the bow-legged General Jackson that you'd have blood! blud! B-L-U-D D!!!

I'm a peaceable man, Mr. Editor; I love peace, but I am riled up now and I've got my red shirt on—when you see me with my red shirt on I've been taking iron—when I've been taking iron I'll fight.

We had a decent road here once and several men had been taught their p's and q's—you know what that is—we all pulled along together sociable and family-like, but one day our master mechanic hired an old chronic to run amongst us; he was one of them critters that always knows more stuff that ain't so than everybody else knows that is so.

We were running "first in, first out" on our division, and had one local run that was simply a job of switching in a yard 113 miles long and one other hard run that went out at 10 P. M., that was hard and nobody wanted, and everybody felt sorry for the fellow that had to take it out; but as there was a couple of dozen of us no one man got it very often

Now the fast freight always caught that local, but the local let it pass and the fast freight man always left a line on register for the local man to register ahead of him and thus take his turn back and get his lay-over at home.

Now Chronic was on local the first few days, and it was all right; then he got a fast line a few whirls, and it killed him to see that other man go home ahead, so he went and sung a little song to the M. M., who was busy and disgusted, and he put up a notice that the men should run by the rules—"first in, first out."

Then came a squabble among the men; the man on local blocking and holding back the fast freight, and the fast man trying to get ahead and run around his less fortunate brother. Then Mr. Chronic got a good fit on, and after running around a man he told the night foreman it was no fair deal, and he registered the other fellow ahead of him and the other man said that old Chronic was a good fellow after all, and stuck to it till the caller went for him to go out on that night run, and he discovered that Chronic had been back over the register and "figured" a little—that other fellow was me.

Then we all commenced to figure; we had work to do, we were sick, our wives were sick, our mother-in-laws were dead—anything or everything to miss the moonlight.

This will show you the plan; if it was not one scheme it was another; we quarreled among ourselves, we abused our officers, we lied, we cheated, and we disfigured the golden rule till its own mother, if she could have seen it, would have wished it had died aborning.

But the judgment day came on apace, and the first case was Chronic's and the M. M. stopped his pay; there was hand-shaking and prayers and a feeling of relief; the wipers got cigars for *not* wiping extra clean, the M. M. got a gold watch, and men shook hands and were friends who had not spoken to each other for months. Why, before two days my wife went over to Jim Nixon's and borrowed baking powder and sassafras.

But the seed was sown and some of the weeds are here yet; we meet in the division room Sunday and talk about each other—talk about engineers when we ought to be talking about engines.

Look at our Grand Lodge; it is run, and has been for years, to satisfy a lot of men who wouldn't be satisfied with King Solomon for grand chief and the Queen of Sheba for inside door slammer. They met a few years ago, and one man who wanted a grand office found out that there was a smarter man running, who was not there—he at once schemed through a law preventing any member not a delegate from holding office; then the companies got to picking out our best and smartest men for master mechanics, traveling engineers, foremen, etc., so some more cranks put through a law preventing a man from being a delegate who was not actually running an engine—barred all our best men out. Then they barred out men who belonged to the firemen, so that now our annual convention is composed principally of men able to compete for our premiums on ignorance—figuring on being a delegate this fall myself.

Now I heard the other day that the Baldwin Locomotive Works had issued an order that the men would hereafter be required to buy their own chalk, slate pencils and file handles. I hope this isn't so, but I'm afraid it is, and if it is the blame can be divided up about equal between the men and the company. Such an order was no doubt called out by the wanton waste of this material by a few men—here the men are to blame. Instead of punishing 2,000 workmen and belittling itself, the firm should have hunted up the real offenders and made a burnt offering of them for the benefit of the rest—for not doing this the management is to blame.

The engineers of America have harbored too many excuses and incompetents who have hurt the reputation of the order; we have asked too many unreasonable things, we have had too many grievance committees stalking up and down the land seeking whom they might devour, and we have sent for Pete Arthur so often that there is not a big company from Hudson's Bay to Jehrico that will listen to us, right or wrong, and P. M. has about as much influence as I have.

I told you I was a kicking and I ain't half through—I'm loaded for bear, but I suppose you will choke me off along here somewhere, and so I quit. But I want to go on record as shouting in a loud voice, and telling some of our high and lofty legislators that there is a short rail just ahead of us, our road-bed is run down, bridges rotten, equipment old fogy—but nickel-plated, and looks well at a distance; but, no matter how we look to ourselves, we are not a going to make much of a record with the public unless we get rid of our old hook-motion ideas and modernize a little.

We have got a parallel road side of us now, new layout complete, young, progressive officers, enterprising, modern—72 inch boiler, 175 on the gauge, plain paint but a new, first-class machine—and we have got to equal their service, become second hand, consolidate, or be leased for 99 years for side track and repair yards.

Bless you, my dear sir, it is 11.81 that little Alexander is popping off at 180, with only a flutter in the lower gauge; and judging by the sound of the exhaust from the back bedroom Mrs. A.'s nightmare is trying to pull a full train on one side; the "gurril" has just come in and all is well, and so I go—not like the galley slave, scourged to his dungeon, but strengthened and sustained by an unaltering faith (that I have told you the truth) I can seek the spiral feathers of me downy couch, wrap a wire screen about me and lay down to pleasant dreams.

JOHN ALEXANDER.

Some Northern Pacific Roundhouse Kinks.

Editor The Locomotive Engineer:

I notice in your March number of 1889, devices for pulling cellars, and spring remover, and send you a rude sketch of tools used for that purpose up here on the N. P. R. R. Spring puller, cellar puller, and a crosshead mover. (Figs. 1, 2, 3.)

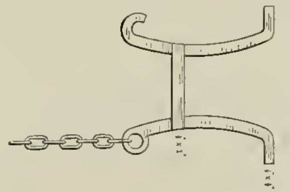


FIG. 2.

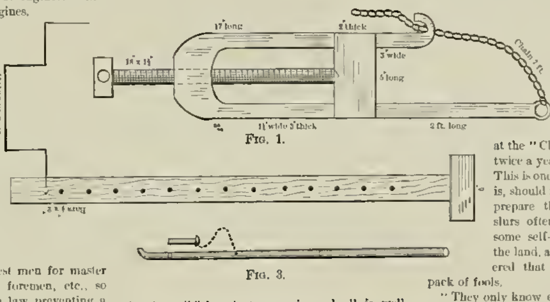

FIG. 1.

FIG. 3.

The spring puller is used by placing the fork over the spring and the frame, and securing as close as possible with the chain, then tighten by the screw.

The cellar puller is a very simple one; you hook the points into the bolt holes, throw the chain around the hook on the other side, pass it through the other side of engine where you can get at it, and the harder you pull the tighter it holds.

The crosshead mover is simply a flat bar with a head, to place against the cylinder, chest or guide yoke, and has, near its other end, a crooked iron hoop, as shown; this is so shaped that it will hook through or over any style of guide, and support the bar. With the lever the crosshead can be moved easily by inserting the fulcrum pin in the best place. The pin is chained to the lever, to prevent its being lost.

Roundhouse Foreman.
Little Falls, Minn.

From Wisconsin—Some Practical Obstructions to Debating Clubs.

Editor The Locomotive Engineer:

I admire the ideas of J. H. Davey, expressed in May issue of your paper. The Norfolk Debating Club may well be proud of its progress, and of Mr. Davey. You remark they followed your suggestions when they laid the foundation of their "Club." I will add that they have also copied after the N. A. S. E. (stationary engineers), who frequently listen to similar papers by men of Mr. Davey's stamp. Others help out with blackboard drawings; and conclusions drawn from such explanations are easily understood by all. The benefit of this is well known, but how to bring it into general adoption on railroads is a leading question.

A locomotive engineer said not long ago, "The company don't use us as good as street-car horses. Horses eat three times a day, and we don't."

Do men feel much like attending a Club meeting when they are living on ten square meals and part of three nights' sleep each week?

The companies hire men to man their "loco's" *and pull the cars!* No matter how much a man may say and explain at a "Club" meeting, if he can't get out of bed about midnight and pull a "full train over all the hills," and make time in a cold, blinding rain, and do all this for fifty miles on an empty stomach, he is "N. G."

He must buck snow when it is as high as telegraph wires, at the same time protect her crown sheet and "spring no pins."

Davey's ability ought to count for something, but R. R. Co.'s want these other things done, regardless of *meals, sleep or bad weather*, and if a man can "get there on time" with a full train, silence from headquarters is an "O. K.," and this engineer has convinced some one that he knows something. The company would never acknowledge any attempt he might make at the "Club," even should he be once or twice a year get rested enough to attend. This is one side of the question; the other is, should not enginemen in this country prepare themselves against insulting slurs often cast at them? Frequently some self-appointed cuss goes through the land, announcing that he has discovered that the American engineers are a pack of fools.

"They only know enough to pull her out and shut her off," etc., etc. With sufficient rope these missionaries have always hung themselves; but R. R. engineers ought to prepare against such attacks. Talent and good conduct oft times bear good fruit, but more frequently the biggest sucker about the office will get to the front, if he never was seen under his engine, which may be about to fall down.

"The Club" has little attraction for a train man who has been on duty for 71 hours continuously. Time cards are seldom made out to suit the meal hours of the men, compelling them to live for weeks on lunches.

Several of your correspondents are discussing whether it is better to run an engine in the company's notch or the center. You mentioned some time ago that there was in every locomotive a point that could be found for "throttle and lever" where she would do the best, and seem to work with less effort. That ought to settle it, for every engineer of experience knows that it is so.

I think we could profitably discuss the question of shutting off an engine coming into a station. I fear steam is often worked too close to stations, this is wasteful of steam, and dangerous for brakemen on top of train, in a cloud of black smoke. Engineers will often, in making a pull out of a side track, work steam till brakes have to be set to give hind man who has closed the switch a chance to go on same train. This is wasteful of fuel, wears out a train crew, and often adds to the danger.

LENNOX.

The second paper on Indicating Locomotives, by Cyrus F. Richmond, will appear next issue; it was received too late to get engravings made for June.

CONTENTS.

A New Name.

The Fireman's Brotherhood is composed of engineers, firemen and hostlers, and, in many lodges, there are as many engineers as there are firemen, so that the name, Brotherhood of Locomotive Firemen, is misleading and unsatisfactory.

The *Magazine*, official organ of the order, proposes a change in name to Locomotive Enginemen, Locomotive Men, or some name that will cover the three classes entitled to membership. Locomotive Enginemen is a little cumbersome, and is as much too broad in its scope as Firemen is too narrow; and Locomotive Men might reasonably include machinists and wipers.

We are inclined to think a change would be beneficial if a good name were selected. A quarter of a century ago, when the engineers' brotherhood was organized by W. D. Robinson, he called it the Knights of the Footboard; but some influence, with a love for long titles, soon got it lengthened into Grand International Brotherhood of Locomotive Engineers.

While we believe in leaving knights to the chess board, the queen's garter and the history of the sixteenth century, there is something modern, inspiring and fitting in the word "Footboard"; it is the deck of the locomotive, where the engineer, the fireman and the hostler stand while on duty, and where no other employe does stand; it covers the three classes entirely, and includes no outsider, and as these three co-employes are brothers, why would not "Brotherhood of the Footboard" cover them all, and be pre eminently the proper name?

Let the Firemen's order become the Brotherhood of the Footboard. Let them preserve, respect and live up to their grand motto of Benevolence, Sobriety and Industry. Let them disband their grievance committee, and thereby two-thirds of their grievances, and put their striking power into the hands of the grand officers.

Let them establish higher standards of membership—expel men for drunkenness before, rather than after, they have been discharged by the master mechanics. Let them establish lodge-room discussions, buy books and models, seek instruction, court examination, and offer to railroad companies better posted, better selected and more reliable men from the ranks of the order than can be secured outside of it, and they will have found a practical solution of their dream of federation; for in ten years the Brotherhood of the Footboard would soar above orders with any other foundation, just as an eagle soars above a toad.

Federation and Insurance.

We have been asked to state our objections to federation, and why we consider it best that the engineers, firemen and other employes of the operative departments of railroads should not pool their issues and stand as one body on all questions concerning the service, also our opinions of assessment insurance.

We want to say right here that we do not object to federation; if it could be brought about it would be a grand, good thing—so would the millennium.

We advised against attempting a broad application of the scheme, because we were satisfied then, as we are now, that the parties to the contract would not "stay."

The engineers believe that they have an organization of their own that is better than all others, and hence object to their members belonging to any other labor order. They grant no favors, and ask few—unless they are in a tight pinch. It is not to be hoped, judging by the past, that they will consider other orders and stand on an equal footing with them. This fact alone makes a big hole in the proposed ranks of the federated army.

The bringing into one body for an aggressive defense of "rights" of conductors, brakemen and switchmen, with enginemen, brings too many interests in conflict.

There will soon be a flourishing order of conductors whose laws are like the rest of the railway orders, and whose members will not be encouraged by their grand officers to lower their standard of manhood and offer their services in places they are not fitted for, or capable of filling.

We would prefer to see all the independent orders pass laws prohibiting members from performing any duties of other employes on strike. We would prefer to see each order give the weight of their endorsement to each other when asking for fair pay, or protesting against a reduction—not declaring that one class of employes were receiving pay due another class.

We would like to see all grievance committees disbanded, and the settlement of grievances placed in the hands of the officials of the orders.

All this would be one form of federation, but an independent kind.

The Brotherhood of Locomotive Firemen are presenting the most arguments, and making the initial moves in schemes for federation, and in so doing prove that their motives are unselfish and in the interest of the whole body of men in the service; for, of all the orders, the firemen have the least to gain and the most to lose by any change in the existing order of things.

The firemen are the men who—if they would take them, which they never have—get the places of the engineers in case of a strike, and a higher rate of pay. They are the young fresh blood; they get a year's experience as firemen, pay a good initiation fee, are examined by a physician, and insured in the order; they pay their assessments a few years and become engineers, join the B. L. E., and, by its laws, withdraw from the firemen. This keeps the firemen's order full of the youngest, most vigorous and recently examined men, and withdraws them from the insurance before they get old, making the firemen's the only safe and successful insurance on the assessment plan. In all other insurance schemes on the assessment plan, every benefit paid where the beneficiary has not paid in the full amount creates a loss that must be disastrous in the end if all the insured members stay in the swim.

The firemen take in a safe subject, assess him for a few years, and then he is drawn out, having paid in something and drawn out nothing.

The engineers would be the gainers by federation, but, as they will not see it that way, there is no use in hoping for any action on their part.

There is no more reason for any ill-feeling between the engineers and firemen than there is between a father and son. The orders should be together under one head; their interests are identical. Proposing federation between them is like leading a horse to the spring; making them federate is like forcing the horse to drink when he don't want to.

The Tsar and His Serfs.

Both the Brotherhood of Locomotive Engineers and the Brotherhood of Locomotive Firemen have been complimented by the delivering up of the charters of all the divisions and lodges on the Reading Railroad. Men who will surrender every vestige of manhood and independence, and conduct their private business to suit the whims of such men as the Reading officials can best serve any order by getting out of it.

The Reading Railroad, from top to bottom, from first to last, from the men at the mahogany desks in the general office to the coal-pits, where half naked Huns toil from sun to sun for a pittance of 60 cents, is manned—in the main—by such things as these.

The Reading officials demand for their service men who dare not look up and say they are free and independent men; to be sure there are a few who will, and who defy the autocrats who would disrobe them of their manhood; but the great majority are the kind of clay that fall down and lick the sweat off their master's belly, and then swear it is holy water. The service of the road shows it, their shops show it, their reputation shows it, and their business will show it.

We have not so far lost faith in human nature as to believe that people will continue to patronize a road conducted upon such principles, by such excuses of men, under the orders of such slave drivers as openly declare that they want no one in their employ except that they surrender soul and body to the service of the company.

These are not the first individuals invested with a little brief authority who have tried to make money by injustice, oppression or force, and by outraging every sense of right, justice or humanity. Pirates used to do so, but they finally got to the end of the string. Public opinion, like the mills of the gods, grinds exceedingly slow—but it eventually gets there. In the case of the Reading it is long over-due, but it is thundering down grade—and the brakes are beyond control.

While we can hardly find language strong enough to condemn railroad officials who oppress the men under them for not conducting their private business to suit them (the officials), we have very little sympathy for the Reading men; they have not the requisite manly independence to make good Brotherhood men—or hardly good citizens. When the Knights of Labor trouble came on there, two years ago, the Engineers' Brotherhood offered themselves for service (with the approval of their officers), and became the tools with which the officers of the road knocked out the Knights; last year, when the "Q." trouble came on, the Reading Knights "got even," and, the officers of the corporation, seeing that they could pit the one against the other, did so—and then fired them both.

By this process the Reading will be able to keep their men just where they want them, and, as we said in the first place, the orders are to be complimented on getting rid of them so easily.

Some Finances of the Q. Strike.

Wherever we go we hear complaints from Brotherhood engineers about the manner in which funds were distributed during the C., B. & Q. strike—dissatisfaction, uncertainty and suspicion. During that struggle, the B. L. E. received and paid out between $800,000 and $1,000,000, as fast as received at the general office, it was sent to the front in big blocks, and receipted for in bulk by the chairman of the committee in charge; he may have paid every dollar out to the men or kept half of it, no one knows but himself—suspicions are rife. The engineers should not blame the chairman, right or wrong; it is their own slip-shod way of doing business that is to blame. They can well learn a lesson in correct business methods from the firemen. When the strike commenced, Grand Secretary and Treasurer Debs took it upon himself to keep the finances straight; he prepared a pay roll for every lodge that had men in the struggle, and every month sent these pay-rolls to the lodges, with a draft for the total amount; the officers of subordinate lodges verified every name on the rolls, and paid each man his money, taking his receipt therefor, so that to-day there is in the Grand Lodge office a receipt for every dollar of the $459,000 that they expended, by the men who got it; there was not a dollar lost or wasted. It was worth thousands of dollars in money and existence itself in harmony and confidence to the B. L. F., to have a man in charge of the great seal, and the combination to the safe, who knew how to meet the emergency when it came, and carried the financial part of the programme through without the loss of a penny or the breath of a suspicion.

The Fireman's Magazine.

A bound volume of the *Locomotive Fireman's Magazine* for 1888 is before us. The volume is bound in morocco, gilt edged, and handsome. Editor Debs has the reputation, not only in his own order, but among railroad men in every part of this great country, of saying just what he honestly thinks ought to be said, regardless of who it pleases or displeases. Careful not to wrong any man, he fearlessly defends the right, and denounces the wrong, without caring who is hit or missed, so long as it is the right ones.

The *Magazine* is the best family magazine published for railroad men; it contains ringing editorials on the live subjects of the day, of interest to the head of the family, and giving advice that can be safely followed; it has an interesting mechanical department, in which practical railroad subjects are discussed, and a woman's department, equal, if not better than that of any metropolitan magazine.

Presuming that bound volumes are for sale, we would say that no one interested in labor subjects can afford to miss the chance of preserving the honest, able and eloquent opinions expressed in the editorials of the *Magazine*, from the pen of so fearless a champion of right as Eugene V. Debs.

Proportion of Flue to Grate Area.

On some of the 8-wheeled passenger engines on the O. I. & W., that M. M., King has lengthened out, he experimented a little with flues. He had plenty of room for 200 2-inch flues, but did not believe that so many were necessary or desirable. He put 200 in several of the locomotives, however, and in several others he put but 150. Engineers and firemen report no perceptible difference in the steaming of the engines, while the ones with the fewer flues carry their water better, while in repairing there are 50 flues less to calk or replace.

Flues, as heating surface, do not begin to be as efficient as the same surface in the fire-box, and many mechanics believe in putting in only as many as will carry off the smoke and gases from the fire. A rule that has given good results is to make the area of flue opening equal to one-eighth the grate area.

With fewer flues we have more water in the boiler to draw our supply of steam from.

Making Fast Time.

The new ocean steamship, City of Paris, arrived in New York May 8th, having made the trip from Queenstown in five days, twenty-three hours and seven minutes—the fastest trip on record by nearly three hours—the best day's run being 511 miles; this is but $21\frac{7}{24}$ miles an hour.

This shows the importance of steady work, and keeping at it, for getting any place.

Half the roads in America can and do run trains at and above 50 miles per hour in places, but the constant stopping and slowing down soon bring the average record of 3,000-mile runs pretty close to average ocean travel.

If ocean steamers had to stop as often as freight trains, sailing vessels would beat them across the great salt lick.

During a recent visit to Troy, N. Y., we visited the rooms of the Y. M. C. A., maintained especially for the railroad men. The building was built especially for the purpose, is located next to the union depot, and is under the care of men especially trained for the work.

There is an ample reading-room, well supplied with books and papers, writing material, etc.; there is a separate room for card, chess and checker playing, a very large gymnasium provided with upwards of a hundred different exercising devices, a bowling alley, bath-rooms and bed-rooms. All these privileges can be enjoyed by any railroad man at an expense of but $2 per year. Such places are doing much good in providing a wide range of entertainment and exercise for a class of young men especially exposed to evil temptations.

There is no excuse for not reading up current literature, writing home, keeping clean, and developing the muscles, when all the cash it costs a man is four cents a week.

The suggestion of our correspondent, Lennox, as to using a blackboard in discussing locomotive subjects, is a good one. A blackboard can be seen, and a few rough sketches often explain matters wonderfully.

Books Received

SAFE RAILWAY WORKING. By Clement E. Stretton, C. E. London, Crosby, Lockwood & Co.

This volume, of 300 pages, was issued in 1887, and is a treatise on English railway accidents, their causes and prevention, and contains numerous illustrations of devices in use in Great Britain for safety to trains, including cuts of the prize car couplers, the Westinghouse and vacuum brakes, and a complete plan of the best and most successful signal systems—these are shown in large colored plates.

In England, when any accident of importance occurs, there is a board of trade investigation, and the fault has been many times fixed upon the trainmen, and severe punishments meted out; the injustice of many of these trials are shown up in the book, and faults of equipment placed where it belongs. Mr. Stretton is now employed by the Association of Engineers and Firemen to attend these trials, and see that they are given no more than they deserve. The price of the book is not stated, but it would be of service to any student of practical railway subjects.

The Syracuse Tube Co. are again running their mills full time, having settled their labor trouble.

ASKED & ANSWERED.

(20) J. C. Hess, Connemaugh, Pa., asks:

Will you kindly give through the columns of THE ENGINEER the dimensions of the cylinders of the Corliss engine used in Machinery Hall during centennial? *A.*—Bore, 40 inches; stroke, 10 feet.

(21) S. S., Kokomo, Ind., asks:

Have chilled valves or seats ever been tried, and with what result? *A.*—Some years ago there were a good many experiments of this kind tried throughout the country. We understand that the expense of dressing and finishing the chilled surfaces, and their tendency to crack, prevented any great success in that line.

(22) C. S. C., Milwaukee, asks:

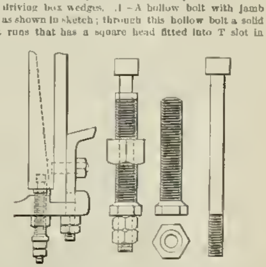
Did not the old Lawrence locomotives, built somewhere in Ohio, many years ago, have a cut-off valve on top of the main valve, substantially as used in many modern stationary engines? *A.*—We do not know of the valve gear of the locomotives mentioned; but independent cut-off valves were in common use on many builds of locomotives thirty years ago or more. A very efficient cut-off of this class—that built by the Norris Locomotive Works—was shown in the February issue of this paper.

(23) Ignoramus, Raton, N. M., asks:

1. Why will an engine slip going down hill, running in forward motion, especially with bad rail? 2. Will an engine flatten her back driving wheel tires more than the forward when slipping, and the cause for doing so? *A.*—1. We do not know that a locomotive slips under these circumstances, unless using steam. 2. While all drivers are coupled, and, consequently, must all slip an equal amount, it is not an unusual thing to find one pair of wheels with tires worn more than the others: this is due to the difference in weight carried on them, caused by poor equalizing; those drivers carrying the heaviest load will wear most under the same amount of slip.

(24) J. D. K., Aurora, Ill., asks:

What device do they use on the Pennsylvania for holding driving box wedges. *A.*—A hollow bolt with jamb nut as shown in sketch; through this hollow bolt a solid bolt runs that has a square head fitted into T slot in



wedge; the wedge is adjusted to proper height by the large screw, then the internal bolt is drawn down firmly by turning nuts on lower end, thus holding the wedge from moving. The whole device is then locked fast to pedestal brace by the large jamb nut.

(25) R. A. B., Chillicothe, Mo., asks:

(1.) What makes an engine pound more taking steam on front side of piston than she does on back side of piston, when she has a loose driving box brass? (2.) Why does an engine pound more backing up than going ahead? (3.) Why does the tire wear more just ahead of main pin than any other place? *A.*—It is generally acknowledged by engineers that there is a difference in pound between the front and back, and it is explained in this way: When the piston is pulling the pin from the back center to the forward center, it pulls the box off the wedge, and the rod and piston are going in the same direction as the engine frame, only faster, and the knock on the front of box will be lighter than it will be when it is driven against the wedge from the front to back center, because the piston not only drives the axle back, but the momentum of the train shoves the frame against the box, producing a blow of greater intensity. It is something like striking a ball with a bat: when striking the ball when pitched *toward* the striker the shock is much greater than if the striker struck the ball in a manner to drive it in the direction it was already going. The angularity of the rod will also cause a slight difference in the intensity of the blow. (2.) In most locomotives, especially old ones, the backing motion of the valve gear is often distorted to keep the forward motion in good shape, and the uneven cut-off causes pounding when backing up. (3.) It has been found that tires often wear most at a point between the two pins when both pins are below the center; and the wear is accounted for by the fact that at this point the engine gives the greatest rotative effect to the wheels.

The Locomotive in America.

By William Barnet Le Van.

FIFTH PAPER.

The majority of American locomotives and cars have cast-iron wheels, the tread or face being chilled. The casting of chilled wheels is an extensive and peculiar branch of American iron-founding. The best mixtures of such irons as are at hand, or which may be procured, require often very protracted experiments and much skill for their determination. An iron is required which is not only strong, but will "chill" evenly and shrink but little. Few if any single varieties combine these qualities. Some of the strongest irons shrink three-sixteenths of an inch per foot. The "chill" (produced by pouring iron while in fusion into or in contact with an iron mould) should penetrate to the depth of about half an inch everywhere on the surface of the tread of the wheel, and should blend with the soft iron beyond it in such a manner as to leave no distinguishing line of separation. To guard against the strain produced by the unequal shrinkage of the hub or nave and rim of cast-iron wheels has been the subject of much ingenuity. The rim being thin, and being poured against an iron mould, contracts rapidly upon the still fluid hub, which in cooling subsequently, tends to tear away from the rim. When all cast wheels were made with spokes, the hub was divided into three separate segments, three slots or openings of half an inch in width each, running through the whole length and thickness. After the wheel had cooled, these openings were filled either with lead or with dowels of iron, and two strong wrought-iron bands were shrunk one upon each projecting end of the hub. The single and double disk or plate form being respectively adopted, these were variously warped, always with the object of accommodating the plate to the strains which came upon it in cooling. These forms have been the subject of something more than a hundred patents.

Mr. Asa Whitney's (of Philadelphia) plan was to cool the whole wheel equally in all parts. The wheels, as soon as they have taken their "set" after pouring, and while they are yet red-hot, are taken out of the flasks and deposited in deep pits of brick-work, previously heated red-hot, and where, all access of air being excluded, they are from three to four days in cooling, and must necessarily cool equally fast in all parts. This treatment so thoroughly provides against all internal strain in the wheel, that while an ordinary solid-hub spoke-wheel broke of itself on being cooled suddenly in the open air, a wheel from the same pattern, but cooled in the "annealing kilns," did not break, even after a ⅞ inch hole had been drilled through the width of each of five spokes, leaving only a film of iron of less than ⅛ inch thickness on each side of the hole. It had been supposed by many that the process of very gradual cooling would injure, if it did not destroy the chill. The result proves that the chill retains its hardness perfectly. It is believed that the peculiar arrangement of particles, recognized as the chill, occurs at the moment the iron enters the solid state—that is, on the "set" of the casting, and that no heat below that point, subsequently applied, can draw the chill—in the same manner that steel, hardened to one color, will not lose its temper at lower heat. The cast wheels for passenger cars cooled by Whitney's annealing process have each a single plane disk, stiffened with straight radial ribs on the back, and are about 33 inches in diameter and weigh about 450 pounds each. The truck wheels for locomotive tenders and freight cars are generally 30 inches in diameter and 500 pounds in weight. As before stated, they are cast of special mixtures of the best qualities of iron, the requisite conditions being great absolute strength to resist both sudden and progressive strains, and the property of taking a deep and uniform chill. But little of the cast-iron employed for wheels has a tensile strength of less than 15 tons per square inch; test specimens broke with a fracture, almost suggestive of fiber, and of a dark gray color, but when chilled of a silvery whiteness.

Chilled wheels run from two to six and even seven years, according to the traffic, before becoming so much worn as to require removal, representing a service of from 80,000 to 200,000 miles run, and their usual load is two tons each. Locomotive driving wheels of from 4 to 5 feet in diameter have been cast with chilled faces, thus requiring no tires, and chilled tires from 4 to 6 feet diameter and 3½ inch face have been extensively and successfully employed at fair rates of speed, say 30 miles an hour; but with the increased speeds of the last ten years steel tires are only now used for locomotive driving wheels.

The chilled wheels are all made of the disk form, their weight necessarily increasing into a ratio nearly as the square of the diameter. To overcome this, cast-iron spoked wheels were tried, but it was found that the chill was less hard opposite the ends of the spokes than elsewhere, and thus they soon showed flat spots; spoked wheels are therefore seldom made, except for driving wheels, which are not chilled, but are turned on the tread and a steel tire shrunk thereon.

Driving wheels, although cast usually to receive steel tires, require considerable care to prevent being strained in cooling. These wheels are made almost always with radial spokes. The hub must be solid, hence the rim is quite commonly divided by slots, into three segments, which, as the hub contracts, can draw towards each other without strain. In such wheels the counterbalances are cast whole with the wheel; wrought-iron dowels are inserted in the openings in the rim, and the tire then shrunk on, which thus binds the whole firmly together.

Many of the best cast-iron driving-wheels are now cast with hollow spokes; and sometimes even the main hub, and that of the crank-pin also, are cored out hollow. In such cases the rim is cast whole, the distribution of the iron in the hub being relied on to equalize the shrinkage.

SPARK-ARRESTER.

A spark-arrester is an appendage to the chimney of a furnace or boiler, and is designed to retain the sparks, fine coal, or coke-dust, etc., which would otherwise be carried up by the draught through the chimney, and discharged, to the danger of combustible objects and the annoyance of individuals, in the immediate vicinity. The necessity for spark-arresters arose with the introduction of wood-burning locomotives in 1830. For many years wood only was employed as fuel in America, and, as it produced great quantities of sparks, as annoying to passengers as they were dangerous to the freight hauled, and the barns along the line, much ingenuity was directed to the problem of separating and withholding them from the escaping smoke and steam; and the voluminous "spark-arresters" were very successful in this respect, while they gave also an individuality to the locomotives.

There is no peculiarity in the adaptation of the engine to burning wood, as compared with that for burning coke or coal, excepting that the blast-pipes are smaller in the latter, and in the former the spark-arrester is applied to arrest and retain the sparks.

The spark-arrester is peculiarly an American institution, and possesses but little practical value beyond that derived from American practice.

One of the earliest, and, as experience has proved, the best arrangements for the purpose, is that known as the "bonnet-pipe" shown in Figure—

An inverted conical deflector, having a rolling edge like the rim of a tea saucer, is placed a few inches above the mouth of the ordinary chimney. This deflector inverts the draught, the sparks by their weight remaining in the bottom of an annular casing outside the chimney, whilst the steam and smoke rise and pass off through a wire-cloth screen, or bonnet, at the top. This form of spark-arrester was applied by William T. James, of New York, to a locomotive built by him, in 1833, for the Baltimore & Ohio Railroad; but it was not generally adopted until 1837. This form of spark-arrester is still extensively used for wood-burning locomotives, but in locomotives using bituminous coal has given place generally to the modification usually termed the "diamond" stack, in which the cone and netting are retained and the outer casing reduced in dimensions. The diamond stack, with various modifications of detail, was in use to a greater extent than any other up to about 1880, when the extended smoke-box system began to come into general use. This form of stack was patented by John Thompson, of Boston, May 29th, 1860, upon the theory that the sparks would "pass out of and beyond the current of smoke, so as to be deposited in the box by the action of gravity, and not carried up the chimney." It proved a failure, and has been since improved on by Hovey, Hill, and others. In the writer's judgment it is wrong in principle; the error lies in *expanding* the capacity of the smoke-box, the dimensions of which, in the ordinary construction, are too great.

BOILER.

The standard four-coupled American passenger locomotive boilers burning anthracite coal are of the type known as the "wagon top," the shell or barrel and fire-box casing being united by a long, tapering ring. The rings being oval in cross-section have to be strengthened. The usual and best way is to rivet to the flat places on each side of the tapering part, heavy **T** pieces. The diameter of the cylindrical part of the boiler is about 50 inches, and the thickness of the plates ⅜ inch. The total length of boiler from end to end is about 20 feet. The material used for the boiler and fire-boxes is steel, the ultimate standard test of which for tensile strength is 60,000 pounds per square inch—a slight excess or diminution in this strength causing a rejection of the plate, especially if the elongation falls below twenty-five per cent. in a piece twelve thicknesses in length from a test strip cut off by the maker from each plate, which is marked in such a position that a part of the mark remains on the plate and a part on the strip. Beside the test for elongation and tensile strength, a strip is also bent double while cold, untempered, and afterwards tempered. The grate is formed of tubes *two* inches in diameter, and are placed three inches apart from center to center, one of the tubes is left out, a solid bar put in its place and is termed a "dummy-bar," which is placed in the middle, and is withdrawn when hauling the fire. The flues are composed of about 160, two inches in diameter and about twelve feet in length, giving a total heating surface of about 1,000 square feet. Another set of two-inch tubes traverse the fire-box, they are attached to the front of the fire-box flue sheet about two feet from the grate, and, passing upward, are attached to the crown sheet about sixteen inches from the front fire-box sheet. There are four of these tubes in the width of the fire-box, and are attached to the fire-box sheet by screwed ferrules; on top of them are placed a number of fire-brick slabs three inches thick, extending from the tube plate up to within twelve inches of the crown plate. The fire-box stays are spaced about four inches apart. The stay-bars for crown-sheet consist of two bars one inch apart, ⅝ inch thick, and four inches deep, recessed slightly on the underside at the ends to receive the upper edge of the side plates of the fire-box. The stay bolts are ⅞ inch diameter, with square heads, the body of the bolt inside of the head being slightly tapering, and the hole in crown-sheet made to fit it. Between the top of the crown-plate and the underside of the stay-bar is ⅞ inch, and this space is occupied either by a brass distance-piece at each bolt, or by a washer. Similar washers are employed at the top of the bars. As before stated, the tapering portion of the boiler being oval, this part is stayed with three **T** bar stays four inches by ⅝ inch, the first one 2½ inches from the fire-box flue sheet and the other two six inches apart from center to center. They are riveted to the sides of the boiler through the sole plates at the end of each stay. Between each pair of roof stays a tie-rod ⅞ inch in diameter passes across the boiler and is screwed into and riveted to the shell, and every alternate roof stay is attached to the boiler by two braces, each consisting of a short link passing between each pair of roof stays, and pinned to the latter at the lower end, while the upper is connected to a pair of braces 2½ inches by ⅝ inch bolted to a double angle iron bracket riveted to the boiler shell. Where the steam dome comes, these braces are replaced by single rod 1¼ inch in diameter, forked at the lower end to receive the link, and riveted to the dome at the top by means of a palm.

Mr. Rogers was the first in America to adopt, and to establish by adoption, on the large scale of his own business, the present proportion of boiler for a given cylinder. He enlarged the grate area and heating surface liberally. He was the first to establish the six-foot wheel in general use for express

(*Continued on page 12.*)

REDUCING VALVES.

—THE—

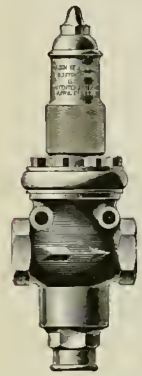
MASON REDUCING VALVE

—FOR—

CAR HEATING

is used by nearly all the leading railroads. It is also the standard used by the Martin, Sewall, Standard and Erie Car Heating Co.'s, who used 1,500 last winter. We guarantee it, and send it on trial.

AIR BRAKE GOVERNORS.



The accompanying cut shows our

NEW PUMP PRESSURE REGULATOR FOR AIR BRAKE PUMPS.

During the past year we have thoroughly tested them on engines of the Boston & Albany, Fitchburg, and several other railroads. They have not required a particle of attention during this time. We now guarantee them. As the air pressure chamber is entirely separate from working parts, any dirt in train pipe cannot get into working parts. Weight, 7 lbs.

We make these so that no extra fittings are required for applying to the air pumps on brake systems.

SEND FOR ONE ON TRIAL.

COMBINED REDUCING VALVE & TRAP.

This device has been put on the market for use on each car where it is found to be necessary to carry a pressure of about 40 lbs. on the train service pipe, and then reduce the pressure separately for each car for heating. This valve not only reduces the pressure, but traps the condensation, thereby avoiding the necessity of buying both trap and reducing valve separately. It is fitted with couplings, and occupies scarcely more than the space of a globe valve. **IT WILL NOT FREEZE.**

Any of above goods sent on trial by

MASON REGULATOR CO.,

10 CENTRAL ST., BOSTON.

In order to insure prompt delivery when the heating season arrives, we would request that railroads favoring us with orders, do so at earliest convenience.

passenger locomotives. He was the first to adopt the present form of boiler, the elevated crown of fire-box, the rounded corners and double domes. He established the link motion as a standard element, making it in its adjustments superior to any other valve motion, and in workmanship one of the best points in the American locomotive. He adhered to the outside connections, and placed the cylinders horizontally in all his engines; he improved on the previous cylinder fastening, making it both lighter and stronger. He was the first in America to insist upon and to practice the counterbalancing of the entire reciprocating parts; the first to thoroughly protect the cylinders and valve-chests from radiation.

The spread truck with center bearing was established in its most approved form in the Rogers locomotive. The expansion brace now used in al American locomotives for fastening the boiler was due to Rogers.

From the above it will be seen that while, up to 1850, there had been adopted many dissimilar patterns of locomotives there was since that period a steady assimilation of style, until in 1860 there became in America one well-recognized standard of locomotive, not only for a single class of traffic, but, indeed, for nearly all classes. This is the conventional eight-wheeled locomotive, with four drivers and a truck frame; and in its leading details there is an almost exact agreement in the practice of the different builders.

A One-Dollar Library.

The writer recently met a young fireman who had served in that capacity less than two years, and on a smdl road. He asked a number of questions about sight-feed lubricators and air-brakes that convinced us that he was pretty well posted on these devices, and we wondered at it,,as neither device was in use on his road. A little questioning developed the fact that he got his information from circulars of the manufacturers.

The writer spent an hour in this young man's room, and there inspected his "library"—which he laughingly called it.

This young man is away from home, but supports his mother, and has all he can do to make both ends meet; but there is something in him besides days' work, and we feel sure that he will eventually make his mark.

The only ornament in his room is a picture of his mother, and beneath it the words, written by himself: "To love, honor and obey." There is a beacon light that will keep him off the shoals that wreck the lives of so many young men.

On the table there were well-worn copies of Forney, Sinclair, Alexander's Ready Reference, and a time card. On a shelf, two years of the *Fireman's Magazine* were piled up, all the copies of THE LOCOMOTIVE ENGINEER, and a few odd papers he had bought from time to time. In his trunk was the "library," and it was arranged and classified in good shape, all matter on a subject being together.

He said that he set aside $5 per year for papers and books—could not afford more—and when he saw a new device mentioned that was in his line of business, he sent for circulars if he could not find them around the office of the master mechanic.

He had quite a collection, and had made good use of them. Said that he got a good deal of information from them, and that the whole "library" cost less than a dollar. He knew more by far about the details of the air pump than does many a fireman who has sat within hearing distance of one for three years—and was deaf—and more than some men who are daily handling the 3-way cock, and making passengers sea-sick.

Our English Brothers—Real "Twins."

We are indebted to Clement E. Stretton, C. E., Leicester, England, for copies of the *Association of Locomotive Engineers and Firemen's Monthly Journal*, published at Leeds.

This association is a sort of a combined brotherhood with benefits. There are regular entrance fees and monthly assessments, and benefits are paid for accidents, sickness, death of member's wife, old age—according to length of time a member—legal defense, discharge, allowance while suspended, and if a delegate is reduced, his pay is made good till he is restored; if discharged he receives £100 ($500), and fifteen shillings per week while seeking employment. They evidently do not intend to let their delegates be discharged. They employ a consulting engineer and a firm of solicitors to protect them, and see that justice is done them in all investigations of wrecks, etc.

Their prospectus states:

"The objects of this society are to form funds, by entrance fees and weekly contributions, for the relief of its members in sickness, incapacitation by old age, or accident, from following their profession or calling, by paying a sum of money at death of members or their wives, and for the relief or maintenance of members when on travel in search of employment, or when in distressed circumstances, and to advance the interests of its members in their various professions and callings, by procuring a reduction in the excessive hours of labor, regulating the speed of trains, the adoption of modern improvements for the general safe working over all railways in the United Kingdom, and generally in such other manner and to such extent as the executive committee may determine.

"Those men who do not wish to join for full benefits, may join for trade purposes only."

The *Journal* is a 32 page magazine, and devoted to the order and its members. We are glad to place it on our exchange list.

A Direct Guarantee for Journal Bearings.

The well-known manufacturer, D. A. Hopkins, has now under way at his factory, journal bearings to equip 7,500 cars, for which his bearings were called for in the specifications under the terms of a peculiar guarantee. It was agreed between Mr. Hopkins, the car builders and the company for which the cars were being built, that Mr. Hopkins should be directly responsible to the road, and not to the car builders, for the performance of the bearings in service. The plan has the advantage of enabling the railroad to put its finger directly on the guilty party, if the bearings prove unsatisfactory.

The *Railway Register* and the *Northwestern Railroader* are fixing up some changes in railway terms for use both in England and this country; they propose "station" for "depot," "stoker" for "fireman," "car" for "carriage," and "*locomotor*" in place of "engine driver" or "engineer." There is about as much sense in calling a locomotive engineer a mocolotiveer executioner, a locotitioner or a billy-goat, as a locomotor. If any change were possible from the English "driver" or the Yankee "engineer," it should be "locomotive runner," or simply "runner," much used by the men themselves; but even that would be hard to grind into use.

LOCOMOTIVE ENGINEERS AND FIREMEN
AND TO
LOCOMOTIVE MAINTENANCE AND REPAIRS.

VOL. II, NO. VII. NEW YORK, JULY, 1889. $1.00 per Year. or 10c. a copy.

Compounds.

While the compound locomotive now at work on the Pennsylvania is awkward and uncomfortable to our enginemen, it is acknowledged by all that she does do well on a long run, has made up time on the runs between this city and Philadelphia, and burns on an average two to three tons of coal less than our standard engines on a round trip. There is, no doubt, some economy in the compound system, and when a locomotive of good design, adapted to our service, with but two cylinders, and arranged to use high pressure steam in both at will, is put on trial, it will, we believe, meet with success. A cast-iron man could not stand to ride the Webb over our rough tracks.

Historical Locomotives.

EIGHTH SKETCH.

The locomotive shown on this page was one of three remarkable little engines that had a great deal to do with the reputation of American-built machinery abroad.

They were extra finished models, one fourth actual size, made at Philadelphia, Pa., by William Norris, founder of the locomotive works that bore his name, and one of the most progressive and enterprising designers and builders of locomotives during the first thirty years of their use on this continent.

One of these little locomotives was presented to the Emperor Nicholas of Russia, one to the Archduke Francis, father of the present Emperor of Austria, and one to Louis Philippe, king of France.

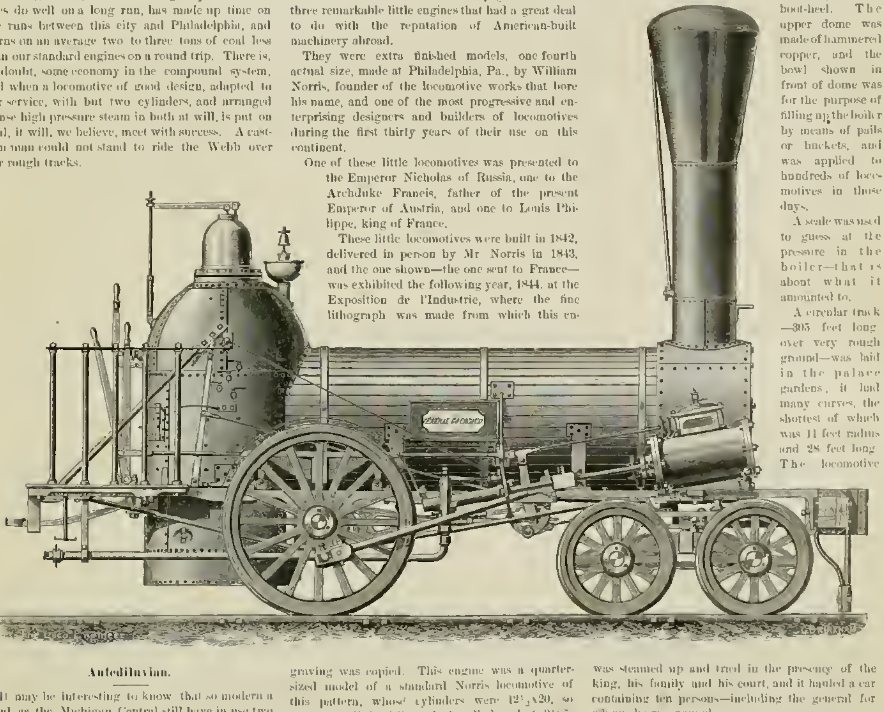
These little locomotives were built in 1842, delivered in person by Mr Norris in 1843, and the one shown—the one sent to France—was exhibited the following year, 1844, at the Exposition de l'Industrie, where the fine lithograph was made from which this engraving was copied. This engine was a quarter-sized model of a standard Norris locomotive of this pattern, whose cylinders were $12\frac{1}{2}$x20, so that these little fellows had cylinders but $3\frac{1}{4}$x5. The guides were round bars, the valve motion being the drop hook, full stroke, plain valves were used, and no provisions made for cutting steam off short. An extension of the valve stem went to the cab on each side, and connected to "starting bars," both being arranged on the right side of the foot plate—it was before the day of cabs. These levers worked all the time when the locomotive was in motion. Drop hooks were used, the reverse lever, which is shown in front near the gauge cocks, merely rocked the U-shaped tumblers shown just under the rocker arm, each end of these U's carried a roller that supported the hook, and when one end lifted up the go-ahead hook the back-up hook dropped down and was "hooked on" by moving the rocker by means of the starting bar in the cab. The boiler was what was known as a "dome boiler," and had a half-round fire box—the shape of a boot-heel. The upper dome was made of hammered copper, and the bowl shown in front of dome was for the purpose of filling up the boiler by means of pails or buckets, and was applied to hundreds of locomotives in those days.

A scale was used to guess at the pressure in the boiler—that is about what it amounted to.

A circular track—305 feet long over very rough ground—was laid in the palace gardens, it had many curves, the shortest of which was 11 feet radius and 28 feet long. The locomotive was steamed up and tried in the presence of the king, his family and his court, and it hauled a car containing ten persons—including the general for whom she was named.

It was the first time that a locomotive had been tried in France on uneven ground—such as would be encountered in building across country—and proved the claim of the American designer, that no such expensive permanent way was needed as the then, French practice. King Louis extended to Mr Norris the thanks of France, invited him to establish works in the country and take charge of roads.

Quite a number of locomotives of this design were then ordered, and were built in the Philadelphia shops for the French Government, and the first one was named the same as the model—General Gourgaud—and was just like her, except that it was four times as large. The little locomotive



Antediluvian.

It may be interesting to know that so modern a road as the Michigan Central still have in use two hundred locomotives not provided with any kind of cab oilers, the firemen being obliged to go out to chests to oil. About twice per year a man is knocked off by the snow and killed. Inside oil cups are now being put on as fast as the engines are shopped—thanks to an intelligent railroad commission. Outside oilers have a right to a place in history, but not on locomotives in use to-day.

The Canadian Pacific's new moguls have lunch pail boxes in the roof of the cab over the gangway.

"Jack the Ripper" now carries a standard P. R. bell—the laws of New Jersey require it.

given to the Emperor Nicholas was as well received, and the writer has been allowed to read a letter from the chamberlain of the Czar, accepting the present of the distinguished American engineer who "prayed the privilege of doing homage to the Czar," and directing that he be presented with a "golden ring enriched with diamonds," a request to assume control of the road between St. Petersburg and Moscow, and granting Mr. Norris many favors and conferring many honors.

Our energetic countryman was not seeking a fat position in charge of a Government road, but a chance to introduce American locomotives. At the Court of Austria he was still better treated, and he was induced to establish large works in Vienna to build these locomotives, and was given charge of the Vienna & Trieste road—then the most important in the kingdom.

Mr Norris had these works running and turning out locomotives in 1847, but the opposition to "foreign ideas," and the intrigues of opposition works got him into a dispute with the Government over a lot of locomotives ordered from him, payment being refused after the locomotives had been in use for from six to ten months, until Mr. Norris became disgusted and quit the business.

He also established a large factory at Paris, and was about to commence turning out locomotives when the revolution of 1848 came on, depriving Louis Philippe of his throne, exiling him to England, and wiping out almost every form of industry, locomotive building with the rest.

While some of our earlier roads imported a few locomotives from England, Mr. Norris paid them back, for he went over there and took double the usual load for horses up the great Lickey inclines, a feat that was considered impossible with a traction engine—this exhibition secured him an order for twenty engines for that work.

He built 150 locomotives for Germany and Austria, also a number for France, Russia and Italy. This little engine deserves a place in history as showing the entering wedge of American industry, ingenuity and ability that was fast gaining the upper hand in European locomotive design and building, only checked and hindered by the shifting fortunes of war, and finally wiped out by the scourge of revolution and anarchy.

Indicating Locomotives.

By Cyrus F. Richmond.

SECOND PAPER.

There are several expert mechanical engineers who have written much about the indicator and its uses, and have done it so well that it would seem unnecessary for a junior at the business to attempt to give another description of it; yet I have found that a great many locomotive engineers and firemen have never given the subject attention. Some never heard of such a thing, too many of them are afraid it is beyond their comprehension, and skip by everything they see in a paper or book that looks like a shoemaker's last to them. To those who know all about the indicator, this paper may seem like a lesson in the "card class"—I mean the days of short pants—and I hope they will bear with me for the sake of some reader who has not had time or opportunity to make a study of this branch of engineering.

The indicator is an instrument for registering the pressure of steam in the cylinder of an engine throughout the stroke of piston. The figure registered is called a card or diagram, from which is computed the mean effective pressure; that is, the average steam pressure forcing the piston during the complete stroke one way, or in one direction, minus the steam pressure that holds it back.

Although there are several makes of the indicator, they are all constructed on one general plan, namely, a steam cylinder and a paper drum. The steam cylinder is so arranged when applied to an engine as to receive the steam whenever the engine receives it, thus forcing the small piston within, up, which, in turn, communicates a straight line motion to a pencil, which is made fast to an arm.

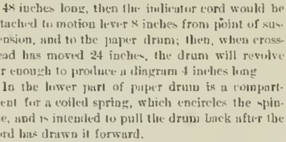
The movement of piston is multiplied by various devices, so that when piston has moved up but one-quarter of an inch, the pencil will move an inch. (I might add that the proportion is not the same in all makes of indicators, but this is immaterial, as it is only done to obtain a suitable size diagram with as little movement of piston as possible.) Above the piston is a spring of very high tension. They are made to some known tension, and numbered accordingly. The number of spring denotes the pressure of steam recorded when pencil has moved up one inch. For example, when a number 80 spring is used, it means that in one inch of height of diagram from atmospheric line there is 80 lbs. pressure of steam, and with a number 60 spring there would be 60 lbs. pressure of steam, etc.

An arm is attached to the outside of steam cylinder, on which is mounted the *paper drum*, which is simply a cylindrical tube or shell, so constructed as to rotate with the motion of piston in engine. This motion is imparted to it by means of suitable levers, and taken from the crosshead of engine, and is reduced to any required movement that is within the range of size of drum used. For instance, the movement of crosshead is 24 inches, and a diagram is desired 4 inches long, our motion lever is 48 inches long, then the indicator cord would be attached to motion lever 8 inches from point of suspension, and to the paper drum; then, when crosshead has moved 24 inches, the drum will revolve far enough to produce a diagram 4 inches long.

In the lower part of paper drum is a compartment for a coiled spring, which encircles the spindle, and is intended to pull the drum back after the cord has drawn it forward.

The paper, or card, as it is called, is wrapped around the drum, and held in place by a slotted bar, called a finger bar.

Now it can be readily seen that, with the pencil point touching the paper on this drum, and the



pressure of steam from cylinder of engine forcing the indicator piston up, which, in turn, communicates a straight line movement to pencil, and the drum being moved or rotated simultaneously with the crosshead of engine, a correct diagram of the steam pressure in cylinder of engine will be drawn on paper.

We will assume that the piping has been arranged, and indicator attached, as shown in the May issue of Locomotive Engineer, then, after paper is put on drum, we start the drum in motion by releasing the dog or ratchet, open the three-way cock just the least bit, and count the revolutions by the exhaust of steam from a little hole in the three-way cock. After some practice one will be able to count them correctly, by counting for 15 seconds and multiplying by 4, to obtain number of revolutions per minute. After this is done, close the cock and draw the atmospheric line, then turn the cock down and draw the diagram from back end, being careful not to allow the pencil to run over more than once, then turn cock the other way and draw diagram from front end of cylinder, then stop the motion of drum and take card off, write the time and number of revolutions, steam pressure in boiler, and the notch that the reverse lever is in on the card, and you have sufficient data to calculate the horse-power from. The size of cylinder and such data need not be taken into account until you have finished taking the cards.

Of course the shape of diagram will depend entirely upon the way in which the steam pressure in engine acts, for the indicator is in direct communication with it; so, if the steam were admitted at the beginning of stroke, and admission continued to the end of stroke, then exhausted, the figure would have four right angles, or be *square*, as some would say. In practice this is not done, so we will try to represent a diagram in which the steam is admitted at beginning of stroke, and valve closes when piston has moved but eight inches, exhaust taking place when piston has moved 18 inches. It must not be understood that this card was taken from an engine, as its purpose is to simply show what the various lines are called, and what we learn from their shape.

The straight vertical line, at the left of figure, is drawn on card to show the amount of clearance space filled with steam, and is called the *clearance line*. The distance from this clearance line to the beginning of diagram represents the space filled with steam, from piston—when at end of stroke—to the valve face. The straight vertical line in diagram is called the *admission line*, and its height, from atmospheric line, represents the pressure of steam in cylinder of engine at beginning of stroke. The horizontal line at top of diagram is the *steam line*, and in this case shows that steam was admitted to cylinder of engine while piston traveled six inches of its stroke, and was then abruptly cut off.

The curved line at top of diagram is called the *expansion curve*, and each successive height from atmospheric line represents the pressure of steam forcing the piston ahead, and, as it is losing its force in doing so, the pressure drops, consequently the pencil. It will be seen that, should the exhaust not occur until the piston had reached the end of stroke, that there would still remain considerable steam in cylinder, and this would tend to hold the piston back when making its return stroke; so exhaust occurs at sixteen inches of stroke, and we have another change in direction of diagram, and this line is called the *exhaust line*. Would say that in reality this line extends back to the admission line, for the exhaust does not close—in this case—until the piston has reached the end of stroke. But the bottom line is called the *back pressure* line, and its height from atmospheric line shows the amount of steam that remains in cylinder, and is acting against piston on return stroke. The line below the diagram is called the *atmospheric line*, and is drawn when there is no steam in cylinder, and represents the pressure above a perfect vacuum, which is 14.7 lbs. Would say that this line corresponds to the zero on steam gauge.

Origin of the Variable Exhaust.

Ross Winans, of Baltimore, patented in the '40's a variable exhaust nozzle, but had any amount of trouble in defending his patent, Wm. Norris, of Philadelphia, having built many of them before Winans' invention. We recently had the pleasure of reading over some old letters on this subject that passed between Mr. Norris and the Hawthorne Engine Company of England.

They applied it in 1839, and built most of their early engines with it, and furnished the drawings to Mr. Norris in 1842.

The opening of the blast nozzle was varied in these old engines by turning a hand-wheel that operated a bell-crank by use of a worm gear, raising and lowering a plug in the pipe.

A New Disease.

The new London & Northwestern Railway "racing" locomotive "Teutonic" has not proved such a brilliant success as was anticipated, as when it was attached to the 3.45 P. M. express from Crewe to Manchester, on Saturday week, it "jibbed," and could not be got to start, and subsequently had to be ignominiously taken back to its stable, and replaced by a "jumbo," which ran off with the train forty minutes late.—*R'y Herald* (London).

Say, neighbor, what is "jibbed"?

Master Mechanic J. N. Lauder, of the Old Colony, recently made the statement before the New York Railway Club, that to Wm. Mason and John P. Laird belonged the credit of spreading the forward truck. He put the time as 1852. There is little doubt that to Wm. Norris, of Philadelphia, belongs the credit of first spreading the truck wheels and placing the cylinders horizontal. We have before us a lithograph of a Norris locomotive, made in 1850, with this arrangement—this was before Wm. Mason commenced to build locomotives.

An Improved Drop Pit.

Any kind of a drop pit is an improvement over the old-fashioned "slings," still much used in the East, especially in New England, for removing driving wheels and trucks; and a good transfer jack is an improvement over a drop pit.

Wm. A. Foster, Supt. of M. P. and M. of the Fall Brook Coal Company's road, has devised and has in use in his shops at Corning, N. Y., a very neatly arranged and efficient set of hydraulic cylinders to do this heavy work.

Fig. 1 shows the general plan; two gauges of track are laid over a pit—one the regular gauge of 4' 8½", and another track with a gauge of 8' 9". On this track runs the trucks that are used in place of blocking under the locomotive after her wheels are removed. The drop pit itself is as wide as the widest track, and the rails across it for the 4' 8½" track are removable. In the center of this pit is planted the large cylinder, as shown in Fig. 3, and in detail in Fig. 4. As all sizes are given, no reference will be made to them, suffice to say that at 90 pounds of water pressure this jack will lift eight tons. A "pulling cylinder" is hung up overhead, as shown in Fig. 1, and by using one or both of the pulley blocks shown, a dead engine can be pulled back and forth over the pit at will, so that it is no trouble to place her in any desired position.

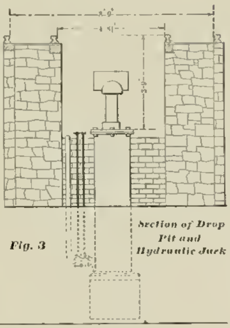


Fig. 3 *Section of Drop Pit and Hydraulic Jack*

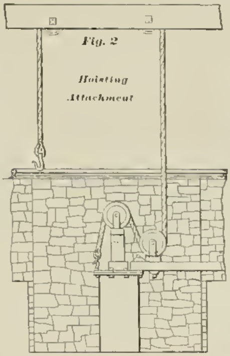

Fig. 2 *Hoisting Attachment*

Fig. 4

Fig. 5

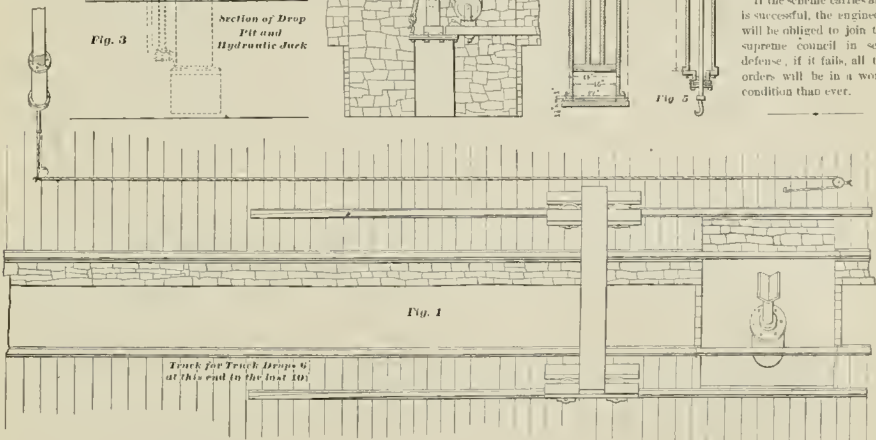

Fig. 1

When in position the big jack is put to work, and its forked head is forced up and embraces the axle in the center, the dummy truck on the wide track—which is slightly inclined—is run up under the load, the section rails over the drop pit are removed, and the pair of drives let down into the pit, the engine moved off of the pit, the wheels lifted, the rails replaced and the wheels rolled away.

By removing the V-shaped head, and placing a pulley on the piston, as shown in Fig. 2, a very powerful hoisting attachment is made.

The pulling cylinder, as shown in Fig. 5, is a very useful lift for lathes, planers and presses—it will lift two tons with 90 pounds pressure. The arrangement of water and exhaust valves is very plainly shown in Fig. 2, and, as all sizes are given in the drawings, a duplicate pit can be made without further drawings by any of our readers so inclined.

The details of this rig are so ingeniously worked out that two men can remove or replace all the drives and trucks under a locomotive with very little trouble and no exertion.

How to Set Non-Lifting Injectors.

On a very few roads they use non-lifting injectors only, and they give good satisfaction.

They are not so quick on the start as a lifting injector, but they are much simpler, cost less, and require less for repairs. They have another advantage, generally overlooked, and that is the fact that they do not fill up with scale as badly as lifters.

We all know that injectors scale up ahead of the combining tube—never at or back of the steam tube; this is because the heat deposits the foreign matter in the water upon the interior of the injector—just as a teakettle is coated on the inside with lime. When an injector is shut off it is hot, and any lime or other matter of a like nature is baked upon the interior by the heat.

Now, the non-lifter is below the water line of tank, and when shut off the overflow is closed, and it immediately fills with cold water, and there is very little, if any, deposit.

The main objection to them is this fact, that the overflow must be closed—it is often forgotten, and the water wasted.

One of the best posted men in the injector business proposes that the overflow pipe of the non-lifter be brought up above the tank level, so that it will stand full of water, then the instrument could be easily started, the overflow would be up where a man could see it, and the overflow cock would never have to be closed, except when it was desired to use the heater. We would say in this connection that the overflow cock should be so arranged that, when shut, it would open the bottom of overflow pipe to drain it, thus preventing a freeze-up.

The best non-lifters are now made so that the tubes can all be taken out without disturbing the pipe connections, so that repairs would be cheap, and the nuisance of a shower bath arrangement in the cab would be avoided.

Put a long overflow pipe on that left-hander that you never use, and see if it don't work as good as any other.

Federation.

Federation is an accomplished fact. The firemen, brakemen and switchmen are now united under one supreme council. The constitution is a secret one, but we have it upon good authority that it is a very fair one withal, and fully provides for every emergency. It will be a difficult matter to order a strike under its rules, and can only be done after several other expedients—fully provided for—have failed.

In our estimation, the only question of success in any scheme of federation is the loyalty and staying qualities of the parties to the contract.

That federation is right, goes without saying. This arrangement will deprive the engineers of the co-operation of the firemen in case they (the engineers) choose to strike, as they will remain neutral—not running engines as scabs—but firing their regular engines until called out by the supreme council.

The several orders remain intact, and use all their present machinery to settle their troubles, using the grand federated body only as a court of last resort.

If the scheme carries and is successful, the engineers will be obliged to join the supreme council in self-defense; if it fails, all the orders will be in a worse condition than ever.

In a run of 59 miles on the Bound Brook line, the "Strong" engine, "A. G. Darwin," took four cars over the line in 73 minutes. The same day a standard engine took the same load over the line in 65 minutes, burned less coal, evaporated less water, carried 25 pounds less steam, and weighed over 30,000 pounds less herself. The question is now being discussed, why the engineer did not let the Strong go.

The Pennsylvania Railway lost 33 locomotives in the recent floods at Johnstown, 27 of them have been recovered, but are almost total wrecks. The tenders, being light, were carried far below the locomotives, and are not worth picking up.

William Norris, grandson of the founder of the Norris Locomotive Works, has become interested in the American Supply Co., Kansas City, Mo. They can furnish everything from a spike to a trunk line.

The E. T. V. & G. are running a six inch single nozzle in their consolidations.

Ride on a Fast Engine.

The writer had the pleasure, on June 13th, of a ride on one of the new fast express engines of the N. Y. C. & H. R. R. between this city and Albany. Engine 677, Archie Buchanan, engineer, Fred. Schenider, fireman.

Angus Sinclair, of the *National Car and Locomotive Builder*, sat in a little dog-house in front of the left cylinder, and took indicator diagrams, while chief draftsman, Phil. Lonnergan, and the writer, took turns at collecting data and cinders in the fireman's corner.

The engine had seven heavily-loaded sleepers on the "special", time from New York to Albany, 3 hours and 20 minutes—an average speed of 42.9 miles per hour.

Engineer Buchanan is a remarkably even runner, making his time with very little manipulation, most of the distance being made with the throttle a little over half open, and the reverse lever in the fourth notch from the center.

At Hudson the train was delayed on account of a hot-box, and left there eight minutes late, seven minutes of this time was made up between there and Albany—28 miles—a speed of 59 miles per hour being made, with wide-open throttle and lever in fifth notch.

The engine is Mr Buchanan's latest design—is a heavy 8-wheeler 19x24, with a wagon-top boiler with smallest ring 63 inches in diameter. This locomotive steamed remarkably well, and rode better than any engine of her size we have ever been upon.

There is in use on this engine a steam jet to prevent the throwing of black smoke. The best smoke-preventer we know of is an intelligent fireman, and the young man on the 677 is of this class. The fire-door has a very large damper, and an inside deflector that also assists in the prevention of smoke.

Webb's Double-Barreled Boiler.

Mr. Webb, designer of the compound locomotive now running in this country, has invented, built, and put in service a new form of boiler, something on the Strong style—only worse.

He uses two fire tubes, entirely surrounded by water, but one is above the other, so that the back head of the boiler looks like an exaggerated figure 8. The fire door is between the two tubes, and the lower tube carries the grate, the hot gases return ing toward the fire door and going into the upper chamber—which serves the purpose of a combustion chamber—and into the flues.

The device has some of the heads corrugated, and is stayed only in the central part, where the two tubes are connected, and over the top tube, which is flattened on top and supported by crown bars, near the tube sheet.

The device abounds in Adamson joints, seams, and peculiar shaped throat sheets.

It is being tried on a "goods" locomotive, and will, of course, be a great success—such inventions have to be successes on the home road.

The excuse for going into this form of box is given as the high price of copper. The fact that steel boxes of enormous size are standing, and have for years stood 150 pounds per square inch in America, does not prevent the English mechanics from declaring it necessary to put it into different shape to make it a safe fire-box material.

Angus Sinclair recently indicated several of the big engines on the New York Central road. Strange to say, this is the first time an indicator has been used on this system. The indicator is as old as steam engines, and in every-day use in almost every branch of steam engineering; that it should be unknown upon one of our first and greatest trunk lines seems a wonder.

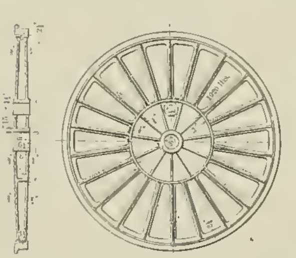
Every month we are obliged to leave over long letters intended for correspondence, this we very much dislike to do, but limited space compels it. We will ask our contributors to try and have all their say in articles not over two columns long—wait till winter; it is too hot to read five-act stories now.

One of the Earliest Cast-Iron Driving Wheels.

During a recent very pleasant visit to Isaac Dripps, of Philadelphia, we came into possession of the original drawing for the first cast driving wheels placed under the 8 foot wheel engines on the Camden & Amboy road in 1849.

This drawing was made June 14, 1848, by Mr. Dripps himself, and was designed to take the place of the wrought-iron wheels imported for the John Stevens (shown in February issue), which broke the spokes after a few trips. The wheel shown has a webbed disk out as far as the crank-pin making a very strong section and leaving the spokes all of the same length and weight and bearing the same load and strain. These wheels were used as long as the locomotives ran, and never so much as cracked a spoke; the spokes were of the I section, afterward much used by the Norris Locomotive Works. They were hard wheels to clean, but were strong and light. The Stevens' wheels were filled in between the spokes with thin wooden boards, to facilitate cleaning. Mr Dripps was the first man to run the John Bull on the Camden & Amboy road, yet occupied the position of master mechanic then. The first trip on the road with an open chimney set the country afire, and the experiments then entered into, that led to the adoption of the cone and netting, are interesting.

Mr. Dripps was master mechanic for the Stevens' brothers, and of their road and steamboat service, was Superintendent of the Trenton Locomotive Works for five years in the forties, and was one of the first master mechanics of the Pennsylvania road,



the first Supt. of Machinery of the P., Fort Wayne & Chicago, and for many years Supt. of M. P. for the Pennsylvania at Altoona He commenced with the earliest forms of imported English engines, and saw, assisted at, or himself developed many of the improvements made from 1831 to 1875.

A history of his long and eventful life would be as interesting as a novel, but it could not be written without writing a history of American railroads and American development of the locomotive.

Mr. Dripps lives in Philadelphia, happy in the possession of all his faculties, and is an open mine of information and experience to young men interested in railroading.

An Electric Signal.

F. H. Young and Frank I. Davis, of Port Morris, N. J., have invented an electric blocking signal. The plan provides for poles along the line of road, with a a clock dial upon them; this dial has the usual figures, and but one hand—the minute. The clock is provided with works that run continuously, but the spindle carrying the hand does not turn, except when held against a plate by a horseshoe magnet.

A tripping device beside the rails moves this plate back against the magnet every time a train passes. When a train passes the target, the hand releases from 12, where it usually stands, and is revolved by the works until it marks 45 minutes on the dial, or is released by another train.

An engineer passing the target can see how long it has been since a preceding train has passed.

The inventors claim that, by using a line of wire and batteries, the device can be rigged to tell how long since a train has passed a signal post *ahead* of the one displaying the signal.

All that is wanted is a device that will tell that the preceding train has passed the block ahead; any device that will do this automatically will be a successful device, but an arrangement that calls for winding a clock at every block, every day or every week, subject to all the ills of cheap clock gears, that depends for action on magnets or batteries, and that is operated by triggers along the rails, has many objections, and many chances to fail in bad weather.

Several of our subscribers have evinced some interest in this invention, and have asked our advice as to its usefulness.

We think it ingenious, and no doubt able to work nicely under favorable circumstances, but think it depends upon too many contingencies for permanent success.

The Inventor of the T-Rail.

American railroad men are so thoroughly familiar with the common T rail that the shape excites no interest at all. Yet it may be of interest to them to learn something of the difficulty its designer experienced in trying to introduce it.

In 1830 Robert L. Stevens went to England to study the railroad problem, and while there ordered the locomotive John Bull—the first locomotive to run on the old Camden & Amboy Railway On the trip over, Mr. Stevens began to study on the most desirable form of rail, and busied himself in whittling out model rail sections, finally hitting upon what has since become the standard rail of the continent. There were at that time no works in America that could roll rails, and Mr. Stevens ordered a lot of rails made to his model.

He was informed that such a section could not be made, and the work was refused, but he persisted, and finally leased a mill, giving heavy bonds to return it in as good condition as when received, and manufactured the rails himself.

Correspondence

Special Brand of Sand.

Editor The Locomotive Engineer.

In May number you illustrate a device for preventing sand pipes from clogging, it shows a fine stream of sand running just to a queen's taste I have had one of those things on my mill, and want to say that the photo was taken for that cut when using pet sand dried at Altoona; not common wet stuff. The bell is almost as good as a common pipe, and don't appear to stop up any worse.

Philadelphia. KEYSTONE.

Pull of Reverse Lever and Setting Eccentrics.

Editor The Locomotive Engineer :

In the December issue, "Primer," of Germantown, Pa., claims that the pull on the reverse lever is caused by the friction of the eccentric in the straps, and that the angle of the links has nothing to do with it. Now, Primer, why does the reverse lever pull very hard when the angle of the links is in the same direction, and not pull so hard when the links are at opposite angles? It is just exactly as you state, that "the angle of the link tends to lift the block in one-half of its travel, and pull the other." When both links are pulling, the reverse lever pulls hard; when one link is forced up and the other down, the reverse lever can be moved towards the center of the quadrant with ease. Primer, which makes the reverse lever pull the hardest, a warm eccentric, or a valve that is dry? I agree with you that it is "better not to know so much, than to know so much that is not so." I have waited for the draftsmen to answer this as you requested, but they don't tackle it.

Then, in May number, C. W. K tells us "to set the engine on the forward center, put the throw of the back-up eccentric down, move it toward the pin enough to give it the amount of lead, and fasten." How far down do you move the eccentric, exactly perpendicular? If so, do you not allow for the lap of the valve also in moving it towards the pin?

Some of us young runners would like to know about these easy and *sure* ways.

Lansing, Mich. C. B. CONGER.

A Good Suggestion on Indicator Rigs.

Editor The Locomotive Engineer.

In Manning's rig for indicators I note the convenience and improvement in putting a wooden extension on the tumbling shaft arm, and noting point of cut-off at the chest instead of the cab. I would suggest that this rig would be further improved by making the rod long enough to reach *by the chest* far enough to allow its being seen by the man on the left side, and making another set of marks on the left side of it for his benefit.

Meridian, Miss. JOS. E. HOWELL.

Criticisms on Honesty.

Editor The Locomotive Engineer:

One prominent feature marks your publication that I have noticed—the absence of controversy. This is, indeed, commendable. Let each reader take his exceptions to himself, and there let them rest. I have no desire to intrude on what should be an iron-clad rule established by the editor; but the last issue of your paper calls up expressions of silent thought and opinion. John Alexander's statement is quite personal, uncalled-for and out of place (in your paper). It should be classed with his wet-nurse story in April issue. Doubt dawns on me that John will not name his last baby "Pete," if it is of that sex. I hesitatingly attempt to use your columns for personal criticism. John made a statement; I hope I can do the same, and fairly say, without fear of truthful contradiction, that he errs. It is true that men may be at fault "talking about each other" during meetings held in their division rooms. This is ofttimes excusable, for they frequently do not meet "to pass the time of day" at other times, but your paper is no place to discuss what is done at B. of L. E. meetings. We expect mechanical notes in a monthly that is devoted to mechanics. I know there are readers of THE LOCOMOTIVE ENGINEER that will agree with me in saying we want more facts about locomotives, and less regarding grievance committees. I want to learn more of the Webb Compound. Your squib in last issue is not satisfactory. If "Jack the Ripper" was pulling the "Paoli accommodation" you should have given us a full report, and not a mere guess; a telegram to and reply from Philadelphia the day you went to press would have advised you if she made the time or not. The absence of side-rods on the Webb is probably one point in her favor. The Strong engine "gets a shot" also quite frequently. As yet I cannot determine what she is doing towards proving the correctness of design. Men in the West know the Strong Duplex No. 444 made the time, and pulled a full train with one-half the steam pressure the "Standards" did. She was no "cabbage cutter," if the Shaw and the Webb are. Mr. E. V. Debs may well feel proud of the several liberal mentions of his name in your last issue. The editor of THE LOCOMOTIVE ENGINEER seems now to concur with Debs in everything, much more so than at the time of the removal of Mr. Smith, M. M., P. D. & E., about one year ago. You rather held up to scorn the Grand Intercolonial International B. of L. E. grievance committee on account of the action they seemingly took. Mr. Debs expressed his ideas in his magazine in a very forcible, logical manner, upholding the men and denouncing Smith, quite unlike your scathing comments—considering the Debs article—as possibly could be. Several favored Debs, many advocated his ideas and endorsed his statement. We expected he would call you to time, he never did, but ought to all the same. We want more "kinks" from practical men. Agitation is an evil, and such matters should be confined to the monthly meetings of engineers and firemen. Your continual allusions to the grievance committee excites some suspicion. I hope you never wrestled with one. Some men think and act as if they thought life was a big joke. Others seem to live for the sole purpose of trying to be as mean as they can, instead of attending to their own business and doing much good thereby. Others want to put the bit in one's mouth, if they fail and can't drive, they explode. If they criticise they do it in a way to attract attention solely, while others would take a different and much more effective course. If your production would give us more facts and ideas, or detail more closely the tests of late designed locomotives, would it not be better and look as if you were not prejudiced? We must be progressive from this time on, for railroad companies are looking to their p's and q's, and the many leaks and small losses. Coal and water, in readiness to be put on an engine, have different values; economical use of fuel will take the lead. Men must educate themselves for the coming of improved locomotives—judging from progress in other lines of mechanical appliances. They have been, in many cases, like the master mechanic on the Erie in 1849—Brant by name—who told Thos. Rogers, when he delivered to the Erie the first link motion engine, "that the links were not worth a damn." In reference to Q. finances you are late with your report, your late trip to Indiana ought to have been made sooner. The writer is convinced, beyond the shadow of a doubt, that the funds were distributed in a business-like way—economically and prudent. You report engineers expressing different opinions. Well, men do frequently trump up a lame excuse for not subscribing for every publication in the market. Some may have offended the representative of your paper, and offered this excuse for not putting up one dollar, and adding their name to your list. He who does so makes a grand mistake, for ideas contained in one issue are ofttimes worth *one* dollar. Mr. Smith, of Delaware, Ohio, wrote several worthy articles for you one year ago, which appeared in your paper. They were good, and I miss his valuable contributions. If the N. P. adopted his heater, will Bro. Phelan advise us of the net results?

The *Scribner's Magazine's* railroad articles did not put enough stress in any way upon the fact that railroad men are frequently overworked. How would it do for you to look this matter up, as you did the grinding and fitting of steam pipe joints? Why not solicit reports from our many friends of the footboard, asking them to state the hours of natural rest they are deprived of each week (inter-state commission N. B.) and the consequent bad results? While this is being done, tell us what you know about the remedy for a hard riding engine, where to look for the many causes, solicit reports from men qualified to suggest effective changes that will remedy the *hard riding obstacle*. Kidney cures are now a profitable invention, and the retail sales are on the increase every year. Can't you help to offset the growing evil? Acknowledgment of the truth is very wholesome. Let us contemplate and reason together; build up and not pull down.

Watertown, Wis. CHAS. E. STRAW.

[This correspondent commends an iron-clad rule, and then asks privilege to break it, and were it not for the fact that we are not only opposed to iron-clad rules, but want all sides to be heard, and *do* favor controversy to a certain extent, we should not publish his article—as it simply challenges our right to criticise B. L. E., B. L. F., or Grievance Committee actions, to honestly say what we believe and to report what we hear.

As we gave our correspondent John Alexander room to say something of the trouble in the orders, and he gave a rather comical view of the case, we let this article appear in answer.

Let us say right here that this paper is run in the interests of the engineers, firemen and railroad mechanics of this country, not in the interests of one class or order, that its editor is a Brotherhood engineer, and a firm believer that all the railroad orders have done good in the past and are capable of doing much more good in the future, but that this paper reserves the right to approve of all the good, and condemn all the bad it can see, both in and out of the orders. There are no strings to us. The curt reference to grievance committees falls short of the mark—our "wrestle" with them has been limited to a job of serving on one. They have gotten the orders into lots of trouble, caused endless dissatisfaction and discontent, and are, in our humble estimation, the curse of organized labor—and we are not afraid to say so.

If a monthly tried to keep telegraphic reports of an experimental locomotive like the Webb, dodging from run to run every three days, forty pages would not contain the report. She has been fully illustrated and described in this paper, and each month since, items given of her service—item in another column is not a guess, simple record of what she is doing. The "Strong" engine was fully described in all the mechanical papers, before this journal was established, and we did not deem it necessary to show up an old thing because another of the class had been built. We have said that we did not believe it was the future engine of the country, because they cost about twice what a Standard locomotive does; they are complicated, heavy, clumsy and very difficult to repair. The "Duplex," that our western engineers know so much about (?), has never equaled a Standard locomotive service of the same weight and carrying the same pressure. (The "Duplex" carried 180, the Standard 140.) The new Strong, the Darwin, has not steamed well, has her nozzles bushed to 3¼, and we simply ridiculed some of the ridiculous claims made for her, and will do so again—when other papers invent another story to praise her other than the "80 miles per hour and holding her back" idea.

The praise we gave to E. V. Debs was no fulsome eulogy, but in each instance was called out by some act of his in the interest of laboring men, or mankind in general. We propose to commend modest worth and ridicule the big head wherever and whenever we stumble onto it. Mr. Debs and the editor of this paper differ on many subjects, but not necessarily on all. He said Smith was to blame in the trouble on the P. D. & E. on general principles. We investigated both sides of the story and found out that there was dirty work on both sides of the fence—and said so. Our subscriber admires the *other* Smith, of Delaware, O. (because he was not assailed by the engineers there), he may be interested to know, however, that they are one and the same Smith.

Our criticisms on the finances of the strike were made in the interests of the engineers' order and with a view to having the laws changed so as to remove suspicion from committee men. In this connection we may say to the cross-examiner of our methods that there never has been a representative of this paper soliciting subscriptions anywhere, except self-appointed men on their home road. When a stranger solicits subscriptions for THE LOCOMOTIVE ENGINEER, put him down as a fraud. The editor of this paper has never asked a man on earth to take it—and never will. We propose to make it so valuable to the class it is published for, that they will *order* it.

The animus of the correspondent is plain; he is not consistent; he wants everything detailed except such as tell any unpleasant truth about the affairs in our order—cover everything up there, ask no questions, make no comments, suggest no changes in the existing order of things—be a clam. Then he goes on to say what we must do, how progressive we must be, studying economy, watching the leaks, etc., etc. If our correspondent will look back over our files, he will see that this is just what we have been teaching. We have advised discussion of things—not men—in the lodge rooms, we have preached progress, study, discussion and self-help—and we are not half through. To answer all men who may think as our correspondent does, we will say that this paper will run along on the line of independence on which it has started, that it will condemn the wrong, and extol the right of everything that is of interest to the men, be it in the lodge room or the general office.

We are not responsible for the private opinions of correspondents, but for every line in this paper the editor has to answer—and will do so, but when we feel it necessary to refrain from criticising the wrong acts of any one man, or set of men, or to extol the doubtful merits of inventions for advertising purposes, we will surrender our pen to some sycophant afraid to say what he thinks and take the consequences.

Every reader of this paper can depend that what is said in it, for or against everything or anything in our line, will be our honest opinions—they cannot be bought, bulldozed or influenced, but we will change them when they are proven wrong.]

Ohio-Built Locomotives.

Editor The Locomotive Engineer:

The locomotives mentioned by your correspondent as "built somewhere in Ohio," were no doubt the old "Cuyahogas," built at Cleveland; many western roads were stocked with them. The Lawrence engine was built at Lawrence, Mass.

Galion, O. OLD TIMER.

About the Swinerton.

Editor The Locomotive Engineer:

In your number for June appears an article signed "Fireman," criticising what I said about the Swinerton locomotive driving wheel in a back number of the *Firemen's Magazine* and to which he takes exceptions I simply wrote about what I saw or had been told by persons whom I have no reason to think were interested one way or another in the device. The action of the engine—or rather of the wheel—and her "pulling" qualities I feel myself competent to pass judgment upon. I have had some experience with undue weight on driving wheels on locomotives. The single-wheeled engine No. 507, built by the Baldwin Locomotive Works, was a case in point. Later on, the engines built by same company, and designed by Geo. W Cushing, Supt. Motive Power for P & R. R. R. Co, was another Their driving boxes *could not be made to run cold.* When I first saw the "Onward," I looked for just such a state of affairs as "Fireman" claims to exist, viz.: excessive weight on driving axles, and, to satisfy myself on the point, felt all the journals of the engine during and at the end of the trips, and found no appreciable difference in the temperature—they were all cold. My authority for statement of weight on the "Onward's" driving axles is the general foreman of shops at Portland. I would much rather believe "Fireman" to be misinformed than that my informant told an untruth. I have met many shrewd Yankees; don't remember ever having ran afoul of a foolish one. It would be supreme folly in the Swinerton Driving Wheel Company to misrepresent the weight on the driving wheels of the "Onward," when 10 minutes on the scales of any R. R. would expose the deception.

"Fireman" says the original weight on the drivers of the "Onward" was 41,000 lbs., and that, as a result, the boxes ran hot; he understands some of this weight has been taken off Does he know how much weight was taken off? and if he does not, how does he know that my statement of the weight on her drivers is not correct?

I will not find fault with "Fireman" because he cannot see the facets on the Swinerton wheel. I have met many men whose physical and mental vision were obtruse, but I have yet to meet the railroad engineer or fireman who ever knew a *flat spot to wear out of a locomotive wheel, driver, truck or tender!* See?

Truth sooner or later asserts itself. If the "faceted" wheel is all that its inventor claims for it, the fact will be manifested; if it is not, experiment will demonstrate that also. I would not have noticed the attack of Fireman on the *device*, had he not made a *personal* reference to myself.

E. J. RAUCH,
Road Foreman of Engines, M E. R W., E. D
New York.

To Set a Slipped Eccentric.

Editor The Locomotive Engineer:

Place the engine on forward or back center, as preferred, on side slipped eccentric is on (it is usually more convenient on forward center, as this brings the set screws forward of axle, and I shall use forward center); if it be the back motion which has slipped, place the reverse lever in the corner, forward motion, loosen slipped eccentric, roll swell to under side and slightly forward of axle, enough to roll off lap and lead; now see that the steam chest gland is tight enough so that valve stem will not move it in passing in and out; make a fine mark on valve stem, even with face of gland, with any sharp instrument, as the point of pocket knife, or anything at hand; now place reverse lever in corner, back motion and roll eccentric forward and upward until the mark on valve stem comes to the same point as before; tighten set screws in eccentric slightly; now place reverse lever in forward corner; if the mark on stem comes to the same point as before, the eccentric is right; if it does not, it will be quite close; if not as close as you would like it, make a new mark, place the lever in back corner and alter eccentric to suit new mark, tighten set screws and the work is complete. To set forward motion, place reverse lever in back motion, roll swell of eccentric above and slightly forward of axle, and proceed as in back motion. I give it in this simple manner, that any engineer with the assistance of his fireman can set a slipped eccentric quite accurately and quick under any circumstances, if he has even as simple a tool as a *pocket knife.* A small, machinist's scriber is a very nice little tool to do this work with, by placing the straight end in the center of one of the gland studs, and marking the stem with the hooked end. L. H. KENYON.

Allegheny City, Pa.

Old Fogy's Canvass.

Editor The Locomotive Engineer.

In the June issue of the *Master Mechanic* one can take pleasure in reading the comments on throttling locomotives, and it is of the same old story of proving it to be facts, by figures, regardless of what the actual results will show when put to a test. Theory nor figures ever pulled enough cars over any road to pay a one per cent. dividend as yet. What the writer is anxious to know is, if the "high science" can be proven by actual labor performed, am of the opinion that it cannot be done. I have made close inquiry on roads where a premium is offered for saving of coal, and the premiums are awarded every month. A performance sheet is published, showing who saves coal and who uses more than the allowance. By following these up month after month, and getting the run of those receiving the premiums nearly every month, and those that run behind on allowance many tons of coal, it gives one a chance to get the dimensions of his man, and how he runs an engine

When you have your men arranged in two rows—one coal savers and the other coal wasters—in the row of coal savers you will not find one "full throttle fiend" out of five "old fogies"; but look in the row of coal wasters, you will find them well huddled together explaining why they did not get any premium, each one having some good excuse—in his mind—why he got left Something like this: "Valves are out—ought to be faced"; "packing all gone—not fit to run", "engine rides so hard—shakes coal all out of fire-box," etc, etc. At the same time the old fogy walks away with his 10, 15 or 20 dollars for not knowing how to run an engine correctly according to rules laid down in our text-books, which are—many of them—written by men that never did a day's work at the throttle, of which they can teach you so much—infallible, and must be correct because it is the true theory of locomotive practice. Now to discuss a question of this kind, and to allow your opponent to make his assertions, and then prove them by his own assertions made at some previous debate, it leaves it a one-sided case. One solid fact will outweigh a whole bookful of "ought to be so's." OLD FOGY.

Germantown, Pa.

[This correspondent refers to the men who regularly earn premiums on the Pennsylvania road. He has made a very complete canvass of the men as to the wide-open throttle plan, with the above results.]

A Man who Remembers the Old Timers.

Editor The Locomotive Engineer:

I see in June number what is written about center of gravity that the C., M. & St P. have a Schenectady, whose center of boiler is 8 ft. 9 in. from rail. What is the object of this? Is it to use large drivers? We have some engines that measure 7 ft. 5 in—we think that is high enough. Is there no danger of such high boilers tipping over when wheels go off the rail, or off end of ties? Are not such high boiler locomotives harder on their springs?

When I first began this business, and I can say for many years since, the study was to keep boilers down as low as possible. "Top-heavy" don't cut any figure now a-days. There is no fear of the result of top heft now. Does this theory hold good over other things, say, on a ship? Do tall masts or spars have any effect on her rolling and tumbling around? Perhaps not. This is on the water, a locomotive is on land, or a rail. *

I note that C. S. C., Milwaukee, asks concerning the old Lawrence locomotives, built somewhere in Ohio. I have long been acquainted with Lawrence engines, but never knew they came from Ohio, was always under the impression they came from Massachusetts. As to the cut-off valve on top of main valve, I never knew of any Lawrence engines with such a valve—but have seen them with a variable cut-off valve working on a separate seat *above* the main valve, and if C. S. C. will go to C., M. & St. P. shop and inquire for Lawrence engines 11 and 12—that used to be their numbers—he will find two engines that used to be of the build I mention; but they were rebuilt to link motions about 1861. They were V hook and variable cut-off, and could run faster with that motion, with less steam, than ever since with the link—and I may say the same of any other engines rebuilt from hook and cut-off to link—who can say different?

One correspondent asks about chilled valves; you don't seem to answer his question just right. Chilled valves and seats were introduced long ago by M. M. Stevens, of the Central Pacific R R, and run for a long time with good success. I have talked with engineers who have run engines with these chilled valves. H. KINGSLAND.

Ft. Scott, Kan.

More Short Cut-off.

Editor The Locomotive Engineer:

Mr. Alexander, after giving us an amusing account of the pleasures (?) of paternity at a late period in life, gives us some of his ideas on the short cut-off and wide-open throttle theory. Mr. W De Sanno has also thought it proper to add his voice to that of Mr. Alexander.

I have a sort of a roving commission to fight for the propagation of right and truth, in any and all fields. I trust that you will grant me space enough to review some of the arguments, statements, and objections raised by your correspondents, to the theory of which I am an ardent advocate, and which I feel assured you would have fairly represented and explained. I am not a believer in running "in the center notch," but do advocate running with the lever as near the center notch as is possible, and in the determination of the proper point to work his locomotive, the engineer has to be guided by the grades, the size of his train, and the condition of the valve gear of his machine. As a rule, no road in the country will send a locomotive over the line without a load, and in nearly all cases this load is just about all that they can get over the grades with. I have found locomotives which were so faulty in their valve gear that they could not be run according to the theory, but when locomotives are sent out to work in that condition, the engineer cannot be held accountable for any waste in fuel or material. In order to get at the best practice of the economical use of steam, let us consider the difference between an old-fashioned stationary engine and the famous Corliss type of engines, which is universally admitted to be one of the most economical of all the various kinds which are competing for public favor. There is no difference in the way in which the steam does its work in the cylinders of the old or the new engines, for in both engines steam is admitted on alternate sides of the piston, to drive it back and forth. In both types of engines we have a governor which regulates the speed, but there the similarity stops; for, while one governs in one way, the other uses an entirely different way. The old-time governor, being adjusted to a certain speed with a given load, keeps the valve open to permit steam to flow to the slide valve, and by it to be admitted to the cylinder Whenever the load becomes less, the speed increases and the governor partly closes the steam valve, thus checking a part of the power there, and wire-drawing the steam, as it is called, and while the slide valve moves just the same as it did before, admitting steam just as far, and cutting off and exhausting at the same points, yet it is evident that we have not near as much power. The governor of the Corliss type is so arranged and connected with the valves which admit steam to the cylinder, as to vary the cut-off just in proportion to the work that is to be done, leaving the throttle unchanged and thus delivering steam, at all times unchecked in speed and power, to the valves, and leaving it to their action entirely to determine the amount of work to be done. This ought to make it apparent that a cut-off in proportion to the work, instead of throttling to the work, is the proper method; and it is the application of this principle which has made the reputation for the Corliss type of engine, and will also give the engineer who follows out the rule, according to the dictates of common sense and good judgment an equally good name.

Now let us see how this principle works when applied to actual practice. On our road we have trains which we cannot pull on less than 7 inches, and sometimes not on that, unless under favorable circumstances. Will Mr. Alexander and W De Sanno please make a note of this as the shortest point of cut-off that we can hope to have in actual practice with full trains on this road! Now, years ago I frequently ran a Cook locomotive at the rate of 15 miles per hour, over a portion of the road, and found that I could make time on 7 inches, and that the pump would keep the boiler supplied. If I was obliged to use the next lower notch (9 inches) to make the same speed, I found that the pump would not supply the boiler, even if I closed the throttle in part. The pump running at the same speed over a given piece of track would certainly force as much water at one time as at another, it is therefore self-evident that by using 9 inches, instead of 7, we are using up water faster, and, if so, that more heat has to be expended, and thus more fuel consumed to produce this heat. Some engineers, however, seem to imagine that, by throttling the steam, they do not admit as much as they would by a full throttle, this would imply a piston moving partly by steam pressure, and partly in vacuum. Natural laws, which tend to destroy a vacuum, forbid the assumption that the partial closing of a throttle only permits a partial filling of the cylinder with steam, for the boiler, being in direct communication with these parts, would send out its steam not only by its expansive force, but even as a supply to fill a vacuum, in the same manner as air will fill all spaces accessible to it. As air cannot enter to fill any portion of this imagined vacuum, steam stands ready and is the substance which does fill this space, and being filled it ceases to be vacuum. Believing, as I do, and so many practical engineers concur, that steam follows the piston to the point of cut-off, no matter in what shape you may place the throttle, I deprecate the idea of running on 15, 13, 11, or even 9 inches whenever 7 inches will make speed and time and make a square exhaust. (While the square exhaust does not help make time, it is as unpleasant to a trained ear as a lame horse is to sight of a merciful man.) Mr. De Sanno views the matter from a machinist's point, saying that he had faced valve seats, which had been cut down one-eighth of an inch in the center, with planer marks still visible at the end of full travel; all of this being done in one trip of 214 miles. Now this was certainly an exceptional case, and I take it as such, for, from the very words which De Sanno uses in his description, I am led to believe that it was the only one as bad as that, which he could find. I am willing to admit that valve seats wear out faster in the center than at the edges by a short cut-off, but attribute this to the fact that, with the short cut-off, the valve does not come in contact with so much of the seat, and as its load is thus carried by a less surface, its attrition is greater. The objection raised by De Sanno, that the pressure on the valve becomes too great by admitting steam with full pressure, and that he actually ran faster by relieving a valve of this pressure, is not borne out in practice, or why should the most approved methods be for an increased boiler pressure, and what would be the use of increasing this if it were good policy to kill it again before permitting it to do any work? Again I would ask which takes the most power to move, a valve under a given pressure 7 inches or 10 inches for each revolution, or in that proportion? The probable answer will be in favor of the short stroke, even if loaded somewhat heavier. The question thus resolves itself into something like this. As valves and valve seats will wear out and require facing under any circumstances, will it be good economy if I wear the faces out once in six months oftener, if I can by this means do my work easier, save labor for my fireman, and put over a thousand dollars into the treasury of the company, through a smaller bill for fuel? Or which is the most $1,000, or $10? These figures are not fancy sketches, but have been verified by actual experiences, and comparison of the fuel bills of locomotives of the same class, doing the same work, and yet showing a balance in favor of the short cut-off and wide-open throttle locomotive of over $2,000 per year. Is this not an item worthy of attention, on a road using a hundred or two of locomotives, and which would form a surplus of a million of dollars on a road employing 500 locomotives? Some roads, however, seem to pay no attention to the fuel question at all, permitting their men to take as much or as little as they please, and not even making any attempt to ascertain the amount consumed by each locomotive, but charging all to a grand total coal bill, and that, with such management, it is not a very small one, follows as a matter of course. By late paragraphs in the press, I see that the Penn. R. Road has adopted a plan of paying each engineer and fireman a certain sum, for all coal saved by the men from a stated adequate allowance, and this will no doubt put all on their mettle, for each one is sure to be rewarded for everything saved, even if he should not be the most economical, and gain a prize, as is sometimes given by other roads to those who have made the best show for a year. VULCAN.

[Our correspondent makes unfair comparisons: there is no similarity whatever between a Corliss engine's valve gear and the link motion. The Corliss gives a full port opening at any point of cut-off—the valve unhooks and drops to its seat. While the exhaust valves, being independent, and not under the control of the governor, allow the steam to follow the piston almost to the end of the stroke. When a locomotive is cutting off very short, the exhaust occurs proportionately early, before the steam has time to do much work when the pin is in position to best convert it into motion. In an ordinary 8-wheeled locomotive, 17x24 cylinder, valve travel 5 inches, lap ¾ on each side, and steam port 1½ inches, cutting off at 6 inches, the exhaust occurs at about 12 inches of the travel. Of course this would depend on radius of link and amount of lead. With no lead at all, exhaust occurs at about 17 inches, and with a lead of ⅛ at 6 inch cut-off, which is about or below the average, it occurs at 12 to 13 inches, and, the valve being line and line inside, compression begins at half stroke, or the point where exhaust occurs.

In cutting off very short the exhaust opens too early, and compression commences too soon. On locomotives having very short eccentric blades, where the lead increases excessively when hooked up, the compression often exceeds the steam chest pressure, and lifts the valve, allowing steam to blow through into the exhaust, making the engines pound badly and ride hard.

With our correspondent John Alexander, we do not believe in full stroking engines, nor yet in working them so close to the center as to make them disagreeable to ride and hard to steam. He says he believes in working the lever where the engine will pull her train easily, clear herself, and not show symptoms of excessive compression, and in working the throttle in any position that will do the work and make the time—and we agree with him.

Correspondent De Sanno was perhaps a little over zealous in saying "the center," when he manifestly meant very close to it, and we do not believe in full stroking to save valve seats, but he has, no doubt, had a great many years of experience, and, like the majority of other men on the road, knows that trains cannot be successfully or economically handled with a full throttle all the time, and speed governed by the lever.

In discussing this subject it would be well for all to remember that wire-drawn steam, as it is called, does not represent the loss indicated by the difference between boiler and chest pressure. In wire-drawing it we have created friction, and friction makes heat. In some recent experiments made in this city by Prof. Denton, of Stevens Institute of Technology, by using a high pressure of steam, and wire-drawing it excessively, it was superheated enough to entirely do away with cylinder condensation.

So good an authority as Prof Rankine called attention to this point several years ago, as a matter of great importance.

With an engine having an early cut off, early exhaust, and therefore excessive compression, it is always necessary to have more clearance in the cylinder. All single-valve automatic engines have more clearance than plain slide valve or throttling engines of good design, and we all know that clearance is a necessary evil, and we want as little of it as possible

Just what our correspondent means when talking about vacuum in cylinders, caused by partially closed throttle, is not clear. He seems to be the first to think of such an idea

We want all sides to be heard in this discussion, however, and invite all those interested to have their little say.]

Pump for Machine Tools.

While at the Schenectady Locomotive Works recently, we noticed that on every machine tool cutting wrought-iron, a pump was used to return the water, oil or suds that ran off the work back to the tank. A very simple pump—which we show in the engravings—is used. The frame is cast in two pieces bolted together, as shown; the shaft, carrying a small pulley, runs in solid boxes, and has on its outer end a head with a slot through it, as shown in Fig. 2. There is a cap screwed on the frame, and enclosing this head. The head turns in the cap, but just clears the top, while it is ¼ an inch or so from the bottom. The head on shaft fills the cap endwise, and two flat bars of iron fitted into the slot in head, and held apart at the center by a small coil spring, make a practically tight packing. The supply or suction pipe enters at one side near the top, and the delivery is tapped from the other side near the top. As the shaft is revolved toward delivery pipe, and from the supply, the wings of the head force the water ahead of them, and the proximity of the head to the top of case prevents its running around to the other side, so it goes up the pipe

These little pumps are easily made, do not wear fast or become clogged, as is the case with valved or plunger pumps, and will pump any kind of fluid, no matter how dirty, if it will go through the pipe They can be belted to most any shaft and run at any reasonable speed

In the ones we saw in use, the head was about 2' in diameter, running in a 2¼ case.

Pedrick & Ayer, Phila., have adopted this pump, and all their milling machines will hereafter be fitted with them.

The Souvenir Advertising and Ball Ticket Nuisance.

We wish to warn the different orders of railroad men of the false and humiliating position they are getting their organizations into, by attempts to raise money, for fraternal and benevolent purposes, by drumming advertisements from manufacturers of engineering supplies for convention and picnic programmes, and in sending out "blocks of five" ball tickets to distant cities, expecting manufacturers to buy them—to keep their wares in favor with the men. No other inducement is urged; the manufacturers cannot attend the ball. No one not on the inside, can imagine to what magnitude this nuisance has grown in the larger cities.

Locomotive engineers, firemen, stationary engineers and many other noble orders have let this disease grow upon them unawares.

We know of one very large firm, who annually set aside a large sum of money for this purpose, mark the amount "loss" on their ledger, and enter it upon their cash books as "blackmail money." This is not very complimentary to those who receive it.

Locally, the selling of tickets, or even advertisements in a programme are all right; the ball or other entertainment is a good thing for the business men of the town, they cater to the cash trade of the railroad men, and it is but fair that they should help the boys out once or twice a year. We notice that even the churches fish for the boys. When they have a fair they always have up a clock, a cane, a watch, or a slipper-case for the most popular engineer or conductor—and let the boys pay about four prices for them.

The idea of asking big prices for a little local advertising, from manufacturers at a distance, deserves the epithet of blackmail. We recently saw a letter from a local lodge of mechanics in an interior town of an interior State, who sent with it five ball tickets with a bill of $5. The letter went on to say that they were getting up a fund for a library, and that they proposed to favor the goods of those men who patronized them. If the manufacturer would accept the tickets—and pay for them—they would be pleased to give his goods the best show, and try to have them used where they were employed. This is a shameful confession of incompetency as mechanics, and disloyalty to employers. By the payment of a few dollars they would agree to decide on the use of tools and appliances regardless of their merit as the best tools for the purpose—this is the "something in it" idea—it is pretty close up to the blackmail idea.

These very men would resent as an insult the charge that they were begging—yet they would stand higher in the estimation of all, if they substituted begging for present methods. We recently ran across a man from one of the interior villages of New Hampshire, who was canvassing the city of Philadelphia for advertising for a programme of a sacred concert, given by an association of mechanics, that is what we would call unadulterated gall.

Friends and brothers would it not look better, more independent and more manly to abandon this idea?

Would it not be better to confine these ball and picnic collections to your own towns?

Would it not be better and look better, for our grand lodges to meet as a body of dignified business men, and transact business only—and not have a jamboree, sociable, side show attachment? Now each succeeding committee of entertainment try to eclipse the programme of the last one—have a bigger ball, a finer banquet, more carriages, and a more expensive excursion.

It seems to us as if it would be more independent for each lodge to pay the legitimate expenses of its delegate and then let him entertain himself.

Confine the duty of the committee to the work of securing hotel accommodations for the delegation, and securing and decorating a hall, but prohibit them from investing money in a banquet or other entertainment. Let the citizens do what they care to, but do not say to manufacturer Jones, in a far-off city, "Put up, or we will condemn your injector, drill press, packing or axle grease, and recommend that of manufacturer Smith."

You have an influence in the purchase and the success of all devices placed in your hands—no one can deny that—but let it be understood that your approval or disapproval will be given on merits of the different devices—not that you can be bribed to recommend an inferior device.

This matter has grown to be a disgrace, brothers, and to one and all we would say that a prompt setting down upon the idea in every form will add to the self-respect, independence and reputation of your orders and the members thereof. Think it over and—Don't.

"Pauper Labor."

We are under obligations to General W. S. Rosecrans, Register of the U. S. Treasury, for an advance copy of the report of the Congressional Committee sent to investigate the labor troubles in the anthracite coal regions of Pennsylvania.

This committee was sent out to investigate these troubles after the great strike of 1887—'88, and to find out why it was that the Philadelphia & Reading Railroad Company could not or did not comply with the provisions of the Interstate Commerce Act.

The committee took a vast amount of testimony, including that of the general officers of the Reading Road, and all classes of men in all employments in the district, including some of the sixty-cents-a-day miners.

The report of the committee is fearless and sweeping, showing the manner in which the mine owners, the railroad officers, the Pinkerton coal and iron police and the officials of the commonwealth, combine to defraud labor of its just reward, force the public to buy coal at a fictitious price, and gamble away the rights of the people.

Such an arraignment of a public officer as Gov. Beaver gets, we have never seen in print—they wring in the deadly parallel on him.

The way the coal miners live (in good times) is awful, and in hard times can only be imagined. The book abounds in tales of suffering, oppression, wretchedness and crime.

To those of our friends who are reading the *Century* articles on Siberia, and want to scalp the Czar and all his minions, we would like to say that there is no use to go so far away from home for a chance to revenge wrong.

The American people are afflicted with "far sightedness"; they can see the half naked and suffering Hottentot in the African jungle, and immediately send a missionary to his relief (?), but they cannot or do not see the equally naked and suffering white children in the hovels of New York.

They read with indignation of the sufferings and the cruelty in the mines of Siberia, but they cannot or do not see the slavery, the cruelty, the suffering and the crimes committed in the mines of Pennsylvania.

We talk pityingly about the condition of the people of Siberia, of Ireland and of India, and, smiting our breasts, brag of the free born American, who is a nobleman and jealous of his liberties, but after carefully reading a report on the condition of laboring men in his own country, and by a committee of the national Congress, our free born American nobleman ought to have a chill, and never again be heard harping about the "pauper labor" of the old world until he has moved heaven and earth to make a change in the condition of the "pauper labor" of Pennsylvania.

Jay Gould.

It has come to be every-day practice for all who wish to attack monopolies, corporate power, greed, injustice or despotism, to fairly froth at the mouth at the very mention of the name of Jay Gould.

The devil is not always as black as he is painted, and we wish here to remind the railroad boys that there are several things about Jay Gould's management that is to their best interests, and that brings him above the average railroad manipulator—so far as the employes are concerned.

While no doubt Mr Gould is a shrewd stock speculator, who does not hesitate to wreck a road, or a dozen roads, to gain his ends, he invariably treats his employes well—as good or better than the average.

There are few if any roads in the United States to-day where the men receive better pay or are treated with any more consideration than are the employes of the Missouri Pacific and the other roads entirely under the control of Jay Gould. We know from positive inside information that Mr. Gould always gives his vote in directors' meetings in favor of buying the best machinery and supplies—not because he likes to see it, likely, but because he is sharp enough a business man to see that, in the end, the best is the cheapest. Every time Jay Gould gets the cinch on some of the stock gamblers in Wall street, we hear a cry about the "great octopus, etc.," and the claim is made that he has robbed poor widows and orphans who owned stock in some road. So far as we are able to see, Mr. Gould is a little bit bolder and more aggressive than other men in his line of business, and when he rakes in a pot of a million or two, he collects it from other gamblers—not poor widows and orphans. Poor widows and orphans are not in the habit of owning stock in railroads.

As long as Mr. Gould treats his army of railroad employes as well as the best, and does nothing in the way of money-making that any of us would not do if we but had the chance, we can see no good reason to abuse him. Of course no man is capable of earning, by his own industry, a fortune like Mr Gould's, wealth is produced by labor applied to nature, and if one man works as much and as intelligently as another, he should receive as much for that work, and where we find a few thousand men like Mr. Gould, worth millions, and a few million of workingmen worth nothing, it is but natural to infer that the few are receiving part of the remuneration due the many. It is not those who come to the top, like Jay Gould, that we should blame—it is the system and the false conditions under which we live. Who would not do as Jay Gould does, if he could?

The Master Mechanics' Convention.

The American Railway Master Mechanics' Association is not a secret order, but a great educational debating club, where the men in charge of our railroad motive power meet to discuss devices and methods, compare work and results, and pick up ideas to enable them to do their work better or cheaper.

Their 22d annual meeting was held at Niagara Falls on June 18, 19 and 20, was attended by something like a hundred members, who discussed a number of important subjects.

It is the plan of the association to choose a number of live subjects, appoint a committee on each to prepare a paper to be read at the next regular meeting, when it will be discussed, each member knowing that the subject will be up, goes to the meeting prepared to tell his practice in that line, and compare it with that of his neighbors.

One hour is set aside each day for the discussion of topical subjects handed in by the members, so that discussion is not confined to cut-and-dried subjects.

The meeting just held was a particularly interesting one, papers on the following subjects being read and discussed:

Purification or Softening of Feed Water, Exhaust Pipes and Nozzles; Tires, Advantages of Thick or Thin, Driving and Engine Truck-boxes, Boiler Covering, or Lagging, Driving Brakes; Proportion of Flue and Grate Area, Foundation Ring for Boiler Leg—Advisability of Double Riveting, Water Space Surrounding Fire-box and Flues, Magnetic Influence on Watches of Engineers.

There were several topical questions brought up and discussed, the one occupying the most time and attention being on the cause of bursting of steam chests, introduced by Mr. Stewart, of the Fitchburg road, who had come to the conclusion that this accident invariably happened just after oiling the valves, and was caused by the formation of gas. Engineers who have blown off covers by pulling their engines over to avoid collisions, and long after oiling, will not take kindly to the gas theory. It was remarked by many old members that, when they had the old slide throttles, chests were not blown off, as the air pressure pumped by the pistons could not exceed that in the boiler, as the valve would lift. We doubt if a chest was ever taken off by reversing if the throttle was opened.

Many exhibitions of new and old devices were exhibited in a room set apart for that purpose—which is an improvement over the old plan of having the exhibition at the hotels. The *Northwestern Railroader* published a daily, reporting the meetings very accurately.

John Thompson and George Richards, two active members from the start of the association, were placed on the Honorary List, and quite a number of new members were admitted, the young men just coming to the front in motive power work, show their appreciation of the help to be derived by such associations, and are anxious to identify themselves with such an educational institution.

The election of officers places R. H Briggs, of Memphis, Tenn., in the chair as president; John Mackenzie, of Cleveland, Ohio, 1st vice-president; Albert Griggs, of Providence, R. I., 2d vice-president, O. Stewart, Charlestown, Mass., treasurer, and Angus Sinclair, New York, secretary. J. H. Setchel, the retiring president, has been in office, either as secretary or president, for nineteen years, and has been an efficient and able officer. The vote of thanks and the cheers he received were flattering testimonials of his worth by his associates.

Within the next six months the executive committee will decide on the next place of meeting, choosing between Chattanooga, Montreal and Buffalo.

The subjects for discussion at the 1890 meeting are particularly interesting and live subjects. They are as follows:

Compound locomotives—Their relative efficiency as compared with simple engines. Is the saving in fuel large enough to compensate for the extra cost of compounding and of maintenance of increased number of parts? Proper proportions. Are the conditions of the American system of railroading such as to render compounding advisable?

Testing laboratories—Chemical and mechanical. Are they desirable in connection with the mechanical departments of railroads? Does a marked saving in expense, by insuring best material through chemical analysis and physical test, result?

Link—As compared with other valve motions, Wilson's, Joy's, Walschaert's, etc. Has any device been found worthy to supersede the old-style link for economical service on locomotives, all points considered, first cost, cost of maintenance, length of service, convenience, etc?

Steel *versus* iron axles—As relates to friction, wear of journals and journal bearing, liability to breakage in service.

Brick arches in locomotive fire-boxes—Best manner of supporting them, their efficiency in consuming the various gases composing black smoke, saving of fuel when used in connection with extension front, and as compared with the diamond stack, first cost, and cost of maintenance. Aside from increased grate area, are there any other advantages to be gained by placing fire-boxes above the frames?

Locomotive tanks, or tenders—Best method of preventing corrosion in coal space—will it pay to shield the surface exposed to coal? If so, what is best material, and how should it be applied? The best proportion of steam passages in relation to size of cylinders and steam pressure.

The following subjects were added to the list:

The best form and size of axles for heavy tenders.

What is the relative value and length of small and large flues?

Secretary Sinclair received deserved praise for the prompt and efficient manner in which he had performed his work, and especially for the quick time in which he got out the report. His salary was fixed at $1,200—the only salary the association pays. The American Railway Master Mechanics' Association is a grand example for enginemen, holding open discussions on interesting subjects pertaining to their business, and the work done and plan followed by them could be followed on a smaller scale by railroad men everywhere.

Railroad men in every department of the service are daily meeting with new conditions and working to overcome new difficulties, each is having experience worth time and money to any one in the same business, and if many can come together at stated intervals, and, by discussion, each man get the benefits of the experiments of twenty other men, it stands to reason that the benefits are proportionately great.

ASKED & ANSWERED

(26) E. T. B., Toyah, Tex., asks:

What is the father of the "American," or 8-wheeled locomotive? *A.*—Henry R Campbell, of Philadelphia, in 1836, patented the form of locomotive with a double truck and four pairs of coupled wheels that has since developed into the standard engine of the country

(27) N. E. W., Brooklyn, asks:

How long will it take to release the vacuum brake on a train of five 30-foot cars, when there is a vacuum of 20 inches shown upon the gauge? *A.*—Air flows into a vacuum at the rate of 1,157 feet per second, or a little over 13 miles per hour. The brake would probably release in about 1/10 of a second; of course the beams and shoes would not drop back to place in so short a time, but they would be relieved of all strain from the diaphragms

(28) Henry S. Tierney, Waterbury, Ct.:

Would you please tell me what an engine that had four wheels connected and a pony truck would be called? They use them on the N. Y. & N. E. and they call them hogs. *A.*—We know of no particular name for the class of locomotives mentioned, except light passenger engines and 4 wheel connected with pony truck. The name "hog" was originally given to consolidation locomotives having a wagon-top boiler, but was soon used by the men for any large locomotive

(29) T. McC., Taunton, Mass., writes:

Please decide a dispute—a friend claims that Geo. Stephenson invented the counterbalance for locomotive driving wheels. I claim that the credit of this invention is due to Wm. Mason. Who is right? *A.*—Thos Rogers, founder of the locomotive works bearing his name, counterbalanced the weight of the engine connections of the first locomotive he ever built, and applied for a patent on the invention in 1837. The idea was ridiculed by other builders for some time.

The New Engineer's Brake and Equalizing Discharge Valve.

Since the last issue we have received several letters asking us how we expected men to come three or four hundred miles to see the air-brake sections, and asking for cuts and explanations for the benefit of those who could not see the sections. They will be found on page 10.

If the student will take the trouble to cut out the handle view, cut out the ports *j* and *o*, and shade the cavities *p* and *c*, which do not go through the valve, they will find it a great help in studying the problem. The disk on handle represents valve 13. We refer students to description of this valve in Air-brake Practice in April number.

The objects sought in using this valve instead of a 3-way cock are to have a reserve of 20 pounds more air in the engine drum than in the auxiliaries and train pipe, in order to insure the prompt release of the brakes, to provide for brakes being set in service stops without the sudden jerks and jars, and releasing of forward brakes caused by sudden closing of cock, and to provide a device in which the manipulation was always the same and that would in itself provide for the number of cars in the train and reduce the *pressure* in the train pipe, regardless of the *volume*.

All connections are marked on the cuts, in the upper left-hand cut 11 is simply a key attached to the handle, which turns valve 13 on its seat, in its present position it is in full release position, and the air from the main reservoir goes up the connection on left, over top of valve, down supply port *o*, around under valve to direct application port *l* to train pipe, charging the auxiliary drums and releasing the brakes

When the handle is moved to "position while running" (see lower left-hand cut) a bridge in the valve shuts off the larger supply port, and the air is obliged to go to the train pipe through the feed ports marked *f f*, and in so doing is obliged to lift the spring-seated valve 20 (see right cut) under plug 19, this retains 20 pounds more pressure in the engine drum than can be gotten into the auxiliary drums, and insures the release of brakes after any stop. When the valve is in this position, the equalizing port marked *g* is open, and the pressure forces down the piston 17, closes the valve on its stem, and fills a small drum attached at 24. This small drum is entirely independent of the train, and is used to measure the air pressure in reducing train pipe pressure to set brakes; this drum has a gauge attachment at W; there is also one at R, and the air gauge has two sets of works and two pointers.

When it is desired to set the brakes in service stop, the handle is moved to "on lap" position; this closes the equalizing port g, and entirely isolates the air over the piston and in the small reservoir, and a farther movement between the stops brings a port over the preliminary exhaust passage e, and allows air from the small drum to escape through a small port in side of case.

A reduction of pressure above the piston causes it to be lifted by the train pipe pressure under it, thus opening valve on its spindle and allowing air to exhaust to the atmosphere through pipe n, up, and air escape at n until the pressure in the entire length of train pipe is reduced slightly below that above the piston, so that a runner is not called upon to guess at the amount reduced, and exercise fine judgment in handling trains of different lengths—by reducing the pressure above the piston a given amount, the equalizing discharge valve takes care of the rest.

In case of accident, handle is pushed around to emergency stop; this cuts out all action of the piston, and puts the large exhaust port back of valve in direct communication with train pipe through the large passage marked Y.

We notice in riding on locomotives that there is a tendency on part of the engineers to leave valve in

Air-Brake Practice.

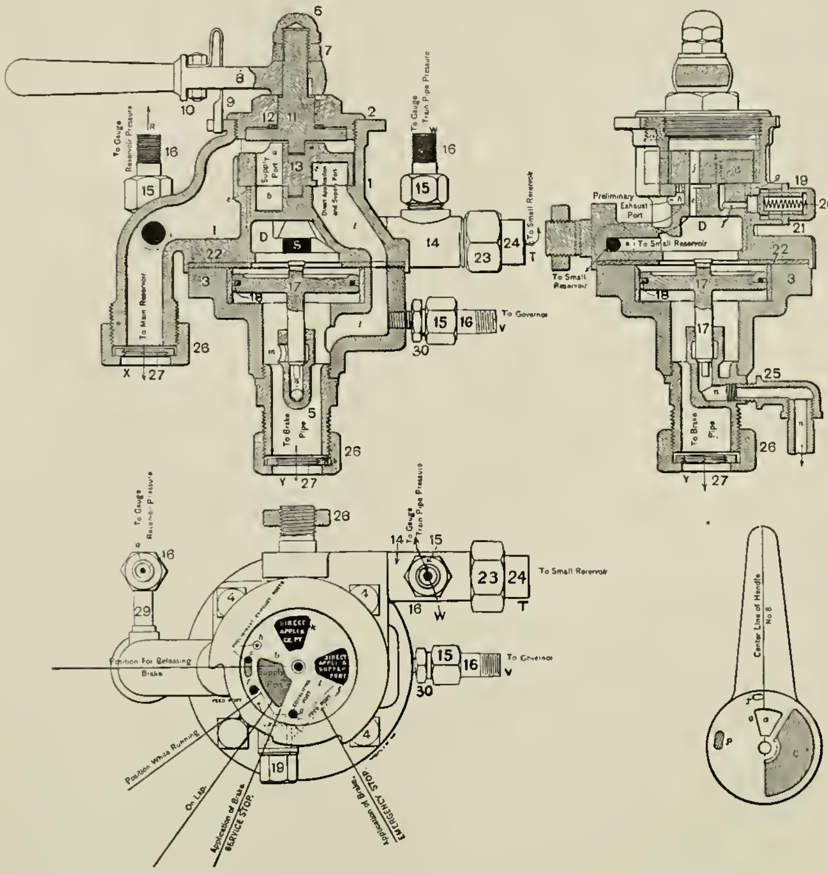
By J. E. PHELAN.

FOURTEENTH PAPER.

This paper treating of the triple valve—retaining and quick-acting triple valve—readers may set it down as a dry roast.

The triple valve is located under each car, close to auxiliary reservoir or brake cylinder, and connected to main air pipe, auxiliary reservoir and brake cylinder by suitable piping.

Triple means three-fold, or probably three of a kind, having similar purpose in principle and work,



which should be carried under running board so as not to confuse the operator.

In handling this valve you do not depend upon hearing escape of air at all, but watch the gauge; reducing pressure above the piston, say eight pounds, will keep the valve and piston up until the pressure below it is reduced slightly below that above, when it will close.

The valve n is so small that the escape of air is slow, no shocks occurring, and the perfect working of the brakes insured.

The small drum contains, say one cubic foot of air, and in setting the brake you reduce the pressure in it ten pounds; if you have one car behind you with one cubic foot of air in its train pipe, as soon as the piston has reduced the pressure below that of the air in the small drum that pressure will close it, and if, instead of the one car, you have thirty, the piston will remain full release position; this is wrong; some claim that they thus have the full pressure in the auxiliaries in case of accident If the pump governor is attached at v, as it often is, only so much air as it will allow to be pumped can be put into the train pipe, no matter where the handle is left, and if it is put at "running position" just as much is put in the train pipe, and 20 pounds extra retained in the drum to insure release.

The *Ry Herald*, London, says the Canadian Pacific are using locomotives with 84-inch boilers —guess the measurement was taken lengthwise.

The London & Northwestern owns and runs 2,500 locomotives; the largest number owned by one road in the world.

will express it better. A triple valve, to look at, is a cast-iron casing attached by piping to main air pipe auxiliary and brake cylinder.

Within this casing a piston valve works; on end of this piston valve rod a slide valve works; within this slide valve a small valve, called a graduating valve, works. Hence a piston valve, a slide valve, and a small valve within the slide valve makes up the combination of triplets.

To chamber, or part of casing in which piston valve works, is attached what is called a drain cup. Within this cup, and located in center, and within a hollow extension of nut in end of drain cup, is a brass stem or rod with a head provided on end, barely entering chamber wherein piston valve travels. Around this stem, and also within the hollow of extension of nut, is a coiled spring. This spring is called the graduating spring, and the stem is called the graduating stem; purpose of both is to assist valve or triple valve on its return trip after setting brakes. The graduating device can be called the triplet's "caller."

The graduating spring and stem perform an important part in light application of brake, as per fourth paper, August, 1888, THE LOCOMOTIVE ENGINEER.

Air pressure reaches the triple valve through main air pipe from main reservoir.

When brakes are released the triple valve is up or toward auxiliary, and pressure from train pipe holds it there, while air pressing on piston valve continues to flow past it through suitable groove inside of chamber wall or face, until equal pressure is gained in auxiliary to that in train pipe.

While triple valve is in this position, the slide valve of triple holds open a passage from cylinder to atmosphere.

To set brakes a reduction of pressure is made in train pipe, this causes less pressure on train pipe side of piston valve than on side nearest auxiliary, and in consequence pressure from auxiliary moves it, and by its movement covers the feeding groove, so that air cannot flow from train pipe to auxiliary, at same time it moves the slide valve in similar movement, and passage from brake cylinder to atmosphere is closed, at same time a passage from auxiliary to brake cylinder is opened, and air rushes from auxiliary reservoir to brake cylinder, and moves piston in brake cylinder in connection with the brake rods, etc., and sets the brakes. See fourth paper.

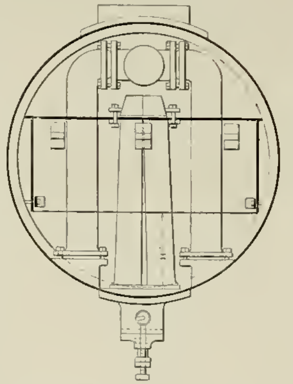
Brakes are released by returning pressure in train pipe, coming from main reservoir, being greater than that held in auxiliary; hence triple valve is forced back to release position, opening passage from brake cylinder to atmosphere, through which air that sets brakes escapes. Piston in brake cylinder then returns to release position, and air from train pipe continues to feed into and refill the auxiliary reservoir for further action.

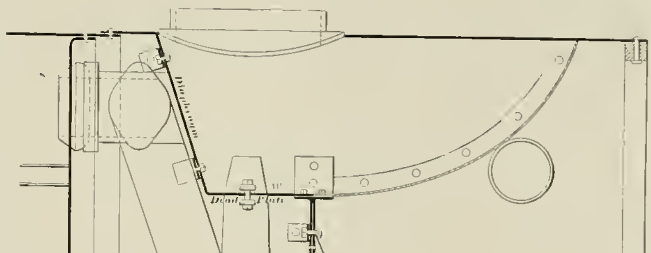
Connected with old style triple valves is what is termed a four-way cock, used for adjusting the brake to condition of service, *i. e.*, when handle of four-way cock is in position parallel with train pipe, triple valve is in communication, as here described, for automatic service. When handle is pointing down, or at right angle with train pipe, the auxiliary reservoir and triple valve is cut out from service, and communication left only with brake cylinder from train pipe—this for straight air. When handle is in position midway between the two positions—the auxiliary brake cylinder and triple valve are cut out, and car in such condition runs without advantage of reliable braking power. In one form of triple valves, four-way cock in midway position serves to bleed the brake to which it applies.

Where the passage from brake cylinder to atmosphere opens, it is called the exhaust port from brake cylinder. Attached to this exhaust port, for brakes used in mountain service, is a small pipe leading to a retaining valve, usually attached to one of the cross-beams of car bottom.

Within body of this retaining valve is a small valve, controlled by a weight, similar in principle to the feed valve and spring of the engineer's brake valve. This valve is cut in for action or cut out by means of a small handle projecting from body of valve. When cut out, handle points down; when cut in, handle should point away from valve body. When retaining valve is in use, air exhausted from brake cylinder in releasing brakes must all pass through the retainer.

When the valve is cut out, a free passage exists through retainer for air to escape, or exhaust from brake cylinder when brakes are releasing.





O. I. & W., FRONT END.

When the retaining valve is cut in and brakes released, action of the retaining valve retains about 20 pounds pressure in brake cylinder, *i.e.*, prevents that amount from escaping into atmosphere. Retaining this amount keeps piston in action, so that brake shoes rest fairly against the wheels, and exert a moderate braking power, while engineer re-charges auxiliaries for renewed action in effective power for stopping.

In ordinary service the retaining valves are not used. In mountain service, before descending grades, they are cut in by trainmen, and when foot of hill is reached they are cut out.

The retaining valves are located, on some roads, near end of platform on passenger cars, so that they can be handled without getting off the cars; on some freight cars they are located near the running board close to roof of car.

When located in such places, and air having to exhaust from brake cylinder through such a long line of piping, there is reason to fear retarded exhaust, and some trouble in consequence.

The retaining valve is applied to both the old style triple valve and new design of quick-acting triple valve, when subject to mountain service.

The new design, or quick-acting triple valve, is identical in form and action, so far as principle and parts stated in commencement of this paper are concerned.

For purpose of acting in conjunction with quick-acting parts, the slide valve of triple valve has a corner cut away from end near auxiliary. Also a port leading into end of slide valve, and out of its side near auxiliary.

The four-way cock is done away with in the quick-acting triple valves, and brakes controlled by this valve can be used for automatic brakes only, therefore cannot be altered for use in straight air practice.

In reality the new triple valve is made up of two sets of triplets. The improvement consists of doing away with the four-way cock, and adding to body or casing of regular triple valve an additional casing or body, containing an additional set of three valves, viz.: emergency valve piston, emergency valve and check valve, and check valve spring.

The main air pipe connects onto this additional chamber or casing, and through fair sized passage feeds directly into drain cup of triple valve, and feeds into auxiliary past piston of triple valve, as described in beginning of this paper.

While train pipe feeds in this direction its pressure also bears against check valve and emergency valve, but does not pass these valves until acted on as described later.

The emergency valve has a leather or rubber seat.

So long as the triple valve is worked by engineer's brake valve to bring small or graduating valve within slide valve into active work (see fourth paper), the action is identical with old style triple valve. When the reduction from train pipe through engineer's brake valve is sufficient to cause triple valve to move, so that part of slide valve corner, cut away for the purpose, uncovers a port leading to emergency valve piston, and air passing through this port, and acting on emergency valve piston, works it down, and causing the piston to act on the emergency valve moves emergency valve from its seat, then pressure in train pipe unseats check valve and flows from the train pipe directly into brake cylinder, past check valve and emergency valve.

The air started in this way continues to flow into brake cylinder until pressures in train pipe and brake cylinder are equalized, when a greater pressure in train pipe ceasing and failing to keep check valve off its seat for passage of air, the check valve automatically closes by action of its spring and auxiliary reservoir pressure, and its closing in this way prevents auxiliary reservoir pressure from flowing back into train pipe, as we understand it, if train pipe should become emptied, etc.

At or about the instant the air flows from train pipe into brake cylinders, the port in end of slide valve—noted before—puts the auxiliary reservoir into communication with brake cylinder also; hence it can be noted that brake cylinder must be quickly filled with air when acted on in this way, and action of brakes made correspondingly quick.

In conclusion, say we reduce pressure enough from engineer's brake valve simply to start the first triple valve in action, and open its port from brake pipe to brake cylinder. The amount flowing into brake cylinder causes so much additional reduction in train pipe pressure, and acts on each and all triple valves in train in proportion to reduction made, and action of each quick-acting triple valve corresponds with action of first one moved.

Arrangement of Deflector Plate and Netting, O. I. & W.

So much trouble is experienced with extension fronts for burning soft coal, that successful arrangements are of interest. While the majority of railroad men think the extension a good thing, it has been our experience that where the road, transportation and mechanical departments are all satisfied, the enginemen were not.

On the O. I. & W. road out of Indianapolis, we found all hands satisfied, and the engines steaming well and throwing no fire, so we investigated. That the division officers were all satisfied went to show that there was no fire, no delays and few repairs; that the enginemen were satisfied proved that the engines steam, do not burn the fronts and required little sparking.

The arrangement of the front end netting and diaphragm are plainly shown in the engraving on page 11. Mr King, the master mechanic, did away with the long netting on top and around nozzles and extended the dead plate above the diaphragm out in front of nozzle, this is hinged to the top plate, which is stiffened by angle irons, and can be swung out and in slightly, thus raising or lowering its lower edge; the apron does not extend to the sides, but an angle piece is riveted there, that supports the apron; the netting is fine, number 10 wire three openings to the inch, the fronts are not sparked at all. One front was opened for our inspection—a passenger engine—that had not been sparked for over six months. We are inclined to the belief that the open stack deserves the credit generally accredited to the extension arch; with it a locomotive will steam with a larger nozzle than with a diamond stack. The Webb compound steams with only one light exhaust to a revolution, using a short front, open stack and open pipes to carry off cinders.

Different grades of coal make all the difference in the world; the coal used on the O. I. & W. crumbles up very fine; on some roads, using coal that makes a hard cinder, the fronts would fill up. The object of the front is to catch sparks; if they will wear out and go out through a fine netting with an extension, they will do so without it.

An Irish Catastrophe.

On the 11th of June a train on the Great Northern Railway of Ireland, containing 1,200 members of a Sunday-school, met with an accident through the criminal action or inaction of those in authority, resulting in the slaughter of seventy-four, and the crippling of nearly a hundred. We do not remember of ever reading of another wholesale slaughter where there was not some shadow of an excuse—some unforeseen complication that led up to the wreck. In this wreck not only was there no such mitigating incident, but every precaution that could be invented was used to further the awful sacrifice of life.

The excursion left Armagh in three trains, a few miles from that place, where a heavy grade is ascended on a fifty foot fill. The second section was stalled—the train being much heavier than the engine was capable of pulling; here several cars were cut off and held by stones chocked against the wheels, and the engine proceeded to "double"; the lone cars started back down the grade, crashing into the third section with the results stated above. The people were locked into the compartment cars, or nearly all could have got out and off while the train was starting back at a slow speed—many did break the windows and escape in that way. The engineer, with the front of the train, tried to catch the runaway cars, but the crude devices they use in that country prevented their coupling on—automatic couplers would have saved the train.

Automatic brakes would have saved them if an intelligent "guard" were in charge of the lone cars.

Of course they have arrested the guard, the engineer and fireman, and the traffic manager's clerk, as responsible. What they ought to do is to arrest the officers who are responsible for the lack of modern appliances of safety—carrying a sack of powder through the public streets in one hand, and a lighted torch in the other, should not be tolerated.

Scotland Yard detectives are searching for the murder of a few fallen women in Whitechapel—why not look for the murderers of these little children—for murderers they are.

If the people of Great Britain need any stronger argument against their compartment hearses, and for automatic brakes and automatic couplers, than that written in the blood of the children of Armagh, they are welcome to it.

CAST STEEL WORKS of FRIED. KRUPP, ESSEN, Germany.

Represented by THOMAS PROSSER & SON, 15 GOLD ST., NEW YORK.

These works cover an area of 1,200 acres, employ about 18,000 men, have the most improved plant, and stand unique, from the fact that they have their own Ore and Coal Mines, Blast Furnaces, etc., and that *every* stage of manufacture is under their own supervision, and are not (like others) dependent on the open market for a miscellaneous assortment of crude material; which, in connection with 75 years' experience, enables them to turn out a product of a very superior quality, second to none, and at the same time the different grades of Steel are always of the *same uniform* quality.

Locomotive Tires, Crank Pins, Piston Rods, Spring Steel, Steel-Tired Wheels, Etc.

After a test of over 25 years the "KRUPP TIRE" has proved itself the best in the market. If a reliable article is wanted, which will give satisfaction, get KRUPP'S.

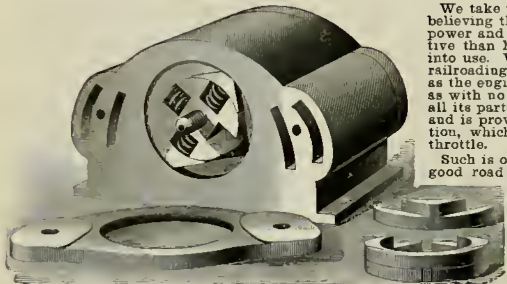
BOUND VOLUMES (cloth), comprising all the issues of 1888 (Vol. 1.) Price $2.00, postage paid, or $1.75 at this office. The volume complete, UNBOUND, will be sent by mail to any address in the U. S., Canada and Mexico, at the regular yearly subscription rate, $1.00. Single copies (any issue) sent by mail at 10 cents each.

AMERICAN MACHINIST PUBLISHING CO., 96 Fulton Street, New York.

THE TRIPP PATENT PISTON VALVE.



We take pleasure in presenting this Valve to Railroad men and others, believing that its use on a Locomotive Engine will effect a greater saving of power and expense in the maintenance of the working parts of the Locomotive than has been accomplished since the Locomotive was first brought into use. We also believe that its use will add largely to the safety of railroading, and prevent the destruction of many lives and much property, as the engine can be reversed as easily with 160 lbs. pressure on the Valve as with no pressure, it being a **Perfect Balance Valve.** The Valve in all its parts is as durable as any of the working parts of the Locomotive, and is provided with a relief device, simple in its construction and operation, which relieves back pressure instantly when running with closed throttle.

Such is our confidence in this Valve that we will furnish a pair to any good road for trial, on their furnishing following dimensions: 1st. Diagram of cylinder face showing ports. 2d. Travel, inside and outside lap of valve. 3d. Distance from cylinder face to center of valve stem. 4th. Size of valve stem. 5th. Length, width and height of steam chest from cylinder face. Internal measurements.

Said Valves not to be paid for until they have demonstrated their value to the satisfaction of the road.

Prices, terms and additional information furnished on application to

Historical Locomotives.

NINTH SKETCH.

On this page will be found an engraving, taken from the original drawings, of another historical locomotive that had the distinction of being the first of a species of locomotive engine now very popular in America—the ten-wheeler. This locomotive was built for the Philadelphia & Reading Railroad, by Norris Brothers, in 1847.

It was invented and patented by Septimus Norris, a brother of Richard and William, and the author of several engineering works.

It was thought by many that the engine would not keep the track, but she did, and the Pennsylvania Co. at once ordered twenty of them. The engine was called the "Chesapeake" and ran in the shape shown until 1862, when she was rebuilt into an anthracite coal burner by Jas. Milholland, then M. M of the Reading road, she got a new boiler, but much of the old engine was used; in 1878 she was cut up finally. The Norris independent cut-off was employed, the reverse lever and the cut-off lever being shown as standing together.

The side rods were simply two round rods of iron that extended through guide backs each side of the brasses, and provisions to take up brasses and change length of rods is plainly shown.

The side rods were in two sections entirely independent of each other and the main rod connected to main pin between the two sections; this style rod was much used in those days by Norris as well as by Ross Winans, of Baltimore, and other builders. It will be seen that the drivers were without counterbalance. The barrel of the boiler only was lagged, no jacket used. At the time this locomotive was built it was considered necessary that the driving boxes should be a very nice fit in the jaws of the frame, and to keep the axle in contact the full length of the box when one wheel raised up on the tack. A peculiar and expensive set of driving boxes were made for this locomotive. The sides of box were independent of the bearing and fitted simply the jaws, the box part being pivoted to them by large, short trunnions forward and back, the spring saddle was a rocker that could roll on top. The idea was that the inequalities in the tack would let the box have great freedom of movement without the necessity of lateral play or loose fits between box and frame.

The following data were taken from the books of the Norris works:

ENGINE AND TENDER "CHESAPEAKE."

The first 10-wheeled engine ever built.

Tried in shops March 15, 1847.

Placed on road March 19, 1847.

Boiler, 44 inches diameter.

Fire-box, 37¼ inches square inside. Height from grate to crown, 50 inches. Upper surface of grate bars, 17 inches from rail. 2½ inches water space on throat and 2 inches around sides, which will extend down to form ashpan.

Cylinders, 14½" x 22"; 6 feet 8 in. center to center; flanged drivers, six, 46 inches diameter; axles, 5 inches diameter.

Truck, 4 wheeled, 26" diameter; axles, 4' diameter.

Tender, 8 wheeled, 30" diameter, axles, 4 diameter.

133 tubes, 2 inches diameter, 12 feet long.

Pumps under cylinders worked by arm from piston rod.

Wrought-iron rock arms, bearings inside of frame.

Frames straight from end to end, pedestals fitted with wedges and vibrating boxes.

Sand-box with copper pipes 2 inches diameter leading in front of drivers.

Roof extending from front of dome to extreme hind of platform, with wrought-iron columns.

Whistle on engine.

Bumper after plan of company.

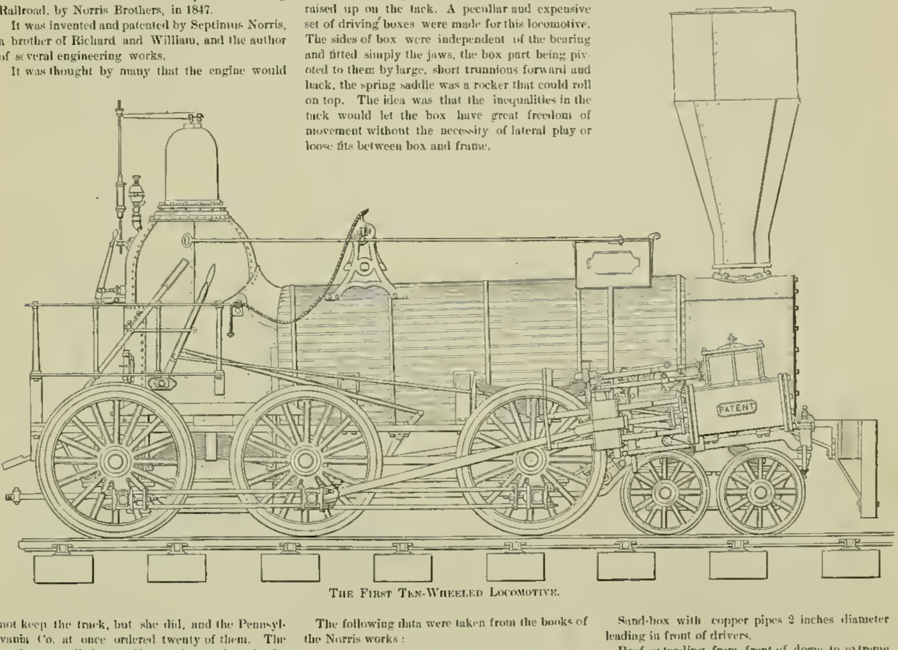
Smoke-pipe after plan of company, 14 ft. 3 in. from rail.

Tender held 2 cords wood and 2,000 gallons water.

Platform on each side of engine.

Duty To haul 100 loaded coal cars weighing (without engine tender) 710 tons of 2,240 lbs., with the wood as used for fuel on the road.

Weight of engine with wood and water, 44,074 lbs.



THE FIRST TEN-WHEELED LOCOMOTIVE.

Collar Fastener for Solid Rods.

On the Philadelphia, Wilmington & Baltimore road they use solid-ended rods on what appear to be common pins with solid collars. The collar fastening used is the invention of and was patented by Master Mechanic H. D. Gordon, and is shown in the engraving.

In some cases he uses a screw-headed bolt and a loose collar, but prefers the solid bolt and collar as shown. The pin is counterbored at the back end, so that the nuts do not project beyond the inside surface of the wheel.

The device is cheap, strong and neat. The usual thick collar, with a huge split key through it, is unsightly, hard to clean, and hard to get off in case of breakdown on the road.

A New Grease Cup.

The use of a heavy grease in place of oil for crank-pins, guides, eccentrics, etc., is coming more and more into use, the heavy grease having some peculiar advantages over oil.

We illustrate on this page a new rod cup, designed to feed heavy grease and now in use on several lines of road. The usual method with grease cups is to have a piston fitted on top of lubricant, with a spring to force it down, the tension on the spring controlled by a screw, the trouble with this device was that it took time to handle the screw, which required running clear out to admit of refilling, and the runner never knew what the cup was doing.

In this cup the plunger is not removed to fill, the cup opening at the bottom, thus it can be tighter, the spring can be compressed by shoving down the small handles shown at the side, and locked in any of the three degrees of compression instantly, and can be relieved from pressure at end of run by simply twisting handles out of notch.

The piston carries a cap above the handles in the upper case, that always shows how much grease is in the cup.

The regulating plug—set with a screw-driver—is in the shank, and the hole is so much smaller for grease than for oil and a feeder, that the shank is stronger—a desirable feature.

The construction of the cup is plainly shown in the cuts. They are made by the Lackawanna Lubricating Co., Scranton, Pa., who will furnish any other information desired.

Indicating Locomotives.

THIRD PAPER.

BY CYRUS F. RICHMOND.

Having named the various lines and explained their meaning, it will probably be of interest to study the lines of a card that was actually taken from a locomotive, and note the difference from the regular lines and sharp *points*—for that is a term applied to the beginning and ending of the various lines—shown in July issue of THE LOCOMOTIVE ENGINEER.

We will select a card that can be easily read; that is, the *points* are sharply defined.

Fig. 3 is a copy of a diagram taken from a locomotive when running at 84 revolutions per minute, boiler pressure, 132 pounds; No. 80 spring being used in indicator; reverse lever in fourth notch, which in this case cuts off the steam, or rather, valve closes the steam port when piston has traveled about one-half its stroke.

It will be remembered that the height of diagram from the atmospheric line represents the pressure of steam, and the length corresponds to stroke of piston. So we start from the point *A*, which is about the place that the valve commences to open for the lead—the vertical lines representing the ends of stroke—the pressure rises rapidly, for at this point in the stroke of piston the eccentric has its greatest throw, and consequently moves the valve quick and opens the steam port quite wide.

The pencil having reached the highest point the conditions will permit, at 1½ inches from atmospheric line, we know from number of spring used that the *initial pressure*—that is, steam pressure in cylinder at beginning of stroke of piston—must be 120 pounds, which is maintained for about 1½ inches of stroke of piston. Then we notice a gradual falling, which is due to the gradual closing of steam port, and about at the point *B* we notice quite a sudden drop. Here the valve has entirely closed the port,

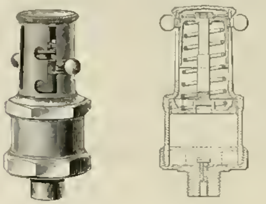


Fig. 1 *Fig. 2*

A NEW GREASE CUP.

and steam is being used expansively until it reaches the point *C*; here we have another sudden drop, and this is caused by the valve opening the exhaust port and allowing the steam to escape to the atmosphere, but it will be seen that the exhaust did not open early enough to allow all the steam to escape, and there is about 17 pounds pressure per square inch, tending to retard the piston at the beginning of back stroke, although the exhaust port still remains open, all the steam does not escape, and

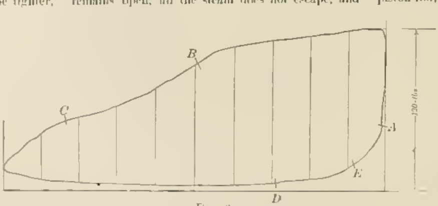

Fig. 3

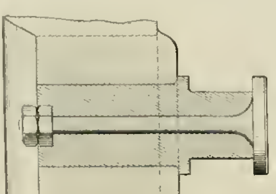
INDICATING LOCOMOTIVES.

the back pressure reaches as high as four pounds.

At the point *D*, the valve has commenced to close the exhaust, and as all the steam ahead of piston did not escape, it is being compressed into a smaller space, consequently causing the pressure to rise. The exact point at which the valve closes the exhaust cannot be determined easily, but we should judge it to be about at the point *E*, as at this position of the reverse lever—fourth notch—the exhaust port is closed when piston has traveled about 19



COLLAR FASTENER FOR SOLID RODS.

inches of the back stroke. The compression continues to the point *A*; therefore the curved line from *D* to *A* is called the *compression line*.

Now, by a little reflection, it will be clear that the space or area enclosed by the diagram in Fig. 3 represents the pressure or force urging the piston, which in turn communicates motion to the wheels and performs work. What we wish to determine is the average amount of this pressure during a complete revolution of the engine, so a diagram is taken from each end of cylinder, and the average pressure of the two diagrams is used in computing the horse-power.

There is an instrument made called a planimeter, which will measure the areas of irregular figures, but it is not always easy to obtain such an instrument, and the mean or average pressure must be obtained by dividing the length of the diagram up into any number of equal parts—usually 10 is chosen—and then erecting perpendiculars, or, more properly, ordinates, through these points of divisions. Then by carefully measuring the length of each of these lines, and adding the measurements together, then dividing the result by 10, or the number of divisions in the card, the desired result will be obtained.

In measuring the length of these lines a scale must be used that corresponds to the number of spring that was used; for instance, if the cards were taken with a No. 80 spring then it will be necessary to measure the ordinates with a scale that has 80 divisions to one inch. Such scales are usually provided with the indicators.

An easy method of obtaining the length of these lines has been suggested, and, with a little care, is quite as accurate as measuring each line and averaging the result.

Take a strip of paper and lay off one after another the several distances. Then measure the whole length at once with the proper scale, and divide the measurement by the number of divisions or spaces. Only *one-half the sum* of the first and last lines should be used. It is best to lay off the length of the end lines first, and take one-half of this measurement; then no error will arise in the calculation.

Having obtained the mean effective pressure, diameter of cylinder, stroke of piston, diameter of piston rod, number of revolutions per minute, we have all the data necessary to compute the horse-power. For the product of the mean effective pressure expressed in pounds per square inch, the net area of the cylinder, in square inches (by the net area we mean the area of cylinder minus one-half the area of piston rod), the length of the stroke in feet, and the number of strokes per minute (which is twice the number of revolutions) will give the number of *foot pounds* of work done in one minute, and as the old rule goes, 33,000 pounds raised one foot high in a minute is one horse-power, we divide the product of the foregoing by 33,000, and obtain the horse-power. Thus: Mean effective pressure, 94 pounds; net area of cylinder, 250.93 inches; stroke of piston, 2 feet; number of strokes per minute, 168. Combining the last two we obtain a piston speed of 336 feet per minute. Then

$$\frac{94 \times 250.93 \times 336}{33,000} = 240.16 \text{ horse-power.}$$

The method of marking out the ordinates is shown in Fig. 3. Variations from this will be shown in another paper.

In another column will be found illustrations and description of a novel speed-recorder for use while indicating locomotives. Mr. Wootten seems to have done away with the nuisance of stop-watches or other timepieces that have to be watched, stopped the ever-present chance for grave inaccuracies in counting, and provided for a written record of the exact speed for every card taken. The instrument can be located in the cab or on the front end, and not only tells the speed, but denotes a slip as well. Perhaps Mr. Wootten will use this little instrument to give us some reliable data on the alleged "imperceptible slip."

President Briggs, of the Master Mechanics' Association, is a prompt officer, he has already announced by special circular the committees for the following year. There are eleven live subjects up for next meeting—and not a chestnut among them.

The N. P. Ry. furnish their engines with a large combination pipe wrench, a handy thing in breakdowns. There are many roads that will not furnish monkey wrenches and red flags, let alone anything for the convenience of the men.

Combined Hose Coupler and Stop-cock.

At the master mechanics' meeting this year there was exhibited a new air-brake hose coupler, the invention of J. H. Porter and E. A Grosvenor, two engineers on the Michigan Central Railway.

The object of the invention was to avoid the possibility of trainmen forgetting to open or close the train pipe cocks—as is often done

Their improvement consists of a turret ported valve held in the brake-head, and operated by a lever. The valve is slightly tapered, and is held to its seat by a coiled spring around the stem, as shown in Fig. 3.

To couple the hose it is necessary to hook one of the notches in the curved lever upon the pin of the other lever—no difference which one—and then bring the heads together and couple them, same as is necessary with the old head. In doing this the cocks are opened, and the heads cannot be coupled unless they are opened.

To uncouple, the heads are "broken" by twisting upward same as of old, and before the heads are apart the valves are closed. If, however, a straight and strong pull is made on the hose, as is done when trains part, the heads will pull apart, leaving the valves open and thus setting the brakes. Fig 2 shows the position of levers when coupled.

The improvement does away with the cocks in pipe at each end of car, and, as they can be applied to common hose heads by screwing into the place of the present cap that holds the gaskets, it ought to be cheap and easily applied.

There are few engineers who do not know of "circumstances" caused by forgetting the cocks in train pipe, and we believe that our brother engineers have got around the difficulty, and added another safeguard to the greatest of all safeguards of our railway system—the Automatic Air-brake.

This device has been in use for the past nine months on the Michigan Central road, we are informed, with perfect success.

A Generous Proposition.

The *Railway Herald*, of London, Eng., has the following:

"It is an unfortunate fact that the railway men found guilty of culpable negligence by the coroner's jury, at the inquest on those killed in the Armagh disaster, are none of them members of any society or trade union which can afford them legal assistance on their trial. The reason for this is not far to seek. Irish railway men are, of all those of their class in the United Kingdom, the worst paid, although it may be truly said they are not, as a rule, the hardest worked.

"As these men are not in a position to afford the necessary outlay to pay for their own defense, we think it only right to do everything in our power to insure them a fair hearing at the trial, and that every point that can be urged in their favor shall be placed before the jury by a skilled advocate.

"With this view we have decided to open a subscription list in these columns, to which we confidently invite, on the ground of common interests, subscriptions from all grades of the service in the kingdom, as well as from those either directly or indirectly connected with railways."

This goes a little further than American orders do. We think we are doing nobly if we are just to outsiders, let alone being generous.

The Pennsylvania seem to be having their share, and more too, of accidents, the details of which are published This road has always had as many accidents, in proportion to number of train miles made, as the average of roads, but have always been able to keep all mention of them out of the press unless some one was killed.

Too Much of a Good Thing.

Eugene V. Debs, Grand Secretary and Treasurer of the B. L. F., and editor of the *Magazine*, paid us a call on a recent visit to New York.

If Bro. Debs was not a little more popular than J. L. Sullivan, we might get a chance to talk to him a few minutes when he comes to town without a gang of railroad men blockading the stairs for a chance to shake hands with him. We never want to get as popular as Debs is; when we get so popular that we can't go quietly into a cheap restaurant and enjoy our stewed giblets and liver without a host of admirers insisting on standing behind our chair and fighting to see who will fill our coffee cup with champagney water, or pin button-hole bouquets on us, we are going to crawl off into the seclusion of private life.

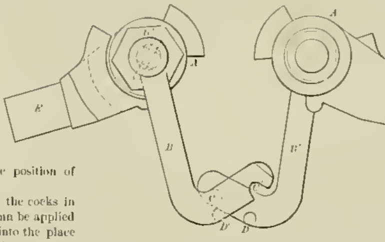


Fig. 1

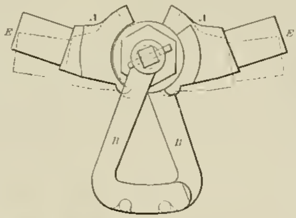

Fig 2

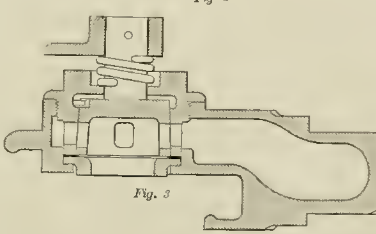

Fig. 3

COMBINED HOSE COUPLER AND STOP-COCK

White flags soon become gray, then black; red becomes brown, then brindle; so that, in order to use up the bunting, it is necessary that engineers should not be color-blind to any of the *symptoms* of red or white or green. Sheet-metal flags do not wear out, wind up on the staff, change color or blow away why don't you make some sheet-iron flags?

Some miscreant who was concealed in the bushes fired a shot at a passenger train on the Chicago & Northwestern at Coon Siding, Iowa, July 7, and the bullet struck engineer Henry Barron in the face, breaking his jaw. The plucky engineer remained at his post, however, until he reached Boone, Iowa, 25 miles distant.—*Ry. Age.*

Many of the Pennsylvania engines have black-faced steam and air gauges with white painted pointers, figures and graduations, they look neat, and the figures are easily seen.

A Fast Run.

We have received the printed record of a fast run on the Pennsylvania Limited from Ft. Wayne to Chicago, on May 19, engine 200; engineer, John S Christie; fireman, E. E. Crawford. Train consisted of five cars, weighing 438,500 pounds; engine weighed 91,900 pounds, 18x24 cylinder, 62-inch drivers. The road has many grades and curves, and the distance is 148.3 miles; it was made in 2 hours 59 minutes, including stops, actual running time, 158 minutes. Average speed, running, 56.3 miles per hour. The fastest run was 6.3 miles in 5 minutes 20 seconds, or 71 miles per hour

We are pleased to note that the last legislature of Michigan appreciated the efficient services of the engineer on the board of railroad commissioners enough to raise his salary handsomely. Brother Conger is worth every cent he gets

You have just got metallic packing all around; well, have you got anything to hold the valve stem in case you have to disconnect? Remember, you can't cramp the gland

Engineer John Heath, of the Northwestern, has been in the service of that road for nearly 30 years; has made 93,658 miles as fireman, and 905,117 as engineer, without an accident.

The U. S Metallic Packing Co. have favored us with a bird's-eye view of their exhibit at the Paris Exposition.

Correspondence

Where Was He Brought Up?

Editor The Locomotive Engineer.

When I read the statement in italic, near the close of Mr. E. J. Rauch's article in the July number, the above question immediately presented itself to my mind. I am not an "old timer," neither do I wish to appear smart; but I will guarantee that I can take a 2-inch flat spot out of the tread of a tire inside of sixty days, on any road in the Northwest during the winter months, with plenty of snow to "buck." And if I did not want a sure thing I would say it could be done in thirty days. If Mr. Rauch wishes to see some enginemen who have seen flat spots worn out, I can give him letters of introduction to perhaps twenty-five men who have seen the thing done. I have also known of instances where flat spots on truck wheels, caused by sand holes and chill blisters, have disappeared by wear.

Chillicothe, Mo. A. H TUCKER.

Who is Keystone?

Editor The Locomotive Engineer:

I notice a letter in your paper of this month signed Keystone, trying to make fun of a sand bell, but don't know how, simply because he is not posted on what he is talking about. I cannot believe this man to be an engineer, as wide-awake engineers never condemn a thing until they are sure they are right.

Now Mr. Keystone is off his base on this sand bell The sand bell he claims to have had on his mill has a plug inside, and is made by the Penna. R. R. Co at Altoona The cut shown in your May number is not the same kind and does not throw sand to the *queen's taste*, but places sand on the track, as it should be, and does not clog at all. Neither does it require a *special brand of sand*. Now, Mr Keystone, let me hear from you.

JAMES REAGAN

Germantown, Philadelphia, Pa.

Locomotive Speed Indicator.

Editor The Locomotive Engineer :
